CHAPTER 26

Healthcare-Associated Eye Infections

Marlene L. Durand, David J. Weber, and William A. Rutala

Worldwide, 314 million people are visually impaired and 45 million are blind (1). Cataracts account for nearly half of all cases of blindness, while uncorrected refractive error, glaucoma, and age-related macular degeneration (AMD) are the next three most common causes of vision loss worldwide (1). The most important infectious causes of blindness are trachoma and onchocerciasis, which cause 4% and 1% of blindness worldwide, respectively (1). Ophthalmia neonatorum due to *Neisseria gonorrhoeae* and *Chlamydia trachomatis* blind several thousand children each year. Although 75% of worldwide blindness can be treated or prevented, approximately 90% of blind patients live in poverty and have limited access to healthcare.

Healthcare-associated eye infections are currently a small cause of vision loss worldwide, but will become increasingly important as access to healthcare improves. Cataract surgery, for example, would restore sight to over 20 million blind people worldwide and improve sight in many millions more, were this surgery available to them. A vision-threatening complication of cataract surgery is bacterial endophthalmitis, which occurs in approximately 0.1% of cataract surgeries in the developed nations. This is a small percentage but would be a large absolute number of cases if all needed cataract surgeries could be performed.

Regardless of the number of people affected, healthcare-associated eye infections cause significant morbidity in those patients affected. Sight is important to everyone, and losing sight to a preventable infection is a tragedy.

SURVEILLANCE DEFINITIONS

The Centers for Disease Control and Prevention (CDC) defines a healthcare-associated infection (HAI) as a localized or systemic condition resulting from an adverse reaction to the presence of an infectious agent or its toxin, provided that there is no evidence of the infection at the time of admission to the acute care setting *(2)*. The source of these infections may be exogenous or endogenous. Infections occurring in infants that result from passage through the birth canal, such as ophthalmia neonatorum (i.e., neonatal conjunctivitis), are also considered HAIs. An infection that occurs after surgery is considered HAI if it occurs within 30 days after the operative procedure if no implant is left in place, and within 1 year if an implant is placed "and the infection appears to be related to the operative procedure" *(2)*.

Eye-related HAIs are divided into only two categories by the CDC for reporting to the National Healthcare Safety Network (NHSN): (a) "conjunctivitis" and (b) "eye, other than conjunctivitis" *(2)*. For the second category, the eye infection must meet one of the following criteria: either (a) positive cultures of the anterior chamber, posterior chamber, or vitreous, or (b) at least two of the following three symptoms, eye pain, visual disturbance, or hypopyon (layer of white blood cells in the anterior chamber), *and* either physician diagnosis of eye infection, positive antigen test on blood (e.g., *Haemophilus influenzae*, *Streptococcus pneumoniae*), or microorganisms cultured from blood *(2)*.

There are two areas of uncertainty in the CDC criteria. The first is that these surveillance criteria will identify nearly all eye-related HAIs, but not all. For example, a patient who develops candidemia from an indwelling central catheter may develop classic chorioretinal lesions due to fungemic seeding of *Candida* in the eye. This would be easily diagnosed as a *Candida* endophthalmitis by the ophthalmologist based on examination of the eye, but may be asymptomatic. A vitreous culture would not be necessary in this case, so there would be no intraocular cultures to fulfill the first criterion nor symptoms to fulfill the second, yet this case of *Candida* endophthalmitis would clearly be a HAI. We recommend including such cases as HAIs in local facility surveillance data even though they do not meet the CDC criteria outlined above.

The second area of uncertainty is whether to extend from 30 days to 1 year the window of time that a postcataract endophthalmitis case qualifies as an HAI. Nearly all cataract surgeries implant an intraocular lens (IOL), so the 1-year window would seem to apply. However, nearly all major studies of postcataract endophthalmitis use 6 weeks or less as the postoperative cutoff. For example, a major National Eye Institute–sponsored randomized trial of postcataract endophthalmitis used 6 weeks *(3)*.

POSTSURGICAL EYE INFECTIONS

Eye surgery is commonly performed in the United States, and each procedure may result in a postoperative HAI. Surgeries may be divided into those of the anterior segment

TABLE 26-1

Infections Following Eye Surgery

Surgery Type	*Infection*
Anterior segment surgery	
Corneal transplant	Keratitis, endophthalmitis
Keratoprosthesis (artificial cornea)	Keratitis, endophthalmitis
LASIK	Keratitis, endophthalmitis
Glaucoma surgery	
Filtering bleb	Blebitis, endophthalmitis
Ahmed shunt	Orbital abscess, endophthalmitis
Cataract surgery	Endophthalmitis
Posterior segment surgery	
Scleral buckle	
For retinal detachment repair	Orbital abscess, endophthalmitis
Intravitreal injections	
For AMD, DME	Endophthalmitis
Vitrectomy	
E.g., for diabetic retinopathy, retinal detachment repair	Endophthalmitis

LASIK, laser *in situ* keratomileusis; AMD, age-related macular degeneration; DME, diabetic macular edema.

(structures from the lens forward) and those of the posterior segment (vitreoretinal surgery). The major types of eye procedures and their infectious complications are listed in Table 26-1 and will be considered here.

Infections After Corneal Transplant

Corneal transplant, or keratoplasty, is performed in over 40,000 patients in the United States each year. The major indications for transplantation include keratoconus, pseudophakic bullous keratopathy, Fuch's dystrophy, herpetic corneal infection, and trauma *(4)*. In the United States, cadaver donor corneas are stored by local eye banks in an antibiotic-containing solution by protocols established by the Eye Bank Association of America (EBAA).

The traditional corneal transplant is a penetrating keratoplasty (PK), or full-thickness transplant. During this transplant procedure, the surgeon trephines a central disk from a donor cornea and uses this to replace the central disk of the patient's native cornea. The donor cornea is sutured to the residual rim of the patient's native cornea. The patient typically uses topical corticosteroid eye drops for months to years postoperatively to prevent rejection; many patients are continued on these indefinitely. Sutures are left in place for months to years. Healthcare-associated infections include donor–host transmission of systemic infections, keratitis (infection of the cornea), and endophthalmitis (infection of the vitreous).

Systemic donor infections have rarely been transmitted through PK. Premorbid bacterial sepsis in the donor appears to have no effect on the incidence of posttransplantation endophthalmitis in the recipient *(5,6)*. Diseases transmitted from donors to recipients via corneal transplantation that have been reported in the literature include three cases of Creutzfeldt–Jakob disease *(7,8)*, eight cases of rabies *(9–14)*, and two cases of hepatitis B virus from the same donor *(15)*.

The possibility of transmission of herpes simplex virus (HSV) from donor cornea to recipient has been demonstrated in some cases and suspected in others *(16,17)*. HSV in the donor cornea may cause primary graft failure and keratitis after transplantation *(18)*. Cases of healthcare-associated herpetic graft infection are rare, however. Other viruses that potentially could be transmitted through PK include human immunodeficiency virus (HIV), cytomegalovirus (CMV), Epstein–Barr virus (EBV), adenovirus, and rubella *(19)*. The EBAA requires review of the donor's medical history and recommends serologic screening for hepatitis B, hepatitis C, and HIV-1 and HIV-2 *(20)*. Patients who have died from progressive encephalopathy are also excluded as cornea donors. The recommended screening is highly effective. Eye banks affiliated with EBAA provided over 400,000 corneas during a 12-year period, and there were no cases of donor to recipient transmission of a systemic infectious disease during this time *(20)*.

A more common infectious complication after PK is infectious keratitis. Many cases occur beyond the postoperative time period and would not be considered healthcare-associated. A retrospective review of 885 transplants performed over a 16-year period revealed a 4% overall incidence of infectious keratitis, but a 1.5% incidence over the initial 2 months postoperatively *(21)*. A similar study of 285 patients who received transplants over a 5-year period found a 2.5% incidence of keratitis in the first 3 months, but an overall incidence of 7% *(22)*. Bacteriology in these studies was not specified by time of onset of infection, but *S. pneumoniae*, *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and *Serratia marcescens* were the most common pathogens. Risk factors for keratitis included persistent corneal epithelial defects and suture abscesses. Suture abscesses may develop months after surgery. One study of 18 suture abscesses found they developed 1 to 53 months postoperatively (mean: 21 months), so few would be considered healthcare-associated *(23)*. A recent study from India of 37 patients with suture-related corneal graft infection found that 31 developed the infection within 1 year postoperatively *(23a)*. The median time to onset of corneal infiltrates in the latter group was 87 days.

Endophthalmitis, or infection within the eye involving the vitreous and/or aqueous humor, is a rare but potentially devastating complication of PK that occurs in 0.2% to 0.4% of recipient eyes (24,25). Onset of symptoms is within 2 months of surgery, but most cases occur within 2 weeks. Both bacterial and fungal endophthalmitis have resulted from PK. In a US study of 1,010 corneal transplants, streptococci caused three cases and *Candida* one case of posttransplant endophthalmitis *(25)*. A study from Saudi Arabia reported a cluster of endophthalmitis that developed in four patients 1 week after PK (three *Enterococcus faecalis*, one *Candida glabrata*) *(26)*. Contamination of the donor corneas during storage was the likely source of infection. Endophthalmitis due to aminoglycoside-resistant *Alcaligenes* has been described, and this is significant because aminoglycosides are the only antibiotics present

in standard tissue storage media *(27)*. Eye bank corneal storage media contain either gentamicin (McCarey-Kaufman media) or gentamicin plus streptomycin (Optisol GS). No antifungal agent is present, and candidal endophthalmitis has occurred in patients who received *Candida*-contaminated corneal tissue *(28,29)*.

The source of infection in nearly all cases of post-PK endophthalmitis is thought to be microbial colonization of the donor cornea. Most corneal surgeons routinely culture the unused rim of the donor cornea at the time of surgery in an attempt to predict patients at risk for endophthalmitis. The value of this practice is controversial, as the incidence of culture-positive donor rims is high but post-PK endophthalmitis is low. This was illustrated by a study of 774 donor corneal rim cultures in which 5% were positive, yet no patient who received these corneas developed endophthalmitis *(30)*. The only two patients in this study who did develop endophthalmitis received culture-negative corneas. However, Wilhelmus and Hassan found that positive donor rim cultures did have predictive value (24). They performed a meta-analysis of studies involving 17,614 corneal grafts and found that 14% had positive donor rim cultures and only 0.2% developed endophthalmitis. However, using Bayesian analysis, they showed that positive donor rim cultures predicted a 1% endophthalmitis risk overall, and donor rims that were culture positive for fungi predicted a 3% probability of developing fungal endophthalmitis. The significance of a positive donor rim fungal culture was also seen in a study from New York Eye and Ear Infirmary *(29A)*. In that study, 13% of nearly 2,500 donor rim cultures were positive during a 5-year period, and 28 of these (8.6%) grew fungi. All were *Candida* species, and 4 of the 28 recipient eyes (14%) developed fungal infections. The Medical Review Subcommittee of the EBAA reviewed 121 culture-positive post-PK endophthalmitis cases reported to eye banks from 1994 to 2003, and found that 49% had concordant donor and recipient microbial isolates (29b). The prevalence of concordance was greater in fungal than bacterial post-PK endophothalmitis cases. Longer storage times increase the risk of developing post-PK endophthalmitis, and this may be especially true of *Candida* endophthalmitis. Another study from the EBAA found that the chance of developing fungal endophthalmitis was 3.4 times that of bacterial endophthalmitis when donor corneas had been preserved 4 days or longer *(29C)*. It is unknown whether prophylactic antifungal eye drops should be prescribed to eyes that receive donor corneas with rim cultures positive for fungi, but these studies suggest that may be a consideration.

New Corneal Transplantation Techniques In the past several years, new techniques have been developed that allow transplantation of only a portion of donor cornea to replace the specific level of diseased cornea in the patient's eye. Some patients have an abnormality of their corneal endothelium, the single-cell-thick layer of the cornea that abuts the aqueous humor. Conditions that require endothelial replacement include Fuch's endothelial dystrophy, pseudophakic bullous keratopathy, and failed previous graft. These patients may be helped by a posterior lamellar keratoplasty procedure, such as Descemet's Stripping Automated Endothelial Keratoplasty (DSAEK) or Descemet's Membrane Endothelial Keratoplasty (DMEK). The first procedure, DSAEK, has become the preferred treatment for endothelial dysfunction over PK, because it allows faster visual recovery and retains the strength of the eye better than PK. In 2007, 85% of corneas provided by the EBAA for patients with endothelial dysfunction were used in endothelial keratoplasty procedures *(31)*. The second procedure, DMEK, was first used in humans in 2006 *(32)*. A recent prospective multicenter study found that DMEK provided a higher rate of 20/20 vision compared with DSAEK, although donor preparation and attachment were more challenging than that with DSAEK *(31)*. A case each of *Candida* keratitis and endophthalmitis has been reported after DSAEK *(33,34)*.

Other patients have a surface abnormality but a normal corneal endothelium; these patients may need only the anterior layers of their cornea replaced, by Deep Anterior Lamellar Keratoplasty (DALK). In DALK, the patient's corneal endothelium is functional and only the more superficial layers require transplanting. With DALK, banked donor corneas that would be unsuitable for PK due to endothelial deficiencies can be utilized, or even the same cornea that supplied the endothelium for DMEK could supply the anterior layers for DALK. In a study from France, nearly 50% of donor corneas at one eye bank would have been unusable for PK, but over 70% of these were used for DALK *(35)*.

Eye bank technicians now routinely dissect corneas for DSAEK. This may increase the risk of contamination of tissues to airborne bacteria during microkeratome processing (36).

Infections After Keratoprosthesis (Artificial Cornea)

A keratoprosthesis (KPro) is an artificial cornea implanted in eyes that are blind from corneal disorders but in whom corneal transplants have failed. A major complication of KPro is endophthalmitis, which occasionally occurs during the first year postoperatively so would be considered healthcare associated, but usually occurs abruptly years later. It is similar in that regard to bleb-related endophthalmitis (see below). A widely used type of KPro is the Boston KPro, a plastic implant shaped like a collar button that replaces the central part of a corneal transplant. The rate of endophthalmitis in patients with a Boston KPro is now very low since these patients use long-term daily prophylactic antibiotic eye drops (e.g., vancomycin plus a quinolone) (37).

Infections After Laser *In Situ* Keratomileusis

Laser *in situ* keratomileusis (LASIK) is one of the most commonly performed eye surgeries. Unlike other eye surgeries, LASIK is performed in patients who have normal eyes except for refractive error, i.e., the need for glasses. Over 1 million LASIK procedures were performed in the United States in 2000, up from 400,000 procedures in 1998 and 200,000 in 1997 *(38,39)*. The LASIK uses a microkeratome to cut a thin, hinged flap across the corneal surface, exposing the corneal stroma beneath. A laser then ablates some of this central stroma and the flap is replaced, leaving a flattened cornea. The procedure is often performed using only semisterile technique (e.g., the microkeratome blade is sterile but the microkeratome handle is not).

The procedure is an outpatient procedure and is often performed in free-standing LASIK centers. Many centers are owned by the ophthalmologist who performs the procedures, so underreporting of complications is likely.

The most common complication of LASIK is keratitis, both infectious and noninfectious. In a study from Salt Lake City, Utah, of approximately 10,500 LASIK procedures, the incidence of post-LASIK keratitis was 2.66%, and 88% of these cases were noninfectious *(40)*. Most noninfectious keratitis cases in this study and others were due to diffuse lamellar keratitis (DLK). This syndrome, also called "sands of the Sahara" because of the granular appearance of the corneal flap/stroma interface, occurs in 1% to 5% of eyes *(39)*. The etiology is unknown, and cultures are negative. One outbreak in 52 patients in which cultures were negative was thought to be related to endotoxins *(41)*. Sterilizers used at the center were found to have reservoirs contaminated with gram-negative bacterial biofilms, and it was postulated that these biofilms produced endotoxins that contaminated the instruments during sterilization.

Infectious keratitis occurred in 0.3% of eyes in the Utah study, and viruses caused 70% of these 33 cases *(40)*. All 18 cases (55%) due to adenoviral keratitis recovered 20/20 vision, while all 5 (15%) of the eyes with herpes simplex keratitis lost one to two lines of visual acuity. Ten cases (30%) had a bacterial, fungal, or parasitic etiology. A study of 204,586 LASIK procedures from a private ophthalmologic institution with 19 centers in Spain found that infectious keratitis developed in 72 eyes (63 patients) during the first 6 months postoperatively, for an incidence of 0.035% (42). A majority (60%) of patients developed symptoms within 7 days of the procedure; the mean time to presentation was 16 days. Cultures were obtained in 54 eyes and were positive in 21, and all were due to gram-positive bacteria: *S. epidermidis* (nine cases), *S. pneumoniae* (eight cases), *viridans* streptococci (two cases), *S. pyogenes* (one case), and *S. aureus* (one case). There were no case clusters in this study. Khan et al. *(39)* reviewed the world literature through 2001 and found that in the 31 eyes with positive cultures, rapidly growing nontuberculous mycobacteria, primarily *Mycobacterium chelonae*, accounted for 29%. *S. aureus* (31%) and molds such as *Aspergillus* and *Curvularia* (16%) were other important etiologies, although the high incidence of molds likely reflected the contributions of reports from tropical areas. Nontuberculous mycobacteria and *S. aureus* were also the major pathogens in a study of 13 patients (15 eyes) with post-LASIK keratitis referred to an eye institute in Miami from centers in Florida and South America *(43)*. Nontuberculous mycobacteria (e.g., *M. chelonae*, *Mycobacterium abscessus*) caused six of 15 cases, whereas *S. aureus* caused four. Two cases involved gram-negative bacilli (*Pseudomonas*, *Stenotrophomonas*). Excluding two patients with late (>6 months) onset of keratitis due to molds and related to trauma, patients developed keratitis symptoms an average of 16 days postoperatively (range 2–65 days).

Nontuberculous mycobacteria have been the cause of several outbreaks. Freitas described an outbreak of 10 cases of *M. chelonae* that occurred in a center in Brazil during a 2-week period in 2000 *(44)*. Corneal infiltrates appeared during the third postoperative week. The CDC investigated a California cluster of *M. chelonae* post-LASIK keratitis and then emailed members of the American Academy of Ophthalmology to solicit reports of other cases of nontuberculous mycobacterial keratitis *(45)*. Forty-three additional cases were reported, including 31 that were part of 2 unrelated LASIK-associated outbreaks.

Post-LASIK *S. aureus* keratitis likely represents contamination from normal colonizing eye flora, and the incidence may be increased in patients with chronic meibomian gland dysfunction (e.g., marginal blepharitis). These patients should be free of any signs of eyelid disease at the time of the procedure to minimize infectious complications. The nontuberculous mycobacterial infections likely represent environmental contamination at the time of the procedure. For this reason, some authors recommend that LASIK be performed with sterile technique, including sterile instruments, sterile plastic bags covering portions of the laser that can't be sterilized, sterile gloves and drapes, eyelid antisepsis with povidone iodine, and prophylactic topical antibiotics *(43)*.

A rare complication after LASIK is endophthalmitis. A recent case was reported following a retrobulbar injection of saline to assist with globe suction by the microkeratome *(46)*. Ten days postoperatively, the patient presented with visual acuity of count fingers and presumed bacterial endophthalmitis. At surgery, a perforation site was found in the inferonasal retina. Following intravitreal antibiotic therapy, vision returned to 20/20.

Infections Related to Glaucoma Surgery

Glaucoma that is refractory to medical therapy may be controlled by placement of a filtering bleb. This is a surgically created defect in the sclera that allows excess aqueous to filter out of the eye and into the systemic circulation. The bleb may become infected (blebitis) and bacteria may rapidly enter the eye and cause endophthalmitis. Bleb-related endophthalmitis usually occurs abruptly, months to years postoperatively. Early-onset cases are rare. One study of 988 procedures in China found only one case of early-onset infection *(47)*. A retrospective review of 49 cases found that endophthalmitis developed an average of 2 years after bleb placement (range 1 month to 8 years) *(48)*. Most cases of bleb-related endophthalmitis are therefore not considered HAIs.

Another way to control severe glaucoma is through use of glaucoma drainage implants, such as the Ahmed shunt. These plastic devices have a tube, inserted into the anterior chamber, that directs aqueous humor out of the eye and into a perforated reservoir ("plate") sutured to the superior surface of the globe. Aqueous humor then leaks slowly out of this reservoir into the overlying conjunctiva and thereby the systemic circulation. Endophthalmitis is a rare complication of glaucoma drainage implants, and as in filtering blebs, most cases occur beyond the postoperative period so are not HAIs. In a retrospective study of Ahmed shunts placed in 542 eyes between 1994 and 2003 at one eye hospital in Saudi Arabia, endophthalmitis had developed in 9 eyes (1.7%) *(49)*. Eight of the nine cases occurred more than 6 weeks postoperatively (range 30–330 days). *S. pneumoniae*, other streptococci, and *H. influenzae* were the primary pathogens, accounting for six of the infections, similar to the situation in bleb-related endophthalmitis.

Postcataract Endophthalmitis

Cataracts are the leading cause of blindness worldwide and affect nearly half of all people over age 65. A cataract is a clouding of the lens, and this occurs naturally over time with exposure to ultraviolet light. Other factors may also lead to cataracts, including trauma, diabetes, chronic use of corticosteroids, and chronic inflammation in the eye (e.g., uveitis).

Cataract Surgery Cataract surgery is one of the most common surgical procedures performed in the United States, with over 2 million cases annually. Surgery has been performed on an ambulatory basis since 1985, when Medicare instituted a policy that covered only outpatient cataract surgery. Surgery involves making a small incision through either the sclera or cornea, removing the native lens pulp (leaving the posterior lens capsule intact), and replacing it with a synthetic IOL. The most common technique for native lens removal is phacoemulsification, in which the lens is ultrasonically broken up and aspirated. This allows for a very small incision that may be left unsutured, as it self-seals. "Clear cornea" surgery, where the incision is made through the cornea rather than tunneled through the sclera, was first described in 1992 but is now commonly performed. The incision is small (4 mm or less in width) and self-sealing. The stroma of the cornea remains swollen for up to 24 hours postoperatively so aids in this sealing process *(50)*.

Incidence, Pathophysiology, Risk Factors for Endophthalmitis Endophthalmitis is the major infectious complication of cataract surgery, occurring in approximately 0.1% of cases (range 0.08–0.3%) *(51–54)*. This incidence has been stable for decades. Onset of symptoms is usually within days of surgery: 75% present within 1 week of surgery. Symptoms include eye pain, redness, and decreased vision, but the patient otherwise feels well. Patients are afebrile, the white blood count is normal or only slightly elevated, and blood cultures are negative.

Nearly all cases are due to microorganisms introduced into the aqueous humor at the time of surgery from the patient's own ocular surface flora. Contamination of the aqueous humor during surgery with surface flora is common, with between 8% and 43% of aqueous cultures positive at the end of surgery in uncomplicated cases *(55–58)*. Endophthalmitis is rare, however, presumably because of aqueous turnover rate (every 100 minutes) and the immune system's ability to clear small inocula of bacteria from the aqueous *(59)*. The vitreous is gel-like and permanent, so it is much less resistant to infection than the aqueous.

Risk factors for developing postcataract endophthalmitis include surgical complications, such as inadvertent bleb creation, wound leak, or posterior capsule break. The last allows communication with the vitreous ("vitreous wick"), increasing the risk of endophthalmitis 14-fold *(60)*. Clear corneal incisions may carry a higher risk of postoperative endophthalmitis than does traditional scleral tunnel surgery *(61)*, although clinical features, microbiology, and outcomes of endophthalmitis resulting from either type of incision are similar *(62)*. In one large European study, the use of clear corneal incisions was associated with a 5.88-fold increase in risk over scleral tunnel incisions *(63)*. That study also found that the use of a silicone IOL rather than acrylic IOL had a threefold increased risk of developing endophthalmitis.

Microbiology The bacteriology is well defined. In a study of 420 patients with acute postcataract bacterial endophthalmitis, cultures of vitreous or aqueous were negative in 30% (*3*,64). In the 70% with positive cultures, gram-positive cocci caused 94% of cases, with coagulase-negative staphylococci the most common etiology (70% of culture-positive cases). *S. aureus* (10%), streptococci (9%), and gram-negative bacilli (6%) were other causes. Visual outcome depends on the etiology, with streptococci of any type producing the worst outcomes, followed by *S. aureus* and gram-negative bacilli. Infections due to coagulase-negative staphylococci, or culture-negative cases, fare best.

Chronic Postcataract Endophthalmitis While most cases of postcataract endophthalmitis present acutely, there are rare cases that present subacutely or chronically. These are usually due to *Propionibacterium acnes* or fungi. Cases due to *P. acnes* usually present with low-grade, chronic inflammation in the aqueous that mimics anterior uveitis. The diagnosis may not be suspected until months postoperatively. Fungal endophthalmitis following cataract surgery is rare, but more common in tropical countries than those with temperate climates.

Outbreaks Clusters of endophthalmitis cases due to contaminated instruments or ophthalmic solutions have been described, but are rare. Three outbreaks due to *P. aeruginosa*, two in Europe and one in the United States, have been linked to use of a contaminated phacoemulsifier *(65–67)*. In all three outbreaks, the outbreak pathogen was found contaminating the internal pathways of the phacoemulsifier. Intrinsically contaminated fluids or lenses used in ocular surgery have led to outbreaks with *P. aeruginosa* or *Bacillus* species *(68)*, *P. aeruginosa (69)*, or *Paecilomyces lilacinus (70,71)*. Contamination of trypan blue solution used to mark the anterior lens capsule during cataract surgery in Spain led to an outbreak of 6 cases of *Pseudomonas* postcataract endophthalmitis at one center within 4 months *(72)*. A cluster of 20 cases of a multidrug-resistant *Pseudomonas* endophthalmitis occurred during a 2-month period in 2008 at an eye center in southern India *(73)*. *Pseudomonas* was recovered from the phacoemulsifier's tubing, the povidine-iodine solution, and the operating room's air conditioning system; most strains tested similar to the air conditioner's strains. Contamination of humidifier water in a ventilation system with *Acremonium kiliense* led to four cases of endophthalmitis in an ambulatory surgical center *(74)*. *Aspergillus* endophthalmitis occurred in five patients during a period of hospital construction, which again demonstrates the need to follow standard guidelines during renovation or new construction *(75)* (see Chapter 83). An outbreak in Thailand from 1997 to 1998 in which 9.4% of patients developed postoperative endophthalmitis was determined to be due to inadequate sterilization procedures and use of multidose intraocular irrigating solution *(76)*.

Prevention The optimal method to prevent postcataract endophthalmitis is unknown. A number of nonrandomized or retrospective studies have tried to determine efficacy of various interventions. Speaker and Menikoff *(77)*, in an open-label nonrandomized trial, compared 5% povidone-iodine topical solution as prophylaxis in one operating room suite with silver protein solution prophylaxis in another suite. Surgeons continued to use "their customary prophylactic antibiotics." The study found a significantly lower incidence of culture-positive endophthalmitis in the suite using the povidone-iodine (0.06% vs. 0.24%). Since this study was published, it has been generally accepted that 5% povidone-iodine solution should be used on the conjunctiva during preoperative preparation. Whether the iodine should be then flushed with sterile saline is unknown.

Other nonrandomized studies have advocated intraoperative irrigation of the anterior chamber with antibiotics, antibiotic injection into the aqueous at the end of the case, postoperative subconjunctival antibiotic injections, and perioperative topical antibiotics. Preoperative and postoperative topical antibiotics are routinely used, with topical moxifloxacin and gatifloxacin most commonly used for this purpose in the United States A retrospective study of 20,000 cataract surgeries performed at the John A. Moran Eye Center at the University of Utah found an overall incidence of postcataract endophthalmitis of 0.07%, with no significant difference between groups that used moxifloxacin versus gatifloxacin eye drops *(78)*. In another retrospective study, the Utah group found that prophylaxis with fourth-generation quinolone eye drops was more effective than third-generation quinolone eye drops (ofloxacin, ciprofloxacin) in preventing postcataract endophthalmitis, 0.06% versus 0.2%, $p = .001$ *(79)*.

There are few prospective randomized trials evaluating optimal prophylaxis for cataract surgery, since a large number of patients would need to be enrolled given the low incidence of postcataract endophthalmitis (0.1%). Recently, a prospective trial involving 24 eye clinics in 9 European countries (Austria, Belgium, Germany, Italy, Poland, Portugal, Spain, Turkey, and the United Kingdom) has been published *(80)*. This study by the European Society of Cataract & Refractive Surgeons (ESCRS) used a 2×2 design and placebo control to evaluate the efficacy of (a) intracameral injection of cefuroxime (1 mg in 0.1 ml normal saline) at the end of the cataract surgery, and/or (b) perioperative levofloxacin eyedrops. The study was started in September 2003 and stopped early, January 2006, due to interim analysis showing clear benefit from intracameral cefuroxime injection. The incidence of endophthalmitis in the control group (23 cases per 6,862 surgeries, 0.34%) was nearly five times higher than in the group that received intracameral cefuroxime (5 cases in 6,836 surgeries, 0.07%), and this difference was significant ($p = .002$). This includes both culture-positive and culture-negative cases; the difference was even greater if only culture-positive cases were considered. Of note, the incidence of endophthalmitis in the control group was higher than most previously published studies. The use of perioperative levofloxacin eye drops was associated with a small reduction in risk, but this was not statistically significant.

Environmental controls should include standard operating room environmental air controls (i.e., at least 15 air exchanges per hour with at least 3 air changes per hour being fresh air, air filtered through filters of at least 90% efficiency). All operative equipment and irrigating fluids should be sterile prior to use, and the use of multiple dose dispensers should be avoided or limited.

Scleral Buckle Infections

Retinal detachments occur with an incidence of 18 per 100,000 persons in the United States (81). One method used to reattach the retina is a scleral buckling procedure, a procedure popularized over 50 years ago. In this surgery, a single long silicone sponge or solid band of silicone is placed around the eyeball encircling it like a cinch, or segments of silicone sponges are sutured to the episclera. In each case, the underlying sclera is pressed inward against the detached retina, allowing reattachment. Silicone is the primary material used for scleral buckles. Hydrogel implants were also available between 1979 and 1994 but then were removed from the market by the manufacturer; late orbital complications years later due to continued swelling of the material have been described *(82)*.

Healthcare-associated scleral buckle infections often occur acutely. Patients typically present with signs of orbital cellulitis, with eye pain, chemosis, and proptosis. Vision may be decreased due to sympathetic vitreous inflammation. The vitreous is usually sterile, although in severe cases endophthalmitis may also be present. The incidence of acute scleral buckle infections is 0.4% to 0.8%, and was 0.6% in one large retrospective study *(83)*. In this study of 4,480 scleral buckle procedures, 15 patients developed severe infections 4 to 47 days postoperatively. The main pathogens were *S. aureus* (58% of the 12 culture-positive cases) and *S. epidermidis* (25%). Staphylococci are the major pathogens in other studies as well *(84)*. Atopic dermatitis may increase the risk of postoperative *S. aureus* scleral buckle infections. In a study from Japan of 293 eyes with scleral buckles placed between 1995 and 1997, 7 developed acute infections and all were due to methicillin-resistant *S. aureus* (MRSA). Six of these seven patients had atopic dermatitis, giving an infection rate of 19% in patients with atopic dermatitis, but only 0.4% in those without this condition *(85)*.

Scleral buckle infections may also present subacutely, typically with scleral buckle extrusion through the conjunctiva months to years postoperatively *(86)*. In many cases of extrusion, mechanical erosion occurred first and the exposed buckle became secondarily infected. In some cases, however, an indolent infection of the buckle is responsible for extrusion. It may be difficult to determine whether infection played a primary or secondary role in these subacute and chronic cases.

Two recent retrospective series of explanted scleral buckles, one from India and the other from Wisconsin, unfortunately do not report the interval from surgical placement to time of removal *(87,88)*. In the study from India of 66 patients who underwent scleral buckle removal for infection, 83% of buckles were culture positive. Although *S. epidermidis* was the most common isolate, similar to other studies, fungi were isolated in 15%, a much higher rate than other studies.

Prophylactic preoperative intravenous antibiotics are not routinely used in scleral buckle surgery, and there are

no studies evaluating the efficacy of systemic antibiotic prophylaxis. Scleral buckles are often soaked in antibiotics just prior to placement intraoperatively, based on the results of a 1974–1981 prospective study *(89)*. In this study, half of the patients received Silastic sponges ("soft" scleral buckles) that had been soaked for 30 minutes in penicillin plus gentamicin solution, and half received unsoaked sponges. More patients who received unsoaked sponges than soaked sponges developed acute infections (1/450 vs. 9/471, $p = .01$). This study has not been repeated. A retrospective study of patients who received a scleral buckle that either had (389 cases) or had not (735 cases) been soaked in a gentamicin solution for 30 minutes preoperatively found no cases of acute infection in either group *(90)*.

Infections after Intravitreal Injections

Injections of medicines directly into the vitreous are increasingly used to treat retinal diseases. Two such diseases are AMD and diabetic retinopathy. Both diseases are major causes of blindness, particularly in Western nations. Monthly injections of the anti-VEGF (vascular endothelial growth factor) drug ranibizumab (Lucentis) into the vitreous prevent visual loss in "wet" AMD and actually improve vision in some patients. The less expensive parent anti-VEGF drug, bevacizumab (Avastin), may be equally effective. Ranibizumab injections plus laser photocoagulation were recently found to be very effective in halting vision loss in diabetic patients with macular edema. Typically, topical povidone-iodine drops are applied to the eye prior to injection and a sterile lid speculum is used. The incidence of endophthalmitis following an intravitreal injection is approximately 0.02% to 0.1% (*91*,92).

Infections after Vitrectomy

Vitrectomy, or surgical removal of the vitreous humor, is performed for a number of indications. A retinal detachment may be repaired by removal of the vitreous by vitrectomy, followed by instillation of a gas bubble or silicone oil. Vitrectomy is also used to remove vitreous hemorrhage, commonly caused by diabetic retinopathy. Endophthalmitis following vitrectomy is rare. One multicenter study of over 12,000 vitrectomy surgeries found 18 postoperative endophthalmitis cases, for an incidence of 0.07% *(93)*. Coagulase-negative staphylococci caused seven of these cases. Another study of a single center over 20 years found 6 cases in over 15,000 surgeries (0.04%), with the 5 culture-positive cases due to *S. aureus* (3 cases), *Proteus*, and *Pseudomonas (94)*.

HEALTHCARE-ASSOCIATED OCULAR INFECTIONS NOT RELATED TO SURGERY

Conjunctivitis

Conjunctivitis is a common condition worldwide. It is characterized by conjunctival injection ("pink eye"), discharge, and a sensation of eye irritation or pruritis. However, true eye pain is not present unless there is also involvement of the cornea, or "keratoconjunctivitis." Vision is normal, unless the cornea is also involved. A watery conjunctival discharge suggests a viral or allergic etiology, while a purulent discharge suggests a bacterial process. Hyperacute conjunctivitis, due to *N. gonorrhoeae* or *N. meningitis*, is rare but is characterized by such a copious discharge that reappears as soon as it is wiped away.

Healthcare-associated conjunctivitis falls into two major groups: ophthalmia neonatorum (also known as conjunctivitis of the newborn), and healthcare-associated viral conjunctivitis.

Ophthalmia Neonatorum

Ophthalmia neonatorum refers to conjunctivitis that develops during the first month of life. According to the World Health Organization, this includes both microbial and chemical causes *(95)*. However, the most important causes are *N. gonorrhoeae* and *C. trachomatis*, and the term "ophthalmia neonatorum" is often used to refer specifically to these infections, so "conjunctivitis of the newborn" is a more inclusive term. Other causes of conjunctivitis of the newborn include bacterial microbes, herpes simplex, and chemical conjunctivitis due to the instillation of silver nitrate into the newborn's eye. The relative importance of each of these etiologic agents around the world depends on the prevalence of *C. trachomatis* and *N. gonorrhoeae* genital infections in women giving birth and whether silver nitrate prophylaxis is used. Silver nitrate 1% solution causes some chemical conjunctivitis, although much less than Crede's original 2% solution *(95)*. The United States has used erythromycin ointment for years both because of the concern for chemical conjunctivitis from silver nitrate and because the latter is not active against Chlamydia. Chemical conjunctivitis following prophylaxis with tetracycline or erythromycin is rare. Silver nitrate ophthalmic solution is no longer available in the United States.

Clinical Features of Infection *N. gonorrhoeae* causes hyperacute conjunctivitis with marked purulent exudate, chemosis, and injection. Severe complications include corneal ulceration and perforation, which may lead to visual loss. Inadequate prophylaxis may delay the onset of disease or minimize its severity. *C. trachomatis* conjunctivitis is characterized by mild unilateral or bilateral purulence, lid edema, conjunctival injection, and profuse exudate. Onset of conjunctivitis is typically 5 to 12 days after birth. Newborns lack lymphoid tissue and fail to develop an acute follicular conjunctivitis, which is typical of the adult infection. Chlamydial conjunctivitis may be associated with pneumonia, which has a subacute presentation, with onset usually between 1 and 3 months after birth.

Prophylaxis The latest CDC comprehensive guidelines for treatment and prevention of sexually transmitted diseases in the United States were published in 2006 *(96)*. These guidelines recommended applying either erythromycin ophthalmic ointment 0.5% or tetracycline ophthalmic ointment 1% (single application each eye) for prophylaxis against gonococcal ophthalmia neonatorum. The application should be given as soon as possible after delivery, preferably in the delivery room. Infants born by caesarian section should also receive prophylaxis, as infection may occur by the ascending route as well. Tetracycline ophthalmic ointment became unavailable in the United States after publication of the 2006 CDC guidelines,

so currently only erythromycin ophthalmic ointment 0.5% is recommended by the CDC. This is well tolerated by the infant. There was a shortage of this product in 2009, and the CDC recommended azithromycin ophthalmic solution 1% during this shortage *(97)*. The CDC initially (August 31, 2009 letter) recommended that if neither erythromycin ophthalmic ointment nor azithromycin ophthalmic solution were available, then either gentamicin ophthalmic ointment 0.3% or tobramycin ophthalmic ointment 0.3% could be used *(97)*. The Food and Drug Administration (FDA) and CDC subsequently received reports of eyelid swelling and dermatitis from gentamicin ophthalmic ointment (no other adverse effects were seen in the eye or orbit), and by October 21, 2009, the CDC advised limiting the contact exposure of gentamicin ophthalmic ointment on the skin. The update of March 4, 2010 by the CDC notes that there is no longer a shortage of erythromycin ophthalmic ointment 0.5%, so other methods of prophylaxis recommended during the shortage should no longer be used.

Silver nitrate 1% solution is not used in the United States but may be used in other parts of the world for prophylaxis against ophthalmia neonatorum. This solution often causes a chemical conjunctivitis in the newborn, however, and is expensive. Expense is a major consideration worldwide. A World Health Organization 2001 publication listed costs of the following in the developing world: 5 mL of povidone-iodine $0.10, tetracycline $0.31, erythromycin $0.74, and one dose of silver nitrate $7.30 *(95)*. Povidone-iodine 2.5% is very effective against both *N. gonorrhoeae* and *C. trachomatis* conjunctivitis, and causes less chemical conjunctivitis than silver nitrate. It does cause a burning sensation, so recent studies have looked at a 1.25% solution of povidone-iodine, which appears to be very well tolerated *(98)*. The CDC does not recommend povidone-iodine due to concern that the detergent-containing formulation will be mistakenly used.

Screening of pregnant women for gonorrhea and *Chlamydia* infections is recommended to prevent ophthalmia neonatorum. Topical erythromycin ophthalmic ointment 0.5% and silver nitrate prevent gonococcal conjunctivitis in the newborn but do not prevent transmission of *C. trachomatis* from mother to infant. Infants with conjunctivitis during the first 30 days of life should have testing for chlamydial infection, and if present, treatment with 2 weeks of oral erythromycin *(96)*. Early diagnosis and adequate therapy of ophthalmia neonatorum, especially gonococcal infections, can prevent corneal ulceration and blindness. Infants born to women with untreated gonococcal infections should receive one dose of parenteral ceftriaxone. Infants who have gonococcal ophthalmia should be hospitalized.

Epidemic Keratoconjunctivitis

Viral conjunctivitis may be caused by several different viruses. Acute hemorrhagic conjunctivitis is caused by enterovirus type 70 and coxsackievirus type A 24. Pharyngoconjunctival fever, an acute and highly infectious illness, is characterized by fever, pharyngitis, and acute follicular conjunctivitis. It is caused by adenoviruses, most commonly types 3, 4, and 7, but has also been associated with types 1, 5, 6, and 14. Epidemic keratoconjunctivitis (EKC) is the most serious of the adenoviral eye infections, because it typically involves the cornea (keratitis) as well as the conjunctiva, and consequently can lead to corneal scarring. The cornea has many nerve fibers, so EKC is typically painful. As the name implies, EKC is associated with healthcare-associated outbreaks. Infection control measures are important in preventing such outbreaks: the virus has been shown to be very hardy, surviving for up to 2 months on door handles that have not been properly disinfected.

EKC has been most commonly associated with adenovirus types 8 and 19, but also has been reported with other serotypes, including types 2 to 4, 7 to 11, 14, 16, 29, 37. All types produce a similar clinical picture, but types 8 and 19 are much more likely to be involved in large epidemics.

Attack Rates and Symptoms The prevalence and incidence of EKC are unknown *(99)*. During outbreaks in medical facilities, attack rates as high as 25% have been reported (Table 26-2). More cases are reported in the fall and winter months. The incubation period is approximately 8 days, and disease is unilateral initially, although most cases become bilateral via self-contamination. In patients who progress to bilateral disease, the second eye becomes involved in 4 to 5 days. Ford et al. *(99)* have summarized the symptoms and signs of EKC reported in the literature. Ocular symptoms included a foreign body sensation (43%), photophobia (15%), lacrimation (99%), and eye redness (98%). Extraocular symptoms included fever/malaise (1–33%), upper respiratory tract symptoms (1–63%), diarrhea (2–3%), nausea/vomiting (2–14%), and myalgias (2–12%). Ocular signs include conjunctival hypertrophy (95–96%), chemosis (26–50%), pseudomembranes (1–38%), focal epithelial keratitis (55–65%), diffuse epithelial keratitis (42%), stromal edema (18–47%), anterior uveitis (11%), preauricular adenopathy (15–94%), and decreased visual acuity (17–78%). Keratitis often begins 3 to 4 days after the onset of corneal opacities (infiltrates). Usually, these infiltrates resolve within several months and do not result in permanent loss of vision.

Transmission Large outbreaks of EKC have occurred in medical facilities *(100–129)* (Table 26-2). The major modes of transmission are person to person via the hands of medical caregivers and ophthalmic instruments (e.g., tonometers, slit lamps) or ophthalmic solutions (e.g., wash stations, topical anesthetic solutions). Infected healthcare workers may serve as both a reservoir for infection and a means of transmission of infection to other patients. In more than half of the outbreaks summarized in Table 26-2, a healthcare worker became infected. The direct cost of a single outbreak was calculated as approximately $30,000 *(124)*.

Adenovirus type 8 is extremely hardy when deposited on environmental surfaces, and this accounts for the fact that fomites play a significant role in healthcare-associated transmission. Gloves should be worn for contact with patients infected with adenovirus for two reasons. First, hand washing with soap has been shown to be ineffective in eliminating infectious virus *(113)*. Second, adenovirus can be recovered from the hands of approximately 50% of patients with adenoviral conjunctivitis *(130)*. Adenovirus can be recovered from plastic and metal surfaces for more than 30 days *(131)*.

Effective Disinfectants Recently, Rutala, Weber and colleagues published results of an experimental study to evaluate 21 different germicides for their ability to sterilize adenovirus 8 from fomites (132). Virus was allowed to dry on metal discs, then various germicides were added. After 1-minute and 5-minute contact times and using various suspending media, the virus-germicide mixture was assayed for viable virus. A 3-$\log_{10}$ reduction in virus was considered effective. Only seven germicides were effective after 1-minute contact time when using the most challenging conditions (hard water plus 5% fetal calf serum). These included a 1:10 dilution of Clorox (6,000 ppm chlorine), Clorox Cleanup (1,900 ppm chlorine), Cidex (2.4% glutaraldehyde), 2.65% glutaraldehyde (Wavicide-01), Cidex OPA (0.55% orthophthalaldehyde), Steris 20 sterilant (0.2% peracetic acid), and Lysol disinfectant spray (79.6% ethanol with 0.1% quarternary ammonium compound). All of these also produced a 3-$\log_{10}$ reduction at 5 minutes except for 1:10 Clorox dilution (6,000 ppm chlorine), which only produced a 1.5-$\log_{10}$ reduction. This is surprising considering that Clorox Cleanup, which has one-third the concentration of chlorine (1,900 ppm chlorine), was effective at both 1 and 5 minutes. Two additional disinfectants produced 3-$\log_{10}$ reduction at 5 minutes under the most challenging conditions, but these failed at 1 minute: 70% ethanol and 65% ethanol with 0.63% quarternary ammonium compound (Clorox disinfectant spray). Not all disinfectants are safe to use on ophthalmologic equipment such as tonometer tips. The CDC previously recommended using one of four germicides to disinfect tonometer tips, but the Rutala study found that two of these, 70% isopropyl alcohol and 3% hydrogen peroxide, were not effective against adenovirus 8.

Tonometer Tip Disinfection Goldmann applanation tonometry is considered to the most accurate way of measuring intraocular pressure. A "tip" containing a prism is placed on the ocular surface to measure pressure. Disposable tips are available but costly to a busy practice. Reusable tips are standard and cost approximately $100 each. The CDC recommends that these tonometer tips be cleaned with soap and water (or an alternative agent suggested by the manufacturer) and disinfected by soaking for 5 to 10 minutes in a solution containing a 1:10 dilution of bleach (Dakin's solution, or approximately 5,000 ppm chlorine), or in 70% ethyl alcohol, providing compatibility with the manufacturer's recommendations *(133)*:

> *"Wipe clean tonometer tips and then disinfect them by immersing for 5 to 10 minutes in either 5,000 ppm chlorine or 70% ethyl alcohol. None of these listed disinfectant products are FDA-cleared high-level disinfectants. Category II."*

After disinfection, the device should be thoroughly rinsed in tap water and dried before use. Prior to the study discussed above by Rutala et al., only limited data were available on the efficacy of different methods for disinfection of tonometers. Threlkeld et al. *(134)* demonstrated that a tonometer tip contaminated with adenovirus type 8 could be disinfected by wiping or soaking for 5 minutes with isopropyl alcohol, hydrogen peroxide, or an iodophor. However, alcohol swabs have been shown ineffective in eliminating adenovirus type 5 from experimentally contaminated eyelid speculums *(135)*. Two studies have found that disinfection of tonometer tips between patients with a 70% isopropyl alcohol wipe contributed to an outbreak of EKC *(113,115)*. These wipes are still widely used, and the American Academy of Ophthalmology includes wiping with "an alcohol sponge" as one of the acceptable methods for cleaning tonometer tips *(136)*. However, they also may be ineffective against other pathogens in addition to adenovirus. One experimental study found that 5-second isopropyl alcohol wipes were ineffective in eliminating hepatitis C virus from tonometer tips *(137)*.

We are aware of anecdotal reports and personal experience that deterioration of Goldmann-type tonometer tips has been observed with soaking in 5,000 ppm chlorine (1:10 solution of bleach). Since 2,000 ppm of chlorine has been demonstrated to be effective in inactivating adenovirus 8 on tonometer tips (132), this lower concentration likely would successfully disinfect the tonometer and might produce less damage to the tonometer. This issue warrants investigation by the manufacturer.

Infection Control Because of the highly contagious nature of EKC, the CDC recommends the following work restrictions for healthcare workers with conjunctivitis: "Restrict personnel with EKC or purulent conjunctivitis caused by other microorganisms from patient care and the patient's environment for the duration of symptoms" *(138)* (Table 26-3). It is recommended that if symptoms persist longer than 5 to 7 days, the healthcare worker be evaluated by an ophthalmologist before return to work.

In an evaluation of effectiveness of an infection control program to control EKC, Gottsch et al. *(139)* reviewed the experience of EKC in a large teaching eye institute from 1984 to 1997. Following the implementation of an infection control program, the number of annual outbreaks fell from 3.89 to 0.543 ($p < .005$) and the number of affected patients from 54.09 per 100,000 visits to 5.66 per 100,000 patient visits ($p < .0005$). The infection control program included patient screening and isolation, hand hygiene, instrument disinfection, medication distribution, and furlough of infected employees.

Conjunctivitis Due to Other Microbes

Community-acquired conjunctivitis is most commonly due to *S. aureus*, *S. pneumoniae,* and *H. influenzae*. Both endemic and epidemic HAIs may be caused by these pathogens. Healthcare-associated outbreaks have been most commonly associated with neonatal intensive care units (NICUs) and nursing homes. In NICUs, outbreaks due to MRSA and gram-negative bacilli, including *Pseudomonas*, have been described *(140–143)*. The problem of antibiotic-resistant conjunctivitis in NICUs has increased. In a CDC study of 149 NICUs over 10 years (1995–2004), "late-onset" (after 3 days of age) infections due to MRSA increased 300% over the time period, and 17% of cases were MRSA conjunctivitis *(140)*. In most reported healthcare-associated conjunctivitis outbreaks, usual person-to-person transmission has been suspected. However, intrinsic contamination of a triclosan-containing soap with *S. marcescens* led to an outbreak of conjunctivitis in one newborn nursery *(144)*.

TABLE 26-3

Guidelines for the Prevention of Epidemic Keratoconjunctivitis

- Evaluate all medical personnel with conjunctivitis for EKC
- Furlough all medical personnel with clinically diagnosed EKC for the duration of their illness (~2 wk)
- All patients with known or suspected EKC should be seen in a separate area of any outpatient facility. The room, including all surfaces (e.g., doorknobs), should be disinfected after use
- All hospital personnel should wear disposable gloves when examining and caring for patients with known or suspected EKC; careful hand washing with an antimicrobial agent should precede and follow all patient contacts
- All equipment that comes into contact with the mucous membranes of the eye should be sterilized or undergo disinfection between patient uses. Appropriate disinfection methods include immersion for 5–10 min in 5,000 ppm chlorine (Dakin's solution = 1:10 dilution of Clorox) or 70% ethyl alcohol. After disinfection, the device should be thoroughly rinsed in tap water and dried before use
- Only single-use vials of ophthalmic solutions should be used when examining patients with EKC
- All persons with EKC should be cautioned against sharing towels, face cloths, glasses, goggles, or any other item that might come into direct contact with the eyes of another individual
- All hospitalized patients with EKC should be placed on Contact Precautions; EKC should be considered potentially contagious for 10–14 d

In nursing homes, outbreaks of MRSA conjunctivitis and nontypeable *H. influenzae* have been described *(145,146)*. Because resistant microorganisms may be present, it is important to obtain a Gram stain and culture of conjunctival discharge in healthcare-associated cases of conjunctivitis.

Keratitis

Keratitis means infection of the cornea. Because the cornea, with overlying tear film, accounts for 75% of the refractive power of the eye, keratitis often causes decreased vision. It also usually causes severe pain, since the cornea has many nerve fibers (although no blood vessels). Patients who have had a corneal transplant, or patients with repeated episodes of herpetic keratitis, may have decreased corneal sensation so may present with keratitis late. Symptoms of keratitis include a unilateral red eye with moderate to severe pain, photophobia, tearing, and decreased vision.

Keratitis may be caused by viruses, bacteria, fungi, and the parasite *Acanthamoeba*. Healthcare-associated adenovirus outbreaks have been discussed above (see "Epidemic Keratoconjunctivitis"). HSV keratitis is the most common cause of keratitis in the United States, with 500,000 people affected annually and 20,000 new cases per year. Nearly all cases are due to reactivation of previously acquired HSV type 1 infection, however, and almost none are healthcare associated. Contact lens wear is the number one risk factor for keratitis due to nonviral pathogens, and ocular surface disease is the second most important risk factor *(147)*. *Pseudomonas* is the most common cause of contact lens–related keratitis; *Pseudomonas* present in tap water may colonize contact lens storage cases.

Outbreaks Related to Contact Lens Cleaning Solutions There have been worldwide outbreaks related to contact lens cleaning solutions. Keratitis due to molds, such as *Aspergillus* and *Fusarium*, is rare in nontropical regions of the world, but there was a worldwide outbreak of *Fusarium* keratitis related to a particular contact lens-cleaning solution (Bausch and Lomb's ReNu with MoistureLoc, withdrawn from market 2006) between 2004 and 2006 (*148*,149). An outbreak of *Acanthamoeba* keratitis in contact lens wearers was seen in 2007, and was also associated with a particular type of lens-cleaning solution (Advanced Medical Optics Complete Moisture Plus, withdrawn from market 2007) that apparently had inadequate anti-*Acanathamoeba* activity *(150)*.

Keratitis in Intensive Care Units Healthcare-associated keratitis occurs most often in sedated, mechanically ventilated patients in the intensive care unit (ICU). Exposure keratopathy in such patients is common, occurring in 20% to 40% of patients, and ocular surface abnormalities are a major risk factor for keratitis (*147*,151). Colonization of the ocular surface with gram-negative bacteria in ICUs is also common and may lead to secondary bacterial keratitis. One study from Greece found that 77% of ICU patients who were mechanically ventilated and sedated for at least 7 days developed conjunctival colonization with bacteria other than normal flora within 7 to 42 days; pathogens included *Pseudomonas* and *Acinetobacter (152)*. The most common pathogen reported in critically ill patients has been *P. aeruginosa (153,154)*. The respiratory tract is the usual source. Measures to prevent exposure keratopathy are essential in preventing keratitis in sedated patients. The two most common methods, lubrication of the eyes and moisture chambers (e.g., polyethylene eye covers or goggles), are both effective (151).

Healthcare-Associated Keratitis from Contaminated Eye Drops Contamination of eye drop bottles may occur during use in the home or healthcare setting *(155–158)*. Recent studies have reported that bacteria can be cultured from 6% to 8% of in-use eye drops bottles *(156–158)*. Microorganisms vary, but include *S. aureus*, *Pseudomonas*, *Klebsiella*, *Enterobacter*, *Serratia*, *Bacillus*, and *Proteus*. A particular microorganism may be prevalent in a given healthcare facility. In one long-term care facility, 8% of 123 multiple dose solutions were contaminated with bacteria, with 80% due to *Proteus mirabilis (157)*. Multidose vials of ophthalmic solutions are frequently used in healthcare settings. The

same vial of dilating eye drops, for example, may be used for multiple patients in an eye clinic. Contamination of the vial may occur if healthcare workers touch a patient's eyelashes or ocular surface with the bottle tip, but use the same bottle for the next patient. Reports of keratitis developing from use of contaminated ophthalmic solutions are surprisingly rare. Keratitis with *P. aeruginosa (159)* and *S. marcescens (160)* has been reported from use of contaminated eye drops. A recent report from India described five patients who developed secondary *Pseudomonas* keratitis while using natamycin, an antifungal agent, to treat their *Fusarium* keratitis *(161)*. The cultures from the natamycin eye drop bottles being used by all five patients grew *Pseudomonas*. All had poor visual outcomes, with three requiring corneal transplants and one requiring evisceration for panophthalmitis.

Endogenous Endophthalmitis

Endophthalmitis means bacterial or fungal infection within the eye, including infection of the vitreous and/or aqueous humors. Most cases of endophthalmitis are exogenous, with infection introduced from "outside" the eye either from surgery, penetrating trauma, or extension of keratitis. Nearly all healthcare-associated cases of endophthalmitis are postsurgical and are discussed above (see "Postsurgical Eye Infections"). Endogenous endophthalmitis refers to bacteremia or fungemic seeding of the eye. Cases of endogenous endophthalmitis are considered healthcare-associated when the underlying bacteremia or fungemia is an HAI. Note that bloodstream infections may seed the eye, but the reverse does not occur: the infected eye never serves as a source of bacteremia or fungemia.

The most common sources of bacteremia in most series of endogenous endophthalmitis are community acquired rather than healthcare associated. These sources include endocarditis, urinary tract infections, meningitis, intravenous drug use, intra-abdominal abscesses (162,*163*,*164*). In Taiwan and other East Asian countries, liver abscesses due to *Klebsiella pneumoniae* are frequently associated with secondary endogenous *Klebsiella* endophthalmitis, particularly in older diabetic patients *(165,166)*. Community-acquired endogenous endophthalmitis due to molds, such as *Aspergillus* and *Fusarium*, are usually seen in intravenous drug users, or in severely immunocompromised patients (e.g., organ transplant recipients) who have invasive fungal infections, usually involving the lungs *(167,168)*.

Healthcare-Associated Endogenous Endophthalmitis

Healthcare-associated cases of endogenous endophthalmitis usually develop either after procedures that can produce transient bacteremia, such as endoscopy (162), or from infections related to indwelling central venous catheters. One of the most common nonsurgical healthcare-associated intraocular infections is ocular candidiasis. Ocular candidiasis is usually secondary to central line–related candidemia. The term "ocular candidiasis" includes both *Candida* chorioretinitis, characterized by clear vitreous but white "fluff balls" seen on the fundus, and endophthalmitis, in which there is also significant inflammation in the vitreous. The distinction is not always made in the literature, however, with both being described as endophthalmitis. *Candida* chorioretinitis or endophthalmitis is often asymptomatic, so patients with candidemia should have funduscopic examinations to look for intraocular seeding of fungus. In a prospective multicenter study of 118 hospitalized patients with candidemia, 9% were found to have chorioretinitis yet almost none had eye symptoms *(169)*. Candidemia may be clinically silent, transient, and undiagnosed during a hospitalization or rehabilitation stay, yet could have seeded the eye. Undiagnosed chorioretinitis may progress to endophthalmitis, which usually presents as a gradual and painless decrease in vision. Diagnosis is often delayed because symptoms may occur weeks or months after a hospitalization, and after an indwelling central venous catheter has been removed. A 10-year retrospective study of 15 patients with endogenous *Candida* endophthalmitis, 11 of whom had an indwelling central venous catheter, found that the average time from onset of symptoms to treatment of endophthalmitis was 2 months (170). Most cases of *Candida* chorioretinitis resolve with systemic antifungal treatment alone, but treatment of *Candida* endophthalmitis requires vitrectomy plus intravitreal amphotericin B injection in addition to systemic antifungal therapy.

CONCLUSION

Many healthcare-associated eye infections are due to surgical procedures. Such infections are likely to increase in the coming years with the increase in new surgical procedures, such as LASIK, lamellar keratoplasty, implantable plastic devices to treat glaucoma (e.g., Ahmed valve) and corneal blindness (e.g., KPro). The use of monthly intravitreal injections of anti-VEGF medications to treat macular degeneration and diabetic retinopathy may also lead to an increase in HAIs. Examples of healthcare-associated eye infections that are unrelated to surgical procedures include ophthalmia neonatorum, EKC, and keratitis in sedated, intubated patients in ICUs. Meticulous care in following infection control protocols can prevent most HAIs in ophthalmology, as in all fields of medicine.

CHAPTER 27

Healthcare-Associated Central Nervous System Infections

Jeffrey M. Tessier and W. Michael Scheld

Healthcare-associated infections related to the central nervous system (CNS) are a relatively infrequent but important category of hospital-acquired infections. These infections span a spectrum from superficial wound infections, to ventricular shunt infections, to deep-seated abscesses of the brain parenchyma. The patient populations affected are equally diverse, involving neonates, children, and adults, with occurrence on nearly all medical and surgical services.

Healthcare-associated infections of the CNS are usually serious, if not life threatening, and are frequently associated with a poor outcome (*1–4*,5,*6–13*). These healthcare-associated infections present many challenges in diagnosis, and many controversies exist regarding effective prophylaxis and proper management. In addition, the identification of a particular infection as healthcare-associated may not be clear-cut; thus, overlaps and ambiguities concerning acquisition are unavoidable. Fortunately, a heightened awareness has fostered declining rates of infection. In spite of improving techniques and new preventive strategies, the threat is constant, and the stakes remain painfully high. The first part of this chapter focuses on the clinical and epidemiologic aspects of infections related directly to neurosurgical and neuroinvasive procedures as well as infectious processes that invade the CNS secondarily from other sites. The second part of this chapter discusses prevention and control of these infections.

RISK FACTORS

General Risk Factors

Not surprisingly, the patients at greatest risk for acquiring healthcare-associated CNS infections are neurosurgical patients. Patients with surgical site infections (SSIs) are drawn almost entirely from this population. These patients are subjected to procedures that traverse the scalp, violate meningeal coverings, impinge upon the paranasal sinuses, implant foreign bodies, and expose tissues to hematogenous sources of infection. Infection in this setting is often facilitated by the presence of a cerebrospinal fluid (CSF) leak that occurs when the dura is disrupted and the subarachnoid space communicates with the skin, nasal cavity, paranasal sinuses, or middle ear *(14–19)*. This group includes adult and pediatric patients undergoing common neurosurgical and neuroinvasive procedures such as craniotomy, spinal fusion, laminectomy, insertion of halo pins, burr hole placement, and implantation of ventricular shunts and reservoirs. Less common procedures include stereotactic brain biopsy, hypophysectomy, paranasal sinus surgery, acoustic neuroma resection, temporary ventricular drainage, placement of intracranial monitoring devices, nerve stimulator placement, lumbar puncture, spinal anesthesia, myelography, and skull/spinal fixation.

Patients who have suffered accidental head trauma are another population at increased risk to develop meningitis. These individuals have sustained trauma or fractures to the basilar skull and facial bones, facilitating the formation of a CSF fistula. This posttraumatic condition substantially increases the likelihood of CNS infection, particularly bacterial meningitis *(20–22)*. In one series, a CSF leak was a predisposing factor in approximately 9% of cases of healthcare-associated bacterial meningitis (5).

The majority of healthcare-associated CNS infections reported from the National Nosocomial Infections Surveillance (NNIS) system at the Centers for Disease Control and Prevention (CDC) occurred in newborn nurseries and on surgical services (Table 27-1). All other hospital services account for a small but still substantial number of cases. Patients from this smaller population generally have a parameningeal source of infection that is either contiguous (e.g., sinusitis) or occult (e.g., unsuspected CSF leak), reactivation of latent infection, or an infection that has hematogenously seeded the CNS from a distant site. Patients with malignancies (especially lymphoma and leukemia), organ transplants, and other immunocompromised hosts frequently fall into this last category.

Risk factors for SSIs can be classified into host factors and surgical factors. Examples of host factors include age, sex, American Society of Anesthesiologists (ASA) physical status classification, underlying diseases such as diabetes mellitus, nutritional status, presence of other remote infections, and duration of preoperative stay. Surgical factors include whether the procedure was emergent or elective, hair removal technique, surgeon, use of perioperative antibiotics, duration of surgery, type of operation, site of surgery, and whether gloves were punctured *(23)* (see Chapter 21 on SSIs.) One study showed that when

NNIS, National Nosocomial Infections Surveillance system. (*Source:* Centers for Disease Control and Prevention/NNIS.)

patients underwent a neurosurgical procedure, the presence of a postoperative CSF leak was associated with a 13-fold increase in the infection risk *(24)*. Also, a non-CNS concurrent infection increased the infection risk six times, whereas use of perioperative antibiotics was associated with a decrease in the infection rate of about 20%. Three other risk factors—paranasal sinus entry, placement of a foreign body, and use of postoperative drains—were associated with an increased risk of infection, although these associations were not statistically significant. Factors not associated with an increased risk of infection included obesity, surgical reexploration, use of the operative microscope, steroid administration, and acute therapy for seizures. Length of surgery was also not a factor associated with an increased risk of infection. A prospective study of postoperative neurosurgical infections demonstrated a validated five-category classification system for neurosurgical infections based on specific definitions. It found that infection rates were highest for contaminated cases (contamination known to occur, 9.7%), followed by dirty cases (established sepsis at the time of surgery, 9.1%), clean-contaminated (risk of contamination of operative site during surgery, 6.8%), clean with temporary or permanent foreign body (6.0%), and clean (no identifiable risk factors present, 2.6%). In this study, surgery lasting longer than 4 hours was associated with an infection rate of 13.4% *(25)*.

In addition to neonates (see Chapter 52) and patients undergoing neurosurgery, patients undergoing invasive diagnostic or therapeutic procedures that penetrate the CNS are at risk for developing a healthcare-associated CNS infection (see Section VIII). A subgroup of neurosurgery patients at high risk for healthcare-associated CNS infections includes those with ventricular shunts. Since most shunt infections (70%) have an onset within 2 months of surgery, it is likely that the infecting microorganism is introduced during surgery or in the postoperative period *(10)*. Risk factors for shunt infections are discussed in Chapters 49 and 65. The rate of infection varies with the neurosurgeon *(26,27)*. The efficacy of prophylactic antibiotics in preventing shunt infection is controversial and is discussed below (see Prevention). Patients undergoing diagnostic or therapeutic procedures that penetrate the CNS, such as the installation of dyes or drugs, are more likely to develop healthcare-associated meningitis *(28)*. Although such infections occur infrequently in the present era, they should be considered in the appropriate setting.

Device-Related Risk Factors

Infection is a well-recognized complication of ventriculostomy catheters used for monitoring and drainage *(29)*. Aucoin et al. *(30)* noted that the rate of infection was associated with the type of monitor used. The lowest infection rate was associated with the subarachnoid screw (7.5%), followed by a rate of 14.9% for the subdural cup catheter and a 21.9% rate for the ventriculostomy catheter. An intracranial monitoring technique, the Camino intraparenchymal fiberoptic catheter system, is associated with an infection rate of 2.5% *(31)*. The method of ventriculostomy insertion using the tunneled technique has been associated with the lowest rates of infection *(29)*. Use of prophylactic antibiotics did not reduce significantly the risk of infection. In a study by Mayhall et al. *(9)* of ventriculostomy-related infections, risk factors significantly associated with infection included an intracerebral hemorrhage with intraventricular hemorrhage, a neurosurgical operation, ICP of 20 mm Hg or higher, ventricular catheterization for longer than 5 days, and irrigation of the system. The incidence of infection was not related to insertion location when the intensive care unit was compared with the operating room. Infection rates were also not reduced by the use of nafcillin prophylaxis. Several additional studies have confirmed the direct relationship between the duration of ventricular catheters and infection risk *(32–36)*. Additional risk factors associated with ventriculitis include sepsis, pneumonia, urinary tract infection, depressed skull fracture requiring surgery, craniotomy, CSF leakage around the device, drain blockage, reinsertion related to catheter malfunction, and intraventricular hemorrhage. To reduce the risk of ICP monitor–related infections, it is recommended that the device be inserted using aseptic technique, that the device be removed as soon as possible and preferably before 5 days, and that a closed system be maintained. A randomized, controlled trial of external ventricular drain-associated infection compared regular exchange of the drain every 5 days with clinically indicated exchanges and found no difference in the rate of infection between these groups *(37)*. The use of prophylactic catheter exchange and extending the duration of catheterization to 10 days has been proposed, but more data are needed *(29)*. The type of ICP monitor device used influences the rate of infection, with epidural tunneled monitors having the lowest rates.

SOURCES OF INFECTION

Sources of Infecting Microorganisms

Nonsurgical Infections Healthcare-associated CNS infections can be classified into those infections unrelated to surgery and postsurgical infections. In patients with

nonsurgical-related infections, the microorganisms can compose a patient's endogenous flora, such as coagulase-negative staphylococci (CoNS), or arise from an exogenous source, such as from a contaminated solution or device *(28)*. Gram-negative bacilli are usually responsible for infections related to contaminated solutions or devices *(38)*. Microorganisms can gain access to the CSF by hematogenous spreading of an infectious agent, spread to the CSF from contiguous foci, such as an infected sinus, or via a communication of the CSF with the flora of the skin, sinuses, or other mucosal surfaces *(39,40)*. CSF leakage can be obvious in a patient with rhinorrhea or otorrhea, or occult if the subarachnoid space communicates with a paranasal sinus. Rarely, neoplasms erode into the subarachnoid space and produce a fistula. Microorganisms can also gain access to the CSF by direct inoculation of the agent in a patient having a lumbar puncture, especially if a substance is injected. Microorganisms acquired in this manner are usually gram-negative rods *(41,42)*. It is extremely unusual to develop meningitis following a lumbar puncture unless a solution is injected into the CSF.

Infection is a well-recognized complication of chronic epidural catheters and intracerebroventricular devices *(43)* used for control of pain in patients with AIDS or malignancy *(44)* (see Chapter 60). Hayek et al. studied patients with noncancer pain and found a higher infection rate (5.51 infections per 1,000 catheter-days) among patients using tunneled epidural catheters (TECs) for neuropathic pain compared to those with TECs used to treat somatic pain (2.43 infections per 1,000 catheter-days) *(45)*. Staphylococci accounted for 11 of 23 positive epidural space or catheter tip cultures, supporting the hypothesis that most of the TEC infections were due to skin flora migration and colonization of these catheters. Other complications include meningitis and epidural abscess, but prolonged surgery during catheter placement has been found to be the only factor associated with catheter infection *(46)*. Infection may also complicate the use of an Ommaya reservoir *(47)*. Repeated access of these devices may permit colonizing skin flora such as *Staphylococcus aureus, S. epidermidis,* or diphtheroids to produce ventriculitis and meningitis. The source of the infecting microorganisms may also be the hands of the hospital personnel accessing the device, although powder contamination from gloves has also been implicated *(48)*.

Neurosurgical Infections Although many sources of contamination of a neurosurgical operation have been described, it is usually impossible to document with certainty the source for a given SSI. Probably most infections occur at the time of surgery from either direct inoculation of residual flora of the patient's skin or from contiguous spread from infected host tissue. Direct inoculation of microorganisms can also occur occasionally from the hands of surgical team members via a tear in a glove. Rarely, the source of infection is traced to contaminated surgical material such as a solution, device, or instrument. In two neurosurgical patients with postoperative *Bacillus cereus* meningitis, the source of the microorganisms was found to be heavily contaminated linen *(49)*. Occasionally, during the postoperative period, an SSI results from direct inoculation of microorganisms. Airborne contamination at the time of surgery, either from the patient or from operating room personnel, accounts for some neurosurgical infections *(1,50)*. Lastly, a postoperative infection rarely results from hematogenous seeding of a wound from an infected intravenous line or other remote infection.

Outbreaks of neurosurgical infections occur infrequently today, and when they have been described, they have occurred mainly in hospitalized neonates *(51–53)*.

INCIDENCE AND DISTRIBUTION

Healthcare-associated infections of the CNS (excluding wound or SSIs) are relatively uncommon, accounting for approximately 0.4% of all healthcare-associated infections (R. Gaynes, personal communication to Nelson Gantz). Meningitis accounts for 91% of these infections, followed by intracranial suppurations (8%) and isolated spinal abscess (1%) (R. Gaynes, personal communication to Nelson Gantz). When infection rates are examined using data reported from 163 hospitals participating in the NNIS system, 0.56 CNS infections per 10,000 hospital discharges occurred from 1986 through early 1993 (R. Gaynes, personal communication to Nelson Gantz). Comparable rates over the past 25 years have shown a slow decline from approximately one infection per 10,000 hospital discharges to the present lower rate *(54)*. While these numbers are relatively small, it must be noted that CNS infections directly related to neurosurgical procedures (SSIs) are not reflected in these numbers. The majority of healthcare-associated CNS infections occurring in this setting are designated under the larger category of SSIs (22% of all healthcare-associated infections) by the CDC National Healthcare Safety Network (NHSN) system surveillance criteria (see below) *(401)*. Certain healthcare-associated CNS infections may represent a greater proportion of specific types of infection. For example, a retrospective study of acute bacterial meningitis in adults over a 27-year period at the Massachusetts General Hospital found 40% of 493 total episodes to be healthcare-associated in origin (5).

Healthcare-associated surgical site and CSF infections among neurosurgical patients are a primary focus of this chapter. Table 27-2 shows the distribution of SSIs complicating neurosurgical procedures and illustrates the significant proportion of deep infections that occur in relation to the surgical site; these data are derived from the NNIS reporting period 1986–1992. Infection rates as reported in the general neurosurgical literature are often difficult to interpret and compare for a variety of reasons, including differences in definitions, methodology, reporting techniques, and use of prophylactic antibiotics. Not uncommonly, postoperative infections unrelated to the surgical site or CNS are included in the rate calculation *(2)*. An overview of infection rates associated with neurosurgery from some of the more rigorously performed (although nonstandardized) studies over the last 30 years is shown in Table 27-3. Taking into account some of the problems mentioned above, most hospital series report infection rates of <5%. When individual neurosurgical procedures are compared, differences in infection rate become more apparent. The incidence of all CNS infection following typically clean craniotomy may vary from <1% to nearly 9%,

TABLE 27-2

Surgical Site Infections Following Neurosurgical Procedures

		Surgical Site								
Procedure	*Men*	*SA*	*SSI*	*DSI*	*IC*	*IAB*	*Bone*	*Disc*	*Other*	*Total*

(*Source:* CDC/NNIS.)

whereas the rates following laminectomy range from 0.6% to 5%. Postoperative meningitis after clean craniotomy has a reported incidence of 0.5% to 2% when perioperative antibiotics are given *(55,56,72–74)*. Without antibiotic prophylaxis, other studies have found rates ranging from 2% to 7% *(74–76)*. A more recent large prospective study of infections after craniotomy among 2,944 patients found an overall SSI rate of 4%, with meningitis representing approximately 48% of these infections (77).

Infection rates for selected neuroinvasive procedures are shown in Table 27-4. Again, differences in methodology, definition, and duration of follow-up greatly affect the reported rates. Analysis of infection rates following ventricular shunt surgery is particularly complex. Depending on the use of a case rate (occurrence per patient) or an operative rate (occurrence per procedure) of infection and the duration of follow-up, an extremely wide variation in incidence may be seen. Perhaps, when in 1916 Cushing *(107)* stated, "There has never been any infection, even of a stitch in the scalp, in something over 300 cranial operations in the writer's series," he underestimated the situation. A procedure-oriented risk factor analysis is covered in a later section, and additional details are discussed elsewhere in this text (see Chapters 49, 60, and 65).

(Data from Refs. *9,10,30,44,60,62,78–106,409.*)
[a]Includes external drainage and intracranial pressure monitoring devices.

Examination of SSIs reported from NNIS system hospitals between 1992 and 2004 shows infection rates in uncomplicated procedures with minimum risk factors to be 0.91/100 operations for craniotomies, 1.04/100 operations for spinal fusion, 0.88/100 operations for laminectomies, and 4.42/100 operations for ventricular shunts (108) The last rate is the third highest among all operative procedures (108). These surveillance rates, by definition, include both superficial and deep infections related to the operative site (109,*110*). The addition of one or more complications (surgical risk factors) will increase most of the figures to varying degrees *(111)*.

The incidence of both community- and hospital-acquired CNS infections in immunocompromised hosts has been estimated to range from <1% to over 10%, depending on the host population *(112–115)*. Classic studies at the Memorial Sloan-Kettering Cancer Center in the early 1970s revealed an incidence of CNS infections approximating 0.02% of total hospitalizations *(116)*. These infections occurred most commonly in lymphoma patients (33%), followed by neurosurgical patients (30%) and leukemic patients (20%). Overall, meningitis accounted for the majority of infections (71%), followed by brain abscess (27%) and encephalitis (2%). Of note, intracerebral abscess in leukemic patients was responsible for 70% of CNS infections in this group. It has been postulated that conventional incidence figures may significantly underestimate the actual magnitude of CNS infections in this population *(112)*. Other studies have shown similar patterns in cancer patients, with perhaps a higher incidence of CNS infection in transplant recipients estimated at 5% to 12% *(114,115)*. One retrospective study of bone marrow transplant recipients found symptomatic neurologic complications, predominantly infectious (23% of complications), among 16% of patients *(117)*. CNS infections were more common among allogeneic compared to autologous transplants and included cerebral toxoplasmosis, viral encephalitis, and fungal infections. Brain abscess was found to be a common complication in one study of heart and heart–lung transplant recipients, accounting for 35% to 44% of CNS infections *(113,118)*. These abscesses are often caused by fungi, particularly *Aspergillus* species, among liver transplant recipients *(119)*. Bacterial meningitis in the febrile neutropenic patient is often indolent in presentation and masked by the early use of broad-spectrum antibiotics. Disseminated fungal infections are not uncommon in the compromised host and are frequently difficult to diagnose; *Candida* is reported to involve the CNS in up to 50% of cases *(120,121)*. Although the absolute number of healthcare-associated infections in this population cannot easily be determined, the proportion is likely to be high, as many occur after multiple or prolonged hospitalizations and are caused by typical healthcare-associated pathogens.

TYPES OF HEALTHCARE-ASSOCIATED CENTRAL NERVOUS SYSTEM INFECTIONS

Healthcare-associated infections related to the CNS may be broadly divided into two major categories (Table 27-5): postsurgical infections and nonsurgical infections, including those related to neuroinvasive or neurodiagnostic procedures. The first category consists of SSIs (109). Infections of this type may occur following craniotomy, ventriculostomy, and spinal column surgery. Rarely, SSIs complicate other neurosurgical operations, such as peripheral nerve surgery and carotid endarterectomy. SSIs are further classified as superficial or deep incisional SSIs, using the fascial plane as divider. Deep surgical infections unrelated to soft tissues are classified as organ/space SSIs by the aforementioned CDC criteria (109). These infections may present as a local and/or diffuse infectious process. Local suppurative infections complicating neurosurgical procedures include the following: parenchymal brain abscess, subdural empyema, epidural abscess,

TABLE 27-5

Healthcare-Associated CNS Infections

Postsurgical	*Nonsurgical*
Surgical site infections	Contiguous focus or hematogenous
Superficial incisional	Epidural abscess
Deep incisional	Subdural empyema
Organ/space infections	Brain abscess
Local suppurative infections	Meningitis
Osteomyelitis	Meningoencephalitis
Discitis	
Subgaleal collection	
Epidural abscess	
Subdural empyema	
Brain abscess	
Diffuse infections	
Meningitis	
Ventriculitis	
Meningoencephalitis	

discitis, subgaleal collection, and osteomyelitis of the cranium or spine. Diffuse infection of the subarachnoid space defines meningitis or ventriculitis if the process is related to a prior ventriculostomy and essentially remains localized. This latter distinction is somewhat arbitrary. Meningoencephalitis is an infrequent diffuse healthcare-associated CNS infection generally due to prions or viruses transferred during neuroinvasive procedures or via organ transplantation *(122–128)*.

Nonsurgical infections constitute a smaller, but equally important, class of healthcare-associated CNS infections. These infections are acquired by a variety of routes that include spread from a contiguous focus, posttraumatic/CSF leak, and neuroinvasive procedures, as well as hematogenous spread. Meningitis, brain abscess, subdural empyema, and epidural abscess all may occur in this setting.

DEFINITIONS, DIAGNOSTIC CRITERIA, AND CLINICAL PRESENTATION

It is essential for the purposes of identification, surveillance, and management that healthcare-associated infections be defined and diagnosed with as much sensitivity and specificity as possible. Unfortunately, factors such as colonization and aseptic inflammation prevent the establishment of gold standards and place many conditions within a spectrum of disease. Recognition of an infection as healthcare associated is often not straightforward, and CNS infections are no exception. Doubt over hospital versus community acquisition of an infection is a constant problem compounded by the ubiquity of the major pathogens. The time course that defines specific healthcare-associated infections is neither consistently defined, easy to determine, nor universally accepted. Although the CDC outlines strict definitions and diagnostic criteria, the length of hospitalization prior to an infection being classified as healthcare associated is not specified, with the exception that such infections should not be considered HAIs if they are present or incubating at the time of admission to the acute care setting (109). For SSIs related to implantable devices, healthcare-associated infection may be diagnosed up to 1 year after surgery, according to CDC criteria (109). Some experts consider 60 days a more reasonable length of time for healthcare-associated ventricular shunt infections, as the majority of infections occur within this period (129). In addition, the diagnosis of infection ultimately may be left to the discretion of the attending physician and is inherently subjective. A prospective study by Taylor et al. *(130)* demonstrated that 40% of neurosurgical wound infections were diagnosed using nonstandardized criteria by the surgeon. The potential effect on infection rates is obvious. Ventricular shunt infections illustrate several of these problems. CSF profiles may be nondiagnostic, the microorganism involved may be from the normal flora, and the infection may become evident weeks after hospital discharge. This section integrates the CDC definitions with additional clinical criteria to facilitate proper identification and diagnosis of healthcare-associated infections related to the CNS. The CDC surveillance definitions for healthcare-associated surgical site and specific CNS infections have been previously published (109).

Surgical Site and Related Surgical Infections

Studies dealing with SSIs in neurosurgical patients have used a variety of both strict and less stringent diagnostic criteria for identification *(2,4,12,25,57,58,131–136)*. Commonly, these infections are classified in the surgical literature as either superficial or deep. Superficial neurosurgical infections are considered to be limited by the cranial or lumbodorsal fascia. Deep wound infections encompass soft tissue infections below the fascia, including discitis, osteomyelitis, and bone flap infections. However, infections below the dura (ventriculitis, meningitis, brain abscess) have been included under this heading as well *(24,56,131)*. To improve surveillance and clarify potential overlap in reporting, the CDC definitions include the category of organ/space SSI to cover additional sites adjacent to the operative site. Specific organ/space SSIs related to neurosurgery include the following: meningitis, ventriculitis, disc space infection, osteomyelitis, intracranial abscess, and spinal abscess (109). With the exception of infections related to implantable devices, infection occurs within 30 days of the operative procedure. Since the organ/space SSI category includes several non–soft tissue infections, the definitions are relatively liberal. Diagnosis of some of these infections is covered in subsequent sections, as they also occur unrelated to surgical procedures. More detail on SSIs in general may be found elsewhere in the text (Chapter 21).

Incisional Surgical Site Infections

From a practical point of view, the diagnosis of incisional SSIs is usually made clinically. Neurosurgical site infections must be promptly identified because of the propensity to spread to deeper spaces *(137)*. Superficial incisional SSIs tend to be diagnosed at an early stage, usually within the first postoperative week *(59,138,139)*. Generally, the area is swollen and erythematous with local tenderness. Purulent discharge and/or microorganisms isolated from drainage or a wound aspirate complete the picture. Temperature and the white blood count (WBC) are not uniformly elevated; the erythrocyte sedimentation rate (ESR) and CRP may be increased *(2,136)*. Deep incisional SSIs present later postoperatively with a course that may be insidious or progressive. The average time between surgery and the diagnosis of a deep infection in spinal surgery may vary from 10 to 15 days, with the range extending several weeks *(136,140)*. A relatively normal appearance of the overlying surgical site contributes to this delay in many cases *(140)*. Elevations of temperature, WBC, ESR, and CRP, as well as the presence of fever/chills or hyperglycemia in diabetic patients, while clearly nonspecific signs, are not infrequently seen *(136,138,140)*. Patients often complain of increased pain at the surgical site *(141)*.

Infections of bone flaps following craniotomy are well described and account for up to one half of infections following this procedure *(1,56,60,142)*, though a more recent large series described bone flap osteitis in 12% of postcraniotomy SSIs (77) By definition, infection involves either the free (devitalized) or the osteoplastic bone flap following a supratentorial craniotomy. These infections may be obviously symptomatic with high fever, scalp tenderness, and suppuration *(4,143)* or more indolent with a persistent fistula *(2)*. In one series, 12 of 13 bone flap

infections were diagnosed within 30 days of surgery *(139)*; Korinek found a median time to diagnosis of bone flap osteitis of 27 days (77). Sequential nuclear scanning with technetium 99 may have enhanced diagnostic accuracy for cranial flap osteomyelitis, especially to rule out this infection *(143)*. Indium 111–labeled leukocyte scanning is a useful technique *(144,145)*. Plain skull radiographs are helpful, if positive, but lack sufficient sensitivity to be useful routinely *(60)*. The use of magnetic resonance imaging (MRI) is invaluable in establishing a diagnosis, while CT findings are nonspecific and may not help establish a diagnosis of infection (146). In general, a cranial bone flap infection is diagnosed clinically with either radiographic or microbiologic confirmation *(4)*. A subgaleal abscess occasionally occurs adjacent to a scalp surgical site. In this case, a localized collection forms in the space between the galea of the scalp and the pericranium. Scalp tenderness, erythema, fever, and regional adenopathy may be seen. Osteomyelitis or intracranial spread of infection can occur secondarily if the underlying skull integrity has been compromised. Diagnosis of most deep incisional SSIs may be established clinically, via culture of a deep aspirate, or, rarely, with the assistance of radiologic studies. Evaluation of a soft tissue fluid collection with sonography or CT scan can be helpful.

Organ/Space Surgical Site Infections

Discitis (infection of the intervertebral disc space) is a relatively uncommon but potentially serious postoperative complication of spinal surgery *(147–151)*. The fact that almost 20 years of surgery passed before this infection was recognized illustrates the difficulties encountered in diagnosis *(152)*. Patients typically present with worsening back pain and muscle cramping 1 to 8 weeks after surgery and initial improvement of preoperative symptoms *(58,61,153,154)*. In a series of 111 cases of discitis described by Iversen et al. *(155)*, back pain appeared at an average of 16 days postoperatively. Occasionally, overt infection occurs immediately after surgery *(61,156)*. Patient examination may disclose pain with lumbar range of motion, paraspinal muscle spasm, and/or an abnormal straight leg raising test *(58,61,151,157)*. Neurologic deficits are unusual and should raise suspicion for an epidural abscess. Fever is variably present, and the superficial surgical site frequently appears normal. Most notable is the severe and persistent low back pain out of proportion to the findings on physical examination. Routine laboratory studies such as the WBC are generally unremarkable, with the exception of the ESR *(61,155,157)*. Following spine surgery, the ESR rises rapidly (peak 90–110) and falls steadily to near-normal levels within several weeks *(158,159)*. A significantly elevated ESR more than 2 weeks postoperatively correlates positively with disc space infection *(62,158–160)*. Others have found this test less valuable, especially with early infections *(155)*. CRP, an acute-phase reactant, may be useful as a diagnostic tool when followed serially in patients postoperatively. A prospective study of 348 consecutive patients undergoing spinal surgery had CRP measured on days 1, 3, and 5 postoperatively; these values demonstrated a characteristic increase and fall in 96% of patients experiencing a benign clinical course, with mean values of 14.9, 15.4, and 7.9 mg/dL on days 1, 3, and 5, respectively *(161)*. However, 4.6% (16 patients) displayed an abnormal CRP response with a second increase, and five of these patients were ultimately diagnosed with a postoperative spinal infection, though none with diskitis. The sensitivity, specificity, positive, and negative predictive values for the abnormal CRP response in this patient population were 100%, 96.8%, 31.3%, and 100%, respectively.

Several radiographic modalities are helpful in establishing the diagnosis of discitis. Plain films are of little utility in the early weeks, as most decreases in disc height are expected postoperatively. More characteristic findings occur weeks to months later with blurring of the end plate and irregularity and lytic destruction of the subchondral surface *(162)*. Osteomyelitis of the adjacent vertebrae may occur in advanced cases. These findings are visualized in greater detail with CT scans *(163)*. Currently, MRI with gadolinium enhancement has become the procedure of choice for the so-called failed back syndrome following spinal surgery *(164)*. Early changes on MRI may distinguish disc space and vertebral body infection from the normal postoperative spine with a high degree of accuracy *(154,165–168)*. Nuclear imaging is of limited value because of the high level of background positivity *(62)*. Sequential technetium 99 and gallium 67 scans improve sensitivity but require at least 48 hours to complete *(169)*. Although somewhat controversial, diagnosis of infectious discitis should be confirmed by biopsy despite a consistent clinical and radiographic picture. Tissue sampling allows discrimination between septic and aseptic (chemical or avascular discitis) processes and facilitates directed antibiotic therapy. Peripheral blood cultures are rarely positive for the offending microorganism *(58,170)*. Percutaneous needle aspiration of the affected disc space under fluoroscopic or CT guidance is the method of choice. Ideally, antibiotics should be withheld until after the procedure is complete. The results of the Gram's stain and/or culture are diagnostic in up to 70% of cases, and histologic examination may indicate a septic picture in cases lacking positive microbiology *(157,160)*.

Isolated vertebral osteomyelitis is very uncommon following laminectomy and related procedures. When present, it is usually associated with progressive infection of the contiguous disc space (spondylodiscitis) *(154, 170–172)*. Clinical presentation and diagnosis are virtually the same as outlined above for discitis.

Meningitis

The diagnosis of healthcare-associated meningitis requires a high index of clinical suspicion and support from CSF analysis. Excluding ventricular shunt infections, most cases of meningitis following neurosurgery are diagnosed in the early postoperative period. Several series have shown that the majority of cases develop within 10 days of surgery, and virtually all are diagnosed within 28 days *(3,6,7,60,72,173)*. Healthcare-associated meningitis unrelated to surgical procedures has a more variable time course. Posttraumatic bacterial meningitis associated with a CSF leak may occur days to years after the initial injury *(21,174)*. Although some of these infections may develop in the hospital, acquisition of the infecting microorganism likely has occurred in the community environment *(21,22,175)*. Since the CDC definitions do not specify a period during or after hospitalization that distinguishes healthcare-associated

from community-acquired infection, evidence for hospital acquisition must be sought (109). In a review of 197 episodes (157 patients) of healthcare-associated meningitis by Durand et al. (5), 97% of patients were diagnosed more than 48 hours after admission or within 1 week of discharge (5). Interestingly, 41 episodes (10 patients) in this study were recurrent during the same hospitalization. Other studies indicate a similar pattern of presentation *(7,21)*. We consider it reasonable to view nonsurgical healthcare-associated meningitis as developing several days after hospitalization and unrelated to an obvious community-acquired infection. Unfortunately, these distinctions are not always easy to make.

The standard clinical signs and symptoms suggestive of meningitis are often of little help in diagnosing healthcare-associated infection. Fever appears to be the most ubiquitous finding in all healthcare-associated cases *(3,6,7,72,173)*. Neurosurgical patients commonly demonstrate an altered level of consciousness, neck stiffness, and headache reflecting some combination of their underlying disease and the surgical procedure itself in the absence of infection. These relatively nonspecific findings may become more useful if a change over time is noted or a new fever develops. Findings indicative of meningeal irritation are more useful in nonsurgical patients, especially when combined with fever and a change in mental status. Aseptic meningeal inflammation is a common postoperative condition that may further confound the diagnosis. Clinical parameters have been consistently unable to distinguish aseptic from bacterial meningitis *(176,177)*. The use of corticosteroids may blunt the signs and symptoms of inflammation in both surgical patients and compromised hosts *(114,178)*. Neutropenic hosts cannot mount an inflammatory response, and the resultant symptoms are often minimal *(178)*. Low-grade fever, lethargy, and/or headache may be the only clues in these patients *(115)*. Concurrent medical conditions or extremes of age often modify the typical clinical presentation *(6,179,180)*. Finally, the administration of perioperative antibiotics may alter the natural course of clinical responses and laboratory findings (see below).

The signs and symptoms of posttraumatic bacterial meningitis are often similar to those seen in acute bacterial meningitis *(181)*. However, as with the neurosurgical patient, clinical findings may be more difficult to interpret in the patient with considerable head trauma. CSF infection should be considered when there has been any change in neurologic status, or when fever or neck stiffness is noted that was not present initially *(21,182)*. For these patients at increased risk, it is important to establish evidence of CSF leakage when meningitis is a concern. In a retrospective study of 860 patients with moderate-to-severe head trauma, 12 (1.39%) developed meningitis, with 58% of these patients presenting with clinically apparent rhinorrhea (183). The most common signs of a CSF leak are rhinorrhea, otorrhea, hemotympanum, Battle's sign (mastoid ecchymosis), and cranial nerve palsies *(22,184)*. Detection of CSF rhinorrhea is critical and may be performed at the bedside using a glucose oxidase reagent strip to detect increased glucose in nasal secretions, with the caveat that blood, especially when visible in the nasal fluid, may produce a falsely positive test *(185)*. Unfortunately, a negative result does not rule out the presence of a fistula *(186)*. Identification of beta(2)-transferrin in nasal secretions using immunofixation or electrophoresis has shown promise as a useful indicator of CSF leakage (187,*402–404*). A fluorescein dye test can also be used to identify suspected cases of CSF otorrhea and localize the source *(188)*. Radiographic studies are the procedures of choice to document and localize CSF leakage. CT scanning and MRI are superior to plain films in diagnosing basilar skull fractures and identifying fistulae *(189,190)*. Radioisotope cisternography using ^{111}In- or technetium-99m-labeled diethylenetriamine pentaacetic acid (DTPA) is highly sensitive, but specificity is a problem and localization is poor (191,*406*). A combination of different imaging modalities may be required to accurately localize the site of a CSF leak *(405)*; high-resolution CT combined with a fluorescein injection study may offer the best characteristics currently (191). Considering the diagnostic subtleties associated with healthcare-associated meningitis, examination of the CSF assumes a critical role.

Analysis of CSF obtained from hospitalized patients at risk for developing meningitis is often difficult. Neurosurgical patients commonly have abnormal CSF profiles secondary to underlying disease (tumor), procedures, intracranial bleeding, and seizure activity. Perioperative antibiotics will influence the results of cultures of CSF. Nonsurgical patients are likely to be receiving concurrent antibiotics for other infections. Compromised patients may have blunted inflammatory reactions or abnormal CSF profiles from noninfectious processes (e.g., carcinomatous or leukemic meningitis). Despite these limitations, the results are often revealing, and examination of the CSF should be performed routinely in all suspected cases *(407)*.

The CDC definition for healthcare-associated meningitis does not specify abnormal values for routine CSF parameters. As with community-acquired bacterial meningitis, most cases of healthcare-associated meningitis are associated with an increased CSF white cell count, neutrophilic pleocytosis, elevated protein, and depressed glucose (*2*,*3*,5,*7*,*20*,*72*,*137*,*148*,*181*,*192*,193). Neurosurgical patients with culture-proven meningitis generally have more than 100 WBCs/mm^3 with over 50% neutrophilia *(7,72,137,173)*. In the series by Berk and McCabe *(173)*, all patients were noted to have over 100 WBCs/mm^3, with the majority having more than 1,000 cells/mm^3 (median 2,500). In 72 episodes of culture-negative healthcare-associated meningitis described by Durand et al. (5), 97% of patients had more than 300 WBCs/mm^3, and 96% had more than 50% neutrophils. Since an intracerebral bleed or a subarachnoid hemorrhage allows both WBCs and RBCs to enter the CSF, a correction formula may be used to better approximate the number of abnormal white blood cells *(194)*. A CSF protein level >100 mg/dL and a glucose level <40 mg/dL are present in the majority of healthcare-associated cases (5,*7*,*72*,*137*,*173*,*177*). Unfortunately, several studies have found no significant difference in cell counts and other CSF parameters in (early) postoperative patients with septic versus aseptic meningitis *(176,177)*. In these patients, a significantly lowered glucose level (<20 mg/dL) might be the best indicator of an infectious etiology in the absence of culture data (5). The administration of muronomonab (OKT3) to organ transplant recipients during rejection has been associated with the development of aseptic meningitis *(195,196)*.

Routinely, the CSF should be Gram-stained and set up for bacterial culture. In immunocompromised patients, fungal, mycobacterial, and viral studies may be indicated as well. The yield on Gram-stained CSF is lower than in community-acquired cases and approximates 50% overall (5,*78*). Although a positive culture remains the gold standard, it is impossible to make this requirement for healthcare-associated cases if the clinical data and CSF profile are otherwise supportive. In one large retrospective study, a positive culture was obtained in 83% of healthcare-associated cases and a comparable percentage of community-acquired cases (5). Since concurrently positive cultures are often obtained from sites outside the CNS, cultures from blood, adjacent wounds, and urine are suggestive in the appropriate setting *(3,7,60,63,72,137,173)*.

Clearly, the diagnostic value of CSF sampling, under any circumstance, can be greatly influenced by the administration of intravenous antibiotics. The effect of antibiotics prior to lumbar puncture is most marked on the Gram's stain and culture with little alteration of the other standard parameters *(197,198)*. A negative Gram's stain and culture will commonly occur after 24 hours of appropriate therapy *(199)*. The CSF glucose and white cell count usually remain abnormal for at least several days *(194)*. When combined with the baseline abnormal CSF of the craniotomy patient or the tempered inflammatory reaction of the neutropenic host, the effect of prior antibiotics on diagnosis is substantial, and second-line tests assume greater importance. Latex agglutination to detect the capsular polysaccharide of *Cryptococcus neoformans* is a highly efficacious test in immunocompromised patients *(115,178)*. Broad-range polymerase chain reaction (PCR) to amplify the 16S ribosomal RNA sequences specific to bacterial pathogens offers a promising avenue to supplement Gram's stain and bacterial culture, particularly in patients who have received antimicrobial therapy prior to CSF sampling *(200)*.

Final mention should be made concerning the role of neuroimaging in the diagnosis of bacterial meningitis. Although contrast enhancement of meninges may be seen on CT or MRI early in the course of illness, these findings are nonspecific and contribute little to establishing the diagnosis *(164)*. A better use of these modalities is to exclude other CNS pathology or to diagnose intracranial complications of meningitis *(201)*.

CEREBROSPINAL FLUID SHUNT INFECTIONS

A variety of temporary and permanent prosthetic devices are used to access, drain, divert, and monitor the CSF. These devices may be internalized for chronic use or externalized for use in the acute setting. Internalized devices consist of shunts (ventriculoperitoneal, ventriculoatrial, ventriculoureteral, lumboperitoneal), and reservoirs (lumbar, ventricular). Externalized devices facilitate drainage (ventriculostomy, lumbar drain, external shunt) or measure ICP when the device (intraventricular, epidural, subdural) is connected to a transducer. Insertion of a ventriculoperitoneal shunt is the most common surgical procedure performed for the long-term control of hydrocephalus. Infections complicating these devices may occur at any site or compartment traversed by the prosthesis. Proximal infections include meningitis, ventriculitis, empyema, abscess, and infection involving the surgical site (wound infection, cellulitis, osteomyelitis). Distal infections include tunnel infections along the catheter tract, bacteremia, pleuritis, peritonitis, and related intra-abdominal infections. Infections of temporary devices are almost always healthcare associated, because their insertion and use requires hospitalization. The current CDC guidelines define infection secondary to an implantable device as healthcare associated if it occurs within 1 year of the operative procedure and the two appear to be related (109). Such a designation must often be based subjectively on the type of infection, clinical setting, and responsible microorganism. Because of the clustering of shunt infections within 60 days of implantation (*10,64*,*79*,*80*,202,*203*), shorter periods have been suggested to designate a shunt infection as healthcare associated (129). Because of the considerable overlap among infections of different CNS prosthetic devices, this discussion can focus on the diagnosis of CSF shunt infections as the prototype for this group. Certain specific infections potentially related to CSF shunts have already been covered in detail earlier in this chapter (SSIs) or are covered in later sections (intracranial suppurations).

The most important risk factor for the development of CNS shunt infection is the level of training of the neurosurgeon, with neurosurgical trainees having a higher rate of infection *(27)*. Variables such as year of placement of the shunt, age of the patient, length and time of the operation, and exact placement of the distal drain do not increase the risk of infection (202,204). Additionally, elevated CSF protein content does not appear to increase the risk of shunt infection *(205)*.

The clinical manifestations of infections related to CSF shunts, reservoirs, and monitoring devices are quite variable and often nonspecific. Infections of the surgical site or subcutaneous tunnel in the early postoperative period are the most easily recognized, as purulent drainage, erythema, warmth, and tenderness are usually present *(10,79,81,206)*. As will be discussed, infections at these sites are intimately associated with the pathogenesis of deeper and more extensive infections. It has been suggested that CSF shunts be viewed as composed of a proximal and a distal segment with specific signs and symptoms of infection referable to each section *(207)*. Since infection of one shunt section may spread contiguously to involve the entire length of the prosthesis, a patient may present with any combination of signs and symptoms related to the proximal, distal, and intervening sections of the shunt *(82,208–211)*.

In general, fever appears to be the most constant feature of shunt infection (*212,213*,214). Several studies have shown that virtually all patients have a temperature >100°F with the majority febrile to 102°F or higher *(10,82,215,216)*. Unfortunately, the absence of fever cannot be used to rule out infection, as others have demonstrated a small but significant percentage of asymptomatic patients *(81)*. In a recent series examining shunt infections among adult patients (median age: 50, range: 12–80), fever was a presenting symptom in 78%, while neck stiffness (45%) and local signs of infection (49%) were less common (214). Proximal infection of shunts with a ventricular origin is usually associated with symptoms secondary to shunt obstruction

or malfunction *(10,79,81,217)*. Typical clinical manifestations include nausea, vomiting, seizure, malaise, lethargy, irritability, headache, and other indications of increased ICP *(10,13,81,212,213,216–218)*. Classic signs of meningeal irritation (meningismus, photophobia) are present in only one third of patients (*10*,*181*,214). This is due to the inability of CSF to pass into the subarachnoid space of patients with obstructive hydrocephalus or to eventual closure of the aqueduct of Sylvius in shunted patients with communicating hydrocephalus *(219)*. Meningeal signs are more frequently seen in patients with infected lumboperitoneal shunts *(82)*. Manifestations of distal shunt infection depend on the site of the terminal portion. Nearly one third of patients with infected ventriculoperitoneal shunts present primarily with abdominal symptoms in the absence of ventriculitis *(216,220,221)*. Early inflammation about the shunt catheter may result in impaired CSF absorption and loculation of fluid with formation of a peritoneal cyst *(222,223)*. This CSF-oma may present as a palpable mass in younger patients and may represent either a sterile process or an overt infection *(224)*. Multiloculated hydrocephalus, a complication of CNS shunt infection, is more commonly seen as a result of failure to clear a gram-negative bacillus shunt infection following external drainage *(225)*.

Progressive inflammation results in full-blown peritonitis with fever and abdominal tenderness *(212,213)*. An acute abdomen similar to appendicitis may be seen, and intestinal obstruction, bowel perforation, and intra-abdominal abscess have all been described in small numbers *(211,221,226–231)*. Infection complicating a ventriculopleural shunt can lead to the formation of an empyema *(232,233)*. In contrast, patients with vascular shunt (ventriculoatrial) infections tend to present subacutely with lethargy and fever *(10,79)*. The often-indolent presentation of a chronic low-grade vascular infection may delay the correct diagnosis several weeks or longer *(234)*. These patients are also more likely to manifest bacteremia, immune complex nephritis, hypocomplementemia, and thromboembolic complications *(235–237)*. Septicemia, not an uncommon complication in the early years of vascular shunting, is rarely seen today *(208,238)*. A syndrome of immune complex glomerulonephritis (shunt nephritis) is seen in a small number of patients with staphylococcal infections of vascular shunts *(10,239–241)*. Immunoglobulin G and immunoglobulin M antigen–antibody immune complexes are deposited along the basement membrane of renal glomeruli with activation and subsequent depletion of circulating complement *(242–245)*. The nephrotic syndrome may follow generally with mild to moderate impairment of renal function *(246,247)*. Clinically, the patient may have fever, hepatosplenomegaly, proteinuria, hematuria, and an increased ESR *(234,239,247)*. Resolution of the infection usually results in return of the renal function to normal *(234,240)*. Vascular shunt infections may also be accompanied by any of the proximal manifestations mentioned above.

Definitive diagnosis of CSF shunt infections depends on recovery of the etiologic agent from cultures of CSF. However, the physician must always strongly suspect such infection in any patient with fever or evidence of shunt malfunction, as CSF cultures may be negative, particularly if the patient has received prior antibiotic therapy *(248–250)*. As with the clinical presentation, the usefulness and yield of various diagnostic tests differ according to the type of shunt. A recommended diagnostic approach based on the clinical presentation is shown in Table 27-6. The peripheral WBC is generally elevated but may be below 10,000/mm^3 in 25% of patients *(9,10,213,250)*. In patients with ventriculoatrial shunts and chronic bacteremia, positive blood cultures may be obtained in 90% of patients who have not recently received antibiotics *(10,79,82,212,216)*. Conversely, ventriculoperitoneal shunts have a rate of blood culture positivity that approximates only 25% *(79,82,216)*. Urinalysis is indicated when shunt nephritis is suspected, and urine cultures may be useful in patients with ventriculoureteral or lumboureteral shunts. In the early postoperative period, cultures of an infected surgical site or of aspirate obtained from an erythematous subcutaneous tract are always indicated, but the correlation with more definitive CSF cultures is less than perfect. Aspiration of any fluid collection adjacent to the shunt apparatus is also helpful, as a communication with the CSF pathway often exists. Lumbar punctures in patients with ventriculoperitoneal shunts may not reveal evidence of more proximal infection *(207)*. Among 73 CSF specimens collected from adults patients with shunt infections, 66% yielded a positive bacterial culture, with

TABLE 27-6

Clinical Presentation of Shunt Infections and Suggested Diagnostic Steps

Condition	*Diagnostic Procedures*
Meningitis or ventriculitis	Shunt tap and lumbar puncture
Shunt malfunction	Check shunt function by pumping reservoir, shunt tap, contrast radiographic studies of shunt, computed tomography
Wound or shunt tract inflammation	Culture aspirate from inflamed area, shunt tap
Bacteremia (acute or chronic)	Blood cultures, shunt tap, evaluate for endocarditis
Thrombophlebitis or pulmonary embolism	Blood cultures, shunt tap, PE study (CT angiogram, etc.)
Cardiac complications (valve insufficiency, atrial perforation, tamponade)	Blood cultures, shunt tap, cardiac catheterization, echocardiography
Abdominal pain or mass	Culture aspirate from inflamed area along distal ventriculoperitoneal catheter, shunt tap, evaluate surgical abdomen clinically and radiographically
Glomerulonephritis	Blood cultures, shunt tap, urine sediment examination, evaluate for endocarditis

(From Gardner P, Leipzig T, Sadigh M. Infections of central nervous system shunts. *Topics Infect Dis* 1988;9:185–214, with permission.)

valve puncture (91%) and ventricular (70%) CSF specimens more commonly yielding a pathogen compared to lumbar (45%) CSF specimens (214). These limitations make direct sampling of the CSF from the shunt apparatus the most reliable diagnostic test (*10*,*207*,214,*216*,*248*,*249*).

Performing a shunt aspiration enables assessment of shunt function as well as a detailed fluid analysis. Sampling of lumber CSF is of little use, as cultures are often negative (214,*250*). Routine chemical tests are of little value, as an elevated protein or a depressed glucose level is a nonspecific and inconsistent finding *(212,248,249)*. The CSF WBC averages 75 to 150 cell/mm^3; >100 cell/mm^3 correlates with a subsequent positive culture in 90% of confirmed cases *(11,83,248)*. When the cell count is under 20 cell/mm^3, a positive culture is obtained in <50% of cases *(10,79,248)*. All CSF specimens should be immediately Gram-stained, cultured aerobically and anaerobically, and examined for fungus, especially if the host is immunocompromised. The yield of Gram's stain approaches 50% overall and markedly increases with a concurrently elevated CSF cell count or with gram-negative infection *(79,215)*. Although cultures of the CSF appear to be positive in 80% of patients later documented to have infected shunts after removal, the false-negative rate of this test has never been firmly established *(13,82)*. The predictive value of a negative CSF culture may also be substantially decreased in patients whose distal catheters are blocked *(252)*. Supplemental laboratory tests that have been used in diagnosing shunt infection include determination of antistaphylococcal antibody titers and CRP and detection of immune complexes in serum *(252–256)*. In general, the poor sensitivity and specificity of these studies severely limits any clinical utility *(13,252)*. Elevation of the CSF lactate has proven useful in diagnosing postneurosurgical meningitis, but it remains unclear if this readily available test can be used as part of the diagnostic algorithm for shunt infections. In the study by Conen et al., 81% of the patients with shunt infection had CSF lactate values >1.9 mmol/L (214). Neuroradiologic studies such as CT or MRI may give indirect evidence of infection by suggesting obstruction of CSF circulation.

Infection that is essentially restricted to the distal portion of a ventriculoperitoneal shunt is more difficult to diagnose. Peritoneal signs may be present with a normal functional assessment of the shunt and laboratory assessment of the CSF, especially if obtained proximally *(209,222)*. Diagnosis may necessitate a trial of externalization of the distal end with appropriate cultures and close observation for prompt clinical improvement *(203,221,226)*.

Infections of ICP monitoring devices present as proximal shunt infections do. Fever is the most frequent indication of infection, as signs of meningeal irritation are usually absent, and these patients often have an altered sensorium *(34,212,257)*. The most important risk factor for external drain infections is the duration of the device, with a sharp increase in infection rates after 5 days of monitoring in most studies *(14,33–36)*. Infection of the surgical insertion site, ventriculitis, or meningitis is the typical clinical presentation *(9,14,33–36,64,236)*.

In summary, an infection should be strongly suspected in any febrile patient with an indwelling CNS prosthesis. It is important to always consider occult infection as a potential cause of shunt dysfunction *(81)*. All available clinical and laboratory parameters must be utilized in an effort to make an accurate diagnosis. Blood cultures are usually positive in patients with ventriculoatrial shunts, and CSF cultures are positive in the majority of patients with ventriculoperitoneal shunts. Again, it should be emphasized that the CSF may be sterile in a significant number of documented infections. Antibiotic-coated catheters have been proposed as a mechanism to decrease shunt-related infections. A Cochrane meta-analysis examining the use of antibiotic-impregnated shunts (AIS) found that AIS reduced the risk of shunt infections (OR: 0.21, 95% CI: 0.08–0.55) (258). A recent review outlines an approach to treatment of shunt infections using decision analysis *(259)*. This report recommends use of both antibiotics plus shunt removal as the best method to cure shunt infections.

Meningoencephalitis

Meningoencephalitis implies a global CNS inflammation involving the meninges as well as the brain parenchyma. These uncommon healthcare-associated prion and viral infections have been reported following neurosurgical and neurodiagnostic procedures, corneal transplantation, and cadaveric dural grafting *(122–127,260)*. More details on these uncommon infections can be found elsewhere in this text (see Chapter 47), and only a brief overview is offered here.

Generally, meningoencephalitis is characterized by fever and early mental status changes that may later progress to obtundation or coma. The altered level of consciousness and impairment of cognitive functioning may be more impressive than typical meningitis. Focal neurologic features, including sensory disturbances and seizures, are universal findings. Patients with Creutzfeldt–Jakob disease (CJD) develop sensory dysfunction (i.e., ataxia), myoclonus, and cognitive and behavioral abnormalities that progress to overt dementia and finally coma over weeks to months *(261)*. The clinical manifestations of rabies virus have been previously reviewed *(262,263)*. A prodrome of nonspecific symptoms and fever is usually followed by an acute neurologic syndrome manifested by either hyperactivity or progressive paralysis *(263)*. Subsequent coma and death complete the classic picture. Incubation periods of 18 months for CJD and 5 weeks for rabies have been reported in the small number of transplant cases *(125,127)*.

Routine analysis of the CSF is not particularly helpful and usually reveals a nonspecific pleocytosis, elevated protein content, and normal glucose level. The diagnosis of rabies is made by isolation of the virus from saliva, CSF, or brain tissue, or by measurement of neutralizing antibodies in the serum or CSF *(262,264)*. Immunofluorescent staining for rabies antigen may be applied to corneal epithelial cells or to sensory nerves obtained from a full-thickness skin biopsy of the neck *(262,265)*. Histopathologic examination reveals pathognomonic Negri bodies in the majority of cases *(266)*. Patients with CJD exhibit markedly abnormal electroencephalogram results and evidence of cortical atrophy on CT scan *(267)*. Definitive diagnosis of CJD must ultimately be made from brain tissue. Demonstration of pathologic lesions of the cerebral cortex or identification of specific polypeptides (scrapie-associated protein) by immunostaining confirms the diagnosis *(268)*.

Identification of four abnormal proteins in the CSF by gel electrophoresis allows discrimination of CJD from other neurologic diseases *(269)*.

It should be noted that certain bacteria and fungi may cause meningoencephalitis in compromised hosts. The clinical presentation and approach to diagnosis in these patients is essentially the same as for meningitis.

Cranial Epidural Abscess

A CEA or empyema represents a rare infection that occurs between the dura mater and the overlying bone of the cranium. Signs and symptoms are largely based on mass effect, and as these infections often coexist with subdural infections, a composite clinical picture is frequently seen *(270–272)*. Conditions predisposing to the development of a CEA include head trauma, craniotomy, osteomyelitis, paranasal sinusitis, mastoiditis, otitis, and the application of skull tongs *(1,59,273–278)*. Few studies have estimated the number of total cases (as opposed to the incidence per procedure or per hospital admissions) that clearly qualify as healthcare-associated according to the CDC guidelines. However, the reported risk of these infections related to the most common neurosurgical and neuroinvasive procedures appears to be relatively small; most cases (60–90%) are related to paranasal sinus infections *(272)*, and acute sinusitis may be healthcare-associated, especially in the setting of nasogastric intubation.

Healthcare-associated CEA generally occurs as a complication of craniotomy or head trauma. Symptoms include fever, headache, altered mental status, local swelling, erythema, focal neurologic signs, and occasionally seizures *(271,278,279)*. Progression of the abscess is often accompanied by subdural extension and can lead to deterioration of neurologic status, increased ICP, and cerebral herniation *(280)*. The peripheral WBC and ESR are usually elevated, and the CSF profile (lumbar puncture may be contraindicated) reflects parameningeal infection *(270,281)*. The diagnosis is best established by CT, as contrast scanning will reveal a hypodense epidural collection with some degree of ring enhancement *(276,282)*. CEA collections can cross the midline and the underlying brain parenchyma typically appears normal, features that distinguish them from subdural abscesses *(283)*. MRI is likely to be an equally useful modality, but experience remains limited.

Spinal Epidural Abscess

Although hematogenous spread is possible, most healthcare-associated cases of SEA are more likely to be related to spinal procedures (e.g., laminectomy, anesthesia, epidural catheter, injection). In the largest review of published spinal epidural abscess (SEA) cases, 188 of 854 abscesses (22%) were associated with invasive procedures, the most common being epidural anesthesia, extraspinal operations, and spinal operations (284). By definition, healthcare-associated infection becomes evident within 30 days of the procedure, and this is certainly the typical time frame for postoperative cases *(84,285–287)*. However, infection might have been introduced at surgery weeks to months prior to presentation, blurring the distinction between healthcare and community acquisition *(288)*. Patients with SEA secondary to spinal anesthesia develop symptoms from 72 hours to 5 months after catheter placement *(289,290,412–414)* (see also Chapter 60).

The clinical evolution of an epidural abscess as described by Heusner *(291)* occurs in four progressive phases: spinal ache, nerve root pain, radicular weakness, and paralysis. This classic presentation has been well documented in many series, although the rates of neurologic deterioration have been quite variable (*84*,*281*,284,*287*,*288*,*292*,*411*). Backache (71%) and fever (66%) are the most common clinical findings, with one-fifth having local tenderness on exam (284). Other typical symptoms in approximate decreasing order of prevalence include motor weakness, paraparesis, bowel/bladder dysfunction, and sensory deficit (284). Fever, peripheral leukocytosis, and an increased ESR are present in the majority of cases (*84*,284,*287*,*288*,*293*). Rarely, sepsis dominates the clinical picture and the neurologic symptoms go unnoticed *(286)*. In hospitalized patients, initial manifestations may be subtle or difficult to detect because of concurrent conditions, and fever with persistent pain may be the only clue. A small series of postoperative SEAs found a notable absence of fever and peripheral leukocytosis and a paucity of neurologic features *(285)*. Pain and tenderness localized to the surgical site was uniformly present by the second postoperative week *(285)*. Clinical presentations of SEA have also been classified as acute and chronic based on the presence of symptoms for less than or more than 2 weeks, respectively *(84,288)*. Acute cases are likely to be hematogenous in origin, whereas chronic cases are usually related to a contiguous focus of infection *(162,410)*. Although the possibility of an SEA might be considered earlier in healthcare-associated cases, most studies indicate that this is uncommonly the initial diagnosis (284,*287*).

In patients with SEA, CSF analysis usually reflects a parameningeal process with a pleocytosis and elevated protein (*281*,284,*288*,*293*). It might be expected that this profile would overlap considerably with CSF sampling from a relatively early postoperative spinal surgery patient. The CSF white cell count seems to vary inversely with the duration of symptoms *(287)*. Gram's stain and culture of the CSF rarely are revealing; blood cultures are often positive *(287,288)*. Intraoperative cultures are usually positive *(288,293)*.

The diagnosis of an SEA is best confirmed by a neuroradiographic examination showing displacement of intrathecal contrast and/or direct visualization of the abscess. Myelography remains a highly sensitive tool but suffers from the inability to delineate the full extent of the abscess and can cause complications. CT scanning with intrathecal contrast is both highly sensitive and relatively specific but is accompanied by some element of risk *(293–295)*. In selected cases of presumed SEA, CT-guided needle aspiration is useful diagnostically and perhaps therapeutically *(296,297)*. MRI with gadolinium-DTPA contrast is currently the initial examination of choice in patients with suspected spinal infection *(164,166,298)*. MRI is highly sensitive and essentially noninvasive and allows accurate visualization of the full length of an epidural abscess in addition to any contiguous infectious processes *(293,299–301)*. Plain films and radionuclide scans are low-yield nonspecific studies that offer little diagnostic utility. In conclusion, any clinical suspicion should always prompt an imaging study, as rapid neurologic deterioration of the patient may ensue.

Subdural Empyema

Subdural empyema refers to a collection of pus in the space between the dura and the arachnoid. Infection can progress rapidly, as there is little anatomic barrier to spread in this space *(276)*. As with CEAs, most cranial subdural empyemas (CSEs) are related to paranasal sinusitis, otitis media, trauma, and neurosurgical procedures *(302)*. CSEs may be found in conjunction with an osteomyelitis or epidural abscess in 50% of cases. Mortality, near 100% before effective antibiotic therapy, has declined to 9% in one series *(303)*. Clinically, patients present with rapid onset of altered sensorium, meningismus, seizures, focal neurologic findings, and signs of increased ICP following a period characterized by headache and fever *(276,278,303–306)*. A more subacute presentation of CSE has been described in postoperative infections *(307)*. Peripheral leukocytosis and a neutrophilic pleocytosis in the CSF are usually present *(304,305)*. Differentiation from a brain abscess may be difficult on clinical grounds alone. CT scanning or MRI is currently the procedure of choice for diagnosis of CSE, although false negatives may occur *(298,308–312)*. A contrast study will show a crescent-shaped hypodense area with intense enhancement at the brain periphery *(267,309)*.

Spinal subdural empyema is extremely rare; the few cases (61 cases, summarized in reference 297) reported in the literature have been associated with distant sources of infection *(276,313,314,415)*. Presentation is similar to that of SEA except that spinal tenderness on examination may be absent *(314)*. The diagnosis is best made by MRI with gadolinium contrast *(315)*.

Intracranial Septic Thrombophlebitis

Any intracranial suppuration may be associated with septic thrombophlebitis or thrombosis affecting the dura, lateral, sagittal, or cavernous sinuses. Subdural empyema may be complicated by septic venous thrombosis, which can result in brain abscess and infarction. Cortical vein thrombosis has been observed in approximately 25% to 30% of cases and is often associated with a poor outcome *(304,306,415)*. Clinical presentation may resemble parenchymal brain abscess with focal neurologic signs often related to the cranial nerves *(316)*. Similarly, the compressive effects of an SEA may result in thrombosis, thrombophlebitis, and congestion of the epidural venous system *(84,270)*. Again, CT and MRI are the diagnostic methods of choice *(164,267)*.

Brain Abscess

A brain abscess is a focal suppurative process confined to the brain parenchyma. The most common conditions associated with brain abscess include contiguous sources of infection, such as sinusitis, otitis, mastoiditis, dental infection, and cranial trauma (surgical or accidental), or metastatic infection, as in endocarditis or cyanotic heart disease (*64,271,277*,317,*318–320*). Healthcare-associated brain abscess is an unusual complication of routine neurosurgical procedures, paranasal sinus infection, sinus surgery, and transient bacteremia, but may occur following penetrating craniocerebral trauma and in immunocompromised patients *(60,115,321–323)*. In a retrospective study of postneurosurgical brain abscesses, Yang et al. describe 31 patients (0.17% of neurosurgical procedures over a 19-year period) with this condition *(324)*. The period from procedure to diagnosis ranged from 8 to 35 days (mean: 20 days), and there was a male predominance (24 males, 7 females) *(324)*. Gunshot injuries to the head associated with retained bone fragments constitute a particularly high-risk condition *(325)*. Brain abscesses have also rarely complicated the application of cranial tongs and halo fixation devices *(326,327)*. Finally, a brain abscess may follow cranial wound infections, meningitis, shunt infections, or any of the previously discussed CNS-related healthcare-associated infections.

The clinical presentation of a healthcare-associated brain abscess may vary from a relatively acute postcraniotomy suppuration to a more subacute or chronic infection developing secondary to a gunshot wound or indwelling ventricular shunt. Although published data are few, most of these infections appear to present within several weeks of a neuroinvasive procedure. As expected, the healthcare-associated etiology of these infections is often difficult to determine, and supportive evidence is derived from the clinical setting and available microbiology. The presenting features of a brain abscess depend on the size, location, virulence of the microorganism, and condition of the host. Abscesses that evolve secondarily by direct intracranial extension are usually solitary and typically found in the frontal and temporal lobes *(318,319,328–331)*. Infections related to cranial surgery or trauma generally occur in close proximity to the wound (or foreign body), whereas hematogenously spread infection may cause multiple lesions predominantly in a middle cerebral artery distribution *(325,328,332)*. Fever, headache, and focal neurologic findings (the classic triad) are the most common clinical manifestations, seen in approximately 50% of all cases *(329,332,333)*. In the Yang et al. series, fever was present in 17 (54.8%), headache in 11 (35.5%), and motor deficits in 10 (32.3%) *(324)*. Nausea, vomiting, papilledema, seizures, and meningismus are seen in 25% to 50% of patients *(328,332,333)*. Unfortunately, most of these signs and symptoms are difficult to interpret in the neurosurgical patient. The differential diagnosis includes a variety of underlying conditions (e.g., tumor, hydrocephalus, hemorrhage, infarction, thrombosis, and other CNS infections). Any unexpected alteration in mental status or change in the neurologic examination, especially if combined with fever, should prompt a more detailed evaluation (see below). In immunocompromised patients, the abscess must be strongly suspected, as the onset of symptoms may be indolent and the diagnostic clues often are subtle. In these patients, a careful physical examination might disclose purulent drainage or a black eschar on the nasopharyngeal mucosa suggestive of rhinocerebral mucormycosis *(334)*. Proptosis, periorbital cellulitis, ophthalmoplegia, and, ultimately, coma make up the classic rhinocerebral syndrome *(178)*. The spectrum of *Aspergillus* species infections include cellulitis, sinusitis, and pneumonia that may extend to the CNS directly or, more commonly, hematogenously *(335)*. Because of the angiotropic nature of this pathogen, cerebral hemorrhage, thrombosis, or seizure are not uncommon with *Aspergillus* species invasion of the CNS *(114)*.

Peripheral blood studies are rarely useful in the diagnosis of a brain abscess. The WBC may vary from normal to moderately increased, the ESR is nonspecifically elevated in

most cases, and blood cultures are nearly always negative *(332,336)*. Lumbar puncture is generally contraindicated in any patient suspected of having a CNS mass lesion because of the high risk and low yield. When obtained, CSF fluid analysis reveals a mild pleocytosis, elevated protein, and normal glucose consistent with a parameningeal focus of infection (317,*332*,*336*). Cultures are rarely positive unless there is a concurrent meningitis or ventricular rupture has occurred *(337)*. Rapid clinical deterioration and death (presumably from tentorial or brainstem herniation) may occur when CSF is sampled in the presence of a brain abscess, further substantiating the poor risk/benefit ratio of this procedure *(328,329,336)*.

The best approach for the early diagnosis and subsequent management of a brain abscess is provided by radiographic imaging. Previously utilized radionuclide brain scanning with technetium 99 remains a highly sensitive technique (especially in the early cerebritis phase) but has essentially been replaced by newer studies *(267,338)*. The advent of CT scanning has provided a rapid, sensitive, and relatively specific method for diagnosing this intracranial infection. The early phases of cerebritis are characterized by a low-density region on noncontrast scans representing the necrotic center of the abscess. Ring enhancement with contrast occurs variably but may become apparent if delayed images are obtained *(323)*. With formation of a collagen capsule, ring enhancement with contrast is seen in early images surrounding a hypodense center *(323)*. Both edema and contrast enhancement may be attenuated by corticosteroids with minimal effect on a mature lesion *(339)*. Although the sensitivity of CT scans exceeds 95%, the typical findings mentioned above are not pathognomonic and may be seen with neoplasm, infarction, resolving hematoma, and radiation necrosis *(295,339,340)*. Features favoring the diagnosis of abscess include intraparenchymal gas, ependymal or leptomeningeal enhancement, corticomedullary location, multiloculation, ring thickness, and homogeneous capsular enhancement *(323,340)*.

MRI may be the most accurate imaging technique for the diagnosis of brain abscess *(164,312)*. Subtle edema and cerebritis may be detected at an earlier stage on gadolinium-enhanced T2-weighted MRI images than on a corresponding CT scan *(341–343)*. Other potential advantages of MRI over CT include the use of nonionizing radiation, minimal artifact from bone, better delineation of the posterior fossa, and increased ability to differentiate edema from liquefaction necrosis *(341)*. Although the sensitivity of MRI is impressive, the clinical superiority of MRI over CT has not been established *(333)*.

Despite the proper clinical setting and suggestive radiology, an interventional procedure is frequently required to establish the diagnosis, define the etiology, and assist therapeutically. The initial procedure of choice is currently a CT-guided stereotactic aspiration. This highly efficacious technique has an overall diagnostic accuracy exceeding 90% with a reported complication rate (e.g., hematoma, infection, seizure) of approximately 1% *(85,344,345)*. Specific indications for this procedure include (a) the presence of multiple lesions, (b) deep-seated lesions, (c) evaluation for noninfectious etiologies, and (d) the need for external drainage *(344,345)*. Significant coagulopathy is the most common contraindication *(346,347)*. Laboratory evaluation of aspirated material should include histologic examination, Gram's stain, cultures for aerobic and anaerobic bacteria, wet mount, fungal cultures, and viral studies if appropriate. The application of stereotactic biopsy has largely circumvented the use of completely empiric antibiotics as well as the need for a craniotomy.

ETIOLOGY OF HEALTHCARE-ASSOCIATED CENTRAL NERVOUS SYSTEM INFECTIONS

The etiologic agents involved in healthcare-associated CNS infections may be viewed from several perspectives. CoNS, *S. aureus,* and gram-negative aerobic bacilli account for nearly 70% of infections collected through the NNIS system from 1986 to 1992. Table 27-7 displays the distribution of pathogens isolated from neurological SSIs during the period from 2006 to 2007, based on data collected by the NHSN /CDC. Unfortunately, since many healthcare-associated CNS infections are classified as SSIs, only part of the overall picture is reflected in these data. *Propionibacterium acnes,* a gram-positive anaerobic rod, continues to be an increasingly recognized pathogen in craniotomy infections (348). Organ/space SSIs may include meningitis, discitis, and intracranial or spinal abscess. Gram-negative aerobic bacilli are major pathogens in this group, often with significant resistance to antibiotic regimens. Table 27-7 also displays the percentiles of antimicrobial resistance for each respective pathogen. Note that greater than half of the *S. aureus* isolates are methicillin resistant, one-fifth of the *E. coli* isolates are fluoroquinolone resistant, >10% of the *P. aeruginosa* isolates are carbapenem resistant, and nearly one-third of the *A. baumannii* isolates are carbapenem resistant. Yeast (mostly *Candida albicans*) and filamentous fungi (mostly *Aspergillus* species) are involved in an increasing number of CSF shunt infections as the number of susceptible hosts becomes larger. Although the use of rigorous standards makes the NHSN/CDC data extremely useful, further examination of the pathogens responsible for specific healthcare-associated CNS infections, and in specific host populations, is worthwhile. The pathogens in certain infections can be observed to change with the host population (e.g., oncology patients), a particular device, or the duration of follow-up (e.g., CSF shunts). With a few exceptions, the experience with most healthcare-associated infections in the literature correlates well with NHSN/CDC surveillance data.

To a great extent, the pathogens responsible for skin and soft tissue infections following neurosurgery are similar to those found in other surgical infections (see Chapter 21). The close proximity to and often open communication with the CNS underscores the importance of these infections. As will be discussed in the next section, there is a strong association between microorganisms cultured from neurosurgical wounds and isolates obtained from the CSF. *S. aureus* is generally the most common isolate from superficial and deep wound infections following both craniotomy and laminectomy procedures (*1*,*4*,*24*,*56*,*60*,77, *133*,*136*,*347*,*349*). Several studies have identified gram-negative bacilli among the top three isolates; Aucoin et al. *(30)* found these

TABLE 27-7

Healthcare-Associated Pathogens in Neurological Surgical Site Infections 2006–2007, NHSN/CDC Report 2008

Microorganism	*Neurological SSI Percentile*	*Percentile Resistant (Antimicrobial Type)*
Gram-positive pathogens		
Coagulase-negative staphylococci	16.2	
Staphylococcus aureus	50.9	49.2(Oxa)
Enterococcus faecalis	1.2	4.7(Van); 4.1(Amp)
Enterococcus faecium	0.1	56.5(Van); 71(Amp)
Enterococci NOS	1.7	6.7(Van); 10.9(Amp)
Gram-negative pathogens		
Escherichia coli	3.7	22.7(FQ); 2.5 (CARB); 5.3 (CTR or TAZ)
Pseudomonas aeruginosa	4.2	15.9(FQ); 7.9(PTZ); 2.0(AMK); 11.8(CARB); 7.3(TAZ); 5.7(CPM)
Klebsiella pneumoniae	1.8	14.8(CTR or TAZ); 5.2(CARB)
Klebsiella oxytoca	0.4	8.1(CTR or TAZ)
Acinetobacter baumannii	0.8	30.6(CARB)
Enterobacter spp.	4.6	
Fungal pathogens		
Candida albicans	0.4	
Other Candida spp. or NOS	0.0	

(Data adapted from CDC/NHSN Annual Update. *Infect Control Hosp Epidemiol* 2008;29:996–1011.)
Oxa, oxacillin; Van, vancomycin; Amp, ampicillin; CARB, carbapenem; CTR, ceftriaxone; TAZ, ceftazidime; FQ, fluoroquinolone; PTZ, piperacillin-tazobactam; AMK, amikacin; CPM, cefepime; NOS, not otherwise specified.

microorganisms to be the most common isolates from ventriculostomy-related wound infections. Other important microorganisms in decreasing frequency of occurrence include *S. epidermidis,* streptococci, diphtheroids (including *P. acnes*), and *Clostridium* species (*1*,*24*,*30*,*56*,*60*,77,*131*,*133*).

As discussed previously, meningitis is responsible for over 90% of all healthcare-associated CNS infections. The largest single institutional study of bacterial meningitis in adults was published by Durand et al. (5) at the Massachusetts General Hospital. They identified 197 episodes of healthcare-associated meningitis in 151 patients over a 27-year period. The majority of patients had had recent neurosurgery or a neurosurgical device (65%), evidence of immune system compromise (20%), or a CSF leak (9%). The most common healthcare-associated pathogens included gram-negative bacilli (33%), *S. aureus* (9%), CoNS (9%), *Streptococcus* species (9%), *H. influenzae* (4%), *Listeria monocytogenes* (3%), and *Enterococcus* species (3%). The relatively lower incidence of gram-positive infections in this series may reflect changing epidemiologic trends, the increased number of procedures, and improving culture techniques inherent in a long study period. Of note, 41 episodes of recurrent meningitis occurred in this group and were caused primarily by gram-negative bacilli (46%).

Studies examining meningitis following neurosurgery have repeatedly implicated gram-negative bacilli as the predominant pathogen responsible for up to 69% of cases *(3,7,72,173)*. In a series of 23 cases of neurosurgical meningitis reported by Buckwold et al. *(3)*, 19 cases were due to gram-negative bacilli and four cases to *S. epidermidis (3). Enterobacter* species and *Klebsiella* species were the most common microorganisms. In a large prospective single institution study of postcraniotomy meningitis over 6 years (1997–2003), 28 of 86 pathogens isolated (32.6%) were Enterobacteriaceae, 20 (23.3%) were CoNS, and 13 (15.1%) were *S. aureus* (350). Looking at the entity of gram-negative meningitis as a whole, approximately 50% of cases are related to neurosurgery *(7,72,173). Klebsiella* spp, *Enterobacter* spp., *Escherichia coli, Pseudomonas aeruginosa,* and *Acinetobacter baumannii* are the most frequent isolates. So-called diphtheroids (*Corynebacterium, Bacillus* species, and *P. acnes*) are also important pathogens in neurosurgical patients (see below). Wound infection due to *P. acnes,* with and without meningitis, has been reported after neurosurgical procedures (348,*351–353*).

In studies similar to those yielding the NHSN/CDC system data in Table 27-7, staphylococcal species are isolated from approximately 60% to 80% of CSF shunt infections in large series, whereas gram-negative bacilli are found in 5% to 27% of cases *(10,13,79,81,82,181,212,213,216,250,354, 355)*. CoNS (mostly *S. epidermidis*) are isolated in 50% to 75% of cases followed by *S. aureus* in 10% to 25% of cases *(82,86,354)*, although McGirt et al. *(250)* reported that a hospital stay of >3 days at the time of shunt insertion and a prior *S. aureus* shunt infection independently predicted that *S. aureus* was the causal pathogen. There appears to be little difference in the pathogens involved in early versus late shunt infections, although one study suggested that gram-negative pathogens, especially *H. influenza,* may be more common in late infections *(79,250)*. Conen et al. found that late shunt infections were polymicrobial in six of eight adult patients (214). Similarly, the location of the distal end of the shunt catheter does not seem to significantly affect the distribution of pathogens unless intestinal perforation has occurred *(216,356)*. Other commonly encountered pathogens include streptococcal species and

diphtheroids. *P. acnes* is particularly important, as it has been reported to be the second most common pathogen in some series *(357,358)*. Whether the incidence of this pathogen is truly increasing or underestimation occurs secondary to inadequate anaerobic culturing remains unclear *(359)*. *Bacillus* species have also been implicated in shunt infections *(360)*. Anaerobic bacterial and fungal shunt infections have been reported but are seen much less frequently.

The microbiology of infections complicating other CNS prosthetic devices closely parallels the profile seen with ventricular shunts. Gram-positive cocci account for the majority (70–75%) of infections complicating the placement of CSF reservoirs, with the remainder caused primarily by gram-negative microorganisms and diphtheroids *(36,87)*. Ohrstrom et al. *(361)* found gram-positive cocci in almost 90% of 27 ventriculostomy-associated CSF infections. In a large prospective study of ventriculostomy-related infections, Mayhall et al. *(9)* described nearly equal numbers of gram-positive (47%) and gram-negative (53%) pathogens. CoNS were the predominant species, accounting for 32% of isolates. Aucoin et al. *(30)* noted an increase in gram-negative ventriculomeningitis (~75%) in patients with ICP monitors compared with craniotomy alone. A more recent study of ventriculostomy infections by Arabi et al. found gram-negative bacilli in 50% of cases, with gram-positive cocci in 29% *(35)*. *B. cereus* meningitis was reported in two patients with external ventricular drainage and could be traced to contaminated linen used during surgery *(49)*.

The infectious agents responsible for deep CNS and neurosurgical infections (organ/space infections) have generally been well described in the literature. Unfortunately, although significant numbers of these cases are healthcare associated, information relating specific pathogens to healthcare-associated cases is relatively limited. Most healthcare-associated cases of CEA and CSE occur in the setting of trauma, surgery, or paranasal sinus infection *(270,303)*. Infections originating from the sinuses or mastoids are usually caused by anaerobes, streptococci, enterococci, or *S. aureus (303,304,362,363)*. Postsurgical and posttraumatic suppurations are usually due to *S. aureus,* streptococci, or gram-negative bacilli *(304,364)*. Khan and Griebel *(365)* found that most cases of postsurgical and posttraumatic subdural empyemas were caused by *S. epidermidis* or *S. aureus*. A large review of 699 cases of CSE found viridans group streptococci (*S. milleri*, *S. haemolyticus*) in nearly 25% of patients and gram-negative bacilli in 14% (366). Spinal epidural abscess is caused by *S. aureus* in 50% to 65% of cases, followed in frequency by streptococci (9–14%), gram-negative bacilli (8–16%), and *S. epidermidis* (3–9%) *(84,274,287,288,292,362)*. Again, although varying numbers of these infections were healthcare associated, correlation to specific pathogens was not performed. However, a small series of iatrogenic cases of spinal epidural abscess reported by Ericsson et al. *(286)* describes a distribution of pathogens quite similar to the studies cited above. In the largest analysis of SEA cases to date, Reihsaus et al. reported *S. aureus* in 73% of the cases (551 of 753 pathogens isolated) (284). Disc space infection in adults is usually a postsurgical complication, although hematogenous spread occurs as well *(162)*. *S. aureus* is the most common pathogen followed by *E. coli, S. epidermidis,* and other gram-negative microorganisms *(58,61,151,157)*.

Healthcare-associated brain abscess is an uncommon infection that usually occurs in association with neurosurgical procedures or penetrating head trauma *(60,271,323–325,332)*. A smaller number of cases may occur in the setting of sinus infection or generalized bacteremia *(328)*. If present, the abscess is usually related to the surgical site, and staphylococci are usually isolated *(182,332,333,367)*, commonly as part of a polymicrobial infection *(324)*. Other prevalent pathogens in this setting include streptococci, gram-negative aerobic bacilli, and *Clostridium* spp. *(320,324,368)*. Anaerobes, streptococci, and, less commonly, *S. aureus* and gram-negative microorganisms are involved when a paranasal sinus or a mastoid source of infection is present *(329,332,367)*. Hematogenous seeding of the brain may occur during the course of staphylococcal endocarditis and with gram-negative bacterial or fungal dissemination in immunocompromised hosts (see below) *(115,178)*.

In the hospital setting, immunocompromised patients are at risk for a somewhat different spectrum of CNS infectious agents than their counterparts with normal immune function. It is important to recognize the close relationship between the duration and type of specific immune defect and the infections to which the host is susceptible. Table 27-8 illustrates the association between host immune status, typical CNS pathogens, and the clinical syndromes they cause. Several important pathogens (e.g., *Cryptococcus, Toxoplasma, Nocardia*) in this group are not included, as hospital acquisition would be unusual. Studies by Chernik et al. *(116)* identified the pathogens responsible for CNS infections among patients at a large cancer hospital. Of potential healthcare-associated pathogens, gram-negative bacilli (50% *P. aeruginosa*) were the most frequent cause of meningitis, followed by *L. monocytogenes,* streptococci, and, rarely, fungi. Various gram-negative bacilli were also responsible for three quarters of the brain abscesses, although *Aspergillus* was the most common isolate *(112)*. The majority of cases developed during the course of hospitalization. In a follow-up to their initial studies, the same authors noted a high incidence of fungal CNS involvement on postmortem examination alone *(112)*. Other reports have also described an increase in CNS candidiasis with systemic involvement, suggesting a higher-than-expected prevalence of this pathogen *(121,369)*. *Aspergillus* invasion of the CNS is often cited as the most common intracranial infection in cardiac and renal transplant patients *(370)*. Needless to say, these patients are also at risk for the common healthcare-associated pathogens that may complicate neuroinvasive procedures.

OUTCOME

The considerable morbidity and mortality associated with infections involving the CNS place them among the most serious of healthcare-associated infections. Morbidity may be manifested by varying degrees of neurologic deficit, ranging from paresthesia to permanent paralysis. Intellectual impairment can be a particularly devastating consequence. Mortality due to CNS infection is

TABLE 27-8

Healthcare-Associated CNS Infections in Immunocompromised Patients

Defect/Patients	*Pathogens*	*Clinical Syndromes*
Cell mediated

[a]During the period of neutropenia in the early posttransplant period (0–30 days).

frequently difficult to establish with certainty in critically ill patients with other significant medical problems. These patients may have died for reasons apart from healthcare-associated CNS infections, severely limiting the usefulness of most mortality data. Hospitals reporting through the NHNS system determine (subjectively) whether healthcare-associated infections were a contributing factor in patient death. For the period 1988 to 1993, healthcare-associated CNS infections were deemed to be related to death in 49 of 53 patients (92%) who died with a diagnosed healthcare-associated CNS infection (R. Gaynes, personal communication to Nelson Gantz). This finding suggests that healthcare-associated CNS infections may contribute significantly to mortality. In addition, the economic costs of healthcare-associated CNS infections are often substantial and are associated with the need for extended hospitalization, intravenous antibiotics, sophisticated imaging, and multiple surgical procedures.

Superficial SSIs in neurosurgery, although often prolonging hospitalization, are rarely associated with any mortality by themselves *(131)*. The majority of bone flap infections resolve with antibiotics and/or debridement, and a small number develop chronic persistent drainage *(4,143)*. The real danger of these infections lies in intradural extension leading to increasing complications and deaths *(1)*.

The reported mortality related to healthcare-associated meningitis (not associated with prosthetic devices) ranges from 20% to 67% (*3*,5,*6*,*7*,*72*,*173*). Durand et al. (5) found the mortality rate to be 35% for healthcare-associated cases, compared with 25% for community-acquired infections. The complication rate (i.e., seizures) is also high and may be up to 50% in some series *(7)*. However, Baltas et al. found no mortality associated with posttraumatic meningitis and reported the development of hydrocephalus in two (of 12 patients with meningitis) patients who also happened to receive intrathecal amikacin as part of their therapeutic regimen (183). Given the fact that these patients sustained injuries in the community setting, it is unclear whether their favorable outcomes can be translated to those who acquire healthcare-associated pathogens postoperatively. As discussed above, many of these cases involve gram-negative bacilli, and some authors have demonstrated that increased mortality occurs with these microorganisms *(3)*.

Of all infectious complications related to neurosurgery, CSF shunt infections are probably responsible for the largest volume of morbidity and mortality. Walters et al. *(82)* found patients with infected shunts required three times the number of surgical procedures as non-infected patients, and had greatly prolonged hospitalizations and double the case fatality rate. Schoenbaum et al. *(10)* found long-term mortality to approach 40% in patients with infected shunts as compared to 17% in shunted patients without infection. Yogev *(371)* performed an extensive review of success rates in treatment of CSF shunt infections by compiling multiple studies over a 25-year period. Cure rates were directly related to the therapeutic modality as follows: (a) 36% for antibiotics alone; (b) 65% for antibiotics and immediate shunt replacement; and (c) 96% with antibiotics, shunt removal, and external drainage or repeated ventricular aspirates. In a similar analysis by Kaufman and McLone *(207)*, cure rates were nearly identical in each category, with mortality rates decreasing from approximately 24% with intravenous antibiotics alone to <10% with antibiotics plus externalization. One potential drawback of the latter method is secondary

contamination of the ventriculostomy and complications related to a new infection. Retrospective studies have shown that shunt infections are associated with deterioration of intelligence quotient (IQ) scores *(372)*. Infections related to other CNS prosthetic devices are also associated with significant mortality, especially in the setting of gram-negative involvement *(9,30,111)*. Mayhall et al. *(9)* found no untreated patient survived a ventriculostomy-related infection; Smith and Alksne *(88)* found 100% mortality when *P. aeruginosa* was the pathogen.

Unfortunately, the precise relationship between most healthcare-associated organ/space CNS infections and outcome cannot easily be determined from reviewing the literature. Therefore, and because of the low incidence of these infections, only general trends can be examined. Spinal epidural abscess is an infection in which significant neurologic deficit is probably the most common complication. Mortality ranges from 5% to 33%, and persistent neurologic abnormalities (weakness, paraparesis, paralysis) can be seen in 10% to nearly 50% of cases *(84,286–288,292)*. Two large series found paralysis or death in 23% of patients *(287,288)*. In their large meta-analysis, Reihsaus et al. found that SEA mortality improved from 34% during the period from 1954 to 1960 to 15% during the period from 1991 to 1997'. Cranial subdural empyema carries a mortality rate of 15% to 35% with a high incidence of seizures and disabling neurologic sequelae *(268,304,306,365,373,374)*. Kaufman et al. *(304)* described four cases of postoperative subdural empyema in which two patients died and another suffered a permanent neurologic deficit. In a retrospective review of subdural empyema, Dill et al. *(303)* reported an overall mortality of 9%, but 55% had neurologic deficiency at time of hospital discharge. In their review of 699 cases of intracranial subdural empyema, Nathoo et al. report a mortality rate of 12% and a morbidity rate of 25.9%, including 14.7% of 509 patients with clinic follow-up who experienced postoperative seizures (366). The prognosis of a healthcare-associated brain abscess is particularly difficult to estimate because of the low frequency of occurrence and the often-concurrent existence of another serious intracranial infection *(60,323)*. In general, advances in diagnosis and treatment have resulted in a current overall mortality rate of approximately 10% to 32% *(320,375,376)*. Adverse prognostic factors include delay in diagnosis, ventricular rupture, depressed mental status at the time of diagnosis, large and/or multiple lesions, extremes of age, and specific gram-negative or fungal etiology *(328,329,332,336,337,377)*. Since most patients with healthcare-associated brain abscess have one or more of these risk factors, morbidity and mortality can be expected to be high in this population. Even successfully treated brain abscesses can result in appreciable long-term neurologic complications. Chronic seizure disorders and persistent focal neurologic deficits can develop in up to 50% of patients *(328,336,337–379)*. Neurologic outcome is most influenced by location of the abscess and the age of the patient *(378)*. Cognitive and behavioral function may be permanently impaired, especially in younger patients *(377,380)*. In a more recent study, Yang et al. found a mortality rate of 16% (5 of 31 cases) for healthcare-associated brain abscesses in patients after neurosurgical interventions, with death occurring as a result of brain edema and herniation in all five *(324)*. Three of 31 case patients in this series experienced a relapse of brain abscess. Of the 26 survivors, 3 were in a persistent vegetative state, 15 had moderate-to-severe residual neurodeficits, and 8 were able to resume normal activities with little or no deficits. Lastly, postoperative disc space infection (usually healthcare associated) is rarely associated with mortality but may cause significant morbidity. Chronic pain unrelated to the primary problem occurs in many; 39% to 88% of patients are able to return to work after treatment *(58,62,381)*.

The consequences of infection from pathogens of even low virulence are frequently devastating in the immunocompromised patient. CNS infections are often caused by gram-negative bacteria and fungi; eradication of these microorganisms from the CNS is difficult enough in immunocompetent hosts. Chernik et al. *(112,116)* found mortality from CNS infections to be related primarily to the microorganism and the underlying disease of the patient. The highest overall mortality for intracranial infections was seen in leukemic patients (90%), followed by lymphoma patients (77%) and patients with head and spine tumors (59%). Survival was lowest with gram-negative bacterial infection (10–22%) and highest with infections caused by *L. monocytogenes* (63%) and *S. aureus* (76%). Notably, no patient with noncryptococcal fungal infection of the CNS survived in their series. Other series have also described overall mortality rates exceeding 50% from CNS infections in immunocompromised patients *(114,382)*. Darras-Joly et al. describe three cases of cerebral aspergillosis in immunocompromised patients that developed after neurosurgical operations; two of these patients survived after combined surgical debridement, high-dose amphotericin B, 5-flucytosine, and itraconazole *(383)*. These authors reasonably conclude that cerebral aspergillosis should be treated aggressively with a combination of medical and surgical therapy in order to improve an extremely high baseline mortality rate. Subsequent reports in organ transplant patients have documented rare survival with intracerebral aspergillosis *(384)*. Rhinocerebral infection with Mucorales can be cured in over 50% of cases with aggressive medical-surgical therapy and control of acidosis in diabetic patients *(334)*.

PREVENTION

Prevention of Craniotomy Infections

Prior to the 1980s, use of prophylactic antibiotics in neurosurgery was based mainly on data from uncontrolled trials. In the 1980s and 1990s, data from prospective randomized placebo-controlled trials demonstrated the efficacy of antibiotic prophylaxis in patients having clean neurosurgery. A meta-analysis of 2,075 patients evaluating antibiotic prophylaxis prior to neurosurgery found a fourfold reduction in wound infection rate when antibiotic prophylaxis was given *(416)*. Table 27-9 demonstrates at least a three- to fourfold reduction in the incidence of infection after craniotomy using an antistaphylococcal antibiotic such as cefazolin or vancomycin. Some studies have also added gentamicin to the antistaphylococcal antibiotic. Antibiotic prophylaxis is usually administered for 24 hours. Some of the studies

TABLE 27-9

Randomized Trials of Antibiotic Prophylaxis in Neurosurgical Procedures

First Author	*Year*	*Comparator 1 (Infection Rate %)*	*Comparator 2 (Infection Rate %)*
Savitz	1976	Clindamycin (1.2)	None (10.9)
Shapiro	1986	Van/gent (2.8)	None (11.7)
Young	1987	CFZ/gent (1.0)	None (3.8)
Blomstedt	1988	Van (1.8)	None (7.3)
Bullock	1988	Pip (2.1)	None (5.9)
Van Ek	1988	Clox (3.3)	None (10.3)
Djindjian	1990	Oxa (0.6)	None (4.9)
Whitby	2000	CFT (2.5)	TMP-SMX (2.3)
Zhu	2001	Amp-Sul (2.3)	CTX (3.3)

(Data from Refs. *74,385–392*.)
Van, vancomycin; gent, Gentamicin; CFZ, cefazolin; Pip, piperacillin; Clox, cloxacillin; Oxa, oxacillin; CTX, ceftriaxone; TMP-SMX, trimethoprim–sulfamethoxazole; Amp-Sul, ampicillin–sulbactam; CFT, cefotaxime.

used, in addition to the parenteral antibiotics, a bacitracin irrigation solution. In a study of 356 patients given oxacillin or placebo for prolonged clean neurosurgery, there was an eightfold reduction in the incidence of infection in those given parenteral oxacillin compared with the placebo group *(385)*. Use of an antibiotic irrigating solution in that study was not mentioned.

In an uncontrolled study to assess the efficacy of intravenous cloxacillin prophylaxis in patients undergoing craniotomy, the infection rate was 4% *(393)*. Patients with a penicillin allergy received erythromycin. Antibiotics were given for 24 hours. In operations ($n = 17$) when prophylactic antibiotics were inadvertently omitted, the infection rate was 27%. The authors concluded that an antistaphylococcal penicillin such as cloxacillin was effective in reducing the incidence of craniotomy infections to less that 5% compared with the usual rates of 5% to 15% without additional prophylaxis. Whitby et al. performed an open randomized trial comparing cefotaxime with trimethoprim–sulfamethoxazole (TMP-SMX) prophylaxis in patients undergoing neurosurgical procedures (craniotomy, shunt surgery, stereotactic surgery) and did not find a difference in the postoperative infection rate between these groups (2.5% cefotaxime, 2.3% TMP-SMX) *(386)*. Similarly, Zhu et al. performed a randomized, double-blind study comparing ceftriaxone with ampicillin–sulbactam (AMP-SUL) for prophylaxis of neurosurgical SSIs and found no difference between these groups (SSI rates: 2.3% AMP-SUL, 3.3% ceftriaxone) *(387)*. Finally, a recent meta-analysis of randomized trials examining antimicrobial prophylaxis for postcraniotomy meningitis found a significant reduction (pooled OR: 0.43, 95%CI: 0.2–0.92) in this complication when antimicrobial prophylaxis is employed (394).

The American Society of Health-System Pharmacists (ASHP) 1999 guidelines on surgical prophylaxis, currently being updated in collaboration with the Infectious Diseases Society of America, Surgical Infection Society, and Society for Healthcare Epidemiology of America, recommend cefazolin 1gm iv given at induction of anesthesia for elective craniotomy (395).

Prevention of Cerebrospinal Fluid Shunt Infections

The majority of neurosurgical shunt infections occur within 2 months of surgery. Most infections result from the direct inoculation of bacteria during surgery and in the perioperative period. Antibiotic prophylaxis is usually directed against CoNS, the most frequent cause of shunt infections. Numerous studies have been undertaken to determine if antibiotic prophylaxis is effective in decreasing the number of infections that complicate the implantation of CSF shunts *(110,396)*. These studies have yielded conflicting results. In a meta-analysis of 12 controlled randomized trials (1,359 patients), antibiotic prophylaxis at the time of CSF shunt placement decreased the rate of infection by 50% *(397)*. However, only a single trial of these 12 studies achieved statistical significance *(60)*. Most of the studies were performed in a pediatric population and are discussed in Chapters 49 and 65. In the one study including adult patients, oxacillin reduced the infection rate from 20% in the control group to 3.3% in the treated group ($p < 0.05$) *(385)*. Various antimicrobial agents were used in these trials, including cloxacillin, trimethoprim–sulfamethoxazole, cephalosporins such as cephalothin, vancomycin, and gentamicin *(398)*. The duration of prophylaxis ranges from <24 hours to up to 48 hours after surgery. The ideal agent to prevent CSF shunt infections is unknown, since comparative studies are unavailable. Based on the results of susceptibility testing, vancomycin might be the preferred drug, but in one trial a histamine-like rash was noted in 35% of patients, despite being infused over 1 hour *(79)*. Despite the suggested benefit from antibiotic prophylaxis in the meta-analysis of the 12 studies, infection rates in the treated group still averaged 6.8%, with a range of 1.9% to 17% *(397)*. Infection rates in the control groups for these studies averaged 13%, with a range of 5.5% to 24% *(397)*. Such high rates in the groups that received prophylaxis for clean surgery suggest the need for other approaches to prevent infection such as the use of shunts with antimicrobial or antiadherence properties. A 2006 Cochrane

meta-analysis of antimicrobial-impregnated shunts (AIS) concluded that the use of these shunts is associated with a reduced risk of shunt infection (OR: 0.21, 95%CI: 0.08–0.55) but suggested that more evidence be sought via more well-designed trials (258,*408*).

Prevention of Infections After Spinal Surgery

In a classic retrospective study, prophylactic antibiotics reduced the infection rate in patients undergoing a laminectomy for lumbar disc disease *(133)*. However, infection rarely occurs after spinal surgery such as a lumbar discectomy, and antibiotics are usually not given. However, in spinal procedures involving fusion or for operations that are prolonged, antibiotics are often used, although randomized prospective controlled trials are lacking. In addition, spinal procedures in immunocompromised hosts or procedures involving implantation of hardware are usually given antibiotic prophylaxis, although controlled data are lacking. A 2002 meta-analysis of prospective randomized trials and/or trial subgroups that studied antimicrobial prophylaxis in patients undergoing spinal surgery demonstrated a significant benefit favoring antimicrobial prophylaxis (pooled OR: 0.37, 95%CI: 0.17–0.78), despite the failure of any individual trial to find such a benefit (399). No recommendation can be made for a specific antimicrobial based on the currently available clinical trial data; use of a first- or second-generation cephalosporin is suggested.

Prevention of Infection with a Cerebrospinal Fluid Leak

The value of antimicrobial prophylaxis in any patient with a CSF leak remains unclear. Definitive studies to resolve this issue are lacking, and at present their use cannot be recommended *(400)*.

ACKNOWLEDGMENT

We would like to acknowledge the tremendous amount of work done by our predecessor, Dr. Nelson Gantz, in preparing, writing, and editing the prior editions of this chapter.

SECTION V
Epidemiology and Prevention of Healthcare-Associated Infections Caused by Specific Pathogens

PART A. Bacterial Infections

CHAPTER 28

Staphylococcus aureus

Joseph F. John, Jr. and Sanjay K. Shukla

The carrier is the archetypal stranger, both embodying the danger of microbial invasion …and transforming it into the possibility for rejuvenation and growth.

Priscilla Wald *in Contagious*

Staphylococcus aureus throughout history has been the preeminent scourge of *Homo sapiens*. Though not a requirement for homeostasis, its ready integration into the flora of the anterior nares and other moist or hairy bodily areas in over 20% of healthy people suggests that *S. aureus* may function symbiotically at those sites. Yet nasal carriage is the constant element of pathogenesis, the major risk factor for subsequent infection *(1–3)*. After years of tedious delineation of its multiple virulence factors, publications of the whole genomes from heterogeneous strains and new functional studies on regulation and pathogenesis are providing new insights into the mechanisms for invasion of the skin, endovasculature, and solid organs by *S. aureus (4–6)*. Over the last three decades, methicillin-resistant *S. aureus* (MRSA), because of its relative increase, has overshadowed studies of its relative nonresistant counterpart, methicillin-susceptible *S. aureus* (MSSA) *(7)*. Yet, MSSA continues to be a major healthcare-associated problem with the risk of MSSA infection in hospital wards three times that of patients who are not carriers *(3,8)*. Much of the phenotypic identity of MRSA comes from the presence of a staphylococcal chromosomal cassette (SCC*mec*) that with its *mec*A gene, encodes a new penicillin-binding protein PBP2a, which is necessary for expression of resistance to most beta-lactam antibiotics. Studies of specific genes such as *mec*A *(9)* have revealed the complexity of gene expression in pathogenic strains of *S. aureus* (need new reference). Since the expression of other virulence genes in MSSA and MRSA such as those involving surface adherence is highly regulated like *mec*, many years of additional study will likely be required to understand pathogenesis in order to design new antimicrobials and vaccines to reduce invasive healthcare-associated infections due to both entities *(10–12)*.

S. aureus as a community pathogen is best known for its ability to produce furuncles and infect soft tissue. A community MRSA known as USA 300 has recently produced a global pandemic, primarily consisting of severe skin and soft tissue infections *(13)*. Along with traditional (USA 200, USA 400) and emerging healthcare-associated strains, USA 300 now threatens hospitalized patients *(14,15)*. The emergence of new healthcare-associated strains comes as no surprise since, historically, healthcare-associated infections were almost exclusively caused by *S. aureus* until the 1960s, when the prevalence of infections due to gram-negative bacilli increased noticeably *(16)*. That ascent of gram-negative bacteria as the new threat in hospitals lulled hospital physicians into thinking that their old nemesis—*S. aureus*—would remain of historical interest only. Yet by the early 1990s, data from the National Nosocomial Infections Surveillance (NNIS) system at the Centers for Disease Control and

Prevention (CDC) indicated that *S. aureus* was again increasing in incidence as a healthcare-associated pathogen *(17)*, a trend that only until recently has leveled off *(18)*. With broadening resistance to newer antimicrobials and disinfectants, MRSA along with MSSA has become the dominant healthcare-associated pathogen in hospitals worldwide *(19)*. Additional new strategies are needed to limit healthcare-associated spread and consequent morbidity due to MSSA *(20)*. This chapter reviews the role that MSSA continues to play in healthcare-associated infections and serves as an introduction to Chapter 29, dedicated to MRSA.

HISTORICAL PERSPECTIVE

There are several early biblical descriptions of staphylococcal infection. Of the 10 plagues brought by Yahweh onto the Egyptian Pharaoh, the sixth cast boils or sores upon man and beast (Exodus 9:8–12) *(21)*. The boils arose after Moses took ashes and sprinkled them aloft, filling the air over Egypt with dust that induced outbreaks of boils on man and beast, sores that were wretched in their appearance but not fatal. In another biblical passage, Job is stricken by Satan with boils (or ulcers) that made his body turn black (Job 2:7). There is little information about furunculosis during the next millennium, though it must have remained a major problem. The so-called high Middle Ages has been described as a period that was remarkably disease free, though, ironically, it was followed by centuries of epidemics of plague with little attention to other bacterial infections *(22)*. With the advent of Pasteur's techniques to culture bacteria, the coagulase-positive *Staphylococcus* was isolated and assigned a species name in the 1880s *(23)*. Since that time, the number of species of the genus has grown to over 36 *(24)*. Using automated techniques, any clinical laboratory is able to distinguish among the growing number of other species capable of infecting humans *(25–27)*.

Not until the 20th century was a connection made between colonization by specific bacteria and subsequent healthcare-associated infection. The increasing importance of *S. aureus* as a cause of hospital sepsis resounds from the documentary writing of Dr. Wesley Spink *(28)*. In the preantibiotic era, mortality due to staphylococcal sepsis secondary to pneumonia, osteomyelitis, and cellulitis was as high as 82% *(29)*. Osteomyelitis due to *S. aureus*, especially infection of the long bones, was often disabling, although mortality due to staphylococcal sepsis was lower in patients with osteomyelitis. The use of sulfonamides from 1937 to 1942, strangely, was not much better than maggots in the treatment of local or osseous staphylococcal infection *(28)*. The miracle of penicillin became available in 1942 and quickly reduced the mortality rate of invasive staphylococcal infection from 80% to 35%. Penicillin resistance, however, developed rapidly in *S. aureus*, and in hospitals where penicillin was heavily used there were frequent epidemics caused by strains of penicillin-resistant *S. aureus (28,30)*. Multiple advisory groups in the late 1940s, therefore, were assembled to make recommendations for control of staphylococcal epidemics. Pharmaceutical companies, spurred on by the early success of penicillin, mobilized to develop new antistaphylococcal agents *(30a)*.

By the 1950s, Spink et al. established the connection between the carriage in the nasopharynx of hospital employees and the frequent contamination of wounds *(31)*. After penicillin resistance became widespread, Spink's Minnesota group showed again that the reservoir of *S. aureus* was hospitalized patients and hospital personnel. Spink stated that the rise in mortality due to penicillin-resistant *S. aureus* was due to cross-infection of "traumatic and surgical wounds transmitted by healthy hospital carriers or from other patients with sepsis. Patients and hospital personnel were found to be heavily parasitized by highly resistant strains of pathogenic staphylococci primarily within bacteriophage type Group III" *(31)*. Indeed, the problem of staphylococcal sepsis in US hospitals during the early 1950s was the major stimulus for development of infection control committees *(16)*. Such committees, eventually under the direction of hospital epidemiologists, created strict isolation units that, over the next several years, reduced the number of infections at the University of Minnesota and other hospitals. Despite early successes in infection control of staphylococcal infection, Spink's prescient, cautious words resonate today: *"The skin and respiratory tract will remain as the major portals of entry, and staphylococcal sepsis will continue to challenge medical practice."*

Sixty years later, we should remember the intensity of infection control measures that were required for containment of staphylococcal sepsis in the 1950s. Assuredly, during the 1960s and 1970s, newer antibiotics, particularly the semisynthetic penicillins, did reduce the risk of healthcare-associated staphylococcal infection. Extensive use of these agents over the next three decades, however, ushered in international healthcare-associated epidemics due to related MRSA strains *(16)*. In a study comparing the rates of *S. aureus* infection in a tertiary care hospital from the periods 1971 to 1976 and 1989 to 1992, all but one of the MRSA strains from the later period were acquired in the hospital or in a nursing home, whereas about 80% of the infections due to MSSA were community-acquired (D. Musher, personal communication). Since the third edition of this text was published, the problems of healthcare-associated MRSA and more regularly recognized MSSA with the resultant medical literature have clearly burgeoned worldwide. Over the last 10 years, there have been 8,771 MRSA infections references and 695 MSSA infections references in PubMed, respectively.

MICROBIOLOGY OF *STAPHYLOCOCCUS AUREUS*

Species Characteristics

Species Identification *S. aureus* has traditionally been defined by phenotypic traits that distinguish it from micrococci and other staphylococci *(26)*. *S. aureus* is a catalase-negative, coagulase-positive, nonmotile coccus that appears as bluish-black clusters or tetrads after Gram staining. *S. aureus* grows by 3 days as 6- to 8-mm colonies that are usually hemolytic on blood agar and salt tolerant; they become gold-pigmented after 24 to 48 hours of incubation. Laboratory identification can be aided by observing anaerobic acid production from glucose, production of

acid from glycerol in the presence of 0.4 μg/mL erythromycin, and mannitol fermentation, as well as by susceptibility to lysostaphin and furazolidone and resistance to bacitracin *(25)*. *S. aureus* also produces a thermonuclease that is useful in identifying the species *(32)*. Salt tolerance is probably due to the stability of the *S. aureus* cell wall derived from the *N*-acetyl glucosamine residues cross-linked with glycine pentapeptide. Ribitol teichoic acid polymers also link the peptidoglycan *(4)*. Alterations in this structure can actually reduce the minimum inhibitory concentration (MIC) to antistaphylococcal penicillins *(33)*. *S. aureus* has other survival genes including those to respond to low pH and high salinity, and some of these genes are regulated by sigma factors like σ *(34–36)*.

Staphylococci can be identified by both conventional and rapid laboratory methods. Several marketed kits allow rapid species identification with 70% to over 90% accuracy in detecting as few as 10 CFU/mL *(37)*. Mannitol salt agar has traditionally been the selective culture method of choice for isolation of *S. aureus*. Newer chromogenic media designed to recover and rapidly identify *S. aureus* and MRSA appear superior to mannitol salt agar *(38)*. Methods such as restriction fragment length polymorphism (RFLP) of RNA genes (ribotype) and detection of the *S. aureus nuclease* gene by polymerase chain reaction (PCR) or fluorescein tagging are available commercially to differentiate *S. aureus* from other species when specialized tracking is required *(39)*. In the future, other methods like MALDI may also become very useful for rapid surveillance of *S. aureus* healthcare-associated infection/colonization (infra vide).

There are several commercially available PCR assays for use in detecting either *S. aureus* or MRSA from nasal surveillance swabs. While significantly more expensive than conventional culture methods, several of these PCR assays can be performed on the day of admission to enable colonized patients to be isolated more quickly from the general patient population, thus decreasing the risk of healthcare-associated transmission. In addition, patients undergoing orthopedic or cardiothoracic surgery are often tested for the presence of *S. aureus* and/or MRSA and decolonized prior to surgery.

S. aureus can be identified directly from positive blood culture bottles by peptide nucleic acid fluorescence *in situ* hybridization (PNA FISH) or by PCR; the latter method can distinguish MSSA and MRSA. Thus, the healthcare epidemiologist has a growing armamentarium of laboratory methods to expand clinical and epidemiologic investigations.

Strain Identification The healthcare epidemiologist may find it necessary to distinguish among multiple endemic versus epidemic strains of *S. aureus* for purposes of tracing the source of the infecting isolate, identifying reservoirs of antibiotic-resistant *S. aureus*, monitoring the colonization of patients or personnel, and, possibly, identifying virulent subtypes. Identification of epidemiologically related microorganisms at the subspecies level may help determine whether the observed clustering of isolates represents distinct strains or several isolates of the same strain that are causing an outbreak. A typing system is adequate if there is a high probability that two random isolates that are epidemiologically unrelated are indeed different. An ideal typing system would generate about 20 groups with even distribution of random isolates. A high proportion of isolates must be typeable, and the method must be reproducible, easy to perform, and inexpensive, and it must avoid the necessity of a second typing system to provide further discrimination. Because of the increasing need to relate strains of *S. aureus* epidemiologically, methods for typing strains have increased over the last 10 years. Nonmolecular and molecular methods of typing *S. aureus* are shown in Table 28-1.

TABLE 28-1

Nonmolecular and Molecular Methods of Typing *S. aureus*

Molecular Methods	*Nonmolecular Methods*
Plasmid content	Antibiotic susceptibility
Chromosomal REA	Phage typing
Serotyping	
Plasmid REA	Capsule typing
RFLP	Alloenzyme patterns
Gene polymorphism	Immunoblotting
Random PCR	
Repetitive element PCR	Multilocus enzyme focusing
PFGE	SDS-PAGE
MLST	
Whole genome analysis	
Microarray analysis	
SCC*mec* type	

MLST, multilocus sequence typing; PCR, polymerase chain reaction; PFGE, pulsed-field gel electrophoresis; REA, restriction endonuclease analysis; RFLP, restriction fragment length polymorphism; SDS-PAGE, sodium dodecyl sulfate polyacrylamide gel electrophoresis.

Nonmolecular Methods of Typing

Typing systems have been based on differences in antigenic structure, phage susceptibility, antibiotic susceptibility, biochemical profiles, and DNA composition. One antigenic typing method uses antibodies to the 11 known capsular polysaccharides. Healthcare-associated isolates, however, are predominately composed of only two types, 5 and 8 *(40)*, though 24% of strains remain untypeable by this system.

One antigenic system is based on 30 soluble protein or carbohydrate determinants *(41)*. Antigen expression by specific strains depends on the selected growth media, which may be why the antibodies necessary for these systems are not available commercially.

Phage typing has been in use since 1952 and is a laborious method that is performed only by a few reference laboratories. The international set of typing phages, seldom employed but of practical significance, is shown in Table 28-2 *(16,42)*. The phage reactions are relatively stable; lysis is graded from weak to strong, and if no lysis develops at 100 times routine test dilution, the strain is considered untypeable. Strains are considered different if the phage pattern differs by two or more phage reactions that show strong lysis. Yet, the same lysis pattern does not necessarily equal epidemiologic relatedness. Phage-typing methods are further limited, because many strains—particularly MRSA—are not lysed by the available phages and are therefore untypeable *(42)*. Phage-typing patterns can change when *in vitro* selected vancomycin-resistant strains are compared to their vancomycin-susceptible parents *(43)*.

TABLE 28-2

Phages and Phage Groups of *S. aureus*

Phage Group	*Standard Phages that Lyse*
I	29, 52, 52a, 79, 80

IV	Bovine strains
V	94, 96
Miscellaneous	81, 95

Although pulsed-field gel electrophoresis (PFGE) patterns between susceptible parents and resistant selectants remained the same, phage types frequently changed or selectants became nontypeable.

An elegant antigenic typing method, termed immunoblotting, uses pooled human sera for detecting various antigens among *S. aureus* strains by Western blotting *(44)*. Immunoblotting identified eight patterns using different batches of pooled sera that correlated with phage typing. The method was more discriminating than plasmid profiles, but between 2% and 28% of immunotypes were discrepant on repeat testing. The method was capable of identifying strains that were clinically and epidemiologically related. Immunoblotting combined with antibiograms has been used to discriminate a new outbreak strain from an endemic strain of MRSA (45). Applied in another study, immunoblotting could differentiate 43 strains into only two major groups, making it only as good as endonuclease digestion of plasmid DNA *(46)*.

Antibiograms can be useful when a unique resistance pattern prevails. A given resistance phenotype, however, may result from different arrangements of multiply resistant genes, thus not ensuring DNA sequence identity. Furthermore, resistance (R) plasmids mediating traits such as antibiotic resistance are not always stable. The loss of R plasmids would allow otherwise identical parent strains to be typed as different using antibiograms. A clever way to circumvent this problem is through the use of multiplex PCR that will simultaneously generate multiple amplicons signifying the presence or absence of specific resistance determinants like *mec*A, aacA, tetM, and so on *(47)*. Multiplex PCR is the current extension of "resistotype" identification suggested by Elek et al. 40 years ago *(48)*.

Biochemical typing (biotyping) is based on enzyme activities, including the commercial methods of such companies as API and Vitek. Color changes are based on acid production from carbohydrates. Although such typing is relatively inexpensive and easy to perform, the traits may vary over time and geographic areas. They are not highly discriminating and need to be combined with other typing methods. Differences in single enzymes, such as esterase, have been used in typing but are also not discriminatory when used alone *(49,50)*.

Multilocus enzyme electrophoresis (MLEE) is based on small differences in electrophoretic mobility of chromosomally encoded metabolic enzymes. Proponents of MLEE feel that each pattern of enzymes determines a clone. MLEE has identified 11 types of *S. aureus*, though the predominance of type 15 in healthcare-associated outbreaks may limit its usefulness to the healthcare epidemiologist *(51)*. Because it is technically difficult to perform *(52)*, MLEE is also not ideal for hospital outbreaks. Another method analyzes differences in the cell wall peptidoglycan. This method, termed peptidoglycan fingerprinting, separates cell wall components by thin-layer chromatography. Unfortunately, this method is difficult to perform and yields an insufficient number of bands for discriminating among endemic and epidemic strains *(53)*.

In the last 3 years, mass spectrometry has burst onto the clinical microbiology scene as a fast and accurate method for identifying pathogens at a species and even a subspecies level *(54)*. Using one application called matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS), species can be obtained quickly in around 90% of instances. Of course, a mass spectrometry instrument is required for local application, so the initial outlay in startup costs is expensive. Nevertheless, recent studies suggest that MALDI-TOF compares to spa typing (infra vide) for rapid and accurate identification of *S. aureus* clonal complexes *(55)*.

Molecular Typing Techniques

Rapid advances in commercially available DNA manipulation kits, high-throughput sequencing, sophisticated imaging, newer molecular biology instrumentations, etc. have made the molecular genotyping of bacteria feasible in small to advanced clinical microbiology laboratories. DNA-based analysis can differentiate bacterial strains that are similar in phenotypic traits but similar or dissimilar in their genotypes *(56)*. A select number of genotypic methods are described below.

Plasmid Analysis. One of the earliest genotypic methods to distinguish clinical strains of *S. aureus* was plasmid analysis. Plasmid analysis by either visualization of individual intact plasmid bands in an agarose gel or after digestion with an appropriate restriction enzyme has been a classic genotypic method for more than 20 years. But it has major limitations. First, unlike coagulase-negative staphylococci, *S. aureus* seldom has more than three plasmids, so there is little chance of generating a complex fingerprint, thus limiting discrimination. Second, as with other bacteria, *S. aureus* strains may lose plasmids and/or gain or lose antibiotic-resistant genes within a desired plasmid, thus limiting the reproducibility of the method. Third, many strains lack plasmids and are, therefore, untypeable by this method. Fourth, very large plasmids that migrate near the top of the gel may be difficult to differentiate; therefore, precise comparisons between strains with large plasmids would be difficult. In case of large plasmids, inclusion of restriction enzyme digestion steps to digest the plasmid DNA enhances the reproducibility and discriminatory power, though this method is seldom used in clinical microbiological laboratories *(57)*.

Pulsed-Field Gel Electrophoresis. Methods for analyzing chromosomal DNA instead of plasmids overcame many of the limitations of plasmid analysis. PFGE has become one of the most popular methods to genotype *S. aureus*, particularly MRSA in recent years. In PFGE, chromosomal DNA from

S. aureus is digested preferably with *Sma*I (*51,53*,58). *Sma*I digests have been optimized for and shown to be stable in *S. aureus* strains even after repeated subculture. Since *Sma*I fragments are too large to permit electrophoresis with a conventional electrophoresis apparatus, a new system has been developed *(59)*. PFGE requires a relatively expensive, specialized apparatus (e.g., CHEF DR II system, BioRad) to resolve the restricted fragments. In PFGE, high molecular weight DNA is extracted *in situ* from agarose-embedded *S. aureus* cells using lysostaphin and proteinase K to minimize the shearing of DNA. The *in situ* DNA (in agarose plugs) is then digested with *Sma*I, and the digested fragments are resolved in a 1% high-quality agarose gel. During electrophoresis, the direction of the electrical field is alternated to allow the large molecules to be reoriented *(60)*. The alternate or the abrupted electric field enhances the resolution of large DNA molecules (>200 kb and up to 10 MB) by allowing them to snake through the agarose. For *S. aureus*, the number of *Sma*I restricted DNA fragments resolved by this method is <20. The similarity and dissimilarity in the fingerprints of two strains are determined by combining genetic relatedness criteria and the Dice Coefficient *(61,62)*: The equation appears as

$$\mathrm{Sd} = \{2N \times 100\}/F,$$

where the Dice coefficient, Sd equals twice *N*, the number of shared restriction fragments times 100 divided by F, the total number of restriction fragments generated by enzyme digestion *(62)*. Computer software such as Bionumerics is used to establish a DNA similarity matrix based on the Dice coefficient and band tolerance (*63,64*). The simplicity in interpretation of PFGE results has led it to be the "gold standard" for bacterial genotyping methods. Indeed, PFGE has been extensively used over the last 15 years to describe MRSA outbreaks and their changing epidemiology (58,*61,63,65–67*). Although PFGE is highly discriminatory and reproducible within a laboratory, methods and technician experience differ among various laboratories and lead to differences that may arise in gel appearance and difficulties when comparing results from different laboratories. Matching of PFGE types through gel images from different sources to implicate spread from one source to another has its limitations. In addition, PFGE is time consuming and takes up to 48 hours to complete the experiment (Fig. 28-1).

Multilocus Sequence Typing. A DNA sequence-based method termed multilocus sequence typing (MLST) has been used for analyzing large collections of bacterial strains from several genera (Table 28-3). This method overcomes the problems with reproducibility and interpretation created by gel-based DNA typing systems. In this method for typing *S. aureus*, approximately 450-bp long internal fragments of both strands of seven housekeeping genes (carbamate kinase [*arcC*], shikimate dehydrogenase [*aroE*], glycerol kinase [*glp*], guanylate kinase [*gmk*], phosphate acetyltransferase [*pta*], triosephosphate isomerase [*tpi*], and acetyl coenzyme A acetyltransferase [*yqiL*] are amplified and then sequenced to determine their allelic differences (Table 28-3) *(68)*. The sequence is submitted to the MLST Web site (www.mlst.net) for comparison to known allelic variants to obtain the MLST allelic profile of an isolate. Based on the gene sequence of each of the seven alleles, a sequence type (ST) is determined. Further comparisons between STs can be performed using one of several algorithms. eBURST (electronic Based Upon Related Sequence Types) is one such algorithm. Clonal complexes consisting of related groups or STs are thus generated. This strategy has been used to show marked similarities among a highly diverse collection of MRSA and MSSA *(70)*, reflecting the population and the evolutionary genetics because of the large number of possible STs that can potentially exist. Other advantages of the MLST include its portability between laboratories and availability of a large, freely available, constantly updated MLST database (www.mlst.org/). Unfortunately, the ability to perform PCR and rapid DNA sequencing has limited this method to research laboratories. It should be possible for commercial or university laboratories to adopt the methods and rapidly sequence PCR products generated from epidemiologically important isolates *(69)*. combined the MLST technique with RFLP for tracking genomic islands that may insert into different genetic backgrounds to elegantly show the evolution of MRSA strains from ancestral MSSA strains.

Spa Typing. It was mainly developed to overcome the need of sequencing multiple genes in MLST. *Spa* typing is based on the polymorphic 21- to 24-bp variable-number tandem repeat (VNTR) within the 3′ coding region of the polymorphic X region of *S. aureus*-specific staphylococcal protein A. In the *spa* gene, the in-frame, short-sequence repeats are degenerative, variable in number, and variable in the order in which trinucleotide repeats are organized *(70)*. In this approach, both rapid (microvariation) and slow (macrovariation) genetic variations in the *spa* gene are indexed. Indexing two types of variations makes it useful in both local and global epidemiologic studies. The sequencing of the polymorphic region allows one to identify the 21- or the 24-bp repeats designated by a letter code (A–Z, A2, B2, etc.), and the profile of these repeats (Y-1-H1-G1-F1-M1-B1-Q1-B1-L1-O1) gives a *spa* type. A publicly available large database of *spa* types exists (*http://www.egenomics.com/* and Ridom Staphtype software) where one can compare their *spa* sequence profile to obtain the *spa* type. The advantages of *spa* typing are in its lower cost and labor, ease of analysis, and the ever-growing *spa* database. The disadvantages are that 0.1% of *S. aureus* strains are non–*spa* typeable and there is a lack of a strong evolutionary perspective for phylogenetic analysis. Nevertheless, to overcome this shortcoming, BURP (Based Upon Repeat Pattern) has been developed to determine the *spa*-based clonal complexes (*spa*CC). The BURP allows the determination of the founder *spa* types, *spa*CC, and unrelated types as singletons *(71)*.

Each of the three methods, PFGE, MLST, and *spa* typing has its own advantages and disadvantages. An investigator needs to know which approach will be most useful for a particular investigation. In general, disease outbreaks investigations are preferably done by the PFGE and now also by *spa* typing. MLST is the preferred method to study the population structure of the *S. aureus* and global epidemiology. PFGE has been found to be more discriminatory than MLST and in most cases *spa* typing as well. One of the main advantages of the PFGE approach is the characterization of major US MRSA clones described as USA100, USA200, USA300 (CA-MRSA), USA400 (CA-MRSA), … USA1200. These USA reference strains are available from the NARSA database (*http://www.narsa.net/*).

FIGURE 28-1 PFGE dendrogram of *S. aureus* strains collected over 19 years from Wisconsin and Minnesota. The collection was composed of three groups, including nasal isolates of MSSA, clinical isolates of MSSA, and clinical isolates of community MRSA. Each pulsotype (PT) is also characterized by corresponding PFGE-based clonal group (CG), *spa* type, and MLST-based sequence type (ST), and clonal complex (CC). Note also the inclusion of PFGE-based USA genotypes that were included as reference strains. The dendrogram was made using 1.25% tolerance, the Dice similarity coefficient, and unweighted-pair group method using arithmetic averages. Strains were considered related if they had ≥80% genetic similarity. (Reproduced from Shukla SK, Karow ME, Brady JM, et al. Virulence genes and genotypic associations in community-associated methicillin-resistant and susceptible *Staphylococcus aureus*. *J Clin Microbiol* 2010;48:3582–3592, with permission.)

tpi	Triosephosphate isomerase
yqi	Acetyl coenzyme A acetyltransferase

Multiple-Locus Variable-Number Tandem-Repeat Assay (MLVA). This PCR-based assay exploits the VNTRs in the *clfA*, *clfB*, *sdrCDE*, *spa*, and *sspA* loci to obtain PCR amplicon banding pattern that can be used to investigate MRSA outbreaks. (*72*,73). It is comparable to PFGE if >75% relatedness for MLVA criteria is used.

Amplified Fragment Length Polymorphism. Amplified fragment length polymorphism (AFLP), which utilizes a combination of selective PCR amplification of restriction fragments from a total digest of genomic DNA, has also been used to study the population structure of *S. aureus* (74,75). In one study a large collection of *S. aureus* isolates (n = 1,056), AFLP revealed the presence of three major and two minor phylogenetic branches. The above grouping, however, was not able to distinguish virulent strains from the nonvirulent strains as expected suggesting that any *S. aureus* genotype could cause a serious infection although some lineages appear to be more virulent than others *(75)*.

Whole Genome Sequencing. Genome sequencing remains the last resort to conclusively genotype a pathogenic strain. Despite the steadily decreasing cost of sequencing, cost is still prohibitive due to personnel time needed in annotation and characterization of novel open reading frames. Yet, with literally hundreds of *S. aureus* genome-sequencing projects in progress, its pan genome features are emerging. The innovative combined approaches of PCR and sequencing will likely spawn a new genechip-based technology that can not only identify different lineages but also distinguish virulent strains from the nonvirulent ones. Host specificity and susceptibility play major roles in the genesis and persistence of staphylococcal infection. This coming decade of investigation should identify the susceptibility markers for *S. aureus* infection *(75a)*.

Microarray Analysis. A microarray-based approach was published recently that was based on the genome sequence of seven *S. aureus* genomes and their MLST types. The array was able to identify core genes common to all *S. aureus* strains besides 10 dominant lineages, although substantial variations were observed in their mobile genetic elements and associated virulence genes *(76)*. These studies did not find any evidence to show that certain *S. aureus* lineages are associated with invasive isolates in community settings but showed the importance of hypercolonizing strains *(77)*.

Optical Mapping. Optical mapping is a newer tool that relies on the creation of a high-resolution restriction map of a bacterial genome (optical maps) and then comparing with the other optically mapped strains (78). While this is a very powerful technique to visualize major genomic changes with reference to the index or reference genome strains, it is not widely available in clinical microbiology laboratories. It is also limited by the small-sized database of the optical maps.

Optical Fingerprinting by Raman Spectroscopy. Other genotypic tools have been developed in the last few years but are not yet widely available. One novel method has been developed to identify and/or distinguish bacteria clones from the distantly related or the unrelated ones *(78a)*. This method, Raman spectroscopy, works on the principle that Raman Spectra of each bacterial species are a unique clone and therefore could be used to identify the species or cluster them based on their phenotypic properties. Using a small number of *S. aureus* isolates, it has been shown that this method could be highly discriminatory and may reach the resolving power of PFGE *(78a,79)*.

Summary of Molecular Typing Methods. The three most common methods for genotyping *S. aureus* are PFGE, MLST, and *spa* typing. Each of these methods has its own advantages and disadvantages, but there is also a high level of concordance between these three methods. The epidemiologist should ask which genotypic approach will be most useful for a particular investigation. In general, disease outbreak investigations are preferably done by the PFGE because of the ease in interpretation. One of the main advantages of the PFGE approach is the characterization of major US MRSA clones described as USA100, USA200, USA300 (CA-MRSA), USA400 (CA-MRSA), etc. These USA reference strains are available from the NARSA database. *Spa* typing will likely gain acceptance as sequencing will be more easily accessible in clinical laboratories. MLST is the preferred method to study the population structure and global evolutionary genetics of *S. aureus*. Shukla et al. (58) showed that the strain-distinguishing ability of *spa* typing and PFGE were comparable but more discriminatory than MLST for clinical MSSA strains.

PATHOGENESIS OF HEALTHCARE-ASSOCIATED INFECTIONS

S. aureus is armed with many virulence factors housed on as many as 18 "genome islands." *(80)* Most of these virulence factors are highly regulated and are turned on and off depending on the ecological challenge the bacterium faces. Expression of *S. aureus* attachment and virulence factors results from the interaction of a global accessory gene regulator (*agr*), a staphylococcal accessory regulator (*sar*), and RNAIII, a central regulatory function unique to *S. aureus* (Fig. 28-2). Its regulatory flexibility gives *S. aureus* opportunity to attach, colonize, and invade many tissues and organs. Because of its invasive properties, *S. aureus* bacteremia (SAB) has been one of the most studied clinical syndromes *(81)*. In a Brazilian tertiary care hospital, *S. aureus* caused 21% of all bloodstream infections (BSIs) compared to 26% caused by coagulase-negative staphylococci *(82)*. Clinical laboratories have observed an increased incidence of bacteremia caused by *S. aureus* since 1980 *(83,84)*. In a study of healthcare-associated bacteremia of unknown origin, both *S. aureus* and *Pseudomonas aeruginosa*

caused 15% of the cases *(85)*. *S. aureus* also caused 50% of catheter-related bacteremias, the majority of infections associated with insertion of prosthetic materials, and the majority of cases of septic arthritis and osteomyelitis. MSSA as well as MRSA strains are extremely prevalent in the intensive care unit (ICU). Among 49 ICUs in Italy, *S. aureus* caused almost 10% of all ICU infections *(86)*. Understanding the pathogenesis of such a diverse group of infections arising both in the community and in the hospital can be approached by examining the stages of host–pathogen interaction: colonization, attachment, adherence, tissue damage, invasion, dissemination, and metastatic infection (Fig. 28-3) *(4)*.

Colonization

Relationship of Colonization to Infection The major reservoir of *S. aureus* is the anterior nares. Carriage there influences carriage at other sites, including the axillae, perineum, denuded dermis, and mucous membranes *(4,87–89)*. People who are *S. aureus* carriers may harbor *various strains* persistently or intermittently, with intermittent carriage occurring in as much as 90% of a sampled population of carriers *(4,90)*. Some humans, based on genetic and nasal mucus constituents, are noncarriers. Factors that promote colonization include coincident respiratory infection, prolonged hospitalization, needle use (as in intravenous [IV] drug users), diabetics, patients requiring hemodialysis and patients receiving allergy shots, exposure to cold weather, and dermatologic conditions such as eczema *(4,91)*. The elderly, even when they are inpatients, have no higher rate of colonization *(92)*. Antibiotic administration also promotes an ecologic, nasal niche, perhaps through alteration of normal flora that is known to provide resistance to

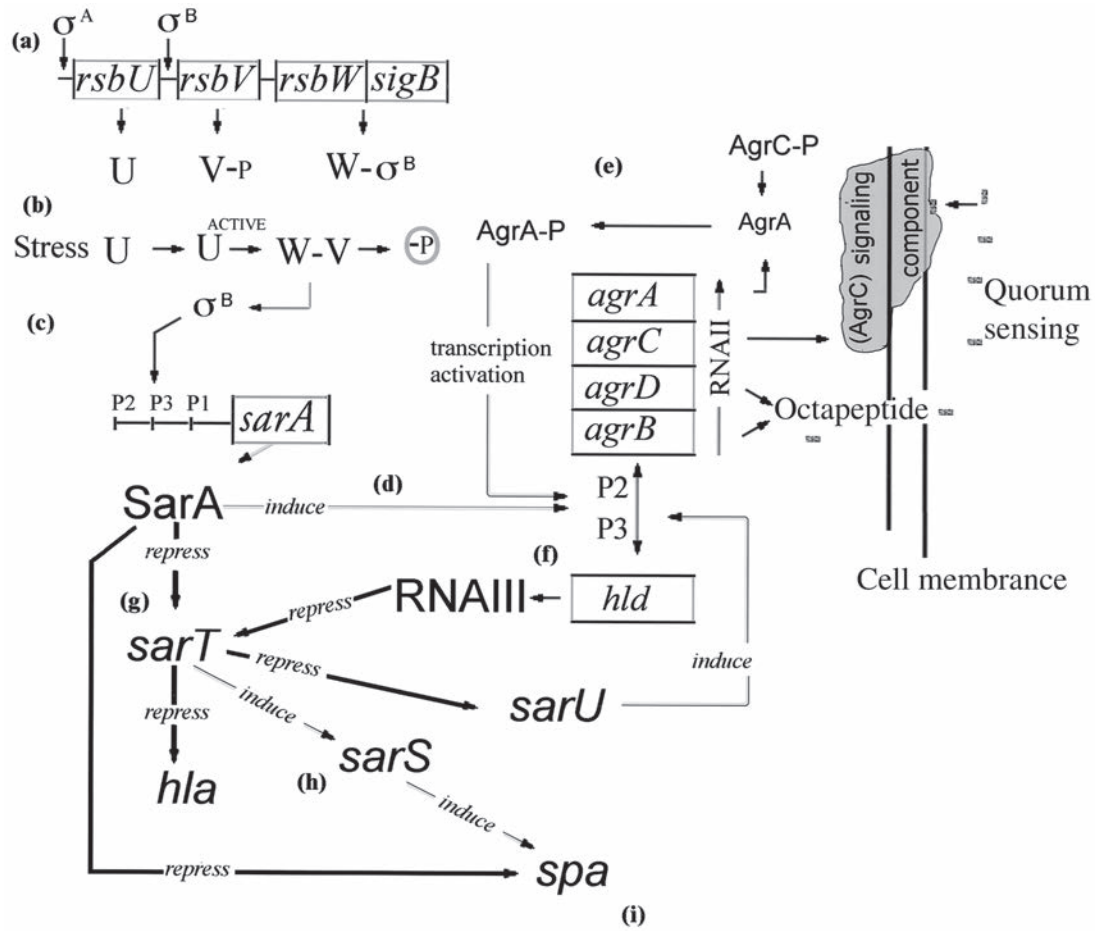

FIGURE 28-2 Overview of the predicted regulatory pathways involved in gene expression for *S. aureus:* (*a*) the *sig*B operon, transcribed under regulation of τ^A, encodes *rsb*U, *rsb*V, *rsb*W, and *sig*B. RsbW is an anti-τ^B factor that binds to τ^B, blocking its activity; (*b*) stress (e.g., high temperature, high osmolarity, or low pH) activates *rsb*U to U active that then can dephosphorylate *rsb*V-P to *rsb*V. *Rsb*V then binds to *rsb*W, releasing τ^B; (*c*) τ^B binds to a consensus sequence on the *sar*A P3 promoter, activating transcription of *sar*A (as well as other promoters); (*d*) *sar*A binds to the interpromoter region between P2 and P3 of the accessory gene (*agr*) locus, stimulating transcription of *agr* RNAII, which encodes *agr*B, *agr*D, *agr*C, and *agr*A, elements of a two-component quorum-sensing system. *Agr*B and *agr*D produce an octapeptide that diffuses through the membrane to bind to and activate *agr*C, a membrane-associated signaling component; (*e*) activated *agr*C phosphorylates *agr*A, which induces transcription of *agr* RNAIII; (*f*) RNAIII, a pleiotropic regulator for expression of virulence proteins, represses *sar*T; (*g*) increased expression of *sar*T during exponential growth causes repression of *sar*U, an inducer of RNAIII expression. *Sar*T represses expression of *hla* (encoding α-hemolysin), and induces expression of *sar*S; and (*h*) *sar*S induces expression of *spa* (protein A). *Sar*A represses expression of *spa (i)*. (Courtesy of Katherine A. Schmidt and Ambrose Cheung.)

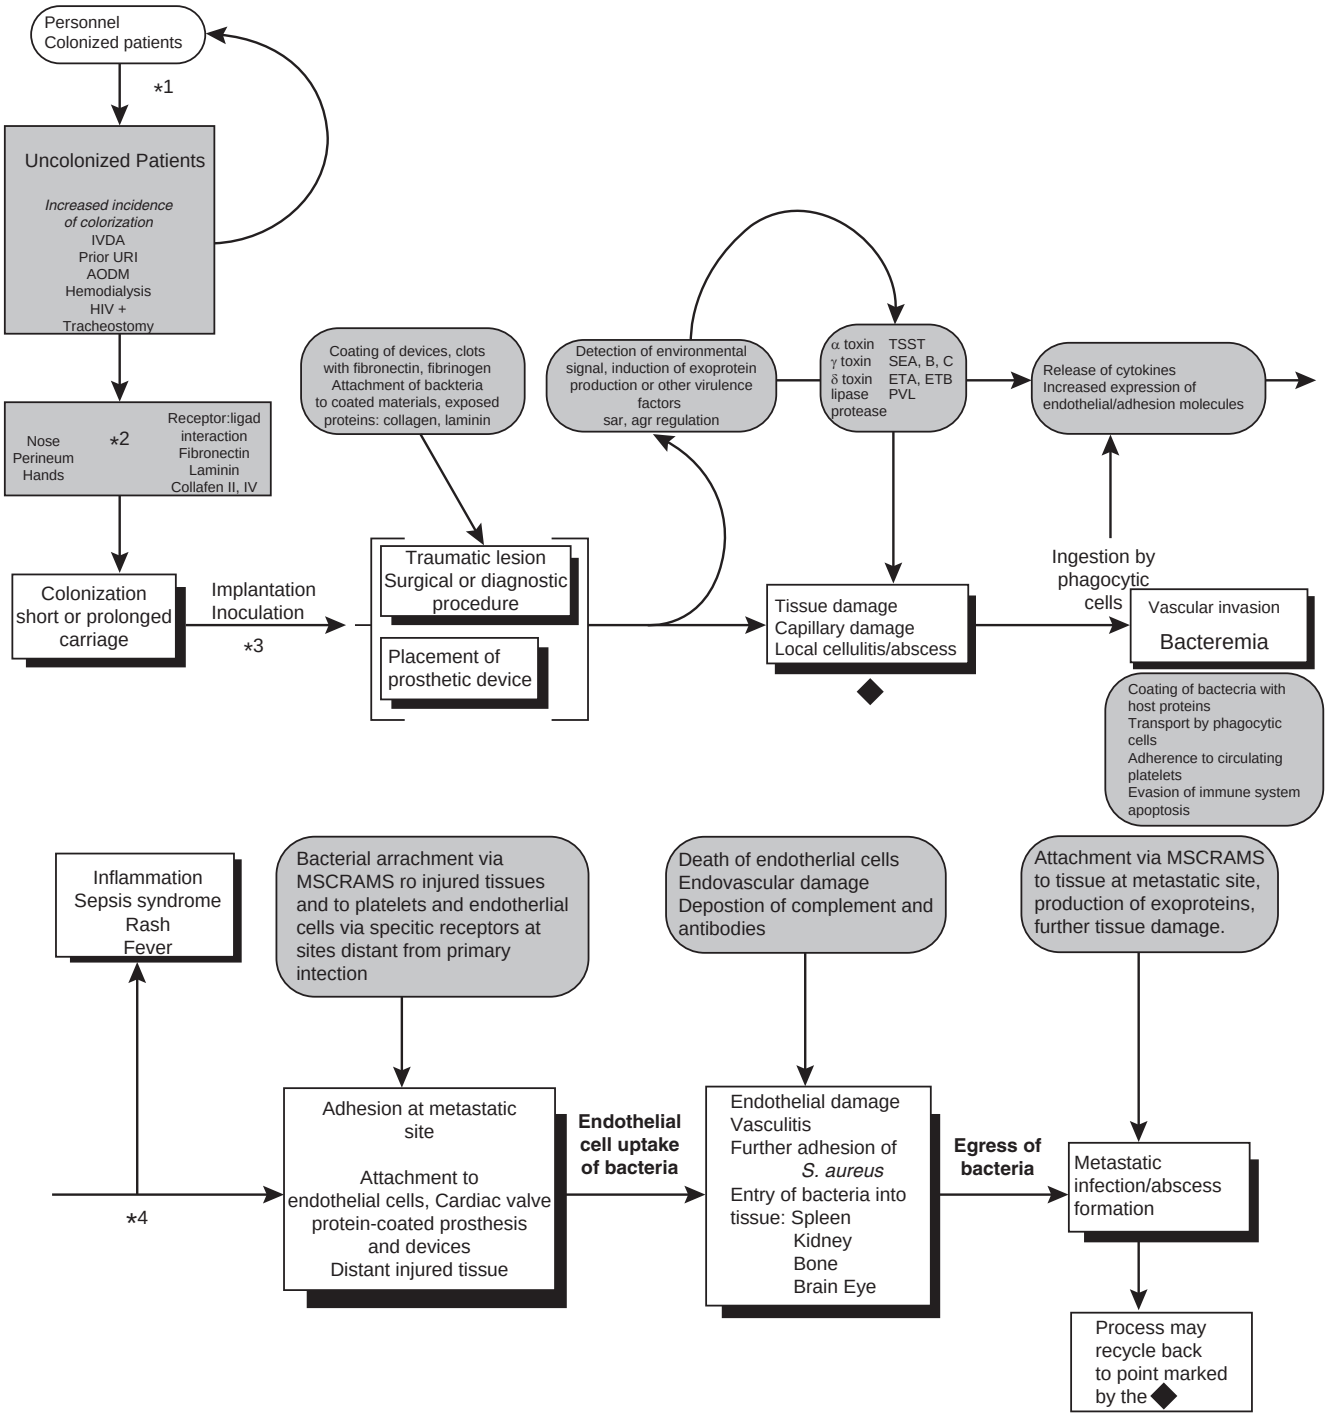

FIGURE 28-3 Pathogenesis of healthcare-associated infection caused by *S. aureus*. *Potential strategies to interrupt the development of a healthcare-associated *S. aureus* infection: (*1*) barrier precautions and decolonization procedures; (*2*) bacterial receptor (microbial surface components recognizing adhesive matrix molecules [MSCRAMMs]) antagonists and competitive colonization; (*3*) perioperative prophylaxis, antibiotic impregnated materials, materials to which *S. aureus* adheres poorly, and active vaccination; (*4*) prompt institution of effective antimicrobials, cytokine antagonists, MSCRAMM inhibitors, and passive vaccination with monoclonal antibodies; (*5*) prolonged treatment of bacteremia to cure foci of metastatic infection.

S. aureus colonization *(93)*. Once a patient is colonized with *S. aureus*, the particular strain may disseminate by person-to-person contact, particularly by spread on the hands of personnel *(94)*, or by the dispersion of *S. aureus* carried on rafts of desquamated skin *(95)*. In this manner, *S. aureus* strains spread among hospitalized patients. Adhesion factors and global regulators also interact to determine the establishment of colonization *(96)*. Since it usually precedes infection, colonization with *S. aureus* remains an important risk factor. The importance of the infection of

concomitant colonization is shown by the analysis of pathogens in surgical site infections (SSIs) and device-related infections. SSI rates were higher in colonized patients than in noncolonized patients *(97–99)*. This relationship is also quantitative: when the density of colonizing flora exceeds 10^6 colony-forming units (CFU), rates of postoperative infections are higher among carriers than among noncarriers. Patients in one surgical ICU study who were nasal carriers not only induced cross-colonization but also were significantly more likely to incur a staphylococcal infection than noncarriers *(100)*. Treatment upon admission to the ICU with nasal antistaphylococcal ointment was associated with a lower rate of *S. aureus* colonization while in the ICU. RFLP patterns were identical for those strains colonizing the nares and causing SSI. Molecular analysis also has been used in clusters of SSIs after heart operations to distinguish between the nasal strain and the strains isolated from SSIs or blood *(101)*.

The relationship between nasal carriage and subsequent SSIs is not straightforward. For example, in a study of 414 patients undergoing elective surgery in Khartoum, Sudan, only 6 of the 98 nasal carriers incurred SSIs caused by the strain inhabiting the nose *(101a)*. Besides demonstrating that nasal carriage was not a significant risk factor for development of SSI, the elegant molecular analysis further demonstrated that noncarriers were at significant risk of acquiring an independent SSI caused by strains with a high degree of genetic heterogeneity.

Further implicating *S. aureus* carriage, the same strains colonizing nonsurgical patients on admission are often the infecting strains *(89)*. Specifically, the same strain colonizing the noses of drug addicts with endocarditis is recovered from blood cultures. Hemodialysis patients are more frequently infected if anterior nares are colonized; 93% of hemodialysis-related infections are caused by the phage type colonizing the anterior nares *(102)*. The same relationship between colonizing and infecting strains was observed for patients on peritoneal dialysis. Nasal carriers had a fourfold higher incidence of dialysis catheter exit site infections *(103)*. It has been estimated that there is a 4% to 16% probability of catheter loss in patients with *S. aureus* peritonitis who are nasal carriers, compared with a negligible risk for noncarriers *(104)*. Finally, in hospitalized patients, there may be preferential colonization of non-nasal sites, for example, the oropharynx in patients undergoing long-term endotracheal intubation *(105)*. Patients admitted to a large hospital in Meunster, Germany, who developed SAB, were found to be infected 80% of the time with their own nasal-colonizing strain *(2)*. MRSA strains were not a problem in that section of Germany at the time of the study. A larger analysis done in Oxford, England, of the relationship of nasal-colonizing strains to subsequent invasive disease, was conducted by Day et al. *(77)* using MLST followed by additional analysis using an elegant whole genome microarray analysis for characterizing isolates *(76)*. The major implication of these landmark studies was to show that *(106)* hypercolonizing community strains mirror the invasive strains and *(8)* no genes including virulence genes are particularly associated with invasive isolates. Thus, these studies have far-reaching implications for infection control in the community as well as in the hospital.

Most recently, we have further evidence that elimination of nasal strains carried by patients admitted to the hospital will reduce subsequent surgical infections *(99,107)*. In the first study, a randomized, double-blind multicenter trial in The Netherlands, the rate of infection in patients decolonized with nasal mupirocin and chlorhexidine baths was 3.4% compared to 7.7% in patients who remained colonized (relative risk (RR): 0.42; 95% confidence interval [CI]: 0.23–0.75) *(99)*. The second study showed mupirocin decolonization of nasal carriers resulted in a reduction of 6.28 to 3.32 cases per 1,000 patient days *(107)*. These data form the rationale for rapid screening of *S. aureus* nasal carriers with subsequent decolonization before surgery.

Adherence and Attachment Strains of *S. aureus* have many potential surface adhesions (Smeltzer book). These adhesions are upregulated by *agr* once a *S. aureus* strain contacts a tissue or a surface, a crucial step in the initiation of infection. Adherence is mediated by a group of surface protein adhesins called microbial surface components recognizing adhesive matrix molecules (MSCRAMMs) and regulated by the *sar/agr* system (*108*). There are three major groups of MSCRAMMs depending on whether they bind fibronectin, collagen, or fibrinogen, and these are present in strains from asymptomatic carriers *(109)*. Early adhesion is facilitated by upregulation of *sar*-mediated MSCRAMMs. Furthermore, *sar*S, a *sar* homologue, is an activator of *S. aureus* protein A *(110)* (Fig. 28-3). Access and adherence to host tissues or implanted materials is mediated by surface receptors that involve host protein interactions. More specifically, the interaction occurs between MSCRAMMS and target structures of the eukaryotic cell. For procedures in which foreign materials are implanted or that result in a thrombus at the surgical site, plasma proteins such as fibronectin are immediately deposited on the materials. Host proteins then act as bridging molecules in the adherence of *S. aureus* to protein-coated surfaces *(111)*.

S. aureus binding can be blocked by antibodies specific for a particular receptor *(6)*. An additional effect of staphylococcal-protein interaction may allow evasion of the immune system *(112)*. Binding of host proteins to the staphylococcal cell wall effectively coats the bacteria and may prevent host recognition of the microbe. *S. aureus* may also adhere to uncoated foreign material through electrostatic forces. This interaction is mediated by surface charge and hydrophobicity of the material and bacteria. *S. aureus* has a net negative charge due to ribitol teichoic acid and protein A *(113)*. Preventionn of infection, however, may require blockade of more than one receptor, a factor that has thwarted development of efficacious staphylococcal adhesion vaccines.

Studies that examine the binding of *S. aureus* to an extracellular matrix typically use a foreign material such as methylmethacrylate coated with a specific protein. Except for albumin, which markedly diminishes *S. aureus* binding to polymethylmethacrylate (PMMA), most host proteins augment attachment. For example, *S. aureus* binding to PMMA is markedly enhanced when fibronectin is present, and this binding is not strain dependent. Fibronectin coats implanted prosthetic material and plastic surfaces and is a major component of the fibrin matrix of clots. Staphylococcal adherence to fibrin clots is increased in the presence of fibronectin *(114)*. Binding to fibronectin

is mediated by two related fibronectin-binding proteins, FnBPA and FnBPB, which have specific ligand-binding domains that recognize the N terminal and the C terminal region of fibronectin. When fibronectin coats surfaces, the N terminal end enhances the binding of *S. aureus*. Fibronectin also binds well to albumin-coated substances and mediates the adherence of *S. aureus* to collagen, endothelial cells, fibroblasts, platelets, and platelet-fibrin thrombi *(115)*. Strains of *S. aureus* that bind avidly to fibronectin are more likely to produce endocarditis in a rabbit model of catheter-induced endocarditis, probably because fibronectin is first deposited on valvular endothelial cells traumatized by the catheter *(116)*. In another experiment, fibronectin binding was shown to be crucial in the pathogenesis of endocarditis. Fibronectin-binding deficient mutants were less likely to adhere to damaged heart valves than was the intact parent strain *(117)*.

Similar interactions between *S. aureus* and other surfaces may also initiate infection. Fibrinogen enhances *S. aureus* binding to and may be preferentially deposited on IV devices *(118,119)*. Staphylococcal clumping factor has been shown to be the SSP1 that binds to fibrinogen *(120,121)*. Phase 2 clinical trials are underway to assess the therapeutic value of products that block clumping factor *(122)*. Laminin, a major component of the basement membrane, also binds *S. aureus* by a specific receptor like fibronectin. However, only a small enhancement of *S. aureus* binding to PMMA was shown *(111)*. Laminin binding may not be a significant factor in the production of intravascular infections, since laminin serum levels are so low. On the other hand, there may be a role for laminin in the production of primary tissue infections, since basement membrane may be exposed after traumatic injury to epithelial surfaces, one of several putative routes that *S. aureus* can escape the bloodstream *(123,124)*.

S. aureus binds to heparin and other glycosaminoglycans by two bacterial cell wall–associated proteins. Glycosaminoglycans are linked with proteins to form proteoglycans and are found in connective tissue, basement membranes, and eukaryotic cell surfaces. These substances bind to heparinized catheters *(125)*; however, the binding is not specific. Other components of connective tissue bind *S. aureus* as well. Type IV collagen binds less avidly than fibronectin and laminin to *S. aureus (126)* but is exposed at the site of tissue injury. Adherence of *S. aureus* to type IV collagen is enhanced in the presence of fibronectin. In addition, *S. aureus* binds to type II collagen by a unique receptor, which has been cloned and sequenced. Strains with type II collagen receptors, isolated from patients with osteomyelitis and septic arthritis, were shown to bind well to cartilage *(112)*. Cutaneous injury may promote exteriorization of cytocollagen 10, providing substrate binding not possible in normal skin *(126a,127)*.

Biofilm formation is discussed in Chapter 31 of this book by Fey et al. In brief, the so-called slime substance central to biofilm formation is a polysaccharide composed of beta-1,6-linked *N*-acetyl glucosamines with partly deacetylated residues. Mutations in the corresponding biosynthesis genes (*ica* operon) lead to a pleiotropic phenotype wherein staphylococcal cells are less adherent and invasive. Several biofilm-negative mutants have been isolated in which polysaccharide intercellular adhesin production appears to be unaffected *(128)*. Other proteins involved in biofilm formation include accumulation-associated protein (AAP), the clumping factor A (ClfA), the staphylococcal surface protein (SSP1), and the biofilm-associated protein (Bap). New antimicrobials are needed that penetrate and disrupt biofilm formation or that are combined with new polymers to resist adherence and attachment *(129)*. Several biofilm-penetrating antimicrobials as well as biofilm vaccines are under development *(130)*.

Virulence and Invasion

Several regulatory systems that control virulence have been described in *S. aureus* (Fig. 28-3). The most important of these are *sar* and *agr*, both affecting RNAIII, which is a global effector molecule capable of upregulating transcription of many staphylococcal virulence genes. Ironically, staphylococcal binding to platelets also causes release of platelet-bound peptide antibiotics that may ameliorate local infection *(4)*. The production of specific virulence factors by staphylococci results in a complicated cascade of effects depending on the interaction of the regulatory components present. Many of these factors contribute to the antiphagocytic and increased intracellular survival of *S. aureus (10)*. The effects that cause the most severe infections may be produced by strains that harbor a particular complement of regulatory and toxin-encoding genes.

Early events in abscess formation are *sar* mediated. Subsequent exoprotein and toxin production is regulated by *agr*. There are at least 34 known exoproteins elaborated by *S. aureus* and their genetic determinants are grouped in pathogenicity islands throughout the chromosome. Certain proteins are highly toxic and are considered virulence factors. These enterotoxins (A, B, $X_{1,2,3}$, Δ, and E) and toxic shock syndrome toxin-1 (TSST-1) compose a related family of toxins causing staphylococcal food poisoning and toxic shock syndrome and act as superantigens once they enter the systemic circulation *(131)*. Superantigens cause intense activation of certain T-cell populations, and subsequent cytokine production overwhelms the immune system, preventing a coordinated response to antigen processing. The net result of this activation, paradoxically, is similar to endotoxin-induced shock wherein excessive quantities of cytokines induce tissue damage *(132,133)*.

More limited in activity, the epidermolytic toxins (ETAs), exfoliatins A and B specifically, attack the epidermis, causing exfoliation seen in toxic epidermal necrolysis (TEN) and staphylococcal scalded skin syndrome (SSSS). The gene for *ETA* is located on the chromosome, whereas the exfoliatin B gene (*etb*) is located on a plasmid. The major pathologic effect of these toxins occurs at a site remote from the site of infection.

Unlike enterotoxins and exfoliative toxins, membrane-damaging toxins produce damage at the site of infection. α-Toxin (heat labile), one of four known hemolysins (α, β, γ, δ), is a major pathogenic factor in that it produces tissue damage after the establishment of infection *(134,135)*. Using allelic replacement to create isogeneic toxin-positive and toxin-negative strains, no lesions were generated by the toxin-negative strain in a murine model of mastitis *(135)*. A-Toxin is the only staphylococcal toxin known to damage actively growing nucleated animal cells and is both dermonecrotic and lethal (30 μg/kg) in a murine model *(135,136)*.

When α-toxin is injected subcutaneously, vasoconstriction and subsequent tissue ischemia result *(30)*. B-Toxin (a heat-labile sphingomyelinase) and δ-toxin (a heat-stable peptide) are dermonecrotic at high doses but are less potent than α-toxin *(134,137)*. B-Toxin is not produced in many strains because of a converting phage inserted in the *hlb* gene *(136)*. A staphylokinase (SAK) is carried by the phage and upregulated by *agr*. Nasal strains usually have SAK intact, whereas SAK-deficient isolates were more than four times as likely to cause a fatal outcome *(138)*.

The δ-toxin peptide is a 26-residue translation product of the *hla* gene located near the 5′ end of RNAIII encoded by the *agr* locus. Leukocidin (heat labile), which is toxic to neutrophils and macrophages, also is a potent dermonecrotic toxin *(137)*. It is composed of two proteins, F (32 kd) and S (38 kd), and induces formation of a transmembrane potassium channel *(138a)*. Both components are necessary for toxicity. Leukocidin and γ-toxin belong to the same family of bicomponent toxins *(139)*. The genes for all the dermotoxins (*hla*, *hlb*, *hld*, *hlg*) are located in the chromosome. One leukocidin, Panton-Valentine leukocidin (PVL), has gained special repute since it is carried by many USA 300 MRSA strains causing community-acquired infection including necrotizing and fatal pneumonia *(139a)*. The extent of the PVL determinant in MSSA strains has not been well studied, but PVL is present in a small number of MSSA isolates (MLST 188) from Malaysia *(140)*.

Other exoproteins, such as proteases, collagenase, hyaluronidase, and lipase, probably act as virulence enhancers and are not as destructive to tissues *(136)*. Although staphylococcal exoproteins are otherwise dissimilar, the expression of at least 12 genes (including α- and β-toxins, exfolitins, enterotoxins B, D, TSST-1, proteases, protein A, and coagulase) is upregulated by *agr (141)*. The *agr* locus is involved in a two-component regulatory system controlling the expression of virulence genes in other bacteria *(142)*. Other regulatory elements, several of which are *sar* homologs, have been recently identified (see Fig.28-3). Thus, the complexity of the regulatory elements suggests that virulence factor expression is most likely responding to a variety of environmental and physiologic conditions specific to the host. The *agr* type and function has recently been related to the mortality associated with staphylococcal bacteremia *(143)*.

Dissemination and Metastatic Infection

After the establishment of local infection, *S. aureus* may disseminate to other sites. Dissemination from cutaneous sites is infrequent in community-acquired infection but may be more common in healthcare-associated acquisition. Spread of staphylococci from a localized cutaneous infection to the bloodstream and then to deep tissue to form abscesses or to cause endocarditis requires access to the bloodstream and rebinding to potential target sites. In part, *S. aureus* may gain access to the capillary vascular tree as a result of local inflammation and tissue damage invoked by specific, highly regulated exoproteins. Phagocytic cells may also contribute to vascular entry by carrying viable microorganisms back into the capillaries. Once entry into the bloodstream occurs, binding to serum proteins would follow, and eventually bacteria might stick to a target cell bearing a receptor to either a staphylococcal MSCRAMM or a serum component bound to the staphylococcal cell wall.

S. aureus can also bind to platelets *(144)*, and the binding may increase the capacity of platelets to bind to injured endothelium. Thus, staphylococci may be transported to a distant site and establish a metastatic focus. The ability of bacteria to bind to platelets correlates with the capacity to induce infective endocarditis. *S. aureus*, with its high capacity to bind platelets, more often caused endocarditis in an animal model than did *Escherichia coli*, with its minimal platelet-binding capacity. Binding of staphylococci to platelets is direct, rapid, and saturable, suggesting that this property is receptor-mediated and dependent on the number of receptors present. Platelet binding is not dependent on protein A. The staphylococcal ligand is most likely a surface carbohydrate and, perhaps, capsular-based. This ligand is resistant to proteases and susceptible to agents that modify carbohydrates and specific anticapsular antigens *(145)*.

After dissemination, *S. aureus* must attach to distant tissues to cause a metastatic suppurative infection. Metastatic infections may develop through interactions of blood-borne staphylococci and endothelial cells. These infections may involve endovascular structures or deep tissues. This may be due, in part, to the higher degree of attachment and invasion of endovascular tissue exhibited by staphylococci *(146)*. The interaction of endothelial cells and *S. aureus* is so efficient that these bacteria adhere to uninjured endothelial cells. Affinity for a specific site usually leads to infection at that site; *E. coli* microorganisms have been shown to attach to specific uroepithelial cell receptors, and this interaction is a prerequisite for urinary tract infection (UTI) *(147)*. *S. aureus* appears to have a specific receptor for endothelial cell surface proteins, which promotes adherence and, perhaps, the initiation of endocarditis and graft infections. As with platelet binding, bacteria that bind avidly to endothelial cells are more likely to cause endocarditis than bacteria that bind poorly and consequently rarely cause endocarditis *(148)*.

S. aureus is also a common cause of prosthetic valve endocarditis. Binding of *S. aureus* to a porcine cardiac valve is a specific receptor-mediated event. In this instance, a binding protein of 120 kd was identified as a potential receptor. This protein was not related to fibronectin. Unlike injured tissues, fibronectin may not augment *S. aureus* binding to endothelial cells. No fibronectin is expressed on the luminal surface of endothelial cells, and no fibronectin is produced by valvular endothelial cells *(149)*. However, fibronectin may augment the binding of *S. aureus* to injured endothelial surfaces and if fibronectin binding is blocked, there is a decrease in adherence to subendothelial surfaces exposed after endothelial injury *(150,151)*.

Investigators have also shown that endothelial cells ingest attached staphylococci. A 50-kd protein from umbilical vein endothelial cell membrane binds to *S. aureus* and facilitates uptake into endothelial cells *(152)*. This protein was shown to be different from fibronectin using a fibronectin antibody assay. Binding is also specific, since albumin or fibrinogen does not inhibit this interaction. Bovine aortic endothelial cells actively phagocytosed *S. aureus*; 65% of bacteria applied to the endothelial cells were ingested. This action can be blocked by cytochalasin B and was independent of fibronectin and complement *(153,154)*. Complement-activated endothelial cells, conversely, have

increased fibronectin binding. Although *S. aureus* cells that were ingested did not multiply within endothelial cells, the endothelial cells eventually died, leading to exposed subendothelial surfaces. Adherence alone does not induce apoptosis since studies show that viable intracellular *S. aureus* is needed to induce apoptosis *(155)*. Ingestion and endothelial cell death, however, do depend on strain and inoculum *(156)*. The clinical impact, ultimately, is that intracellular *S. aureus* may not be affected by most antibiotics, particularly β-lactams, which fail to penetrate eukaryotic cells. Endothelial cell infection would consequently initiate invasion and infection of deeper tissues.

Subsequent interactions between the ingested *S. aureus* and the endothelial cell may lead to local vascular damage. Uptake of *S. aureus* by endothelial cells also increases expression of Fc receptors on the cell surface, hypothetically initiating vasculitis by the adherence of neutrophils and platelets to the endothelial cells. Immune complex deposition would next activate complement or initiate the coagulation cascade. These events could augment further metastatic seeding and invasion *(157)*. Finally, host factors elicited by extravascular infection may alter endothelial cells and increase bacterial adherence. For example, staphylococcal adherence to vascular endothelium is upregulated by *sar* and enhanced in the presence of tissue necrosis factor-α (TNF-α). TNF may further increase the endothelial leukocyte adhesion molecule-1 (ELAM-1) and intracellular adhesion molecule-1 (ICAM-1) *(158)*. Also, the exposure of endothelial cells to lipopolysaccharide increases adherence of bacteria. This effect is duplicated by incubation of cells with the cytokine interleukin-1 *(159)*. Classic agents like aspirin downregulate many pathways associated with complications of endothelial infection and by downregulating global staphylococcal regulons, create novel therapeutic strategies *(145)*.

Specific capsular types of *S. aureus* play a critical role in abscess induction, as well as in avoiding host phagocytic uptake. Capsules are produced by most clinical strains, and serotypes 5 and 8 together account for up to 50% of clinical isolates *(145a)*.

More than 80% of healthcare-associated isolates from bacteremic patients produce capsule type 5 or type 8 *(160)*. Clinical strains with a type 5 or 8 capsule are more resistant to opsonophagocytosis. In a mouse bacteremia model of infection, a capsule type 5 strain sustained a higher level of bacteremia than two capsule-defective mutants, likely due to the antiphagocytic nature of CP5 since *in vitro* assays indicated that the parental strain was only susceptible to phagocytic killing by human polymorphonuclear leukocytes (PMNs) in the presence of capsular antibodies and complement. Although capsule types 1 and 2 confer resistance to complement-mediated opsonophagocytosis by PMNs, strains producing these capsule types do not cause clinical disease. CP5 production has also been shown to block adherence of *S. aureus* to endothelial cells in culture *(161)*. Similarly, in a rat model of catheter-induced *S. aureus* endocarditis, both the type 5 and 8 parental strains are less pathogenic when compared with capsule-deficient mutant strains *(162)*. These findings suggest that CP5 and CP8 may interfere with staphylococcal attachment to the damaged aortic valve *in vivo*. Data from mouse models show that a capsule-defective mutant fails to persist in the murine nares *(163)*. Ways to exploit these observations through active or passive vaccination to reduce the risk of healthcare-associated infection await further study.

SCOPE OF HEALTHCARE-ASSOCIATED INFECTIONS CAUSED BY *S. AUREUS*

Bacteremia and Endocarditis

Bacteremia is a dreaded sequel of localized *S. aureus* infection that often results in production of metastatic foci in almost any organ. SAB is healthcare-associated 20% to 60% of the time, depending on the preponderance of certain variables such as IV drug users in the population at large (*164*, *164a*). SAB has become a field of study in itself (3,224 hits on PubMed on 22 January 2011). Up to 30% of patients with bacteremia fail to be cured when treated with parenteral antimicrobials *(165)*. In the Surveillance and Control of Pathogens of Epidemiologic Importance (SCOPE) program, *S. aureus* was the second most common cause of healthcare-associated bacteremia, with its coagulase-negative counterpart ranking first. Of 2,340 strains of staphylococci reported, 787 were *S. aureus*, 602 *S. epidermidis*, 61 *S. haemolyticus*, 45 *S. hominis*, and the rest different staphylococcal species *(166)*. One third of the cases of community-acquired SAB are associated with endocarditis and that number is rising. In the preantibiotic era, as many as 15% of patients with healthcare-associated staphylococcal bacteremia developed endocarditis, whereas one modern study uncovered no cases of endocarditis related with healthcare-associated staphylococcemia, perhaps because of the preponderance of hospital infections associated with IV catheters *(167)*. Conversely, in hospitalized patients with prosthetic valves, SAB often results in the development of new endocarditis *(165)*.

Healthcare-associated SAB has been closely studied over the last 50 years *(168,169)*. The variable rate of all SABs that are acquired in the hospital—40% to 60%—depends on the type of patients treated at the individual institution *(169)*. In 1989, the rate of *S. aureus* bloodstream infections per 1,000 discharges was lowest in small nonteaching and large nonteaching hospitals (0.46 and 0.44, respectively) and higher in small teaching and large teaching hospitals (0.89 and 1.13, respectively) *(170)*. The rate is also increasing in long-term care facilities, where *S. aureus* is the most common species causing bacteremia and accounts for about 15% of all cases *(171)*. In some countries, new MRSA strains may be particularly virulent and produce epidemics alongside endemic MSSA bacteremia *(172)*. The concern about the rising risk of bacteremic strains being MRSA led workers at Detroit Receiving Hospital to develop a prediction model. The model earmarks patients with a history of hospitalization, a longer hospitalization, comorbid conditions, and exposure to antimicrobials as at risk for MRSA bacteremia, whether healthcare- or community-associated *(173)*.

Patients most susceptible to SAB have underlying conditions such as cirrhosis, diabetes, chronic obstructive pulmonary disease, congestive heart failure, and renal failure requiring dialysis. In one quarter of bacteremic patients, however, the source cannot be found. Patients who have the greatest change in their Acute Physiology and Chronic

Health Evaluation (APACHE II) score after admission to an ICU tend to have the worst outcome *(174)*. Interestingly, nasal MRSA carriage had a RR for bacteremia of 3.9 compared to MSSA carriage in 488 patients admitted to an ICU. The severity of illness induced by SAB relates to the risk of dying, although poor outcome was not associated with poor opsonic activity *(174)*. In the Scottish BURDEN study, morbidity and mortality of in-hospital SAB within 90 days of admission was greater for MRSA than MSSA. The death hazard was high for both, 5.6 for MRSA and 2.7 for MSSA *(175)*.

Over the last 25 years, the proportion of healthcare-associated bacteremias associated with vascular access devices has increased to 30% to 59% *(176)*. At Crawford Long Hospital in Atlanta, the number of device-related bacteremias increased eightfold during the years between 1980 and 1983 and those between 1990 to 1993 *(177)*. Some studies suggest that part of the increase may be due to the emergence of certain clonal strains sharing a common phage type. For example, in a Danish study of 15,000 strains of *S. aureus* isolated from patients with bacteremia from 1977 to 1989, phage type 95 increased from 3.8% to 18.8% during a time when no methicillin resistance was detected *(178)*. Follow-up Danish studies indicate that MSSA is the primary cause of staphylococcal bacteremia and that death is most often associated with septic shock, age over 60, and a daily dose of penicillinase-stable penicillin <4 g *(179)*. MRSA is much more prevalent in the same setting outside of The Netherlands and Scandinavia.

Adults and children with leukemia or cancer, particularly those with granulocytopenia, have been historically at high risk for SAB associated either with the persistent nature of their *S. aureus* nasal carriage or with preventive antimicrobial chemotherapy *(180,181)*. The rate of SAB in patients with cancer increased from 5% in 1973 to 30% by 1979 *(182)*. Japanese hospitals had a reported rate of 6% *(183)*, which has recently increased to at least 10% *(184)*. Interestingly, in a group of patients with leukemia who developed SAB, endocarditis was an unusual outcome *(185)*.

Patients with human immunodeficiency virus (HIV) infection are also at increased risk of acquiring SAB. In one study, half of these cases were healthcare-associated, and IV catheters were considered the likely source of healthcare-associated bacteremia *(186)*. Both healthcare-associated and community-acquired cases had a higher rate of late complications (35%) than was reported in earlier studies not involving HIV-infected patients. Hospitalized hemophiliacs with acquired immunodeficiency syndrome (AIDS) compared to non-AIDS patients again had a higher rate of SAB related to increased exposure to antibiotics and central IV catheters *(187)*. In HIV-infected patients, colonization and infection due to MRSA are related to prior hospitalization, exposure to broad-spectrum antibiotics, presence of dermatologic disease, and presence of a central venous catheter *(188,189)*. In Barcelona from 1991 to 2006, among 1,777 BSI in HIV-infected patients, in the community *S. pneumoniae* and *S. aureus* caused 44% and in the hospital coagulase-negative staphylococci and *S. aureus* caused 38% *(190)*. At Johns Hopkins, SAB occurred in nearly 20 cases per 1,000 patient years, 43.5% of which were MRSA (191).

Bacteremia isolates of *S. aureus* contain a habitual feature of classical members of the pyrogenic toxin superantigen (PTSAg) gene family comprising the staphylococcal enterotoxin (SE) genes *sea-see* and the TSST-1 gene *(192)*. PTSAg/ET genes *seg* and *sei* were found in combination by a multiplex PCR in 55% of strains. The *tst* gene was found in 20.3%. Overall, about half of *S. aureus* isolates tested harbored genes of the classical members of the PTSAg family and ETs (50.8%), and an even higher percentage if the newer toxin genes were included. Newer biologic therapies may be necessary to ameliorate the effect of groups of toxins.

Many challenges remain for optimal therapy of SAB. More patients with risks for SAB emerge constantly making SAB a true continual challenge for infection control. We look to the large numbers of investigators in the staphylococcal field to develop new strategies for treatment and especially prevention *(81)*.

Burns

Infection remains the major cause of death among burn patients *(193)*. *S. aureus* is a threat to patients with burns throughout the course of their treatment. Burn units worldwide continue to report *S. aureus* along with *P. aeruginosa* as the major pathogens affecting these patients *(194)*. In a Brazilian burn unit from 1993 to 1999, 55% of 320 patients developed healthcare-associated infections, with primary bloodstream infection in 189 patients being the most common *(195)*. Overall, *S. aureus* was responsible for 24% of all infections, followed by *P. aeruginosa* (18%) and *Acinetobacter* species (14%). Modern topical therapy reduces the concentration of microorganisms on the burn wound surface, and thus the potential for cross-infection *(196)*. Nevertheless, studies from one unit that discharges burn patients only when their wounds have healed completely have shown that burn wound colonization with *S. aureus* results in prolongation of hospital stay *(197)*. Additionally, burn units allow facile dispersion of *S. aureus* strains, since burn patients disperse *S. aureus* more readily than other hospital patients *(198)*. Moreover, burn patients represent a threat of introducing multiresistant staphylococci to new treatment care areas *(199)*. Bacterial isolation environments have been developed that reduce cross-infection, but they have not enjoyed widespread use. Isolation rooms in burn units have served a similar purpose, but studies are lacking to prove that such rooms actually reduce cross-infection due to *S. aureus (193)*. Quantitative culture of burn wound biopsies has been reported, in some studies, to relate to the development of burn wound sepsis *(200)*. Topical antimicrobial therapy remains the mainstay of reducing the microbial burden in burn eschar, and current susceptibility studies are encouraging for lack of emerging resistance *(201)*. Further epidemiology of bacterial infections in burn units is discussed in Chapter 25.

Dialysis

Hemodialysis As early as 1967, *S. aureus* had become the most frequent pathogen causing hemodialysis shunt infections *(202)*. It has been known for many years that the skin flora in patients undergoing hemodialysis becomes dominated by *S. aureus (203)*. Increased nasal carriage leads to colonization of arm shunts. Replacement of perineal normal flora by *S. aureus* also leads to colonization of shunts in the lower extremity. Colonization of any shunt site results in a shunt infection in two thirds of the sites and in bacteremia in one third *(204)*. When studied carefully, carriage of

S. aureus at nasal, perineal, or shunt sites was either persistent or, more often, intermittent *(203)*. Even the throat may be a secondary site of colonization *(204)*. Since the rates of colonization for dialysis outpatients were just as high as rates for dialysis inpatients, dialysis support staff members with known high rates of *S. aureus* colonization may contribute to the colonization of both groups of patients *(204)*; other factors undoubtedly contribute to *S. aureus* colonization *(205)*. SAB is a major problem in hemodialysis patients especially those with double lumen catheters *(206)*. MSSA as well as MRSA are regularly isolated *(206)*. Metastatic infection is common in hemodialysis patients with SAB and endocarditis is not an uncommon end result. An early study showed that 70% of access site infections and 50% of the cases of endocarditis in hemodialysis patients were due to *S. aureus (207)*.

Because of the association of carriage with subsequent serious *S. aureus* infection, studies have been directed at the development of prophylaxis *(208)*. IV vancomycin reduced the risk of shunt infections but has been impractical for widespread use. Oral rifampin, which can eradicate nasal *S. aureus* carriage, was also effective in preventing *S. aureus* infections in patients on hemodialysis *(102)*. Nasal mupirocin clearly is effective in eliminating nasal as well as hand carriage in hemodialysis patients *(209)*. In another study, Dutch workers evaluated 172 patients to determine the efficacy of decolonization with mupirocin; 67 (39%) were determined to be *S. aureus* carriers *(210)*. Mupirocin given twice a day for 5 days eliminated carriage in 98.5%, of whom 94% and 91% remained negative at 3 and 6 months, respectively. Bacteremia occurred at a significantly lower rate in treated patients (0.03 per patient year) than in an untreated historical control group (0.25 per patient year, $p < .001$). Despite these early optimistic data, there has been an emergence of mupirocin resistance in nasal strains of *S. aureus*, particularly common in long-term mupirocin therapy in dialysis patients *(211)*. The current threat of mupirocin resistance suggests the need for the development of new decolonizing agents and strategies other than antimicrobial chemotherapy to alter the carrier state *(212–214)* (see also Chapter 63).

Peritoneal Dialysis As with hemodialysis, *S. aureus* infections in patients on continuous ambulatory peritoneal dialysis (CAPD) have a clear association with nasal carriage *(208)*. Using molecular tools, Pignatari et al. *(215)* showed that peritonitis was caused by the same subtype as that carried in the nose. In a 10-month study of 63 carriers and 77 noncarriers, the 11 episodes of peritonitis due to *S. aureus* occurred only in carriers, as did 22 of 24 exit-site infections. Exit-site and tunnel infections in these patients are particularly troublesome and are caused by *S. aureus* 44% of the time. Nasal carriage again seems to be the major risk factor *(216)*. Carriage and resultant infection can be more effectively reduced by intranasal application of mupirocin than by neomycin *(217)*. It is not known if hospitals are the origin of *S. aureus* strains colonizing these patients, although the proximity of many hemodialysis units to inpatient units implies a close connection. The morbidity of *S. aureus* infections can probably be reduced by effective decolonization of the *S. aureus* carriers who enter CAPD programs, but the evidence for efficacy in CAPD patients is less convincing than for hemodialysis patients *(218)* (see also Chapter 64).

Gastrointestinal *S. aureus* Infections

Staphylococcal enterocolitis is a controversial disease, since the finding of *S. aureus* in the stool is not unusual and assays for cellular cytotoxicity of stool isolates are tedious to perform. Enterocolitis has been associated with indwelling feeding catheters, antimicrobial exposure, and high-risk neonates *(219)*. In the last group, a small outbreak of necrotizing enterocolitis was due to a strain of *S. aureus* that produced δ-toxin *(220)*. Wound strains more frequently produce staphylococcal enterotoxin C compared to diarrheal strains that more often produce staphylococcal enterotoxin B (SEB) *(221)*. The potential for enterotoxin production by healthcare-associated strains may assume greater importance since SEB-producing strains have been associated with toxic shock–like illness and TSST-1 production. SEB behaves like a superantigen capable of nonspecific cytokine stimulation *(222)*. As many as one quarter of asymptomatic *S. aureus* carriers have strains that produce at least one type of enterotoxin *(223)*, though it is not known if the hospital environment selects out toxin-producing strains. MRSA as well as MSSA clearly have the capacity to cause enterocolitis. An interesting observation from Japan found that enterocolitis caused by the same MRSA PFGE type was preexistent in the respiratory tract *(224)*.

Institutional outbreaks of *S. aureus* gastroenteritis are often overlooked, because the major manifestation is vomiting. In a food-borne outbreak in a Florida prison, 65% of inmates had diarrhea, vomiting, or both. *Salmonella infantis* and *S. aureus* phage type 29/52 and 52A (weak) were isolated from leftover turkey *(225)*. *S. aureus* phage type 29/52 was isolated from two of ten food handlers. Thus, such food-borne outbreaks in institutions can involve multiple enteric pathogens including *S. aureus*.

There have been new observations that microorganisms other than *Clostridium difficile* cause antibiotic-associated colitis. It is true that colonization of the bowel with *S. aureus*, particularly MRSA, increases during hospitalization *(226)*. With other microorganisms like *C. perfringens* and *Klebsiella orazae*, *S. aureus* can be associated with diarrhea after antibiotics, but these microorganisms are not yet accepted as causes for classic antibiotic-associated colitis.

Meningitis—Central Nervous System Infections

Historically, most adult cases of *S. aureus* meningitis have been community-acquired and are secondary to focal staphylococcal disease and endocarditis. Modern neurosurgery with its plethora of cerebrospinal fluid access devices, however, has created a new setting for healthcare-associated *S. aureus* meningitis, discitis, and subsequent vertebral osteomyelitis *(227)*. Prior neurosurgery, placement of ventricular shunts *(228)*, IV catheter–induced bacteremia *(229)*, postpartum endometritis *(230)*, and spinal analgesia (231) are risk factors for the majority of healthcare-associated cases. Very-low-birth-weight newborns with sepsis constitute another major group who acquire healthcare-associated meningitis *(232)*. In this group, predictors of cure included central nervous system (CNS) shunt infections, age less than 1 year, and normal

results with neurologic examinations. Shunts should be placed in newborns with hydrocephalus using a double glove technique with the outer pair removed before handling the shunt catheter *(233)*. Predictors of mortality in adults with shunts include diabetes mellitus, age over 60 years, obtundation or coma on presentation, and bacteremia *(227)*. With the increasing frequency of MRSA carriage in hospitalized patients, it is increasingly more likely that neurosurgery-induced meningitis will be caused by MRSA *(227,234)* (see also Chapter 27).

Pneumonia

Pneumonia caused by *S. aureus* has traditionally been a community-acquired illness associated with influenza virus infection, IV drug use, septic thrombophlebitis, and right-sided endocarditis (235). Patients are at higher risk in contracting *S. aureus* healthcare-associated pneumonia if they are under 25 years of age, suffer trauma, or are infected with HIV *(236)* (see also Chapter 22). The advent of the pandemic of MRSA healthcare-associated infections allows a more precise determination of the prevalence of healthcare-associated *S. aureus* infection, since most of these strains reside within the hospital. Epidemiologic studies of MRSA suggest that healthcare-associated *S. aureus* pneumonia is more frequent than generally is appreciated. In fact, NNIS system data reveal that 20% of all healthcare-associated pneumonia is due to *S. aureus (17,237)*. More recent studies have shown almost 40% of *S. aureus* healthcare-associated pneumonias are still caused by MSSA *(238)*. In one study, rates of mortality, need for mechanical ventilation, or admission to an ICU were no different in the MSSA compared to MRSA group *(238)*.

Other countries do not necessarily reflect this high incidence of healthcare-associated pneumonia caused by *S. aureus*. In a Spanish study of 15,803 isolates of *S. aureus* from healthcare-associated infections, the highest rates were 21% from the skin and 14.7% from the blood *(239)*. Perhaps this discrepancy is due to the high percentage of patients hospitalized in the U.S. who require mechanical ventilation, a major risk factor for *S. aureus* pneumonia. In a study of 1,000 consecutive hospitalized patients, 21.9% developed bacterial pneumonia, and in 23.2% of these the pneumonia was caused by *S. aureus*; six additional patients had polymicrobial pneumonia from which *S. aureus* was isolated *(240)*. Ventilator-associated pneumonia due to MSSA and MRSA has increased over the last decade *(241)*. For example, ventilator-associated pneumonia in 11 of 49 episodes was caused by MRSA, and these MRSA-infected patients were much more likely to have received antimicrobials and to have a fatal outcome *(242)*. In German ICUs, *S. aureus* has become the most common (24%) pathogen followed by *P. aeruginosa* (17%) *(241)*. *S. aureus* can be recovered by the protected specimen brush in 20% of ventilator patients who develop pneumonia and, although some experts advocate bronchoscopic sampling to best guide therapy, some studies suggest quantitative endotracheal aspirate cultures are equally useful *(243–245)*. In less developed countries, about 11% of all healthcare-associated *S. aureus* isolates are from the respiratory tract *(246)*. Most recently, in a large multicenter study of 480 patients with healthcare-associated pneumonia, 89% had *S. aureus* with 30% MSSA *(247)*.

Newborns

S. aureus infection has always been a problem in the nursery, where many factors serve to perpetuate colonization and infection. About 20% of newborns are colonized with *S. aureus* upon leaving the nursery; this figure doubles by 6 weeks after birth. These rates appear to be independent of whether neonatal care is given in a well-baby nursery or in an neonatal intensive care unit (NICU). Other factors, such as the type of device used for circumcision, influence *S. aureus* colonization *(248)*. In neonates, *S. aureus* infections are probably related more to colonization of the umbilicus than of the nares *(249)*. Umbilical infection can be reduced by decolonization of the area *(250)*. In any case, from 2000 to 2007, MRSA caused over one third of *S. aureus* infections in neonatal ICUs. Overall *S. aureus* causes 15 to 20 infections per 1,000 patient admissions, very-low-birthweight infants being the most susceptible *(251)*, as a cause of central-line infection, coagulase-negative staphylococci well outnumber *S. aureus (322)*.

Epidemics due to MRSA in modern NICUs suggest that such strains are healthcare-associated *(252–254)*. Some clones are clearly transferred from adult wards, as can be shown by using a combination of PFGE and *spa* typing *(255)*. Some outbreaks are so difficult to control that at times neonatal units have to be closed to break the cycle of cross-infection *(256)*. Methicillin resistance is not the only resistance marker that can be linked to outbreak strains, as was demonstrated by an erythromycin-resistant strain that caused conjunctivitis in several neonates in one nursery *(257)*. TSST-1 production in nursery strains has been another marker used to follow the spread of a strain causing the toxic shock syndrome in a nursery *(258)*.

Another molecular study has shown that multiple strains of *S. aureus* may circulate in some nurseries. Whereas phage typing could distinguish only nine strains, molecular analysis suggested that at least 20 strains from 23 neonates were involved *(259)*.

Crystal violet reactions of neonatal isolates of *S. aureus* were hoped to become a promising marker for detecting strains that persist after discharge from the nursery. In a study that showed a rise in the rate of colonization from 18% at discharge to 40% by 6 weeks after discharge, the purple-reacting strains, usually of phage groups I and III, were more likely to persist than strains from other phage groups *(260)*. It is becoming increasingly important to conduct surveillance of *S. aureus* clones in neonatal units. One recent study suggested that microbiologic surveillance using nasal cultures is sufficient for the detection of MRSA isolates, and it would seem prudent to use this strategy also for MSSA isolates *(251,261)* (see also Chapter 52).

Prosthetic Devices

There is a broadening spectrum of infections associated with insertion of prosthetic devices including intraocular lenses, cerebrospinal fluid shunts, prosthetic joints, vascular biomaterials, genital prostheses, and breast prostheses. The staphylococci predominate in these infections *(262)*. It is well known that coagulase-negative staphylococci tend to form biofilms on biomaterials more efficiently than *S. aureus*, but almost any staphylococcal species, including *S. aureus*, can produce a complex infection on prosthetic

material, which may include selection of small colony variants (SCVs), making treatment of prosthetic infection difficult *(263,264)*. Ica, one biofilm operon, has been detected in all *S. aureus* isolated from orthopedic prostheses compared to only 46% of coagulase-negative staphylococci *(264)*. A prospective study of Spanish patients with joint prostheses showed that an etiologic diagnosis could be made in 60% of the patients and most of the 58% of gram-positive infections were staphylococcal *(262)*. Seeding of prostheses after SAB is surprisingly common, as was shown by a collaborative study between Duke University and an institution in Auckland, New Zealand, which reported that 15 of 44 (34%) patients with SAB had subsequent infection of the indwelling prosthesis (see also Chapter 65).

Skin and Soft Tissue

In the preantibiotic era, pustules, carbuncles, furunculosis, cellulitis, and surgical site sepsis were common healthcare-associated infections in the United States, and they continue to be major problems in large areas of the world *(4)*. In modern hospitals, healthcare-associated staphylococcal cellulitis often occurs as a manifestation of infected indwelling intravascular devices and prosthetic implants. Pyoderma in healthy neonates and decubitus ulcers in residents of long-term-care facilities remain problems and are addressed elsewhere in this text (see also Chapter 52) *(297)*. Specific problems may arise in NICUs. For example, a group III phage type 42E/54/75 strain of *S. aureus* caused the scalded skin syndrome, which spread through a six-room special care nursery *(265)*. A recent broad-based study from Wenzhou, China, of skin and soft tissue infection caused by *S. aureus* showed that of 111 isolates, 57% were healthcare-associated and over half of all strains were MRSA *(266)*. Many strains harbored PVL genes, but the molecular profiles (per PFGE types) were quite heterogeneous (32 PFGE types). SCCIII was the most common type among both healthcare and, surprisingly, community strains.

Surgical Site Infection

Patients undergoing surgical procedures are at increased risk of developing a healthcare-associated infection; SSIs remain the most common and serious type of infection *(267,268)*. Through 1960, *S. aureus* was by far the most common cause of SSIs *(269)*. Studies done in the early 1960s found that SSI was associated with *S. aureus* nasal carriage and hospitalization during the month of January; this trend was consistently observed over 3 years *(90)*. In the data from the older NNIS system, *S. aureus* accounted for 19% of 11,724 SSIs *(270)*, but NNIS always suffered from proper adjustment of patient case mix *(271)*. New data come from the National Healthcare Safety Network (NSHN) that concentrates on device-related infections (central line–associated BSI), ventilator-associated pneumonia, and UTIs *(271a)*. In developed countries, *S. aureus* is the major pathogen in 30% of SSIs *(272)*. In developing countries, rates are even higher (i.e., *S. aureus* causes almost half of the SSIs) *(273,274)*. In-hospital SSI data are always affected by delayed infections—often due to *S. aureus*—that are manifested months or even years after surgery *(275)*. Diagnosis of other surgical infections, like psoas abscess and mediastinitis, can also be difficult, though Dutch hospitals have collected 4,066 CT procedures producing 183 infections, 2.4% sternal wounds, and 3.2% harvest sites (*276*,277). There was a large variation among hospitals (0.0%–9.7%) suggesting surprising room for improvement. Tammelin et al. in Uppsala did an exhaustive microbiologic study over 2 years of sternotomy patients who were reexplored. Using strict criteria for tissue infection and multiple tissue samples, they found *S. aureus* in 10/32 and *S. epidermidis* in 10/32 infected patients *(278)*. By PFGE, they found eight different patterns among 40 *S. aureus* isolates. Interestingly, the surgeon was readily identified as the source for all cases of *S. aureus* infection but could only be suspected as the source for 30% of the infections due to coagulase-negative staphylococci.

Guidelines for prevention of SSIs have been published many times and, if followed, probably reduce the rate of SSIs to 1% to 2% *(279)*. Adherence to these guidelines is important, because most SSIs result from exogenous strains of bacteria *(280,281)*, some of which are carried in the nares and on the hands of hospital personnel who contact surgical patients. For example, as many as 50% of ungloved examiners may carry *S. aureus* on their hands *(282)*. Because hair carriers have been associated with epidemics of SSI, proper head covering is mandatory during surgery *(283)*. Body coverings and face masks, however, do not guarantee containment of *S. aureus* during surgery. Mask wiggling contributes to an increase in recovery of *S. epidermidis* and *S. aureus* from cultures taken around the operating table *(284)*. In staff working in a cardiothoracic unit, the risk for hand carriage in nasal carriers was 7.4 (95% CI: 2.7–20.2; $p < .001$) (*284a*). Why the high risk? At least half of these hand carriers carried strains self-inoculated from their own nares!

The preponderance of *S. aureus* as a primary cause of SSI has spawned extensive research into the mechanism of SSIs using animal models. Progress has been slow, but several concepts are worth noting. SSIs are influenced by many complex variables in the operating room. The size of the inoculum of *S. aureus* delivered to the surgical site is related to the development of infection *(285)*. In an animal model, by increasing the inoculum from 3×10^6 to 8×10^6 CFU, the infection rate rose from almost 0% to 45%. Surgeons have recognized this fact for years and have tried using quantitative bacterial cultures to predict the likelihood of subsequent infection *(286)*. Size of the inoculum is only one element, however, in a complex process that produces SSIs. For example, the presence of remote infection, including those due to *S. aureus*, may increase the SSI rate two to five times *(287)*. Another study has shown that personnel working overtime (because of understaffing) resulted in an increase in the number of SSIs *(288)*.

For surgery involving exposure of tissues at the surgical site to adjacent contaminated or colonized sites, perioperative antimicrobial prophylaxis using antistaphylococcal agents is now universally advised. Even though antimicrobial prophylaxis is aimed primarily at *S. aureus*, it has been reported as the most common cause of SSI in cardiothoracic surgery *(289)*. B-lactamase production in *S. aureus* may be one factor that has reduced the efficacy of prophylactic cephalosporins to prevent *S. aureus* mediastinal infections *(290)*. New studies have emerged to address

which prophylactic antimicrobial regimens are effective in this era of multiresistant staphylococci *(291)*. A new challenge is judging the significance of contamination of cryopreserved tissue. As many as 64% of arterial homografts may be contaminated at the time of implantation, mostly with staphylococci *(292)*.

Infections after surgical procedures categorized as clean-contaminated, contaminated, and dirty are more likely to be due to nonstaphylococcal species. Yet, *S. aureus* infections after gastroduodenal procedures occur in up to 15% of cases *(293)*, suggesting a need to broaden traditional antibacterial coverage before certain operations. Specific procedures like placement of percutaneous enteral gastrostomy (PEG) feeding tubes, perhaps because of the cutaneous interface, are increasingly complicated by *S. aureus* infection *(294)* (see Chapter 21).

Toxic Shock Syndrome

After being initially described in 1978, staphylococcal toxic shock syndrome (TSS) gained increased notoriety during the early 1980s, notoriety spurred by the paradox that innocent commensals like *S. aureus* could elicit through their toxins a massive, catastrophic, superantigen cytokine response. The study of the interaction of TSST-1 positive strains and the immune system suggests a true duality of the interaction *(295)*. The cell wall of *S. aureus* contains toll-like receptor 2 (TLR2) ligands that trigger proinflammatory and also anti-inflamatory cytokines.

The first healthcare-associated cases were associated with SSIs *(296)*, often after minor surgery. In 12 of 13 patients described, *S. aureus* was isolated from the surgical site. Four were menstruating women but four patients were males. Classic signs of TSS including fever, profound multisystem dysfunction, and desquamative erythroderma usually began within 48 hours of the operation. A gentamicin-resistant strain of *S. aureus* that produced TSST-1 caused recurrent TSS in a nurse working in a burn unit. The strain was shown to spread to patients and other workers *(297)*. Relatively benign procedures *(298)*, including simple mastectomy in a male *(299)*, correction of a bat ear *(300)*, nasal packing after septoplasty, abdominoplasty *(301)*, enhanced external counterpulsation *(302)*, and arthroscopy *(270,303)*, have also been associated with TSS. Another report of an erythromycin-resistant TSST-1 producing strain carried by a neurosurgeon resulted in TSS in two of his patients; the strain from the neurosurgeon and those from the patients were shown to be related by endonuclease restriction-length polymorphism seen with *Tn*554 hybridization studies *(304)*. A moderate number of healthcare-associated strains of *S. aureus* produce TSST-1. In a study of 997 strains of *S. aureus*, 128 occurred with confirmed or probable cases of TSS. Following in frequency those strains associated with menses were those isolated from patients with septicemia, burns, and surgical sites *(305)*. Kikuchi et al. *(306)* at Tokyo's Women's Medical University described TSST-1 in MRSA strains that caused a disease termed neonatal toxic shock syndrome-like exanthematous disease (NTED). Clonal TSST-1 strains of MRSA were widespread in an NICU and a general neonatal and maternal ward where 12.9% of 62 newborns carrying such strains developed NTED *(306)*. SSSS, similar to TSS but caused by another staphylococcal toxin, can also present as healthcare-associated clusters, as has been the case after interarticular injection *(307)*. Strains causing TSS may contain other toxin genes capable of producing similar clinical signs and symptoms *(308)*.

These studies collectively suggest that healthcare-associated strains capable of causing TSS circulate among patients and hospital personnel. The diagnosis of healthcare-associated TSS should be suspected in hospitalized patients who have undergone surgical procedures, who have sites of suspected staphylococcal infection, and who manifest multisystem organ failure, fever, and shock with or without rash. Clustering of such cases that may involve a limited number of clones should alert the healthcare epidemiologist to search diligently for a carrier or common origin of a TSST-1–producing strain of *S. aureus*.

Urinary Tract Infection

Unlike the dogma for the significance of gram-negative bacillary UTIs, there are no quantitative standards for evaluating the clinical significance of staphylococci in urine. Several early studies have shown that *S. aureus* is infrequently cultured from urine *(309,310)*, but the last two decades have seen a change in that dictum. The clinical significance of small numbers of *S. aureus* in the urine of hospitalized patients remains unclear but may often be suggestive of some site of infection in the urinary tract (235,*309*). *S. aureus* bacteriuria in concentrations of at least 10^5 CFU/mL also occurs in the absence of renal infection. In one study using a criterion of $\geq 10^5$ CFU/mL as indicating infection, *S. aureus* was isolated from only 3.3% of the isolates from 17,437 urine cultures. Of 373 patients with *S. aureus* isolated from urine, 132 had $\geq 10^5$ CFU/mL of *S. aureus* in pure culture, and 96 had *S. aureus* in mixed culture *(235)*. Renal carbuncles, which complicate SAB, are localized to the cortex of the kidney and may release small numbers of microorganisms into the urine *(235)*.

Bacteriuria occurs in 15% to 25% of patients with SAB, not a result of colonization but a result of SAB and metastatic infection in the urinary tract or the vertebral column *(311,312)*. One recent study suggested that *S. aureus* bacteriuria may be a predictor of complications, even mortality associated with SAB *(313)*. Otherwise, *S. aureus* with or without a bloodstream origin can infect multiple sites in the urinary tract of hospitalized patients.

Up to 50% to 81% of cases of *S. aureus* UTIs are healthcare-associated in origin and, as such, carry a moderate risk of producing bacteremia. Of 69 patients who did not receive appropriate therapy for their *S. aureus* UTI, 11% had secondary bacteremia, compared with none of 63 who received appropriate therapy *(75)*. Predisposing factors included an indwelling catheter, urinary obstruction, surgical manipulation, or malignancy—factors similar to those predisposing to healthcare-associated gram-negative bacillary UTI (see also Chapter 20). Urologic patients may carry separate risks for *S. aureus* UTI. In a large 10-year study from Japan of 139 patients with *S. aureus* UTI, (45 MSSA, 94 MRSA), a febrile response was associated with certain toxin genes, and those genes were more common in MRSA than MSSA isolates *(314)*. In children with catheter-associated UTI, following *E. coli* (39%), *S. aureus* was the second most frequent pathogen (16%) *(315)*.

Vascular Access Device Infections

S. aureus causes about half of the cases of IV catheter–related phlebitis and bacteremia *(316)*. Over a 10-year period at a hospital in Atlanta, healthcare-associated device-related bacteremias increased eightfold, and 56% of these were due to *S. aureus* in the period 1990 to 1993 *(177)*. It is important to remember that phlebitis is evident in fewer than half of the patients with IV catheter-related sepsis and that sepsis is infrequent when a catheter has been in place <4 days. Many studies have used semiquantitative or quantitative culture techniques to identify the catheter as a source of bacteremia, but the positive predictive value of a single catheter culture remains low.

The suggestion that an IV catheter is the source of SAB has heretofore prompted many clinicians to use short-course antimicrobial therapy. This approach to therapy is surprising, since the frequency of late unpredictable complications of IV catheter–related bacteremia ranges from 0% to almost 70%. These complications include endocarditis, osteomyelitis, and pyelitis *(317)*. With current technology, it is not possible to predict prospectively which patients develop late complications. Nevertheless, short-course therapy has become popular for patients with SAB thought to be related to an IV catheter. In those studies of short-course therapy, the combined late complication rate was 6.1%, which is probably an unacceptably high figure for most clinicians *(317)*. Specifically, endocarditis develops in 2% of patients with catheter-related bacteremia, compared with 6% in other bacteremia patients *(318)*. Thus, short-term therapy (10–14 days) should be reserved for only those patients carefully selected to be at minimal risk for metastatic disease *(319)*. The quantitation of *S. aureus* adherent to a catheter or its related parts may become more meaningful when it helps identify those patients who will benefit from short-course therapy *(320)*.

Colonization of device materials or the surrounding skin precedes infection. With time, the extraluminal or the luminal colonization of the IV device predisposes to phlebitis and subsequent bacteremia. The mechanism of colonization involves development of a biofilm resistant to the bactericidal effects of serum or antimicrobial agents. The role of colonization by *S. aureus* at sites distant to the IV device remains unclear. In fact, one study suggests that nasal colonization with *S. aureus* may reduce the likelihood of phlebitis, but supportive data are lacking *(321)*. The authors suggest that immune mechanisms that reduce nasal colonization may also protect the catheter site from inflammation. In that study, the presence or the absence of *S. aureus* at the phlebitis site was not investigated, so more studies of this nature need to be performed. It has been shown that dwell time for catheters in neonates constitutes a major risk *(322)*.

Patients with catheter-related SAB are at increased risk for developing septic thrombosis or deep-seated infections exclusive of endocarditis. The development of these sequelae is heralded by persistence of fever for more than 3 days *(323)*. One of the most severe complications due to extension of the infected thrombosis is suppurative thrombophlebitis (see also Chapters 17 and 18).

S. aureus accounts for 81% of bacteremias associated with permanent endocardial pacemakers *(324)*. Although this infection may present like an intravascular sepsis, the portal of entry most often is the subcutaneous site where the pacing system is implanted. Similarly, permanently implantable cardioverter defibrillators (ICDs) and other cardiovascular implantable electronic devices (CIED) are an emerging risk for development of local and systemic *S. aureus* infection *(324a)*. One study found that 36% of patients with CIED infection had SAB *(324b)* with about one third presenting a year or more after the device was implanted. Cure usually requires removal of part (the generator) or all of the ICD *(325)* (see also Chapter 61).

Because of their severity, there has been public outcry to reduce vascular-access infections. Meticulous attention to the detail of inserting and maintaining these catheters (with accompanying checklist) can certainly reduce infection *(326)*. Other approaches to prevention have been reviewed recently *(327)*. In particular, a number of antimicrobial-impregnated catheters have been studied to determine if they can reduce the incidence of phlebitis and BSI, and many of these studies are very encouraging *(328,329)*.

EPIDEMIOLOGY

Along with the classic work of Spink et al. already described, the careful study of the epidemiology of *S. aureus* infections in hospital patients performed by Finland and Jones *(30)* shortly thereafter established the basis for modern hospital infection control. The spread of infections caused by *S. aureus* phage type 80/81 is analogous to the problem with infections caused by MRSA in hospitals today. That phage type was responsible for many serious hospital outbreaks of furuncles, carbuncles, pneumonia, and SSI *(330)*. So pervasive was *S. aureus* infection, that, at the University of Iowa Hospital in 1957, *S. aureus* caused infections in 17% of all surgical and 12% of all medical patients; 38% of these infections in both groups were healthcare-associated.

Since the outbreaks of the 1950s, *S. aureus* persisted as the preeminent healthcare-associated pathogen. The NNIS system found that *S. aureus* was the cause of 12% of 70,411 healthcare-associated infections, the number one cause of SSIs (19%), pneumonia (20%), and infections at all other sites (17%) *(17)*. Since the NNIS data, the number of cases of healthcare-associated pneumonia caused by *S. aureus* has increased (from 17% to 20%), and only recently has started to decline *(331)*.

The rise in the number of infections caused by MRSA has also brought attention to staphylococcal infection in long-term-care facilities (see also Chapter 98). Rates of *S. aureus* infections in a nursing home care unit ranged from 0.29 to 0.47 per 1,000 resident-care days *(332)*. Demographics for patients with MSSA and MRSA infections were similar. One study in a skilled-nursing facility found that 35% of residents were colonized with *S. aureus* at least once during a 1-year prospective surveillance study. Surprisingly, rectal carriage alone was present in 13% of residents who became colonized during their stay *(333)*. Outbreaks of MRSA infections have occurred in pediatric residential care facilities as well. One such outbreak was reported in an Arkansas state facility for mentally challenged children *(334)*. From 1978 to 1981, in one cottage, an average of 10 *S. aureus* infections occurred per month, affecting 29 of 35 cottage residents. In July 1981, residents and workers in this cottage were

decolonized with antibiotics, and all residents and personnel were inoculated intranasally with *S. aureus* strain 502A. At a Spanish geriatric hospital, using MLST typing CC5 was found to be the predominate MLST type, but there was a variety of other types among blood and wound isolates *(335)*. Residents of a Spanish LTCF experienced up to a 20% change from MSSA to MRSA carriage annually *(336)*. Yet, one hopeful study from Germany suggested that long-term endemicity with MRSA can be avoided after an MRSA epidemic in the same LTCF *(337)*.

Reservoirs

The many studies of the inanimate hospital environment suggest that *S. aureus* persists on surfaces and fomites in hospitals *(338)*. Since there is usually a human component of contagion during hospital epidemics, it is always difficult to incriminate environmental sources alone *(94)*. Indeed, the contamination of the environment by skin scales from humans is a general index for human colonization *(95)*. In the surgical suite, both settle plate techniques and air sampling have been used to evaluate the potential for contamination. Such studies have not proven a cause-and-effect relationship but suggest that the environment may serve as a way station for strains that preferentially colonize hospital personnel. Nevertheless, because we know that there is heavy contamination of the environmental surfaces, there has been a recent movement to determine how to best modify the hospital environment and its touch surfaces in order to minimize persistence of hospital pathogens in the patient environment *(339)*.

Modes of Transmission

Staphylococci are efficiently transmitted by contact and less efficiently by the airborne route *(340)*. Strains from patients with *S. aureus* pneumonia or burn infections may spread by the airborne route in the hospital. Epidemics are most efficiently maintained by human carriers, both patients and workers, who carry the microorganism in their nares and contaminate other parts of their body, particularly their hands. Modern studies have shown that contemporary MRSA strains can spread quickly and displace susceptible nasal flora in hospital patients and personnel *(254)*.

There are some classic concepts of transmission that are often lost in modern hospital epidemiology. One group of nasal carriers who efficiently spread the microorganism are so-called shedders; 13% of male and 5% of female carriers are shedders with a heavy nasal inoculum who disperse, with normal movement, large numbers of microorganisms from their lower extremities and perineum into the air around them *(341)*. One physician shedder who contracted an upper respiratory infection (URI) was incriminated in an MRSA outbreak *(342)*. The physician carried large numbers of MSSA ($2.8–4.5 \times 10^5$) in both nares but fewer MRSA in either nare. After an experimentally induced rhinovirus infection, the physician could disperse *S. aureus* up to 20 ft, leading to the term cloud adult, in the descriptive tradition of cloud babies who similarly spread *S. aureus* in the nursery *(343)*. In the operating room, similar dispersal is likely related to wearing permeable clothing, including scrub suits *(344)*, and is blocked by polyethylene covering the lower extremities. Fifty years ago, Walter et al. *(344a)* performed many studies to show that orderlies and anesthetists in the operating suite may have twice the *S. aureus* carriage rate as surgeons and nurses, and that carriage may be persistent or intermittent. The modern healthcare epidemiologist would do well to apply these classic concepts.

There has been a historical debate between proponents of the airborne versus the contact routes of spread of *S. aureus* in hospitals. Goldmann *(338)* has aptly summarized the debate, emphasizing that whereas older outbreaks caused by one *S. aureus* phage type may have incriminated a point-source shedder of airborne *S. aureus*, modern outbreaks that feature multiple strains of *S. aureus* are probably initiated and perpetuated by contact transmission. That overview should not totally discount earlier work that showed that personnel who were shedders of *S. aureus* and worked in the operating room were associated with outbreaks of SSIs *(256)* and that removal of shedders from the clinical area resulted in cessation of the epidemics *(346–348)*. A causal relationship between colonization among personnel and subsequent *S. aureus* sepsis in patients remains unclear after years of study. Nevertheless, the "search and destroy" methodology of certain Dutch medical centers respects the potential for personnel to be involved in perpetuating the cycle of colonization and infection of patients, thus allowing for personnel to be removed from work until they are clearly decolonized of the offending strain *(349)*.

Hospitalization itself is a risk for colonization with *S. aureus*. Patients become progressively colonized throughout their hospitalization, though the maximum carriage rate is about 25% in studies from hospitals in the Western Hemisphere *(348,350)*. A deterministic model tested against data derived for the acquisition of tetracycline-resistant *S. aureus* demonstrated that, by about 35 days of hospital stay, the nasal carriage rate stabilizes at 25% *(351)*. Moreover, the nares are not the only site of *S. aureus* colonization. In women followed in a maternity unit, 33% were nasal carriers, but 25% carried *S. aureus* in their perineal region *(352)*. Earlier, in his classic studies, Solberg found that 12% of carriers harbored *S. aureus* at multiple sites *(95)*.

Tracing Spread of Healthcare-Associated Strains

The question of how many different strains of *S. aureus* circulate through a hospital at one time is not easy to answer. Historically, phage typing of strains—a system much inferior to modern molecular methods—formed the basis of epidemiologic analyses. One study of MSSA strains at Walter Reed Army Medical Center found four predominant phage types of 31 *S. aureus* bacteremic strains during a 6-month period in 1979 *(207)*. Control measures reduced bacteremia but not carriage. In the former East Germany, the prevalence of the 94/96 phage complex increased from 9% in 1978 to 16% by 1985 *(353)*. These strains were very similar with regard to biochemical reactions, antigenic structure, and the presence of 16-Md plasmids determining resistance to cadmium and penicillin. Yet, additional experimental phage reactions and the sites of resistance determinants on the plasmids could further differentiate the strains. Such studies raised the question of how far an investigation should proceed in an attempt to establish a relationship between strains.

Newer molecular methods already discussed may simplify this process somewhat (see earlier discussion in section "Molecular Typing Techniques"). Whatever technique is chosen, it is necessary to determine discriminative indices among strains to establish a strong epidemiologic relationship in order to draw valid conclusions. More advanced typing methods using staphylococcal genomics are just now being applied to MSSA strains, suggesting that relationships among healthcare-associated *S. aureus* strains are complex and certainly beyond the implications of phages *(76,77,354)*. Studies from newer multicenter molecular analyses of *S. aureus* strains from healthcare-associated outbreaks suggest that multiple methods are needed to establish clonal relationships among healthcare-associated strains *(58,69,355)*.

PREVENTION AND CONTROL OF *S. AUREUS* HEALTHCARE-ASSOCIATED INFECTIONS

S. aureus has persisted as the predominant cause of healthcare-associated infections. This microorganism is the second most common isolate from blood (16.5%), the most common isolate from SSIs (17.1%), and the second most common respiratory isolate (16.1%) *(356)*. Outbreaks within hospitals continue to occur and have been controlled, historically, by the institution of meticulous infection control measures. Less commonly, epidemics were controlled by the identification and treatment of carriers who were implicated in the transmission of *S. aureus* during such outbreaks *(41)*. The close relationship between colonization and subsequent infection has most recently been reemphasized by the work of von Eiff et al. *(2)*. In Münster, Germany, they found that over 80% of patients with bacteremia at the time of or after admission have a bloodstream clone that matched their nasal clone present on admission. Perl et al. *(357)* further demonstrated that the largest impact in decolonizing nasal carriers was a reduction in SSIs. Thus, the most effective measures for the prevention of staphylococcal infections are those that diminish or eliminate colonization.

Perioperative Prophylaxis

The appropriate use of perioperative antimicrobials has been shown to reduce the rate of clean SSIs at practically any site studied. Such prophylaxis has had a major impact on lowering the incidence of *S. aureus* SSIs, although the emergence of more resistant strains threatens that success *(291)*. In reviewing prophylaxis policies, one should follow several principles. First, determine whether published studies have shown that prophylaxis leads to a significant decrease in infections for the specific procedure. If so, choose an antibiotic with a spectrum that includes the microorganisms most likely to cause infection resulting from the specific procedure, realizing that no antimicrobial agent is capable of preventing infection by all pathogens. Next, determine if the chosen antibiotic achieves effective tissue levels at the site of the procedure. Also, consider the incidence of adverse reactions to the antimicrobial agent. Antimicrobials with high rates of allergic reactions would be undesirable as prophylactic agents. Finally, consider the cost of the antimicrobial agent. Less expensive, but efficacious, agents would control costs because of the large number of patients requiring prophylaxis. For all sites studied at which *S. aureus* is a predominant pathogen, cefazolin or a nearly equivalent cephalosporin (cefamandole, cefuroxime) has been the agent of choice *(358–361)*. With the marketing of several new antistaphylococcal compounds and a rise in strains of *S. aureus* (both MRSA and MSSA) that are only intermediately susceptible to vancomycin, there are now pressures to extend that spectrum of choices *(291)*.

The addition of vancomycin to prophylaxis regimens could be considered if there is a significant incidence of SSIs caused by methicillin-resistant staphylococci. In a study whose findings suggested the value in the use of vancomycin prophylaxis in this setting, the vancomycin prophylaxis group had fewer SSIs than the cefazolin and cefamandole prophylaxis groups, respectively *(285)*. However, there were several SSIs in the vancomycin treatment group due to cephalosporin-resistant coagulase-negative staphylococci. It is important to remember that antimicrobial prophylaxis may cause alterations in the normal flora. When compared to control patients not receiving antibiotics, two studies have shown the emergence of bacteria, including staphylococci, resistant to the prophylactic agents in patients administered prophylactic antimicrobials *(220,362)* (see also Chapter 21). With the marketing of several new antistaphylococcal compounds and a rise in strains of *S. aureus* (both MRSA and MSSA) that are only intermediately susceptible to vancomycin, there are now pressures to extend that spectrum of choices *(291)*.

Antimicrobial prophylaxis cannot prevent all *S. aureus* infections even those caused by susceptible strains. Many patients do not receive prophylactic antimicrobials for certain procedures such as intravascular catheter insertions or dialysis. Other patients may develop SSIs with susceptible strains of *S. aureus* despite adequate perioperative antimicrobial prophylaxis *(290)*. As previously stressed, the initiating event in healthcare-associated *S. aureus* infection is colonization, and we are making inroads in understanding that complex process *(96)*. We do know that patients colonized with *S. aureus* prior to a procedure are more likely to develop a staphylococcal infection after the procedure than are those patients who are not colonized *(363)*. Up to 80% of adults may be colonized if repeated cultures are obtained *(364)*, and those strains colonizing the anterior nares become infecting strains *(2,365)*. For these reasons, numerous strategies for reducing surface colonization have been tried, and there is a search for newer, more effective topical antimicrobial sterilizers, particularly since there is a significant percentage of mupirocin resistance globally *(366)*.

DECOLONIZATION

Use of preoperative showers with a topical antiseptic scrub is a simple decolonization strategy. One study compared povidone–iodine, chlorhexidine, and soap. Only chlorhexidine significantly reduced the numbers of staphylococci inhabiting skin sites. This study did not examine the effect

on infection rates *(367)*. A variety of topical and oral agents have also been studied. Topical gentamicin eliminated carriage rapidly. However, recolonization occurred within 10 days and was usually with the same phage type noted on initial sampling. With oral trimethoprim/sulfamethoxazole, eradication was not observed in a high proportion of patients, and resistance to this agent emerged frequently among patients in the study group *(345)*. Oral clindamycin has also been tried, but resistant strains frequently emerged *(368)*. In a study with limited enrollment, Klempner and Styrt *(369)* found that clindamycin was useful; 3 of 11 untreated patients versus 9 of 11 treated patients were free of infection after 3 months, but relapse of colonization was common.

Rifampin has been used in three studies either as a single agent or in combination with other antimicrobials. Chow and Yu *(370)* reported that rapid resistance to rifampin was observed if this agent was used alone. In a second study, the application of a topical antibiotic, bacitracin, to the external nares plus orally administered rifampin decreased the recovery of *S. aureus* on the forearm and from air samples and eliminated nasal carriage of *S. aureus* in hemodialysis patients. Infection rates were significantly lower in decolonized patients *(102)*. An earlier study, however, showed that application of bacitracin alone was ineffective but that the combination of bacitracin and rifampin was better; the latter combination was not as effective as rifampin alone *(371)*. Widespread use of rifampin and the subsequent increase in rifampin resistance would limit the long-term use of this agent for decolonization. Oral ciprofloxacin appeared promising, as most staphylococci were susceptible to ciprofloxacin. Ciprofloxacin was successful as a single agent in eradicating colonization, but resistance emerged in 7 of 22 patients. If patients were recolonized, the new strain was more resistant to ciprofloxacin than the initial isolate. Eradication did not occur rapidly and required treatment for 2 to 3 weeks *(345)*. Another study corroborated the frequent emergence of strains resistant to ciprofloxacin *(372)*. Other than the bacitracin and rifampin combination, none of the decolonization strategies above could be recommended. Rifampin plus an older antimicrobial, novobiocin, seems to be a promising alternative for decolonization *(57)*.

Topical mupirocin (pseudomonic acid) has been shown to eradicate carriage of *S. aureus* in many studies. Reagan et al. *(373)*, in a double-blinded study, reported that mupirocin decreased nasal carriage. Three months after therapy, 71% of treated subjects versus 18% of controls remained free of colonization ($p < .0001$). Casewell and Hill reported similar success with attempts at eradication *(374)*. In an analysis of six different double-blinded, independently randomized clinical trials of healthy carriers of *S. aureus*, nasal carriage was eliminated based on cultures taken 48 to 96 hours after completion of treatment in 91% of volunteers receiving mupirocin but in only 6% of placebo-treated control subjects *(375)*. The effect lasted at least 4 weeks after therapy. In a smaller study, topical mupirocin eliminated *S. aureus* carriage in 100% of volunteers. In 60% of these subjects, carriage relapsed within 1 year *(376)*. Decolonization of surgical ICU patients with mupirocin has been shown to be effective in preventing subsequent infections with *S. aureus* (RR: 2.78; 95% CI: 1.00–7.78) *(100)*. In this study, an added potential benefit of decolonization was evidence that bronchopulmonary strains were identical to nasal strains and bronchopulmonary colonization was decreased by nasal decolonization. Ultimately, a very well-designed study of MSSA carriage at Erasmus Medical Center in Rotterdam showed that a double-blinded study of decolonization resulted in a nearly 60% reduction in SSIs *(99)*.

On a cautionary note, as mentioned, high-level resistance to mupirocin has been reported *(377)*. A study performed at a long-term-care facility illustrates this point. A prospective study evaluated the effect of mupirocin on MRSA colonization and endemic infections. Carriage was eliminated from 94.7% when both nares and wounds were treated. Nares treatment alone did not significantly decrease overall colonization. The overall rate of recurrence was 34%. Unfortunately, the infection rate did not change with reduction in colonization. Resistance to mupirocin was detected and was mostly low level (MIC = 3.1–62.5 μg/mL); however, for one strain, an MIC greater than 5,000 μg/mL was reported. High-level mupirocin resistance was transferable and plasmid-mediated. Low-level resistant strains were cleared. Because of these findings, the authors did not recommend the use of mupirocin in long-term care patients (378). At a Canadian hospital, mupirocin resistance increased in MRSA strains from 2.5% in 1990 to 65% in 1993 *(379)*. In Brazil, emergence of resistance was related to the extent of mupirocin use: 63% of MRSA strains were resistant in a district hospital where mupirocin was used daily compared to a rate of 6.1% in a region where the topical agent was used infrequently *(380)*. (For a more specific discussion of MRSA, see the following Chapter 29.)

Thus, resistance to topical and systemic antimicrobials remains the major limitation of antibiotic-based decolonization treatments. One must not overlook the fact that *S. aureus* colonizes other sites in addition to the nares. A prospective study has shown that hospitalized patients without nasal colonization may be colonized with *S. aureus* at other sites. The axillae were colonized in 7% of patients, the perineum in 12%, and the toe webs in 5% *(381)*. Up to 13% of nursing home residents may harbor *S. aureus* only in the rectum *(333)*. Therefore, it may be worthwhile to choose strategies for decolonization that are effective at multiple sites. Although nasal carriers may disseminate and spread microorganisms to other body areas, heavy shedders also disseminate from the perineum *(382)*. Few studies have shown that widespread decolonization of hospitalized patients actually reduces the rate of infection. Moreover, in regard to carriers, less than 1% of hospital outbreaks have been caused by colonized personnel *(383)*. Except for selected groups of high-risk patients during MRSA outbreaks or those on hemodialysis, widespread and prolonged use of antimicrobial agents for decolonization is not indicated *(383a)*. Several new agents may soon be available for topical use. Lysostaphin has been shown to be rapidly bactericidal against *S. aureus* and able to decolonize quickly in one or two intranasal applications *(213)*. Alkyl esters are also gaining some attention as topical antistaphylococcal agents since they select minimally for resistance in serial passage *(384)*. Compounds involved in the so-called quorum-sensing mechanism in *S. aureus* may also emerge as candidates to turn off signals necessary for staphylococcal pathogens to persist *(384a)*.

Bacterial Interference

Several other new strategies for prevention of infection besides decolonization have been tried. Competitive interference using a strain of *S. aureus* of low pathogenicity (the 502a strain) was used in nurseries by application of a bacterial suspension to the umbilical stump. The incidence of infections was reduced, but outbreaks caused by the 502a strain occurred *(385)*. Use of this method requires previous treatment with antibiotics to establish 502a colonization. This method has also been used successfully to treat adult patients with recurrent skin infections *(364)*. A major disadvantage of bacterial interference is the ease with which the interfering strain may be eradicated with the additional use of antibiotics. Nevertheless, several worldwide centers are proceeding with studies of recolonization using interfering *S. aureus* strains after decolonization of pathogenic strains.

Vancomycin Resistance

Over 40 resistance genes have already been identified in strains of *S. aureus (386)*. Vancomycin has been utilized for staphylococcal infections for over 30 years. For a decade after the emergence of widespread vancomycin resistance in enterococci, resistance in *S. aureus* to vancomycin remained theoretical. The long-awaited appearance of strains of *S. aureus* with decreased (intermediate) susceptibility to vancomycin (vancomycin-intermediate *S. aureus* [VISA]) finally occurred in Japan in May 1996 *(387)*. The first patient was a 4-month-old child who had undergone open-heart surgery and developed a chronically draining sternal SSI. The patient was treated with several courses of vancomycin and subsequently, after decreased susceptibility to vancomycin was determined, with other antimicrobial regimens. Therapy with all of the antimicrobial regimens failed, and only deep debridement ultimately eradicated the VISA.

The *S. aureus* strain responsible for this first vancomycin-resistant infection termed Mu-50 grows well in 4 μg/mL of vancomycin and displays a heteroresistance to vancomycin in concentrations up to 10 μg/mL. The whole genome sequence of Mu50 and of a related strain Mu3 has been published *(5)*. These strains heralded an emergence of VISA worldwide, which have a variable response to vancomycin presumably because vancomycin is sequestrated in cell walls that have altered cross-linkages of peptidoglycan *(388,389)*. Early surveys conducted in Japan reveal that 1.3% of MRSA strains from nonuniversity hospitals and over 9% of strains from university hospitals display heteroresistance to vancomycin *(390)*. When examined for expression of heteroresistance, Dutch workers also found a surprisingly high (7.6%) rate of isolates with reduced susceptibility to vancomycin *(391)*. VISA isolates are not as concerning as they were a decade ago since there are alternative antimicrobials marketed that are active against VISA strains.

The specter of highly vancomycin-resistant *S. aureus*—VRSA (MICs to vancomycin of over 20 μg/mL) — continues to loom since its first identification in 2001 *(392)*. Most of the 11 well-characterized VRSA strains have been confined to the United States, but several cases of VRSA have now been isolated outside the United States *(392)*. Most of these patients have had extensive exposure to vancomycin *(390,393)*. For infection control personnel, these first VRSA strains of *S. aureus* with high-level vancomycin resistance were very alarming, particularly since the *vanA* gene commonplace in strains of vancomycin-resistant enterococci (VRE) was found to be located on a plasmid *(394,395)*. For reasons that are not clear, spread has been minimal *(392)*. For now, those patients with MRSA infections who fail vancomycin therapy, particularly after long-term therapy, should signal a need for determination of the presence of high-level vancomycin resistance or of heteroresistance in the emerging strain.

Initial recommendations for control of VRSA emphasized extremely stringent isolation of the patient particularly by limiting the number of healthcare workers caring for the patient. Healthcare-associated transmission, when documented, was cautioned to trigger the closure of the ward to new admissions *(396)*. If VRSA strains appear nationwide and worldwide, hospitals will have to wrestle with the issue of how many resources they can expend on the infection control and epidemiologic analysis of these multiply resistant strains of *S. aureus*. Fortunately, there are more antimicrobial options for treatment of patients with VRSA infections *(392)*.

Future Possibilities for Control

The saga of *S. aureus* continues from its early stature as a community- and healthcare-associated pathogen to its acquisition of multiple antibiotic resistance coining a unique eponym, MRSA. The evolution of *S. aureus* as a human pathogen reflects its genetic flexibility including the spectrum of infections it causes as a healthcare-associated plague. Future strategies for the control of healthcare-associated *S. aureus* infections may include more persistent topical decolonizing agents, use of genetically engineered interfering strains of *S. aureus*, more efficacious passive vaccines and biologics *(397)*, use of probiotics, and peptide therapy to modulate pro- and anti-inflammatory cytokines. Catheters impregnated with antimicrobial compounds have been shown to reduce catheter-related infections and bacteremia, but their long-term clinical efficacy is not known *(398)*. New materials used for wound care such as hydrophobic wound dressings would absorb bacteria and tissue proteins. One study showed that fibronectin analogues blocked the binding of *S. aureus* to plastic surfaces coated with human proteins *(399)*. Aspirin has been shown to mitigate the effects of *S. aureus* endocarditis *(145)*. Our growing understanding of biofilm formation offers a host of new targets to discourage adherence and biofilm accumulation.

Such measures may diminish or eliminate colonization and lower healthcare-associated infection rates while reducing antimicrobial selective pressure on susceptible strains. Manipulation of the healthcare environment will likely include ways to use ambient air treatments to cleanse floors and walls, incorporation of antimicrobial elements like copper into touch surfaces, and novel, space-age barrier protection. Clearly, new vaccine strategies are needed to reduce the morbidity of staphylococcal bacteremia *(33,400)*. We await, in fact, a huge clinical trial with a vaccine containing a staphylococcal iron siderophore. A cellulitis model in mice was used to show that vaccination with RAP reduced cellulitis and decreased death suggesting that other vaccine targets in the complex regulatory pathways of *S. aureus* await exploitation (Fig. 28-3) *(401)*. These new advances should be pursued with utmost haste as our foe grows stronger and our patients grow impatient *(402)*.

ACKNOWLEDGMENTS

The authors thank Jeanette Augenstein and Alex Harvin for help with references; Jean Lee and Jodi Lindsay for help with specific sections; and Katherine Schmidt and Ambrose Cheung for work on the *sar/agr* graphic. The authors thank Neil Barg, MD for his contributions as coauthor in previous editions.

CHAPTER 29

Methicillin-Resistant *Staphylococcus aureus*

Cassandra D. Salgado and David P. Calfee

INTRODUCTION

Purpose of Chapter

For many decades, methicillin-resistant *Staphylococcus aureus* (MRSA) has been regarded as an important microorganism within acute healthcare, and much has been described pertaining to MRSA as a cause of healthcare-associated infections (HAIs), factors that place patients at risk for MRSA infections, and the impact of such infections on patients, hospitals, and the healthcare system at large in countries all over the world. Researchers have provided scientific evidence describing how MRSA emerged, how the microorganism has been transmitted, and measures that have been effective for prevention and control. Of note, within the last 15 years, the epidemiology of MRSA has changed considerably with emergence of the microorganism as a cause of infections among community members who lack traditional risks for MRSA acquisition. This has not only captured the interest of scientists and clinicians, but also that of public health officials, consumer groups, print and television media, as well as government officials. There is renewed focus on MRSA and despite all we have learned about this pathogen, many facilities and communities continue to struggle from its effects and with how to implement evidence-based practices for control.

Scope of Chapter

This chapter describes several aspects of the epidemiology of MRSA including its laboratory characteristics, molecular typing characteristics, clinical and surveillance definitions, as well as its emergence and importance within healthcare and the community. Information regarding how to characterize the reservoir for MRSA are also discussed including methods for detecting colonized individuals. Finally, discussion is provided of basic as well as advanced strategies to prevent transmission both within and outside of healthcare.

EPIDEMIOLOGY

S. aureus is a common component of the normal flora of humans and many animals. Population-based studies suggest that approximately one third of the human population is asymptomatically colonized with *S. aureus (1)*. Persistent or transient carriage of *S. aureus* is most commonly detected in the anterior nares, but carriage on other mucous membranes (such as the oropharynx) and the skin is also frequently detected. Common sites of cutaneous carriage include the axilla, groin, perianal and perineal areas, wounds and sites of chronic skin disease, as well as foreign body (e.g., gastrostomy tubes and vascular access devices) exit sites. *S. aureus* is also a highly effective pathogen and is one of the most common causes of bacterial infection in humans. Common sites of *S. aureus* infection are the skin and soft tissues, lower respiratory tract, and bloodstream (including endocarditis) *(2)*, but infection can occur at essentially any body site.

Based on studies performed in Canada and Sweden between 1999 and 2005, estimates of the incidence of invasive *S. aureus* infection have ranged from 28.4 to 33.9 infections per 100,000 persons per year *(3,4)*. Invasive infections are associated with substantial morbidity and mortality, with outcomes dependent to some degree on the site of infection, host- and treatment-related factors. One study reported an overall in-hospital mortality of 19% among patients with invasive *S. aureus* infection *(3)*, and a number of studies that have assessed the outcomes of patients with *S. aureus* bacteremia report crude mortality rates from 18.9% to 34.4% *(5–7)*.

S. aureus is a common cause of HAI. In fact, *S. aureus* was the second most common cause of device- and procedure-related infections and accounted for 15% of all HAI reported by US hospitals participating in the Centers for Disease Control and Prevention's (CDC) National Healthcare Safety Network (NHSN) between 2006 and 2007 (8). The proportion of HAI caused by *S. aureus* varied among types of infection reported to NHSN. For instance, *S. aureus* was the most common cause of surgical site infections (SSIs) and ventilator-associated pneumonias (VAPs), accounting for 30% and 24%, respectively. *S. aureus* was the fourth most common cause of central line-associated bloodstream infections (CLABSI) (10% of cases) and the eighth most common cause of catheter-associated urinary tract infections (CAUTIs) (2%). A number of factors, including capsular polysaccharides, surface proteins, enzymes, toxins, and superantigens, contribute to the success of *S. aureus* as a pathogen and result in its ability to cause a variety of clinical syndromes. Discussion of these factors is provided in other chapters of this textbook.

General Laboratory Characteristics

S. aureus is a gram-positive, nonmotile, facultatively anaerobic coccus. In the laboratory, staphylococci tend to grow in grape like clusters of cells, hence the genus name *Staphylococcus*, which is derived from the Greek word *staphylé* or "bunch of grapes." The species name, *aureus*, Latin for golden, describes the color of *S. aureus* colonies growing in culture. Unlike many other bacteria, staphylococci can grow in environments in which there is a high concentration of salt. This feature is commonly used to assist in the laboratory identification of *Staphylococcus* species. The presence of catalase activity can be used to distinguish staphylococcal species from several other genera of gram-positive cocci, including *Streptococcus* and *Enterococcus*. The production of the enzyme coagulase differentiates *S. aureus* from the other staphylococcal species (i.e., the coagulase-negative staphylococci). Similarly, mannitol fermentation can also differentiate *S. aureus* from most other staphylococcal species.

Historical Perspective

Penicillin-resistant strains of *S. aureus* were identified relatively soon after penicillin became widely available in the 1940s. The mechanism of resistance was production of penicillinase, a beta-lactamase enzyme encoded by the *bla* gene. Subsequently, rates of penicillin resistance increased rapidly among hospital and community isolates of *S. aureus*. By the early 1950s, penicillin was no longer effective for the treatment of most *S. aureus* infections in many parts of the world. In response to the emergence of penicillin-resistant *S. aureus*, semisynthetic penicillinase-resistant penicillins were developed and introduced into clinical practice in the late 1950s and early 1960s. Methicillin was the first of these agents to be developed. In 1961, shortly after methicillin became available for clinical use, the first isolates of MRSA were reported *(9)*. The prevalence of resistance to methicillin among *S. aureus* isolates did not increase as rapidly as had occurred with penicillin resistance in the 1940s, and, in fact, the prevalence remained low until the 1970s and 1980s. Since that time, however, MRSA has become endemic in most hospitals in the United States, Europe (with a few notable exceptions such as Denmark and the Netherlands), Australia, and many other parts of the world.

Until relatively recently, MRSA was considered to be almost exclusively a healthcare-associated pathogen. During the past decade, however, MRSA has emerged as a significant pathogen among persons without typical healthcare-related risks associated with MRSA (*10*,11,*12*). In fact, MRSA has become the most commonly identified cause of purulent skin and soft tissue infections in persons presenting to emergency departments and other outpatient settings in many parts of the United States (13,*14,15*), and its prevalence in this type of infection is increasing in many other countries as well *(16–18)*. Based on data from the CDC's Active Bacterial Core surveillance program, it has been estimated that almost 14% of invasive MRSA disease in the United States in 2004 to 2005 occurred in persons without typical healthcare-associated risks (19). The emergence of community-associated MRSA (CA-MRSA) is the result of clonal dissemination of MRSA that is genetically distinct from typical healthcare-associated MRSA (HA-MRSA). The epidemiologic and genetic differences between CA-MRSA and HA-MRSA will be discussed in greater detail later in this chapter.

Laboratory Definition of MRSA

General Laboratory Characteristics Although typically referred to as MRSA, these strains are resistant not only to the antistaphylococcal penicillins, such as methicillin, nafcillin, and oxacillin, but also to all other currently available beta-lactam antibiotics (with the exception of the recently FDA-approved ceftaroline), including the first- through fourth-generation cephalosporins and the carbapenems.

The antibacterial effect of beta-lactam antibiotics is the result of inhibition of penicillin-binding proteins (PBPs), which are bacterial proteins acting as catalysts of cell wall assembly. *S. aureus* resistance to the antistaphylococcal penicillins, currently available cephalosporins, with the exception of ceftaroline, and carbapenems is the result of production of an altered PBP known as "PBP2a" or "PBP2′." PBP2a has very low affinity for binding beta-lactam antibiotics, which results in the inability of these drugs to exert their antibacterial effect. PBP2a is encoded by the *mecA* gene located on a resistance island, known as the "staphylococcal cassette chromosome *mec*" (SCC*mec*), which can integrate into chromosomal DNA. Several different types of SCC*mec*, known as "SCC*mec* types I-VIII," have been identified to date.

Heteroresistance refers to the situation in which only a subpopulation of the *S. aureus* cells with the resistance determinant (i.e., the *mecA* gene) actually express resistance *in vitro*. This has important implications for detection of resistance because, in the laboratory, the subpopulation that is susceptible to the penicillinase-resistant penicillins may grow more rapidly than the resistant subpopulation at temperatures above 35°C. In order to improve the ability to detect these heteroresistant strains, the Clinical Laboratory Standards Institute (CLSI) recommends incubation of *S. aureus* isolates at 33°C to 35°C for a minimum of 24 hours before assessing susceptibility to oxacillin, methicillin, or nafcillin (20).

In addition to resistance to the beta-lactam antibiotics, most strains of MRSA are also resistant to one or more other classes of antimicrobial agents. This can be the result of mutations in chromosomal DNA or acquisition of exogenous antibiotic resistance genes. In HA-MRSA strains, resistance to several classes of antibiotics is common. In many instances, these additional resistance determinants reside within the SCC*mec*. Two of the more common chromosomal mutations associated with antibiotic resistance are mutation of the DNA gyrase gene (*gyrA*) leading to fluoroquinolone resistance and mutation of rpoB leading to rifampin resistance. In *S. aureus*, intermediate resistance to the glycopeptides (vancomycin and teicoplanin), defined by CLSI as a vancomycin MIC of 4 to 8 μg/mL and teicoplanin MIC of 16 μg/mL, is also due to mutations in the bacterial chromosome. These mutations cause changes in the structure of the peptidoglycan component of the cell wall, leading to a thicker wall with more uncrosslinked D-alanyl-D-alanine terminals. These excess D-ala-D-ala terminals bind to glycopeptide molecules preventing them from reaching their true target *(21)*. Although the terms "vancomycin-intermediate *S. aureus*" (VISA) and "glycopeptide- intermediate *S. aureus*" (GISA) are often used interchangeably, some VISA isolates retain *in vitro* susceptibility to the glycopeptide teicoplanin.

Acquisition of exogenous resistance genes is responsible for resistance to several other classes of antimicrobials among MRSA isolates. Some of the more common and well-described acquired resistance determinants include *erm* (conferring macrolide and lincosamide resistance), *mupA* (conferring high-level mupirocin resistance), *tet* (conferring resistance to the tetracyclines), *msrA* (conferring macrolide resistance), and *dfrA* (conferring high-level trimethoprim resistance). One of the most feared scenarios has been the potential for the development of high-level vancomycin resistance in *S. aureus* (VRSA) due to acquisition by MRSA of the plasmid-mediated vancomycin resistance gene, *vanA*, from vancomycin-resistant *Enterococcus* (VRE). Conjugative transfer of *vanA* from *E. faecalis* to *S. aureus* was achieved in the laboratory in 1992 *(22)*, raising concerns that this transfer of genetic material could occur spontaneously *in vivo* as well. The first clinical isolate of VRSA was identified a decade later *(23)*. Since this first description in Michigan, nine additional cases have been identified between 2002 and 2007 *(24,25)*. In each case, vancomycin resistance was the result of the presence of the v*anA* gene, localized to a plasmid, within a methicillin-resistant strain of *S. aureus*. Commonalities identified among most of the reported cases include significant underlying medical conditions (such as diabetes, end-stage renal disease, and chronic lower-extremity wounds), prior history of VRE colonization or infection, prior history of MRSA colonization or infection, and prior receipt of vancomycin therapy. It is thus presumed that each of these cases developed in the setting of cocolonization with MRSA and VRE with transfer of the *vanA* gene from VRE to MRSA. Fortunately, these all appear to have been isolated, rare events and contact investigations have found no evidence of transmission of VRSA from case patients to their household or healthcare contacts.

Laboratory Methods for Identifying MRSA

A variety of options exist for detection of MRSA in clinical and surveillance specimens. These include conventional culture methods, novel culture-based techniques, and molecular methods. Each method has its own advantages and disadvantages relative to the issues of cost, turnaround time, complexity, performance characteristics (e.g., sensitivity and specificity), and approved uses. Detection of the *mecA* gene or PBP2a, the protein expressed by *mecA*, is the most accurate method for prediction of methicillin resistance (20). In this section, laboratory methods used specifically for the detection of methicillin-resistant strains of *S. aureus* will be discussed. A detailed discussion of the various laboratory methods available for isolation and identification of *S. aureus* in general is beyond the scope of this chapter.

Culture Methods

Oxacillin Screen Agar The CLSI-recommended agar dilution screening test for oxacillin-resistance in *S. aureus* isolates is known as the oxacillin screen agar test. Oxacillin screen agar consists of Mueller-Hinton agar containing 4% sodium chloride and 6 μg/mL oxacillin. In this test, a standardized suspension of *S. aureus* is inoculated onto oxacillin screen agar and incubated at 33°C to 35°C. Identification of growth of one or more colonies after 24 hours of incubation indicates that the tested isolate is oxacillin resistant. The sensitivity of the oxacillin screen agar test is 82.5% to 98%. Specificity has been reported to range from 46% to 100%, with most studies reporting specificities at the higher end of this range (*26–29*).

Cefoxitin Disk Test The cefoxitin disk diffusion screening test can be used to determine the presence of *mecA*-mediated oxacillin resistance. Because cefoxitin is a more potent inducer of the *mecA* gene, the use of cefoxitin disks, rather than oxacillin disks, is preferred for disk diffusion testing. In this test, standard disk diffusion procedures are used to inoculate Mueller-Hinton agar with a suspension of *S. aureus* that has been isolated from a primary specimen. A 30-μg cefoxitin disk is applied, and the plate is incubated at 33°C to 35°C for 16 to 18 hours. If the zone diameter is <21 mm, the isolate is deemed to be *mecA*-positive and reported as oxacillin resistant (*30*). The reported sensitivity and specificity of the cefoxitin disk diffusion test have ranged from 89.7% to 100% and 87.5% to 100%, respectively (*28,31,32*).

Chromogenic Agar Chromogenic agars that allow for simple and relatively rapid identification of methicillin-resistant strains of *S. aureus* are available for use in screening patients for MRSA colonization using swab specimens obtained from the nares, throat, groin, axilla, and perineum. These are selective agars that inhibit the growth of methicillin-susceptible strains of *S. aureus* and many other microorganisms and produce specific color changes in colonies of *S. aureus*. This distinctive color change allows MRSA to be distinguished from other methicillin-resistant microorganisms that grow on the agar plate. Unlike the previously described culture-based methods for detection of methicillin-resistance, specimens can be plated directly onto chromogenic agar, reducing the time interval between specimen collection and detection of MRSA. Positive results can be obtained in as little as 24 hours and final results, positive or negative, are available in 48 hours. The sensitivity and the specificity of chromogenic agars for the detection of MRSA, as compared with conventional culture-based methods and PCR, have ranged from 73% to 100% and 89.7% to 100%, respectively (*32–37*). Use of an overnight broth enrichment step prior to plating samples on chromogenic agar has been shown to increase the sensitivity of this method (38), although it also increases the turnaround time of the test by approximately 1 day. Because similar color changes may occur in colonies of some other microorganisms (e.g., coagulase-negative staphylococci, *Corynebacterium* species, some gram-negative bacilli), false-positive results can occur. The use of additional tests (e.g., Gram stain, coagulase test, and *S. aureus* latex agglutination test) to confirm that isolates suspected to be MRSA based on colony color are truly *S. aureus* has been shown to improve the specificity of these media (*33,34*).

Detection of PBP2a In addition to conventional phenotypic tests, tests that detect the presence of the mechanism of resistance, the altered drug target PBP2a, are available for use in the laboratory to identify MRSA in clinical specimens. As compared with traditional methods of testing for antimicrobial resistance, tests that detect PBP2a allow for more rapid detection of resistance (24–48 vs. <1 hour, respectively). Methodologies for detection of PBP2a include latex agglutination and immunochromatographic

assays. Latex agglutination assays use latex particles that have been sensitized with monoclonal antibodies against PBP2a. These latex particles react with PBP2a that has been extracted from a clinical isolate to result in macroscopically visible agglutination. Isolates that do not produce PBP2a do not cause agglutination of the latex particles. Sensitivity of latex agglutination tests has ranged from 83% to100%, and specificity has been reported to be as high as 100% (*28,29,39–41*). More recently, immunochromatographic membrane assays for the detection of PBP2a have been developed. In a study that used a tube coagulase test and an immunochromatographic assay for the identification of MRSA in blood cultures positive for gram-positive cocci in clusters, the sensitivity and the specificity of the immunochromatographic assay were 94.4% and 100%, respectively, as compared with PCR-based testing (*42*).

Molecular Methods

Polymerase Chain Reaction (PCR) In recent years, PCR-based assays for the detection of MRSA in nasal swab samples have been developed for use in MRSA screening programs. Commercially available PCR assays detect a unique gene sequence at the junction created by the integration of the SCC*mec* (the *mecA*-containing transposon) into the *S. aureus* chromosome. As compared with culture-based methods, these assays have been shown to be highly sensitive (80–100%) and specific (91–98.6%) for the detection of MRSA (*38,43–46*). Positive and negative predictive values for these assays have ranged from 66% to 95.8% and 96.6% to 100%, respectively. The low positive predictive values reported in some studies may be due in part to the identification of a larger number of MRSA carriers by the more sensitive PCR-based technology than detected by the culture-based reference standard due to the ability of PCR to detect a lower density of microorganisms than is possible with culture-based methods. The turnaround time for PCR-based detection of MRSA directly from nasal swabs is shorter than that associated with culture-based testing. As compared to a minimum turnaround time of 24 to 48 hours for culture-based testing, PCR has the potential to provide results within a few hours.

Although the first commercially available PCR assays were approved for use only for nasal specimens, PCR-based assays are also now available for use in detecting MRSA in some clinical specimens. Currently approved assays allow for the detection of MRSA directly from swabs taken from sites of skin or soft tissue infection and from blood cultures in which growth of gram-positive cocci in clusters has been identified. These assays detect sequences within the *S. aureus* chromosome, the SCC insertion site, and the *mecA* gene. As compared with broth-enriched culture methods, this assay demonstrated sensitivity, specificity, positive predictive value, and negative predictive value for the detection of MRSA in skin wounds of 97.1%, 96.2%, 91.9%, and 98.7%, respectively, in a population in which the prevalence of MRSA in wounds was 30% *(47)*. For the detection of MRSA in positive blood cultures, the sensitivity, specificity, positive predictive value, and negative predictive values were 98.3%, 99.4%, 96.6%, and 99.7%, respectively. A second study found the test to be 100% sensitive and 98.4% specific for the detection of MRSA directly from positive blood cultures *(48)*. The ability to more rapidly determine the presence or the absence of MRSA with the use of such PCR-based assays has the potential to improve clinical outcomes of gram-positive bacteremia and skin or soft tissue infection and to reduce unnecessary antimicrobial use. In addition, more rapid detection of MRSA infection may allow more rapid implementation of infection control measures designed to reduce the risk of MRSA transmission. These potential benefits, however, have not yet been fully evaluated.

Laboratory Methods for Strain Typing MRSA

Strain characterization and typing of MRSA isolates has helped describe the epidemiology of the microorganism in many different circumstances such as the evolution of MRSA, epidemic and endemic spread within healthcare and the community, as well as for patient care when it has been necessary to determine the strain causing infection or colonization. Bacteriophage typing was relied upon for decades; however, newer methods such as multilocus sequence typing (MLST), pulsed-field gel electrophoresis (PFGE), staphylococcal protein A (spa) typing, and SCC*mec* typing are the most common techniques utilized today *(49–52)*. Each method of strain typing uses different nomenclature leading to multiple characterizations of the same strain. Furthermore, there is no universally accepted nomenclature for strain typing MRSA and thus, comparison analysis between different labs in different geographic locations has been difficult. Each typing method has its own advantages and disadvantages that include the level of training and equipment necessary to conduct the procedure and interpret the results, discriminatory power, and cost.

Multilocus Sequence Typing MLST is based on sequencing DNA fragments of seven highly conserved housekeeping genes within *S. aureus*. Housekeeping genes are used because they are always present in the species (as they encode for the enzymes necessary for cell survival) but have sufficient variation to produce numerous alleles at a given locus. The resulting sequences of these genes are compared to known alleles at each locus via an electronic database located on the MLST Web site (http://www.mlst.net). Here, each isolate has been described by a seven-integer allelic profile defining a sequence type (ST), and clusters of related STs are defined as clonal complexes (CCs) *(53)*. The sequences that serve as the target for MLST are not subject to rapid change as they are not influenced greatly by selective pressures such as antibiotic-resistance encoding genes. Because of this, MLST has been useful for studying the evolutionary genetic relationships between known MRSA lineages and their precursor MSSA strains *(54)*. In 2000, Enright and colleagues *(52)* validated the use of MLST for *S. aureus* and subsequent studies performed on numerous MRSA isolates have supported the notion that the species population is strongly clonal, but gives rise to well-defined divergent lineages capable of rapid dissemination *(52–55)*. After initial dissemination, the strains may evolve regionally *(56)*.

MLST is particularly useful for these types of large population studies, and its Web-based data analysis system allows it to be extremely portable. However, this method does lack some discriminatory power (when compared to methods such as PFGE) for detecting more subtle differences between strains. Thus, it is often not

the method of choice for smaller outbreak investigations, determination of the relatedness of strains in the same patient, or in any situation where it is imperative to study close genetic relationships between isolates *(49)*. Additionally, MLST is costly and requires special equipment, as well as laboratory expertise.

Pulsed-Field Gel Electrophoresis PFGE is the method most often used for strain typing of MRSA. The procedure involves incorporating the entire bacterial isolate into an agarose plug, which is then subjected to detergents and enzymes that lyse the bacteria and deproteinate the plug. The DNA is then digested with a restriction enzyme (usually *Sma*I for MRSA), and slices of the plug (containing the digested chromosomal DNA) are placed into wells of an agarose gel. The gel is exposed to an electrophoretic current that switches direction according to a predetermined pattern. During this process, the restricted DNA is resolved into a pattern of discrete fragments, which are visualized by staining the gel with a fluorescent dye. The PFGE restriction profiles from different isolates are then commonly compared visually by pairwise fragment for fragment analysis *(49)*. It is relatively easy for the examiner to evaluate the relatedness of strains from a single or a limited number of gels, as is typically the case when evaluating an outbreak, or a limited number of isolates from a single center. However, computerized gel scanning and analysis software is available and allows users to create databases of PFGE patterns that can be used to compare gels from different laboratories or a large number of isolates over an extended period of time *(57)*. The advantages of PFGE over other typing methods include its reproducibility and high discriminatory ability. Thus, it has been an effective tool for outbreak investigations and for determining the relatedness of individual patient isolates. Additionally, the procedure is relatively straightforward. Specialized equipment and training is required, but the cost is not prohibitive *(49,58)*. PFGE can be time consuming, and it is often difficult to compare banding profiles from gels created at different times or at different facilities if the procedure conditions have not been standardized.

Spa Typing spa typing is a DNA sequencing analysis method that targets a polymorphic region of the *spa* gene. This region consists of 24 to 27 base pair repeats that may vary in number and nucleotide sequence. Each resulting unique combination detected through the analysis is assigned a distinct spa type, and this allows objective comparison between bacterial strains *(50,51)*. The method is highly reproducible and with the creation of Web-based tools, which have been developed for classification of the sequences, the data are also portable. There are two major nomenclature models, one described by Ridom (*http://www.ridom.net*) and the other described by Kreiswirth (*http://tools.egenomics.com*) *(50)*. Because spa typing relies on a single genetic locus and requires only a single PCR reaction, it is much less complex and less costly than MLST but it has discriminatory power approaching that of PFGE *(59)*. The portability of the data simplifies information sharing between laboratories and facilities creating large-scale databases for studying global and local epidemiology *(60)*.

SCCmec Typing Several molecular methods for identifying SCC*mec* types have been reported *(61,62)*. Eight major SCC*mec* types have been described (SCC*mec* type I to SCC*mec* type VIII), and their presence in MRSA has been useful for designating whether or not the MRSA strain is of healthcare origin or community origin. Often, SCC*mec* typing is combined with MLST typing as SCC*mec* has been associated with a limited subset of MLST CCs. With this, each MRSA isolate would be classified by a specific chromosomal background defined by MLST as well as the SCC*mec* type (Table 29-1) (20). Understanding the evolution of MRSA isolates and particularly the emergence of the new community-acquired strains requires characterization of the isolate's SCC*mec* element (20). To date, HA-MRSA strains possess only a limited number of SCC*mec* types, including SCC*mec* I first described in the United Kingdom in 1961, SCC*mec* II first described in Japan in 1982, and SCC*mec* III first described in New Zealand in 1985; whereas CA-MRSA strains possess smaller SCC*mec* types IV described in the United States in 1996, type V described in Australia in 1993, type VI described in Portugal in 1996, VII described in Sweden in 2007, and VIII described in Canada in 1996 (20).

Emergence of MRSA

As stated previously, the first MRSA was described from London in 1961, only a year after methicillin was introduced into the clinical arena *(9)* and within that decade came the first reports of healthcare-associated outbreaks due to MRSA in the United States *(63)*. By the early 1990s, MRSA strains were on the rise as a prevalent cause of HAI *(64)*. In a report released by the National Nosocomial Infections Surveillance system, the percentage of *S. aureus* HAIs caused by strains that were resistant to methicillin, oxacillin, or nafcillin was found to have increased among all hospitals more than 10-fold from just 2.4% in 1975 to 29% in 1991. Furthermore, the rate differed depending on bed size of the hospital. For example, in 1991, in hospitals with <200 beds, 14.9% of *S. aureus* were MRSA; for hospitals with 200 to 499 beds, 20.3% were MRSA; and for hospitals with 500 or more beds, 38.3% were MRSA. The authors concluded that hospitals of all sizes were facing the growing problem of MRSA and that control measures, which were being advocated at the time, should be re-evaluated *(64)*. Throughout the 1990s, MRSA infections were largely reported to occur among those who frequented healthcare facilities (e.g., hemodialysis units) or among those admitted into acute or long-term care. It was only on rare occasions that infections originating in the community were due to MRSA and this was typically reported among special populations such as injection drug users *(65)*.

Epidemiologic Definitions of MRSA

Historically, the major determinant in characterizing an MRSA infection as either "healthcare-acquired" or "community-acquired" has been the time of onset, or the time to identification of the infection after admission to the hospital. For example, if the patient had an infection incubating at the time of admission or if the infection was identified within 48 hours of admission, the infection would be classified as community-acquired; and if the patient had an infection develop after 48 hours of admission, it would be classified as healthcare-associated. Over the past 10 to

Strain typing designations for some of the widely used typing systems as applied to prevalent strains of MRSA clones.
(Reproduced from CLSI, Surveillance for Methicillin-Resistant *Staphylococcus aureus*: principles, practices, and challenges; a report. CLSI document X07-R, 2010. Wayne, PA: Clinical and Laboratory Standards Institute.)

15 years, the healthcare delivery system has undergone substantial changes, the most striking of which has been the shift of treatment of more acute illnesses into the outpatient arena, home, and the long-term care facility (LTCF). With these newer models for delivering healthcare and with the continued emerging epidemiology of MRSA and its associated risk factors, it became more difficult to accurately classify MRSA as strictly healthcare-associated or community-acquired. Recently, in two landmark studies by Klevens and colleagues, which described the incidence of invasive MRSA infections in the United States, the epidemiologic classifications of MRSA infections were redefined using two broad categories, "healthcare-associated" and "community-associated"(19,*66*). HA-MRSA infections were characterized as MRSA infections occurring among persons with at least one of the following healthcare-related risk factors: presence of an invasive device at the time of admission, previous history of MRSA colonization or infection, history of surgery, hospitalization, dialysis, or residence in an LCTF in the previous 12 months prior to culture date. Community-associated infections were characterized as occurring in persons who have none of these healthcare-related risk factors. HA-MRSA infections were further characterized as either community or hospital onset. Community onset refers to cases with a positive culture within 48 hours of admission and with at least one healthcare-associated risk. Hospital onset refers to cases with a positive culture result obtained >48 hours after hospital admission (19).

Prevalence of MRSA in Healthcare

Unfortunately, today, most would consider MRSA infections endemic in the majority of healthcare centers not only in the United States, but also in many countries throughout the world. In the United States, the proportion of *S. aureus* HAI resistant to methicillin has continued to increase, with rates of 63% reported from intensive care units (ICUs) in 2004. However, even though this proportion has continued to increase, recent data suggest that the incidence of MRSA CLABSIs has actually decreased in several ICU types since 2001 (Fig. 29-1) *(67)*. Although these findings are encouraging and highlight success in prevention of HAI, it is still important to realize that MRSA remains high in most facilities and many patient groups continue to be at risk for acquisition and infection from the pathogen.

In 2008, the NHSN released a report of antimicrobial-resistant pathogens associated with HAI in the United States between 2006 and 2007. The pooled mean proportion of all device-related HAI due to MRSA was 8%; however, this varied by type of infection and by patient care area within the healthcare facility (8). For example, higher rates of MRSA CLABSI were reported from burn ICUs (0.93 per 1,000 device days), moderate rates from trauma ICUs (0.30 per 1,000 device days), inpatient medical wards (0.28 per 1,000 device days), and medical cardiac ICUs (0.27 per 1,000 device days), and lower rates ranging from 0.11 to 0.20 per 1,000 device days from other areas of the hospitals. Similarly, higher rates of MRSA VAP were reported from trauma ICUs (1.36 per 1,000 device days) and neurosurgical ICUs (1.08 per 1,000 device days), lower rates from pediatric ICUs (0.17 per 1,000 device days), and more moderate rates ranging from 0.43 to 0.75 per 1,000 device days from other areas of the hospitals (8).

In 2009, a report similar to the NHSN document was released by the International Nosocomial Infection Control Consortium (INICC), which presented data regarding antimicrobial-resistant pathogens associated with HAI among 173 ICUs from 25 countries in Latin America, Asia, Africa, and Europe (68). Rates of methicillin resistance among

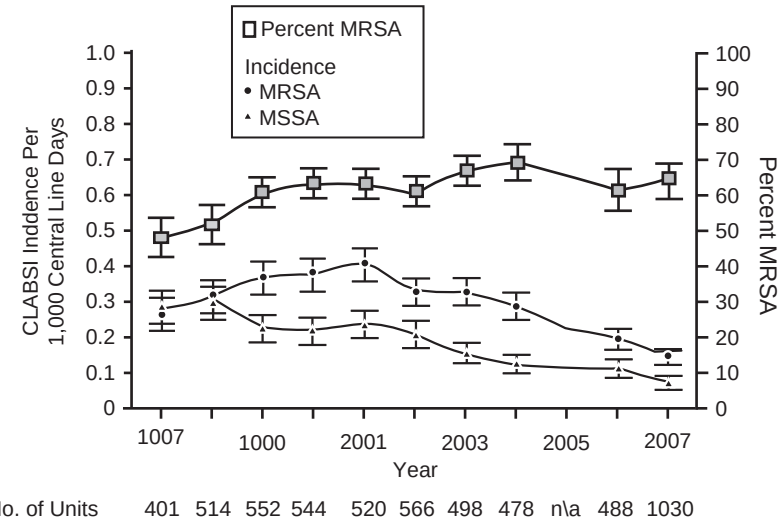

FIGURE 29-1 Trends in percent MRSA and incidents of *S. aureus* central line–associated bloodstream infections in intensive care units—National Nosocomial Infections Surveillance System, 1997–2004; National Healthcare Safety Network, 2006–2007. (Redrawn from Burton DC, Edwards JR, Horan TC, et al. Methicillin-resistant *Staphylococcus aureus* central line-associated bloodstream infections in US intensive care units, 1997–2007. *JAMA* 2009;301(7):727–736, with permission. Copyright © 2009 American Medical Association. All rights reserved.)

S. aureus HAI in INICC ICUs were significantly higher than the rates reported from NHSN ICUs. For example, the proportion of *S. aureus* CLABSI resistant to methicillin among INICC ICUs was 84.1% versus the 56.8% reported among NHSN ICUs. The authors speculated that these higher rates were likely a reflection of the limited resources available for hospitals in these countries to devote toward effective infection control programs, invariably low nurse to patient staffing ratios, and furthermore that the majority of hospitals lacked official regulations for infection control training or compliance (68). Similarly, methicillin-resistance rates reported among *S. aureus* VAP from INICC were 77.5% and among catheter- CAUTIs were 74.4%.

Since 1999, the European Antimicrobial Resistance Surveillance System (EARSS) has been collecting and reporting data from now 33 different European countries (*http://www.rivm.nl/earss/Images/EARSS%202008_final_tcm61-65020.pdf*). The median incidence rate for MRSA bloodstream infections (BSIs) among all countries reporting data was 4.8 per 100,000 patient days in 2008, increased from 3.5 per 100,000 patient days in 2007; however, this incidence rate varied considerably among the different countries from <1.0 per 100,000 patient days in Germany, Estonia, Finland, Iceland, the Netherlands, Norway, and Sweden to more than 8.0 per 100,000 patient days in Cypress, France, Ireland, Israel, Malta, Portugal, Turkey, and the United Kingdom. In 2008, these 33 countries reported susceptibility data for more than 30,000 invasive *S. aureus* isolates and found that 21% were MRSA. These proportions also varied from <1% in Northern Europe to >50% in Southern Europe; however, for the first time since EARSS began reporting summary resistance data, more countries showed decreasing MRSA proportions instead of increasing trends. Nevertheless, MRSA proportions are still above 25% in one third of European countries and >50% in the Mediterranean.

Importance in Healthcare

Healthcare-Associated Infections Caused by MRSA

MRSA is a well-described and common cause of many HAI including CLABSI, hospital-acquired pneumonia (including VAP), CAUTIs, wound infections, and SSIs. The impact of MRSA infections in the acute-care facility may be substantial. For example, a recent study by Filice and colleagues retrospectively analyzed excess costs and utilization associated with methicillin resistance for patients with *S. aureus* infections in their large VA hospital *(69)*. The median 6-month unadjusted cost for patients with MRSA infections was $34,657 compared with $15,923 for patients with MSSA. For patients with Charlson scores ≤3, the adjusted 6-month mean cost for an MRSA infection was $51,252 compared to $30,158 for MSSA, and for patients with Charlson scores 4 and above the adjusted 6-month mean cost for MRSA was $84,436 versus $59,245 for those with MSSA. Additionally, the mortality rate for those with MRSA infection was significantly higher compared to those with MSSA infection (23.6% vs. 11.5%; $p < .001$).

Bloodstream Infections The outcomes and impact associated with MRSA BSI have been the focus of numerous reports and depending on the type of study, patient population, and the methodologies used, results have varied *(7,70–77)*. Mortality rates for MRSA BSI patients have ranged from 20% to more than 35% *(7,71,73–75,77)* and among studies controlling for confounding variables, including severity of illness, when compared to mortality from MSSA, that from MRSA has been reported as significantly higher *(71,73,74)* as well as no different *(7,75,77)*. Regarding outcomes other than mortality, the impact of methicillin resistance has been described in terms of increased length of stay (LOS) and increased costs. An early study by Abramson et al. reported that the median LOS attributable to methicillin resistance among patients with healthcare-associated *S. aureus* BSI was 8 days (4 days for MSSA vs. 12 days for MRSA; $p = .023$), and the excess hospital cost was $17,422 ($9,661 for MSSA vs. $27,083 for MRSA; $p = .043$) *(76)*. A retrospective cohort study at a large academic hospital reported LOS attributable to methicillin resistance among patients with *S. aureus* BSI as increased by 1.29-fold ($p = .016$) and hospital charges as increased by 1.36-fold ($p = .017$) *(7)*, and another found that the average total charge during hospitalization for MRSA BSI was $45,920 as compared to $9,699 for MSSA BSI ($p = .0003$) After stratifying by case mix index (CMI), for those with a CMI >2 the average cost per day for a patient with MRSA was $9,744 versus $4,442 for patients with MSSA *(75)*. A recent

study of 182 patients with healthcare-associated *S. aureus* BSI found that compared to ICU patients with MSSA BSI, those with MRSA BSI had increased median total hospital costs ($42,137 vs. $113,852), increased costs after diagnosis of infection ($17,603 vs. $51,492), and increased LOS after infection (10.5 vs. 20.5 days); however, after analyzing the data utilizing a propensity score to estimate the predicted probability of acquiring a methicillin-resistant pathogen (and thus analyzing the effect among comparable patient populations) no significant differences were found *(70)*.

The impact of MRSA has also been studied outside the tertiary-care academic hospital. Kaye and colleagues conducted a cohort study to compare the outcomes of patients with MRSA infection (BSI or SSI) in community hospitals to that in tertiary care. One third of patients with MRSA infections died during hospitalization and of those that survived, 36.4% required readmission within 90 days and 57% of all MRSA-infected patients died within the subsequent year after diagnosis. Patients treated in community hospitals were less likely to receive effective antimicrobial therapy within 7 days of diagnosis compared to tertiary care (58.9% vs. 74.8%; $p < .001$), and they had a significantly higher 1-year mortality rate (62.5% vs. 52.5%; $p = .02$) *(72)*.

Healthcare-Associated Pneumonia The prevalence of MRSA as the cause of hospital-associated pneumonia has been recently reported by several investigators. For example, a retrospective cohort study of 59 hospitals from 2002 to 2003 to characterize the microbiology and outcomes among patients with pneumonia *(78)* reported MRSA as the cause of 56.8% of *S. aureus* healthcare-associated pneumonia, 48.6% of *S. aureus* hospital-acquired pneumonia, and 34.4% of *S. aureus* VAP. In another retrospective analysis of patients with healthcare-associated pneumonia, 16% to 18% were due to MRSA *(79)*. Similarly, a four country prevalence survey of HAI in England, Wales, Northern Ireland, and the Republic of Ireland found that MRSA was the cause of 7.6% of pneumonias and 18.1% of other lower respiratory tract infections *(80)*.

The attributable mortality that methicillin resistance contributes to those who suffer from *S. aureus* VAP has been debated. Older studies, which compared patients with MRSA VAP to those with MSSA VAP, reported that crude mortality was significantly increased for those with MRSA. For example, Rello and colleagues prospectively analyzed the outcome of 49 patients with *S. aureus* VAP who were similar with regards to sex, severity of illness, prior surgery, and presence of renal failure, diabetes, and coma. They reported that mortality related to pneumonia was significantly higher for those with MRSA compared to those with MSSA (RR, 20.72; 95% CI, 2.78–154.35) *(81)*. Other more recent, larger studies that have controlled for confounding variables such as receipt of appropriate empiric antibiotic therapy and LOS have reported that mortality is not increased for patients with MRSA VAP compared to those with MSSA VAP *(82–84)*. One large retrospective study of 154 patients with *S. aureus* VAP in 59 US hospitals (16 teaching hospitals and 43 nonteaching hospitals) reported that there was no increased mortality due to MRSA compared to MSSA (29% vs. 36%) *(82)*. Similarly, a prospective study of 134 patients with *S. aureus* VAP who had received appropriate initial empiric antibiotic therapy in 12 French ICUs found that after adjusting for differences in populations and controlling for length of ICU stay at time of VAP diagnosis, there was no difference in ICU or hospital death among those with MRSA compared to MSSA (OR, 2.06 and 1.75; $p = .07$ and .10, respectively) *(84)*. However; the impact of methicillin resistance goes beyond mortality with several studies describing increased morbidity and cost of care. Shorr et al. *(82)* found that the average cost of an MRSA VAP was $40,734 and after multivariate analysis, compared to those with MSSA VAP, those with MRSA consumed excess resources of 4.4 days on mechanical ventilation ($p = .03$), 3.8 inpatient days ($p = .05$), 5.3 days in the ICU ($p = .02$), and $7,731. Furthermore, among those with *S. aureus* VAP who received appropriate antibiotic therapy, when controlling for demographics, reason for ICU admission and mechanical ventilation, severity of illness, and duration of mechanical ventilation prior to VAP, infection with MRSA (vs. MSSA) doubled the probability of needing continued ICU care (HR, 2.08; 95% CI, 1.09–3.95; $p = .025$) and increased median ICU stay by 11 days (33 vs. 22 days; $p = .047$) *(82)*. Similarly, a large prospective study in three teaching hospital ICUs found that there was a significant delay in resolution of hypoxemia for those with MRSA (10 vs. 2 days) and after multivariate analysis, regardless of receiving appropriate antibiotic therapy, MRSA required significantly longer mechanical ventilation compared to other pathogens *(85)*. Excess resources included 6.8 days of antibiotic receipt, 13.8 days of mechanical ventilation, and 11 days of ICU care. Another study reported that among 160 patients with MRSA pneumonia, the expected estimated median daily billed hospital charges were $2,888 to $2,993 and the median total hospital charges were $32,024 to $32,636 *(79)*.

Surgical Site Infections As with other HAI, MRSA has increased as a cause of SSI. Among 2,045 *S. aureus* SSI reported to NHSN from 2006 to 2007, 49% were due to MRSA (8). In a study conducted to describe the epidemiology of severe SSI among patients from 26 community hospitals in the southeastern United States, from 2000 to 2005, the prevalence of MRSA doubled from 0.12 infections per 100 procedures to 0.23 infections per 100 procedures *(86)*. Another study of patients with microbiologically confirmed SSI from 97 US hospitals conducted from 2003 to 2007 reported that the proportion of MRSA as the cause of SSI significantly increased from 10.6% to 20.6% ($p < .0001$) *(87)*, and another study reported that among the elderly, MRSA increased as the cause of SSI from 15% in 2000 to 20% by 2005 *(88)*. A recent large retrospective cohort study of adults undergoing orthopedic, neurosurgical, cardiothoracic, and plastic surgeries at 11 hospitals in North Carolina and Virginia (nine community hospitals and two tertiary-care hospitals) found that MRSA was responsible for 50% of SSI in community hospitals and 43% of SSI in tertiary-care hospitals. Among those with *S. aureus* SSI, MRSA was the cause in 62% of cardiothoracic SSI, 54% of orthopedic SSI, 43% of neurosurgical SSI, and in 35% of plastic surgeries *(89)*.

Patients with MRSA SSI also suffer increased morbidity, mortality, and hospital costs. This was initially described by Engemann and colleagues in 2003 *(90)*. This cohort study compared the outcomes of patients who suffered MRSA SSI to patients who suffered MSSA SSI and to patients who

did not develop an SSI. Compared to those with MSSA SSI, those with MRSA had a greater 90-day mortality (adjusted OR, 3.4; 95% CI, 1.5–7.2; $p = .003$) and after controlling for ASA score, hospital, surgery duration, diabetes, renal disease, and LOS prior to infection, methicillin resistance was responsible for a 1.20-fold increase in LOS (2.6 excess days) and 1.19-fold increase in mean hospital charges ($13,901). The median hospital cost for an MRSA SSI was $92,363 *(90)*. Two more recent studies have also described increased morbidity and costs *(87,91)*. One reported that compared to patients without an SSI, those with SSI due to MRSA had an independently increased risk for readmission within 90 days (OR, 35.0; 95% CI, 17.3–70.7), death within 90 days (OR, 7.27; 95% CI, 2.83–18.7), 23 days of additional hospitalization, and $61,681 in excess charges. Compared to patients with MSSA SSI, those with MRSA SSI had 5.5 days of additional hospitalization and $24,113 in excess charges *(91)*. Another study found that compared to SSI due to other microorganisms, those caused by MRSA had significantly higher mortality (1.4% vs. 0.8%; $p = .03$) and that the MRSA SSI risk-adjusted attributable LOS was 0.93 days and attributable increased cost was $1,157 *(87)*.

MRSA in Long-Term Care Facilities

MRSA has also emerged as an epidemiologically important microorganism in other types of healthcare facilities including those that provide long-term care. Epidemiologic descriptions of MRSA in LTCFs are heterogeneous likely because the patient populations cared for in LTCF are heterogeneous, ranging from patients who require long-term physical rehabilitation, long-term psychiatric care, long-term acute care, and those that require permanent or long-term residence. Additionally, LTCF may differ in bed size, geographic location, and through an association with a large tertiary-care hospital, an academic teaching hospital, or a Veterans Administration hospital. Thus, it is important to consider these variables when reviewing studies conducted in LTCF of the prevalence of MRSA colonization or infection (92). Recent studies from the United States have reported a wide range of MRSA prevalence rates *(93–97)*. For example, Mermel and colleagues conducted a multicenter prevalence study of 6 LTCF and found that among 125 residents who had nares cultures performed, overall, 25 (20%) were positive for MRSA; however, this ranged from 10% to 100% among the facilities *(93)*. Furuno et al. reported a prevalence rate of 30% among residents of a 180 bed long-term acute care (LTAC) facility associated with a large university affiliated hospital in Baltimore, and Mody et al. reported that among 73 residents of a VA LTCF, 58% were MRSA-colonized and that among 54 residents of community-based LTCF, 35% were MRSA-colonized *(94,96)*. Another study performed in a 100-bed VA-associated LTCF in Atlanta prospectively assessed colonization rates by performing weekly surveillance cultures and classified carriers as persistently colonized or intermittently colonized. 49 of 83 (59%) residents had at least one nasal swab positive for MRSA, 30 (36%) were persistent carriers, and 19 (23%) were intermittent carriers. Of the 83 subjects who had enough surveillance cultures to be included, 43 initially negative subjects were designated as being at risk for intrafacility MRSA acquisition and ultimately 9 (21%) had a subsequent positive culture for MRSA *(95)*. A large study among nursing homes in four Canadian provinces (Ontario, Manitoba, Saskatchewan, and Alberta) and four nursing homes in adjacent US states (Michigan, Montana, North Dakota, and Minnesota) specifically designed to include only those facilities not associated with an acute care, university, or VA hospital reported that 33% of clinical S. *aureus* isolates were MRSA *(97)*. Outside the United States, MRSA prevalence in LTCF has also varied *(98–102)*. Two recent point prevalence studies from Italy reported disparate results. The first conducted among 551 residents of two LTCF reported that 43 (7.8%) were positive for MRSA and the other conducted in a 120 bed LTCF reported that 38.7% of residents were colonized *(98,100)*. The prevalence of MRSA in LTCF in France has been reported at 37.6% *(102)*, and in Spain a study among nine community LTCF reported an overall MRSA prevalence rate of 16.8%; however, this rate ranged from 6.7% to 35.8% *(101)*.

Risk factors for MRSA carriage in LTCF have also been well described and include antibiotic exposure *(98,100–102)*, recent hospitalization *(95,100)*, certain comorbidities *(98,100)*, and presence of medical devices *(101,102)*. Recently, Mazur and colleagues performed a cross-sectional study of MRSA prevalence and risks for MRSA carriage. Multivariate analysis found that compared to residents who were non-MRSA carriers, those older than 85 years (OR, 1.60; 95% CI, 1.16–2.21), those with impaired functional status, those with a Charlson Index of two or more (OR, 1.50; 95% CI, 1.09–2.08), those with decubitus ulcers (OR, 2.56; 95% CI, 1.58–4.17), those who had received antibiotics (OR, 2.44; 95% CI, 1.75–3.39), those with medical devices (OR, 2.47; 95% CI, 1.35–4.53) and those transferred from acute care (OR, 2.15; 95% CI, 1.39–2.41) were significantly more likely to be MRSA carriers *(101)*. With regards to antibiotic exposure as a risk for MRSA carriage in LTCF, exposure within 3 months of sampling to a fluoroquinolone *(98)* has been associated with a more than fivefold increased risk for MRSA, exposure to three or more antibiotic courses within 1 year of sampling *(100)* has been associated with a more than fivefold increased risk for MRSA, and exposure to third-generation cephalosporins or fluoroquinolones has been associated with a more than 12-fold increased risk of MRSA *(102)*. Decreased risk for MRSA carriage has been associated with use of antimicrobial soaps within the facility and with an increased staff to patient ratio (number of registered nurses per 100 residents) *(97)*.

Risk of MRSA infection among colonized individuals has been well described in acute care (and is discussed below); however, this risk has not been well described in long-term care. Bradley retrospectively reviewed data from six US studies from 1990 to 1997 and found that overall, the incidence of MRSA infection was 6.5% among carriers and that the associated mortality was just 1% *(103)*. Muder compared MRSA carriers to MSSA carriers and noncarriers and found that staphylococcal infections developed 3.6 times more often among MRSA carriers compared to the other groups *(104)*. The most frequently reported MRSA infections among residents of long-term care are skin and soft tissue infections; however, more serious invasive infections such as BSI and pneumonias have been reported (92,*105,106*). In a recent prospective study among community LTCF located in Spain, the incidence of

MRSA infection among colonized residents was 0.12 per 1,000 patient days and only two of those patients required hospital admission; however, MRSA colonization in LTCF should not be viewed as benign as when colonized LTCF residents enter acute care they are at increased risk for MRSA infection *(101)*.

There is also evidence to suggest that the epidemiology of MRSA within the LTCF is changing. In 2009, Tattevin and colleagues conducted a study to describe the prevalence and the genotypes of MRSA clinical isolates over a 10-year period at a large 1,000-bed LTCF in San Francisco *(99)*. Among *S. aureus* isolates, the proportion due to MRSA increased from 38.1% in 1997 to 72.3% in 2006 ($p < .0001$) and the USA300 CA-MRSA clone increased from 11.3% of MRSA isolates in 2002 to 64% of MRSA isolates in 2006 ($p < .0001$). The USA300 clone was most often isolated from skin and skin structure sites and of note, up to 30.9% of USA300 isolates were multi-drug resistant suggesting that these isolates were likely acquired under increased antibiotic use pressure within the facility *(99)*.

Risk of MRSA HAI among Colonized Patients in Acute Care

A relatively large proportion of asymptomatic carriers of MRSA in acute care will progress to invasive MRSA infection. A recent systematic review of ten observational studies determined that colonization with MRSA was associated with a fourfold increase in the risk of infection as compared to persons with colonization with methicillin-susceptible *S. aureus (107)*. This risk, however, is likely to vary substantially among individuals and populations depending on the setting and individual risk factors for infection. In a study of patients who were found to be colonized or infected with HA-MRSA during hospitalization, 29% of colonized and infected persons developed at least one episode of MRSA infection within 18 months *(108)*. Another study of nasal carriers of HA-MRSA identified at the time of hospital admission found that 18.3% of carriers had invasive MRSA infection documented concurrently (29%) or within 18 months of detection of nasal carriage (71%) *(109)*. In a similar study in which patients were tested for nasal *S. aureus* carriage at the time of evaluation for admission to the ICU, 24.1% of MRSA carriers developed an MRSA infection within 60 days. In contrast, only 0.6% of patients with nasal carriage of methicillin-susceptible *S. aureus* developed an MSSA infection *(110)*. One potential explanation for the higher rate of invasive infection among carriers of HA-MRSA as compared with carriers of MSSA is that carriers of MRSA may be at greater risk of infection due to greater or more severe underlying medical conditions and/or a more frequent need for medical interventions that place them at increased risk of infection with their endogenous flora. However, one recent study of patients who were screened for nasal *S. aureus* carriage at the time of ICU admission found that MRSA-colonized patients were more likely to develop *S. aureus* infection while in the ICU than MSSA-colonized patients, even after adjustment for patient-specific factors that are associated with MRSA carriage (adjusted hazard ratios of 4.70 and 2.47, respectively, as compared with patients without nasal carriage of *S. aureus*) *(111)*.

Risk Factors for MRSA Colonization and HAI

A number of risk factors associated with HA-MRSA carriage have been established. Some of these risks are at the level of the individual patient *(112–115)*. These patient-level factors include a variety of chronic medical conditions such as diabetes mellitus, chronic obstructive pulmonary disease, leukemia, HIV infection, and end-stage renal disease. Other patient-specific risk factors include older age, admission to a hospital or a LTCF within the preceding 12 months, prolonged duration of hospitalization, receipt of antibiotic therapy within 3 months, invasive procedures, and the presence of foreign bodies (such as indwelling urinary and vascular catheters, tracheostomy tubes, and feeding tubes). These factors likely all represent exposure to the healthcare system resulting in an increased risk of exposure to or prolonged exposure to HA-MRSA and perhaps an increased risk of acquisition and persistent carriage if exposed to MRSA as compared to persons without these factors.

In addition to patient-specific risk factors, a variety of factors associated with the healthcare system and the healthcare delivery process have been associated with acquisition or transmission of MRSA. Studies have demonstrated that the risk of acquisition of MRSA during hospitalization increases as the prevalence of MRSA among hospital patients increases. In one study, it was observed that when the weekly colonization pressure (i.e., weekly prevalence) exceeded 30%, the risk of MRSA acquisition was five times higher than that when colonization pressure was <10% *(116)*. This finding may be the result of an increased environmental burden of MRSA with subsequent patient-to-patient spread by contaminated healthcare workers and equipment. The role of the environment in MRSA transmission is further highlighted by a study that demonstrated that the odds of acquiring MRSA were significantly higher among persons admitted to a hospital room in which the prior room occupant was colonized or infected with MRSA (OR, 1.4; $p = .04$) *(112)*. Several studies have reported an association between healthcare worker hand hygiene practices and the incidence of MRSA within healthcare facilities *(117–121)*. These studies have observed reductions in MRSA infection and acquisition in temporal association with improved rates of adherence to hand hygiene guidelines or increased consumption of alcohol-based hand rubs (ABHRs). Other investigators have associated increased rates of MRSA infection and colonization with staffing deficits and patient overcrowding *(122,123)*. These findings may reflect an increase in the environmental burden of MRSA or reduced compliance with infection prevention measures such as hand hygiene and Contact Precautions in the setting of understaffing and overcrowding.

Reservoir for MRSA Transmission

In Acute-Care Facilities

Patients There are several reservoirs of MRSA within an acute-care facility that may contribute to the risk of transmission of the microorganism. One such reservoir consists of patients who are colonized or infected with MRSA. As previously noted, the risk of acquisition of MRSA during hospitalization has been shown to be correlated with the prevalence of MRSA among facility patients (*116*). It should be noted, however, that the true prevalence of MRSA

among patients in most acute-care facilities is generally not known and likely varies substantially among acute-care facilities. In a survey of 1,237 US hospitals (representing approximately one quarter of all US hospitals) performed in 2006, the overall reported prevalence of MRSA was 4.6% (*124*). There was substantial variation among the states, with prevalence ranging from 0% to 9.1%. The findings from this survey likely represent a significant underestimation of the true burden of MRSA in US hospitals, because participating facilities provided data based on information that was readily available to the facilities' infection preventionists and most participating hospitals were not using active surveillance testing to identify all colonized patients. Thus, the information reported by most of the participating facilities was based on the results of clinical cultures. Previous studies have demonstrated that clinical cultures alone identify as few as 15% of colonized patients (*125*) and underestimate the monthly average prevalence in ICUs by 18% to 63% (*126*). Recent studies that have used active surveillance to assess the prevalence of MRSA among hospital patients suggest that the true prevalence of MRSA is higher than the estimate derived from the previously described national survey. Rates of MRSA colonization of 2.8% to 6.8% have been observed among patients being admitted to hospitals for cardiac and orthopedic surgery (*127–130*). Assessment of all patients being admitted to an urban hospital in Atlanta, Georgia, found that 7.9% of patients were carriers of MRSA at the time of hospital admission (*113*). In studies of adult patients being admitted to ICUs in hospitals in New York City and St. Louis, 13% to 14.5% of subjects have been identified as carriers of MRSA (*110,111*).

Environment Contamination of environmental surfaces and healthcare equipment in the rooms of MRSA colonized or infected patients is relatively common. Once in the environment, *S. aureus*, including methicillin-resistant strains, can persist for relatively long periods of time (*131*). *S. aureus* in the environment can theoretically be transmitted to other patients either directly, through contact with the contaminated surface or item, or indirectly, by the hands of healthcare workers who come into contact with the contaminated item and then interact with a patient without proper hand hygiene prior to patient contact. This concept is discussed in greater detail later in this chapter.

Healthcare Personnel As mentioned above, healthcare personnel (HCP) may transmit MRSA to patients by transient contamination of their hands or clothing following contact with colonized patients or contaminated environmental surfaces and equipment. MRSA-colonized HCP are an additional potential reservoir for MRSA transmission. Several studies have assessed the prevalence of MRSA carriage among HCP. In an analysis of data from 127 published studies, the average MRSA prevalence among HCP was found to be 4.6% (95% CI, 1.0%–8.2%) (132). The prevalence observed in individual studies varied from as low as 0% to as high as 59%. This dramatic variability is likely the result of differences in the settings in which HCP screening occurred (e.g., outbreak vs. endemic setting, end of a shift vs. beginning of a shift), the occupation of the personnel included in the study, the year(s) in which the study was performed, and the method by which screening was performed (e.g., single vs. multiple site sampling, culture vs. molecular testing). The timing of specimen collection may have a substantial impact on the prevalence of MRSA detected among HCP. This is because a substantial proportion of colonized workers carry MRSA only transiently. For example, 12 (46%) of 26 nurses working on a designated MRSA ward were demonstrated to have nasal or hand carriage of MRSA at the end of a work shift with subsequent loss of carriage before the beginning of their next shift (133,134). Thus, sampling personnel during or immediately after patient care duties may find a larger number of carriers than sampling personnel before beginning a work shift.

Other Healthcare Facilities

Long-term Care and Acute Rehabilitation Facilities As discussed above, MRSA is certainly not limited to the acute care hospital. In fact, the prevalence of MRSA among residents of LTCFs has been shown to be even higher than that observed among patients in acute care hospitals. This is likely due, at least in part, to the fact that many of the patients in these facilities are patients with multiple MRSA risk factors that have been transferred from acute care hospitals. The prevalence of MRSA colonization among LTCF residents has ranged from 9.9% to 40% (*96,135,136*). Of note, the study that reported the highest rate of MRSA colonization sampled multiple sites (nares, oropharynx, groin, perianal area, wounds, and enteral feeding tube exit site) and reported that only 65% of colonized residents were nasal carriers, suggesting that nasal sampling alone may grossly underestimate MRSA prevalence in this population (*96*). Studies that reported lower rates (9.9%–30.3%) assessed residents with the use of nasal swabs alone (*135*). Surveillance testing of persons admitted to an acute rehabilitation facility found that 12% of patients were carriers of MRSA (*137*).

Other Settings and Persons

Household environments Although MRSA contamination of the healthcare environment has been most well characterized, MRSA contamination of other environments has also been detected. These environments include the homes of persons known to be carriers of MRSA (*138*) as well as randomly selected homes (*139*). Surfaces and items within these households that have been found to be contaminated with MRSA include dish towels, sinks, and faucet handles in kitchens and bathrooms. In a study of randomly selected homes, 7% of the sampled kitchen faucets, 6% of sampled kitchen dish towels, and 3% of bathroom sink and tub fixtures were contaminated with MRSA (*139*).

Close personal contacts of persons with MRSA colonization or infection Transmission of HA-MRSA from colonized or infected patients to their household and personal contacts has been well described. In studies that have assessed the prevalence of MRSA among these contacts, MRSA carriage has been detected in 14.5% to 67% of study participants *(140–143)*. In some of these studies, molecular analysis demonstrated that the strain of MRSA carried by the household contact(s) was the same strain as that carried by the index case. Factors that have been associated with acquisition of MRSA by household contacts include providing healthcare to the index patient and having prolonged exposure to the index case.

Importance of MRSA in the Community

Historically, MRSA was considered to be almost exclusively acquired in healthcare; however, over the past 10 to 15 years, MRSA has emerged as a significant pathogen among persons without typical healthcare-associated risk factors (*10*,11,*12,144*). Data from the CDC's Active Bacterial Core surveillance and Emerging Infections Program Network indicate that 13.7% of the 95,000 cases of invasive MRSA disease in the United States between July 2004 and December 2005 occurred in persons without established healthcare-associated risks (19). This rapid change in the epidemiology of MRSA is the result of clonal dissemination of novel strains of MRSA that are genetically and epidemiologically distinct from typical HA-MRSA strains (Table 29-2). CA-MRSA appears to have arisen as the result of migration of SCC*mec* type IV into methicillin-susceptible strains of *S. aureus*. More recently, SCC*mec* types V-VIII have been identified but SCC*mec* type IV continues to be identified in the vast majority of CA-MRSA isolates. Unlike SCC*mec* types I-III that are common among strains of HA-MRSA, SCC*mec* type IV is smaller and more mobile and has thus been able to move into several lineages of MSSA. In the United States, pulsed-field type USA400 (multilocus sequence type ST1) was the first identified clone, but since that time USA300 (ST8) has become the predominant clone. Other than the *mecA* gene, SCC*mec* type IV typically contains few or no additional antibiotic resistance determinants. Thus, CA-MRSA strains are frequently resistant only to currently available beta-lactam antibiotics and perhaps one or two additional classes of antibiotics (such as the macrolides and, increasingly common, the fluoroquinolones) (145). However, resistance to additional classes of antibiotics is being reported with increasing frequency *(146–148)*. For example, isolates of CA-MRSA with resistance to oxacillin and erythromycin as well as clindamycin, mupirocin, and, in many cases, tetracycline have been reported from Boston and San Francisco *(147)*. In those isolates, resistance to the additional antimicrobial agents was due to the presence of the pUSA03 conjugative plasmid that contains multiple resistance determinants, including the genes *ermC* and *mupA* that result in constitutive resistance to macrolides and clindamycin, and mupirocin, respectively. Related plasmids, presumed to have been transferred from USA100 strains of HA-MRSA, have been detected in other USA300 MRSA isolates *(148)*. These findings suggest that the problem of multidrug resistance that has been associated with HA-MRSA for many years may begin to complicate the treatment of CA-MRSA infections as well. An additional genetic difference between most CA-MRSA isolates and typical HA-MRSA strains is the presence of genes encoding the Panton-Valentine leukocidin (PVL) in the former. Because most CA-MRSA strains are PVL-positive and CA-MRSA has been associated with severe purulent skin and soft tissue infections and necrotizing pneumonias, some have questioned whether PVL is responsible for the increased virulence associated with CA-MRSA strains. Studies performed to date have not provided conclusive evidence that PVL is a major virulence factor in CA-MRSA, but the clinical significance of PVL remains controversial and continues to be investigated *(149–156)*.

Skin and soft tissue infections, especially furuncles, abscesses, and other purulent infections, are the most common type of infection caused by CA-MRSA (*14*,145,*157*). In fact, CA-MRSA has become the most common cause of purulent skin and soft tissue infections among patients presenting to emergency departments in several regions of the United States (13). Clusters of CA-MRSA skin infections have also been described among several specific populations, including men who have sex with men *(147,158,159)*, sports participants *(160,161)*, military personnel *(162)*, prisoners *(163)*, rural communities *(164,165)*, and families *(166,167)*. These populations likely represent groups at increased risk for the spread of MRSA and/or for invasive infection if exposed to MRSA due to close skin-to-skin contact, the presence of cuts or abrasions that can serve as portals of entry for MRSA, shared use of contaminated items and surfaces (such as towels and razors), crowded living conditions, and/or poor hygiene. CA-MRSA infections

TABLE 29-2

Genetic and Epidemiologic Differences Between HA-MRSA and CA-MRSA

Characteristic	*HA-MRSA*	*CA-MRSA*
SCC*mec* types	I, II, III	IV (V, VI)
PFGE types	USA100, USA200	USA300, USA400
MLST	ST5, ST8, ST22, ST36, ST45	ST8, ST30, ST1, ST80
PVL gene	Rare	Common
Additional antimicrobial resistance	Resistance to multiple classes of antimicrobial agents is common	Often resistant to ≤2 additional classes of antimicrobial agents
Epidemiologic risk factors	Exposure to healthcare: hospitalization, residence in LCTF, surgery, dialysis	Crowded living conditions; skin-to-skin contact; cuts, abrasions, or other breaches in skin integrity; exposure to contaminated surfaces and items (i.e., fomites); poor hygiene
Common sites/types of infection	BSI, SSI, pneumonia, UTI	Skin and soft tissue infection, pneumonia

HA-MRSA, healthcare-associated methicillin-resistant *Staphylococcus aureus*; CA-MRSA, community-associated methicillin-resistant *Staphylococcus aureus*.

are not, however, limited to the skin and soft tissues. CA-MRSA is also a well-described cause of respiratory tract infections, particularly necrotizing pneumonia (including postinfluenza pneumonia), BSI, otitis media and externa, and joint infections *(109,168)*.

Risk of CA-MRSA Infection among Colonized Persons

The proportion of asymptomatic carriers of CA-MRSA that progress to invasive infection has been demonstrated to be quite high, often higher than the rate of invasive disease among carriers of HA-MRSA. In a longitudinal study of nasal carriers of the USA300 strain type identified through an active surveillance program at the time of hospital admission, 17.9% of nasal carriers had an episode of invasive MRSA infection documented at the study facility concurrently or within 18 months of detection of nasal colonization *(109)*. In a study of nasal carriage of *S. aureus* among community-dwelling children, 23% of the identified MRSA carriers developed MRSA skin or soft tissue infection within 6 months *(169)*. Among the MRSA carriers included in that study, 5 (33%) of the 15 children with carriage of CA-MRSA developed SSTI as compared with none of the 9 children with carriage of the HA-MRSA ($p = .12$). In a study of military personnel living in communal barracks while undergoing training as combat medics, 38% of nasal carriers of CA-MRSA developed soft tissue infection within 10 weeks of detection of carriage *(162)*. In both of these latter studies, the proportion of carriers of CA-MRSA who developed invasive infection was much greater than that observed for carriers of methicillin-susceptible *S. aureus* (8% and 3%, respectively). In a study performed in a clinic in Boston that served largely a population of men who have sex with men, participants were screened for MRSA colonization of the nares, perianal area, and wounds (if present) *(159)*. The overall prevalence of MRSA in that population was 3.8%, and most of the MRSA detected was CA-MRSA. During the 1-year follow-up period, 36.7% of the MRSA-colonized subjects developed skin and soft tissue infection as compared with only 8.1% of those without MRSA ($p < .001$).

Environmental Reservoirs for CA-MRSA Transmission

Several published studies have reported an association between CA-MRSA infection and participation in sporting events, particularly contact sports. This has led to investigation of the potential role of the environment as a reservoir for MRSA transmission in athletic facilities. When environmental sampling was performed in 10 high school athletic training facilities, MRSA was isolated from samples obtained from 90% of the facilities and 46.7% of all surfaces sampled, including water coolers, treatment tables, sink faucet handles, and locker room shower handles *(170)*. A second group of investigators obtained environmental samples in college athletic team training facilities and isolated MRSA from 37 (25%) of the 147 samples that had been obtained *(171)*. After education of the athletes regarding preventive measures and education of custodial staff regarding proper cleaning protocols, subsequent environmental sampling yielded no *S. aureus*. Environmental contamination is not, however, limited to athletic facilities. MRSA has also been recovered from commonly touched items and surfaces in households, such as dish towels, kitchen sink faucet handles, and bathroom sinks and tubs *(139)*.

Emergence of CA-MRSA in the Healthcare Facility

Recent epidemiological studies have also reported that the MRSA strains initially described in the community (such as USA300, SCC*mec* type IV) are now a cause of invasive HAI. From 2003 to 2010, several studies were published describing the emergence of CA-MRSA as a cause of HAI among several different types of patient populations and in areas all over the world including the United Kingdom *(172,173)*, Greece *(174)*, Denmark, as well as Korea *(175)*. Community strains of MRSA have been reported as the cause of healthcare-associated skin and soft tissue infections in postpartum women *(176)*, healthcare-associated prosthetic joint infections *(177)*, HAI among patients with end stage renal disease on hemodialysis *(178)*, healthcare-associated BSI *(175,179–182)*, and invasive HAI among neonates being cared for in the neonatal ICU *(173,183–185)*. Klevens et al. and the Active Bacterial Core surveillance system of the Emerging Infections section at the CDC described the proportion of invasive MRSA HAI due to community strains among three groups of patients from 2004 to 2006. Nine thousand one hundred forty-seven isolates were included and were classified as healthcare-associated hospital onset, healthcare-associated community onset, or community associated. Twenty-eight percent of the healthcare-associated isolates were USA300 strains, 14% of the healthcare-associated community onset isolates were USA300, 2% were USA400, and 2% were USA1000; in other words, 18% to 28% of isolates in patients who had healthcare-associated risks had PFGE banding patterns typical for community strains *(66)*.

The prevalence of community strains as a cause of HA-MRSA BSI has ranged from 19% to more than 60% depending on the patient population and geographic location *(175,179–182)*. One study of consecutive MRSA BSI isolates at a large urban tertiary-care hospital in Atlanta found that overall, 34% of isolates were USA300 by PFGE (28% of healthcare-associated isolates and 20% of hospital-associated isolates). Having a USA300 strain as a cause of your BSI was independently associated with IV drug use (OR, 3.67; 95% CI, 1.10–12.28) and the presence of a concurrent skin and soft tissue infection (OR, 4.26; 95% CI, 1.08–16.84). Admission from an LTCF (OR, 0.09) and receipt of antibiotics within the previous year (OR, 0.10) were associated with a significantly lower likelihood of having USA300 *(180)*. In another large epidemiologic study of HA-MRSA BSI caused by USA300 among three hospitals in Denver from 2003 to 2007, the rates of MRSA BSI due to CA-MRSA strains varied from 19% in one hospital, to 36% in another to 62% in the other. IV drug use and HIV infection were independently associated with having a USA300 strain as the cause of your HA-MRSA BSI (OR, 3.9; 95% CI, 1.0–14.4 and OR, 15.0; 95% CI, 2.5–89, respectively) *(182)*. Evidence also exists that not only describes CA-MRSA isolates as occurring within the healthcare arena, but that these isolates are increasing in their prevalence *(178,179,182,185–187)*. Maree and colleagues retrospectively examined all clinical HA-MRSA isolates (blood, sputum, wounds) from 1999 through 2004 and reported that the inferred SCC*mec* IV phenotype increased

from 17% to 56% over the study period ($p < .0001$). Multivariate analysis identified significant risks for an SCC*mec* IV phenotypic isolate from a wound as the source, MRSA isolated in the later years of the study, and MRSA isolated earlier in the hospital course *(187)*. Popovich et al. compared MRSA BSI isolates from 2003 to 2006 to those from 2000 to 2003 and found that the rate of hospital onset MRSA BSI remained constant; however, the community genotypes responsible for the HA-MRSA BSI increased from 24% in 2000 to 2003 to 49% in 2003 to 2006 (RR, 1.9; 95% CI, 1.2–3.1; $p = .01$). The authors suggested that traditional healthcare-associated strains were being replaced by community strains as the cause of HA-MRSA BSI *(179)*. Patel conducted a retrospective lookback from 2000 to 2004 to determine when USA300 first entered the healthcare system. Isolates were classified as community-associated or healthcare-associated by clinical characteristics (isolated 48 hours or more after admission). USA300 first appeared in the outpatient arena in 2001 and in the inpatient hospital in 2003. By 2004, USA300 was responsible for 40% of inpatient MRSA isolates independent of where patients were being cared for (35.7% of surgical ICU isolates, 16.7% of medical ICU isolates, and 53% of floor isolates) *(186)*. In neonates, Seybold and colleagues found community clones were first described as a cause of colonization or infection in their neonatal ICU in 1998 and that the proportion had significantly increased between this time and 2004, with USA300 accounting for MRSA colonization in 68% of patients in 2004. Vaginal delivery and maternal smoking were associated with community strains of MRSA colonization *(185)*.

Recently, a study by Freitas from a large university hospital in South Carolina, which has been conducting active surveillance for MRSA colonization since 2001, reported that the proportion of patients found to be MRSA colonized by USA300 strains significantly increased from 2005 to 2007 (17%–27%; $p = .003$) *(109)*. Among those colonized with USA300 strains, 18% went on to develop MRSA HAI, and this was no different than those colonized with nonUSA300 strains. Also, risk factors for MRSA HAI between the two groups were similar *(109)*. Mathematical models have been developed to attempt to predict when community strains of MRSA will replace healthcare strains of MRSA as the most common cause of HAI *(188,189)*. Skov *(188)* reported that depending on the number of isolation rooms available, and whether or not active surveillance was performed to identify MRSA colonized patients, after MRSA was introduced into the community and transmission was permitted for 30 years, a new equilibrium would be reached within 7 to 14 years, leading to a prevalence of MRSA carriers with community strains in hospitals as high as 20%. D'Agata *(189)* also reported that the increasing influx into the hospital of patients who are colonized or infected with CA-MRSA will lead to a rapid reversal of dominance with community strains replacing healthcare strains. Additionally, because community isolates of MRSA have been thought to behave more virulently, causing more serious infections compared to healthcare strains, the outcomes of patients who acquire invasive MRSA infections in the hospital due to community strains may be worse. Moore and colleagues conducted a retrospective analysis to compare the epidemiology and outcomes between community-associated and healthcare-associated USA300 infections in their 900-bed tertiary-care hospital in Detroit. Among 160 patients, 47.5% had community-associated infections due to USA300 and 52.5% had HAI due to USA300 (20% acquired in the hospital). Patients with HAI had significantly greater treatment failure rates (38.1% vs. 23.7%; $p = .05$). Independent risks for failure included osteomyelitis as the infection type (OR, 43.56; $p < .001$), pneumonia as the infection type (OR, 3.74; $p = .036$), and previous history of MRSA (OR, 6.18; $p < .001$) *(190)*. These findings have led leaders in the field of healthcare epidemiology to stress the importance of close monitoring of the epidemiological situation and to conduct high-quality research regarding measures for prevention and control of MRSA HAI, including those due to community strains *(191)*.

DETECTION OF MRSA RESERVOIR IN THE HEALTHCARE FACILITY

Surveillance Definitions

Depending on the type of data collected, surveillance can help to quantify or estimate the burden of MRSA within a facility (e.g., the incidence and prevalence of MRSA), the incidence of one or more specific types of MRSA infection (e.g., the incidence of MRSA bacteremia), and the incidence of MRSA transmission within the facility. When surveillance is performed over time, the data can be used to monitor changes in the epidemiology of MRSA. This can be particularly valuable in determining the effectiveness of an MRSA prevention program. In order for the data to be meaningful and for comparisons to be valid, surveillance must be performed using standardized methods and consistent definitions.

Laboratory-Based Surveillance Because of the recognized importance of monitoring multidrug-resistant microorganisms in healthcare facilities and the lack of a standardized approach to do so, the Society for Healthcare Epidemiology of America (SHEA) and the Healthcare Infection Control Practices Advisory Committee (HICPAC) published surveillance definitions and recommended metrics for multidrug-resistant microorganisms, including MRSA, in healthcare settings (192). Although these metrics have not yet been validated for interfacility comparison, they may be useful for monitoring MRSA within an institution. Unlike classic infection surveillance methods, the metrics recommended in the SHEA-HICPAC document are based solely on readily available laboratory and administrative data and, in some cases, basic epidemiologic data. Because extensive review of clinical documentation is not required, this type of surveillance is substantially less resource intensive. In these recommendations, definitions have been provided to assist with epidemiologic classification of MDRO isolates (Table 29-3). Temporal classification definitions categorize MRSA isolates as either "hospital-onset" or "community-onset," based solely on the date of specimen collection and the date of admission to the healthcare facility. Clinical classifications are based on the timing of specimen collection and an evaluation of the patient's clinical and epidemiologic risk factors for acquisition of MRSA. Clinical classifications include "healthcare-associated," "nosocomial," and "community-associated" MRSA. This classification can be used to classify a patient's first MRSA isolate as well as any subsequent MRSA event.

TABLE 29-3

Epidemiologic Classification of MRSA Isolates and Infections

Classification Strategy	*Classification*	*Definition*
Temporal	Hospital-onset MRSA[a]	The specimen from which MRSA was isolated was obtained more than 3 calendar days after the patient was admitted to the hospital. (Note: The day of admission is the first calendar day.)
	Community-onset MRSA	The specimen from which MRSA was isolated was obtained 3 or fewer calendar days after admission to the hospital (or other healthcare facility).
Clinical	HA-MRSA	MRSA that is isolated from a patient with documented healthcare-associated risk factors for MRSA acquisition such as: current or recent admission to a hospital, long-term care, or rehabilitation facility; indwelling vascular catheter; recent surgery; or outpatient hemodialysis.
	Nosocomial MRSA	A subset of HA-MRSA, this classification refers to MRSA that is likely to have been acquired during the patient's admission to the hospital (or other healthcare facility).
	Community-associated MRSA	MRSA that is isolated from a patient without documented healthcare-associated risk factors for MRSA acquisition.

[a]Although the term is "hospital onset," it is meant to indicate that the onset of MRSA occurred within the healthcare facility in which surveillance is being performed. Thus, a better term may be "facility onset" in order to allow wider applicability, such as in long-term care and other types of healthcare facilities.

Infection Surveillance Unlike surveillance that is based on laboratory data alone, infection surveillance includes a review of relevant clinical data to allow identification of specific types of infection and to determine which MRSA isolates represent true infection and which represent colonization. The CDC/NHSN surveillance definitions of HAI and criteria for specific types of infection are widely used for clinical surveillance purposes *(193)*. Surveillance for specific types of MRSA infection, such as CLABSI, SSI, and/or pneumonia, can provide important information to a healthcare facility's MRSA prevention and control personnel. The amount of infection surveillance that can be performed within a facility, however, is often limited because of the resource intensive nature of this type of surveillance. Thus, a combination of laboratory-based and focused infection surveillance may be an effective approach to MRSA surveillance.

Methods for Detection of Patients with MRSA

The cohort of patients who serve as the reservoir for transmission of MRSA is, often likened to an iceberg, composed of (a) a small group representing the tip of the iceberg with clinical MRSA infection and (b) a much larger group who are merely colonized (without infection) with the microorganism, representing the mass beneath the surface of the water. These patients may be identified through the use of clinical cultures or active surveillance cultures.

Clinical Specimens Patients with MRSA infection are most often identified by routine clinical microbiology cultures from specimens obtained when infection is suspected (e.g., blood, urine, sputum, wound cultures). Some patients with MRSA colonization may be identified with clinical microbiology cultures; however, this method lacks sensitivity and the majority are identified through the use of active surveillance cultures.

Surveillance Culture Specimens Active surveillance for MRSA is defined as performing diagnostic testing for the purpose of detecting asymptomatic MRSA colonization (194). With regards to identifying the reservoir of colonized patients in a hospital, studies have demonstrated the benefit of active surveillance over that of relying on clinical cultures *(125,195–197)*. One study from a large tertiary-care academic hospital with a long history of employing the use of active surveillance for identifying MRSA-colonized patients found that of 437 patients discovered to be colonized with MRSA upon admission to the hospital, only 66 (15%) of those patients would have ever been identified as MRSA-colonized if a positive clinical culture was used for this purpose *(125)*. Among those hospitalized in the general wards, this proportion was 12.9% and among those hospitalized in the ICU, this proportion was 21.4%. Another study from a French ICU reported that 12.9% of patients with MRSA colonization discovered on admission through surveillance ultimately had a positive clinical culture during the 3 days before or after transfer to the ICU *(196)*, and another reported similar findings demonstrating that compared with admission surveillance, clinical samples would have identified only 15.8% of known MRSA-positive elderly patients in the hospital *(197)*. Additionally, in a study to determine the value of performing active surveillance cultures on ICU discharge, Furuno and colleagues *(195)* reported that nine (14%) of 65 patients identified as MRSA-colonized by surveillance subsequently had a clinical culture positive for MRSA after discharge from the ICU; however, 54 (83%) would have remained unidentified by relying on clinical cultures.

Sites to Sample The nares are the most common sites of *S. aureus* colonization in humans, including that due to methicillin-resistant strains. Data from two National Health and Nutrition Examination Survey (NHANES) projects describe nares colonization for noninstitutionalized healthy individuals for the periods 2001 and 2002 as well as 2003 and 2004 *(1,198)*. In 2001 and 2002, 32.4% (95% CI, 30.7%–34.1%) of the population surveyed were nasally colonized with *S. aureus* (MSSA or MRSA); however, only 0.8% (95% CI, 0.4%–1.4%) of the study population carried MRSA in their nares. MRSA colonization was associated with age >65 years and female sex *(1)*. Compared to this, in 2003 and 2004, the prevalence of *S. aureus* colonization decreased significantly to 28.6% (95% CI, 27.2%–30%; $p < .01$), while the prevalence of MRSA colonization increased to 1.5% (95% CI, 1.2%–1.8%; $p < .05$) *(198)*. Tenover and colleagues characterized the isolates from the NHANES studies and compared more recent strains from 2003 and 2004 to those from 2001 and 2002 *(199)*. Among all those nasally colonized with MRSA, 45.9% carried the HA-MRSA strain type USA100, and this proportion did not change significantly between the two time periods, and 13.9% carried the CA-MRSA strain type USA300 which did increase significantly from the first time period to the second (8.0% to 17.2%; $p = .03$). The remaining strains consisted of a variety of less common healthcare and community strain types *(199)*.

In addition to the anterior nares, several investigators have evaluated the presence of MRSA at other anatomical sites including the throat, axilla, groin, wounds, sites of foreign bodies, perirectal area, umbilicus, vagina, and perineum *(200–203)*. For example, Currie and colleagues described the relative sensitivities of different body sites for detecting MRSA colonization through culture based methods among adults as part of their active surveillance program. The sensitivity of nares was 68% (95% CI, 64%–72%), the sensitivity of open skin areas was 73% (95% CI, 64%–80%), the sensitivity of the rectum was 62% (95% CI, 58%–66%), and the sensitivity of combining nares and rectal cultures was 96% (95% CI, 94%–97%), a 34% relative increase from the use of nares swabs alone *(204)*. Another study of cultures performed via active surveillance in a large Finland hospital from 1999 to 2004 reported that among MRSA carriers, the nares was positive 67% of the time, the throat 51%, the perineum 31%, the groin 32%, the axilla 19%, and an infected focus 70% of the time *(203)*. When throat cultures were combined with nares, 85% of the positive MRSA patients were identified and when nares, throat, and perineum were combined, 95% were identified. This combined rate is similar to that found by Coello and colleagues *(205)* where a sensitivity of all three sites was 98.3% when active surveillance was performed during an MRSA outbreak at a university hospital in Spain. An early study of the natural history of MRSA carriage reported that the sensitivity of nares cultures (often combined with chronic wound or sputum cultures) was 93% and was considerably more valuable for detecting MRSA than were cultures of the axilla, groin, or perineum (sensitivity <39%) *(206)*. In neonates, for routine surveillance in the endemic setting (absence of an outbreak), nares cultures alone may be sufficient to identify carriers and prevent spread *(207)*; however, Rosenthal et al. reported the sensitivity of surveillance cultures in neonates from two hospitals during a period where both facilities were experiencing an MRSA outbreak. Nares culture sensitivity was 68% to 72% when used alone and this improved to 92% to 100% at one hospital when combined with umbilical cultures, but only to 71% to 84% when combined with rectal cultures *(208)*.

Sites of colonization with community strains of MRSA have not been fully described; however, it has been documented that among patients being admitted to the hospital and undergoing active surveillance of the nares, USA300 CA-MRSA strains were recovered routinely (24% of the time) and that this proportion has increased over time *(109)*. Yang and colleagues examined the prevalence of MRSA at four body sites among patients with acute skin infections to assess the relationship between MRSA colonization and infection in patients with CA-MRSA and other types of *S. aureus*. Among patients with CA-MRSA skin infections, 37% were MRSA colonized, 25% were colonized in the nares, 6% were colonized in the axilla, 17% in the inguinal area, and 13% perirectally. Among those with CA-MRSA skin infections who were also colonized, 96% could be identified using a combination of nasal and inguinal screening *(209)*. Others have suggested that the pharynx (or throat) may be an important site of CA-MRSA colonization *(200)*.

Additional Contributors to MRSA Reservoir

Environmental Surfaces and Medical Equipment

Environmental and medical equipment contamination with MRSA and transmission of the microorganism to healthcare workers and patients has been the subject of numerous studies. Despite this, it has been difficult to fully describe this complex relationship. Staphylococci may survive for extended periods of time in the environment and are generally resistant to desiccation *(210,211)*. For example, staphylococci has been found on plastic charts for up to 11 days *(212)*, on laminated tabletops for 21 days *(212)*, and on stainless steel for 72 hours *(213)*. Similarly, there is ample evidence that MRSA contaminates the clinical patient care environment. This includes inanimate objects such as mattresses, bed linens, patient gowns, nurses' uniforms, doctors' ties, tourniquets, pens, televisions, blood pressure cuffs, infusion pumps, stethoscopes, and telephones as well as touch surfaces such as bed rails, overbed tables, furniture, door handles, sinks, and computer key boards *(214–216,*217,*218–221)*. During an MRSA outbreak, Rampling and colleagues sampled the clinical areas (patient bays) where patients were frequently acquiring MRSA. Approximately 24 items and surfaces were sampled in each bay on each occasion and the percentage of specimens positive for MRSA was calculated. In the beginning of the outbreak, MRSA was isolated from 9 of 28 (32%) samples. After almost 1 year into the outbreak, 72 of 673 (10.7%) samples from environmental sites were positive for MRSA. Radiators, medical equipment, and furniture were the most frequently contaminated items at 36.4%, 13.2%, and 11.3%, respectively *(215)*. In a nonoutbreak setting, Blythe et al. *(219)* conducted an environmental screening study of approximately 1,000 specimens from 41 rooms that had previously been occupied by patients with MRSA and had been terminally cleaned. Nineteen (46%) of these rooms were contaminated

with MRSA. This included furniture and medical equipment, electrical equipment, and surfaces. Boyce et al. conducted a prospective culturing survey of objects in 38 rooms of known MRSA patients. Overall, 96 (27%) of 350 surfaces sampled were contaminated with MRSA. Of note, when patients had MRSA in a wound or in their urine, 36% of surfaces were contaminated, and when MRSA was isolated from other body sites, only 6% of the surfaces were contaminated. Environmental contamination occurred in the rooms of 73% of patients suffering MRSA infections and 69% of patients colonized with the microorganism. Frequently contaminated objects included the floor (50–55%), bed linens (38–54%), patient gowns (40–53%), overbed tables (18–42%), and blood pressure cuffs (25–33%) *(216)*. Another study also demonstrated that the hospital environment can become extensively contaminated with MRSA. In a surgical ward of a London teaching hospital surface, cultures were taken from floors, overbed tables, bed frames, bed raising panels, bedside chairs, door handles, light switches, sink taps, televisions, and remote controls of bays, side rooms, and bathrooms of MRSA patients. Before cleaning, every side room, bay, and bathroom was contaminated with MRSA *(218)*. Additionally 50% of non-MRSA patient bathrooms and 43% of non-MRSA patient bed frames were contaminated with MRSA. After terminal cleaning, 66% of these surfaces remained contaminated. Another study similarly reported a high rate of MRSA contamination among rooms of MRSA patients and through strain typing was able to show that identical or closely related isolates were recovered from the patient and their environment in 70% of cases (217). A recent study by Chang and colleagues compared the degree of environmental contamination from patients who had MRSA identified through clinical cultures to those who had MRSA identified through active surveillance cultures. There were no significant differences in the frequencies of skin and environmental contamination between the groups. Of 24 sets of isolates (patient, skin, and environmental isolate) available for typing, 88% of skin and 79% of environmental isolates were identical to the corresponding patient nares isolate. After multivariate analysis, among patients colonized or infected with MRSA, being bedridden, having a density of 500 or greater CFUs of MRSA in the nares, age >65, and MRSA bacteremia were associated with a higher prevalence of skin and environmental contamination. Recent chlorhexidine bathing and use of antibiotics effective against MRSA were independently associated with lower prevalence of contamination *(222)*.

Even though patient hand carriage is thought to have the greatest impact on the amount of environmental MRSA contamination, other everyday activities such as bed making have been shown to disperse the microorganism within the environment as well if the linens come from an MRSA-colonized or MRSA-infected patient *(223)*.

Transfer of Environmental Contamination to Healthcare Workers and Patients Contamination in the clinical environment is readily transferred to the hands and clothing of healthcare workers who may then become a vector for transmission to patients or other staff. Boyce reported that 65% of nurses who performed patient care activities on patients with MRSA in a wound or in their urine contaminated their uniforms or gowns. Additionally, 42% of personnel who had no direct patient contact but who had touched contaminated surfaces in the patients room contaminated their gloves *(216)*. Another study reported that 17% of contacts between MRSA patients and their healthcare workers resulted in the contamination of the healthcare workers' gloved hands *(224)*. Chang et al. also reported the contamination rate of healthcare workers' gloved hands after touching the skin of an MRSA patient. Overall, 41% of the gloved hands became contaminated and furthermore, there were no significant differences between the proportion of gloved hands contaminated by MRSA patients identified by clinical culture (45%) and those contaminated by MRSA patients identified through active surveillance cultures (38%) *(222)*.

Investigators have also reported on patient acquisition of MRSA when it is present in their environment. Hardy obtained environmental samples for MRSA from the patient rooms in a nine-bed ICU over a 14-month period and correlated these samples with the MRSA isolates recovered from patients receiving care within the unit. Overall, MRSA was present in 188 (21.8%) of 864 environmental samples. Interestingly, there was no correlation between the number of MRSA colonized patients present in the ICU and the number of environmental sites positive for MRSA. When the PFGE profiles of the strains from the patients were compared to those in their immediate environment, they were indistinguishable 35.7% of the time and when they were compared to strains isolated anywhere in the environment, they were indistinguishable 57.1% of the time. Twenty-six patients acquired MRSA in the ICU during the study period and among these patients, 12 acquired a strain indistinguishable from that of another patient in the ICU at the time of acquisition *(225)*. In a multicenter cohort study among six ICUs from six different countries conducted to examine acquisition and crosstransmission of *S. aureus*, 14 patients (4% of the at-risk population) acquired MRSA over the 3-month study period. Preacquisition colonization pressure was significantly associated with MRSA acquisition; additionally, the mean number of beds per nurse was significantly higher for patients who acquired MRSA *(226)*. After spa typing, the authors calculated that crosstransmission possibly accounted for 40% of all *S. aureus* acquisition. Finally, in a 20 month retrospective cohort study, the relative odds of acquiring MRSA among patients admitted to a room in which the prior occupant was MRSA positive compared to patients admitted to other rooms was significantly higher (2.9% vs. 3.9%; $p = .03$). The crude odds ratio of MRSA acquisition was 1.4%, and this excess 1% risk accounted for 5.1% of all ICU MRSA acquisition over the study period and translated into a 1.1% population attributable risk and 1 in 94 exposed room patient stays *(112)*. The authors concluded that even though there was increased risk for acquisition of MRSA among patients admitted to a room previously occupied by an MRSA carrier, this was a minor contributor to the overall transmission of MRSA.

Environmental Culturing and Cleaning Cleaning of the patient care environment is a major component of many recommended strategies to reduce the burden of MRSA (*227*,228,*229,230*). However, cleanliness is difficult to assess and visual inspection does not always correlate with the microbiological risk. There are few modern studies, which have reported that environmental cleaning reduces

the risk of acquiring MRSA in healthcare facilities, and it is worth noting that in today's hospital, patients are generally older, have a greater number of comorbidities, have greater degrees of immunosuppression, and are exposed to far more invasive procedures and medical devices. Additionally, the patient care environments are far more complicated. Thus, patients today are likely at greater risk for acquisition and infection by MRSA from environmental reservoirs (20). Routine sampling of the patient care environment to ensure adequate cleaning has not been generally recommended as a control measure for epidemiologically important microorganisms such as MRSA; however, many experts recommend considering sampling the environment on occasion in high-risk areas of the healthcare facility or during an outbreak when other control measures have not adequately contained spread of the microorganism (20).

Culturing Healthcare Personnel As previously described, the prevalence of MRSA carriage among HCP varies widely (mean: 4.6%, range: 0%–59%) *(132)* and is often transient *(133)*. As seen in other populations of MRSA-colonized persons, colonized HCP are at risk of MRSA infection. Approximately 5% of the MRSA-colonized HCP described in published studies have had evidence or a history of MRSA infection, most commonly of the skin and soft tissues *(132)*. Risk factors that have been associated with MRSA carriage among HCP include many of the factors that have been associated with MRSA carriage in other populations, such as chronic skin diseases and recent antibiotic use. In addition, a number of work-related factors have also been identified, including poor attention to infection control (e.g., poor hand hygiene practices), high work load, close contact with patients, and employment in areas in which there is a high prevalence of MRSA among patients *(132)*. In a recent, single center convenience sample of emergency department, ICU, and prehospital services personnel in an urban hospital, the overall prevalence of MRSA as detected by nasal sampling was 6.6%. Among the various types of HCP included in the study, nurses had the highest rate of MRSA carriage (10% as compared with 3.8%, 3.6%, and 1.9% among physicians, clerical staff, and paramedic/EMT personnel, respectively). The highest rate of MRSA carriage was detected among emergency department personnel (9.6%) *(231)*. A similar study reported that 15% of emergency department personnel (physicians, nurses, and technicians) were carriers of MRSA *(232)*. The emergence of CA-MRSA has resulted in a change in the epidemiology of MRSA carriage among HCP. In recent studies, approximately 33% to 40% of MRSA-colonized HCP were colonized with CA-MRSA *(231,233)*. Whether acquisition of CA-MRSA by these employees occurred within the healthcare setting or the community is not known but the increasing prevalence of CA-MRSA among patients presenting to emergency departments with skin and soft tissue infections may be at least partly responsible for the relatively high rates of MRSA carriage among emergency department personnel reported in recent studies.

Several outbreaks in healthcare facilities have implicated HCP in the initiation or propagation of MRSA transmission. In some cases, transmission was associated with HCP who had active MRSA infections, such as skin infection, sinusitis, or otitis media *(234–236)*. In other cases, the implicated HCP were asymptomatic carriers of MRSA *(237–240)*. In most of these reported outbreaks, cessation of transmission was noted after decolonization therapy or reassignment of the implicated HCP. In addition to the risk of MRSA transmission from HCP to patients, transmission of MRSA from these persons to their household contacts has also been described. In one study, MRSA was transmitted to the household contacts of 4 (40%) of 10 MRSA-colonized hospital employees *(241)*.

Although individual case reports and outbreak investigations have provided useful information regarding the role of HCP in MRSA transmission, the actual frequency of MRSA transmission from these persons to patients has not been established. A recent review of published studies of MRSA colonization and infection among HCP found that 25% of 106 studies reported strong evidence of HCP-to-patient transmission of MRSA and an additional 49% of the studies had some evidence suggesting that transmission had occurred *(132)*. These findings may overestimate the actual contribution of colonized HCP in the transmission of MRSA within the healthcare system. That is because many of the studies included in the review were performed in settings in which there was strong epidemiologic evidence suggesting HCP involvement in MRSA transmission, a scenario that is somewhat uncommon in facilities in which MRSA is endemic. Regardless, the data suggest that HCP play a significant role in the transmission of MRSA within healthcare settings.

Culturing Nonhealthcare Personnel As previously described, 14.5% to 67% of household contacts of persons with HA-MRSA may become asymptomatic carriers of MRSA *(140–143)*. These asymptomatic carriers may serve as reservoirs for re-exposure and thus contribute to failure of attempts to eradicate MRSA carriage in the index patient *(138)*. Screening household contacts for MRSA carriage, with interventions for those identified as carriers, may be considered when attempts to eradicate carriage in an index case are being made or when an initial attempt to eradicate carriage in an index case fails or when relapse occurs.

Healthcare Animals and Pets Just as MRSA has become a well-recognized colonizing and infecting microorganism in humans, it has also been identified as an emerging pathogen among companion animals and among animals who visit healthcare facilities. Several investigators have reported that clonally related MRSA isolates found to be the cause of human infection and persistent colonization, have been recovered from the household pets of such humans *(242–244)*. These reports suggest that household pets may serve as a contributor to the reservoir for MRSA transmission to humans; however, it has not been possible to determine the direction of such transmission. Since many of the recovered MRSA isolates from pets have been identified by genetic typing to be of hospital origin, most would postulate that the animals first became colonized from their human owners and not from a *de novo* emergence of MRSA from a pet's susceptible *S. aureus*. The prevalence of MRSA colonization among house dwelling companion animals has been reported for a number of species including rabbits, birds, and reptiles, but most appropriate for this discussion are data available for dogs and cats. There are little

data regarding MRSA colonization rates among domestic cats; however, reported colonization rates have generally been low (<5%) for dogs *(245,246)*, most often found among those being admitted to a veterinary hospital for clinical infection. Additionally, risks for MRSA colonization among these animals have not been rigorously investigated, but when assessed have included previous exposure to antimicrobials and contact with the human healthcare system (20,*247)*.

Pet therapy and personal pet visitation have become more common in healthcare facilities; thus, it is important to understand the potential risks for patients posed by such animals entering these facilities. With regards to MRSA, one report of the prevalence of MRSA carriage among resident animals of an LTCF found that among 12 animals (1 dog and 11 cats), two (both cats) were found to be colonized with a healthcare strain of MRSA *(248)*. It was not determined if this strain was seen among the residents of that LTCF; thus, the significance of the colonization among the animals is unknown. Another study reported that an MRSA strain responsible for repeated outbreaks in a Dutch nursing home was recovered from a nurse who worked at the facility, from her infant daughter, as well as from her healthy pet dog *(249)*. All were subsequently treated with anti-MRSA antibiotics and all were successfully "decolonized." One recent cross-sectional study of 102 visitation dogs entering participating hospitals in Ontario, Canada, was conducted to assess the prevalence of several zoonotic agents. Fecal, hair-coat brushing, rectal, aural, nasal, oral, and pharyngeal specimens were sent from each dog, and with regards to MRSA, no animals were found to harbor the microorganism. Further epidemiological studies are required to better describe the nature of MRSA infection and colonization in companion animals as well as in animals who routinely visit healthcare facilities. Additionally, no formal guidelines exist regarding if and when to screen companion animals, but logically it is not indicated in most situations. One would consider screening household pets when there is epidemiological evidence of ongoing transmission between the pet and the owner despite implementation of appropriate infection control measures (20). Guidelines do exist regarding animals participating in animal-assisted interventions in healthcare facilities *(250)*. These guidelines do not recommend routine screening of these animals, but focus more on implementing measures to reduce the risk for transmission should MRSA colonization exist. This includes hand hygiene policies, proper grooming of animals prior to their entry into the healthcare facility, limiting the visiting areas of the animals, properly training animal handlers, and ensuring appropriate environmental cleaning after animal visits. Screening for MRSA may be considered in rare situations when a specific animal (or its handler) is suspected of being involved in transmission of the microorganism through epidemiological investigation. If an animal (or its handler) is screened and is found to have MRSA colonization, most would recommend excluding that animal (and handler) from assisted interventions in healthcare until there is evidence that the animal (or handler) is no longer colonized with the microorganism. Decolonization protocols for animals have been utilized and are beyond the scope of this discussion; however, consultation with a veterinarian is advised.

STRATEGIES TO PREVENT AND CONTROL MRSA

Summary of Existing Guidelines and Recommendations

The emergence of MRSA as one of the most common healthcare-associated pathogens has resulted in a recognized need to establish effective programs to prevent transmission of MRSA within healthcare facilities. The extensive amount of research regarding the epidemiology of MRSA transmission and interventions that can disrupt transmission has allowed several governmental, public health, and professional organizations to develop evidence-based policies, guidelines, and recommendations for the prevention of MRSA transmission (194,251,*252,253*) (Infection Prevention Working Party; www.wip.nl/UK/free_content/Richtlijnen/MRSA%20hospital.pdf). In general, the recommendations provided by these groups are similar, but some differences do exist (Table 29-4). In addition to these policies and guidelines, a number of organizations have developed practical recommendations to assist healthcare facilities in their efforts to implement and measure the results of an MRSA prevention program (194,251).

Basic Practices for Prevention of MRSA Transmission

Develop Necessary Infrastructure Needed to Monitor MRSA A basic MRSA monitoring program should have the ability to identify and track all patients from whom MRSA has been isolated in culture or otherwise identified from clinical specimens and, if available, active surveillance testing. Historically, Infection Prevention and Control programs have typically detected MRSA-colonized or MRSA-infected patients by reviewing daily laboratory result reports. Additional methods of detection are now available in some healthcare facilities through the use of electronic databases and surveillance systems. Identified cases are then tracked using a "line list." At a minimum, the line list or the MRSA database should contain the first MRSA isolate, whether from clinical culture or active surveillance, from each patient. Isolates should be classified as either hospital or community onset using standardized definitions, such as those provided earlier (192). In addition to patients identified by the facility as MRSA-infected or MRSA-colonized, patients known to be colonized or infected with MRSA on the basis of testing performed at another healthcare facility can be included in the line list. A facility may choose to include other information in the line list, such as the date of specimen collection, the patient's physical location at the time of collection, and the site from which the specimen was obtained. The MRSA monitoring program should establish a method to obtain administrative data, such as the number of patient days, admissions, or discharges within specified time periods, so that MRSA data from the line list and other sources may be used to periodically generate MRSA incidence or prevalence reports. A plan for routinely sharing this information with key stakeholders should be developed.

The MRSA monitoring program should also have the capacity to ensure that appropriate actions are taken when a patient is newly identified as MRSA-infected or

ND, not discussed

MRSA-colonized. These actions may include education of the patient about MRSA and the infection control measures that will be implemented, institution of appropriate precautions, and completion of any local or state reporting requirements. As more components, such as surveillance for specific types of MRSA infection or active surveillance testing, are added to the MRSA-monitoring program, sufficient resources must be obtained so that other infection prevention and control activities are not compromised.

Conduct an MRSA Risk Assessment As part of an MRSA prevention and control program, an MRSA risk assessment should be conducted (194). The purpose of the risk assessment is to characterize the burden of MRSA within the facility or population of interest. Currently, there are no validated methods of performing an MRSA risk assessment, although a number of metrics have been recommended for use in monitoring multidrug resistant microorganisms, such as MRSA, in healthcare settings (192). Metrics that may be useful components of an initial risk assessment include the proportion of *S. aureus* isolates from the facility or population that are methicillin resistant, the overall incidence of MRSA (i.e., the number of new cases of MRSA colonization and/or infection that occurs within a given period of time), the incidence of one or more specific types of MRSA infection (e.g., MRSA BSI or MRSA SSI), or point prevalence surveys of MRSA colonization or infection. Data from an MRSA active surveillance program allow for a more accurate assessment of the prevalence and incidence of MRSA within a facility; however, a useful risk assessment can be performed even in the absence of such a program. Process measures may also be included in the MRSA risk assessment. Evaluation of current practices and rates of adherence to hand hygiene policies and the use of Contact Precautions, for example, may allow for a better understanding of potential contributors to the transmission of MRSA within the facility. By allowing an assessment of the overall burden of MRSA within the facility, the risk assessment can inform discussions about the allocation of resources for MRSA prevention and control efforts. In addition, information from the risk assessment, such as the identification of specific populations at increased risk, may

help to prioritize the implementation of specific control measures. The MRSA risk assessment should be repeated periodically and compared with prior assessments in order to evaluate the effectiveness of the prevention and control program.

Hand Hygiene Noncompliance with hand hygiene has been described as the most important modifiable cause of HAI (228,*254–256*), and following suit, compliance with CDC or World Health Organization (WHO) Hand Hygiene guidelines are essential for MRSA prevention and control in healthcare facilities. Evidence-based recommendations regarding how to implement effective hand hygiene programs are readily available *(http://www.who.int/patientsafety/events/05/HH_en.pdf; http://www.ihi.org/IHI/Topics/CriticalCare/IntensiveCare/Tools/HowtoGuideImprovingHandHygiene.htm).* Also, in their 2008 Patient Safety Goals, the Joint Commission requires that as a primary means of preventing hospital infections, there must be compliance with WHO or CDC guidelines *(257)*. Despite this, healthcare facilities continue to struggle with maintaining high rates of hand hygiene compliance with most estimates remaining unacceptably low and reported below 50%. The association between hand hygiene compliance and MRSA rates has been well described. Recently, a time series analysis of the impact of use of an alcohol-based hand disinfectant on the incidence of HA-MRSA infection was conducted over a 58-month time period. The use of ABHR was found to have a significant impact on the monthly incidence of HA-MRSA infections ($p < .001$). Specifically, a 1% increase in the volume of ABHR use was associated with a 5.37% decrease in HA-MRSA infections after a lag time of 3 to 7 months *(119)*. Another recent study that utilized a stochastic mathematical model to simulate the outcome associated with hand hygiene noncompliance demonstrated that this noncompliance was associated with increased MRSA acquisition and infection as well as significant attributable hospital costs *(258)*. In a model that simulated 1 million episodes of noncompliant healthcare workers caring for patients of unknown MRSA status, 143 MRSA colonizations resulting in 42 MRSA infections would have occurred at a mean cost per infection of $47,092 and ultimately a mean cost per noncompliant event of $1.98 (95% CI, $0.91–$3.04). Another model that simulated noncompliant healthcare workers caring for an MRSA patient and a patient of unknown MRSA status estimated that 3,340 MRSA colonizations resulting in 980 MRSA infections at a mean cost of $53,598 per infection and ultimately a mean cost per noncompliant event of $52.53 (95% CI, $47.73–$57.32) *(258)*. Most importantly, the authors estimated that for a 200-bed hospital, an annual cost of $1,779,283 is spent on MRSA-related HAI attributable to noncompliance with hand hygiene and that a mere 1% increase in hand hygiene compliance would result in an annual savings of $39,650.

Several recent studies have also described successful programs to increase hand hygiene in healthcare facilities and have attributed reduced rates of HA-MRSA transmission and infection to these improved hand hygiene practices *(117,121,255,259–262)*. Although encouraging, the long-term impact of these interventions is not known, and many employed these increased hand hygiene efforts as part of a multipronged approach to the control of HA-MRSA including Contact Precautions for colonized and infected patients, cohorting or private rooms for colonized and infected patients, antibiotic stewardship, and active surveillance to identify those with MRSA. Of note, a 2-year prospective, controlled, crossover study by Rupp and colleagues of ABHR use in two medical-surgical ICUs concluded that despite a significant increase in hand hygiene compliance (from 37% to 68% in one unit and from 38% to 69% in the other; $p = .02$), there was no substantial change in the device-associated infection rates or in infections due to multidrug resistant pathogens, including MRSA. The rate of MRSA infection ranged from 1.67 to 2.77 per 1,000 patient days *(263)*. The authors stated that the results of their study did not imply that hand hygiene was not important, but that realistic expectations are needed with regards to the effect that hand hygiene alone can have on HAIs (Table 29-5).

Antibiotic Use The relationship between antibiotic use and rates of MRSA has been explored by many. In separate studies, Crossley and Hershow *(264,265)* reported that patients with MRSA infections had a significantly longer hospitalization before infection and were more likely to have received antimicrobial therapy, and Monnet *(266)* has emphasized the importance of a causal, dose–effect association between antibiotic use and MRSA. Additionally, studies that have analyzed the effect of antimicrobial classes separately on MRSA often found that both cephalosporins and fluoroquinolones increased the risk for acquisition and infection from the microorganism *(267,268)*. However, several studies have not found a significant association between MRSA and previous use of antibiotics *(269,270)*. A recent review systematically described the relationship between antibiotic use and MRSA isolation among more than 24,000 adult patients from 76 studies published between 1976 and 2007 (271). The majority of studies were performed in the United States and Europe, but some were from Asia, Brazil, Australia, and Canada. Compared to those who had not taken antibiotics, the risk of acquiring MRSA was increased by 1.8-fold (95% CI, 1.7–1.9; $p < .001$) in patients who had taken antibiotics. The relative risk for single classes of antibiotics was 3.0 (95% CI, 2.5–3.5) for quinolones, 2.9 (95% CI, 2.4–3.5) for glycopeptides, 2.2 (95% CI, 1.7–2.9) for cephalosporins, and 1.9 (95% CI, 1.7–2.2) for other beta-lactams. Distribution of the relative risk of MRSA acquisition in patients previously treated with antibiotic therapy versus nontreated patients, stratified by definition of cases, showed that the combined risk was 1.9 for infected patients (95% CI, 1.8–2; $p = .001$) and 1.6 for colonized subjects (95% CI, 1.5–1.7; $p = .001$) (271).

The effect of antibiotic therapy on the nasal bacterial load of MRSA has also been reported. A prospective study of patients with MRSA infection or colonization found that patients on beta-lactam or fluoroquinolone therapy have an increased incidence of MRSA colonization, have higher nasal bacterial loads, and appear to spread their MRSA into the near patient environment *(272)*. The median nasal MRSA bacterial load increased significantly from 2.78 to 5.30 $\log_{10}$ cfu per swab ($p < .001$) over 21 days during beta-lactam therapy and increased from 0 to 4.30 $\log_{10}$ cfu per swab ($p = .039$) over 14 days during fluoroquinolone therapy. Median bacterial loads were significantly higher for beta-lactam- and fluoroquinolone-treated patients on

TABLE 29-5

Studies Implementing Activities to Increase Hand Hygiene and Impact on MRSA

Study	*Population*	*Intervention*	*Hand Hygiene*	*MRSA*
Pittet *(255)*	Large university teaching hospital in Geneva Switzerland	Hand Hygiene Campaign of educational posters, wide distribution of individual bottles of 0.5% CHG disinfectant, and performance feedback	Compliance increased from 48% to 66% ($p < .001$) Soap and water compliance did not change (30%) CHG disinfectant compliance increased from 13.6% to 37.0% ($p < .001$)	MRSA infections decreased from 16.9% to 9.9% ($p = .04$) HA-MRSA infections decreased from 0.74 to 0.24 episodes per 10,000 patient days
MacDonald *(259)*	Plastic Surgery unit of a 600-bed general hospital in the United Kingdom	Feedback of hand hygiene compliance and MRSA rates, educational posters, and ABHR dispensers installed outside each isolation room	Hand hygiene compliance before patient contact increased from 20% to 47% Hand hygiene compliance after patient contact increased from 42% to 78%	Newly identified patients with HA-MRSA infections decreased from 23 per 1,211 admissions (1.9%) to 11 per 1,261 admissions (0.9%) ($p < .05$)
Harrington *(260)*	350-bed tertiary referral hospital in Australia	Introduced ABHR, posted signs identifying patients with antibiotic resistant organisms, and provided feedback of MRSA surveillance	32% increased use of hand hygiene product from 78.1 L per 1,000 patient days to 102.7 L per 1,000 patient days	Rate of new MRSA patients in ICU decreased from 9.3 to 6.7 per 100 patient admissions ($p = .047$) Hospital-wide MRSA patients decreased from 3.0 to 1.7 per 100 patient admissions ($p < .001$) MRSA BSI decreased from 0.45 to 0.27 per 100 patient admissions ($p = .02$)
Conrad *(117)*	Tertiary-care University Medical Center in Germany	Hand hygiene campaigns focusing on short educational training sessions	Each hand hygiene campaign resulted in a decrease in hospital acquired MRSA	Greater use of ABHR led to a concomitant decrease in the incidence of HA-MRSA (lag time: 2 months; coefficient: –0.001; *T* statistic: –2.33; $p = .23$)
Sakamoto *(121)*	33-bed NICU of a tertiary-care hospital in Tokyo, Japan	Increased placement of ABHR dispensers (one per bed), and short educational training sessions		The amount of ABHR used for one patient per day was significantly associated with MRSA incidence density (lag time: 0 mo; coefficient: –.052; *T* statistic: –2.62; $p = .011$)
Gagne *(261)*	250-bed community hospital in Quebec, Canada	Education of patients and visitors regarding hand hygiene and instructions to cleanse hands twice daily	Hand hygiene compliance not reported	HA-MRSA infections decreased 51% from 10.6 to 5.2 per 1,000 admissions MRSA mortality decreased 71% from 0.7 to 0.2 per 1,000 admissions
Davis (*262)*	Surgical ward in a UK hospital	Red line taped from entrance to ward to ABHR dispenser on wall with instructional posters	Compliance with ABHR increased from 24% to 62.3% ($p < .0001$)	Two cases of MRSA BSI before intervention compared to none after intervention

CHG, chlorhexidine gluconate; ABHR, alcohol-based hand rub; BSI, bloodstream infection.

days 7, 14, and 21 than controls not receiving antibiotics ($p < .05$). These loads then decreased by 2 to 5 $\log_{10}$ cfu per swab 2 weeks after stopping antibiotics. The environment of patients receiving beta-lactam agents (RR, 3.55; 95% CI, 1.30–9.62; $p = .018$) or fluoroquinolones (4.32; 1.52–12.31; $p = .008$) demonstrated more MRSA contamination than the environment around control patients (0.79; 0.67–0.93; $p = .002$) *(272)*.

Researchers have also studied the effect of antibiotic control and compliance with infection control measures on MRSA rates *(273,274)*. One observational, cross-sectional study used linear regression to model these relationships. There was a strong statistical relationship between macrolide use and MRSA prevalence. Also, use of third-generation cephalosporins, all antimicrobial agents, and all antimicrobial agents except glycopeptides was associated with MRSA prevalence. There was strong evidence that infection control policy recommendations, including use of alcohol-based solutions for hand hygiene and placement of MRSA patients in single rooms, were associated with lower MRSA prevalence rates *(273)*. Another study used time series analysis to evaluate the effect of antimicrobial drug use and infection control practices on HA-MRSA incidence over a 5-year time period in a large general teaching hospital in Northern Ireland. Statistically significant positive relationships were observed for the use of multiple antibiotics with various time lags. Temporal variations in HA-MRSA incidence followed temporal variations in fluoroquinolone use with a mean delay of 1 month with on average, an increase (or a decrease) in fluoroquinolone use by 1 defined daily dose (DDD)/100 bed-days resulting 1 month later in an increase (or a decrease) in the incidence of HA-MRSA by 0.005/100 bed-days. Similarly, third-generation cephalosporin use (average delay: 2 months, variation of HA-MRSA incidence: 0.03/100 bed-days), macrolide use (average delay: 4 months, variation of HA-MRSA incidence: 0.002/100 bed-days) and amoxicillin/clavulanic acid use (average delay: 1 month, variation of HA-MRSA incidence: 0.003/100 bed-days) were temporally associated with HA-MRSA incidence. Additionally, increased infection control activity was associated with decreased HA-MRSA incidence and vice versa. Significant relationships were observed for ABHR use, alcohol-impregnated wipe use, and the number of patients actively screened for MRSA with time lags varying from 2 to 4 months *(274)*.

Results of studies reporting only on antibiotic control, mostly of fluoroquinolone and cephalosporin use, and MRSA rates have been mixed. Charbonneau and colleagues conducted a nonrandomized, prospective, controlled interventional "fluoroquinolone-free" study at four large teaching hospitals in northwest France. During the intervention period, fluoroquinolone use was prohibited in one of the four hospitals (unless no alternative was available). Three other university hospitals with similar pre-intervention MRSA rates were used as controls. During the intervention period, the annual rate of fluoroquinolone use decreased from 54 to 5 DDDs per 1,000 patients per day at the study hospital and remained stable in the control hospitals. At the end of the intervention, the rate of MRSA isolation was significantly lower in the study hospital (32.3% compared with 36.8%; OR, 0.82; 95% CI, 0.69–0.99; adjusted for within-hospital correlation; $p = .036$). In a before–after time series analysis, compared with forecasted rates, there was a significant downward trend in observed monthly rates of MRSA isolation at the study hospital at the end of the intervention *(275)*. Another single-center quasiexperimental time series segmented regression study evaluated whether an intervention to limit fluoroquinolone use was associated with a lower rate of HA-MRSA infection at a VA hospital. A physician-directed computerized intervention to limit the use of fluoroquinolones was initiated, and changes in antibiotic use and HA-MRSA infection rates were tracked. After the intervention, fluoroquinolone use decreased by approximately 34% (levofloxacin by approximately 50%). This decreased fluoroquinolone use was offset by increased cephalosporin, piperacillin–tazobactam, and trimethoprim–sulfamethoxazole use. The HA-MRSA infection rate decreased from 1.37 to 0.63 episodes per 1,000 patient days ($p = .02$), but the rate of infection with gram-negative microorganisms increased. In a separate model, the rate of MRSA infection was negatively correlated with the study intervention ($p = .04$) *(276)*. Another study from Thailand assessed the impact of an education and antibiotic-control program on the antibiotic-prescribing practices, antibiotic consumption, antimicrobial resistance, and cost. After the intervention, there was a 24% reduction in the rate of antibiotic prescriptions (640 vs. 400 prescriptions/1,000 admissions; $p < .001$). The incidence of inappropriate antibiotic use also was significantly reduced (42% vs. 20%; $p < .001$), including that of third-generation cephalosporins (31 vs. 18 DDDs/1,000 patient days; $p < .001$) and glycopeptides (3.2 vs. 2.4 DDDs/1,000 patient days; $p = .002$). Rates of use of cefazolin and fluoroquinolones increased. Significant reductions in the incidence of MRSA infections (48% vs. 33.5%; $p < .001$) were observed with costs savings of $32,231 during the study period *(277)*. How long such restrictions in antibiotic usage can be maintained and what is necessary for long-term control of MRSA remains unclear.

Antibiotic cycling as a means of control has also been reported with regards to MRSA control. Cycling is the scheduled rotation of one class of antibiotics with one or more different classes exhibiting comparable spectra of activity. A 2005 review evaluated the efficacy of this type of intervention and reported that due to multiple methodological flaws and a lack of standardization, the results of studies of the efficacy of antibiotic cycling do not permit reliable conclusions regarding efficacy and that further studies are required to resolve this question *(278)*. One study published after this review evaluated the efficacy of empiric cycling of antibiotics active against gram-positive microorganisms in a before–after intervention in a surgical ICU at a large tertiary-care academic hospital. A strategy where the empiric antibiotic of choice for the treatment of gram-positive infections (linezolid or vancomycin) was changed every 3 months. During the 4 years prior to cycling, 105 MRSA ICU infections were acquired (8.8/1,000 patient days). In the 2 years after implementation of cycling, 11 MRSA ICU infections were acquired (1.8/1,000 patient days; $p < .0001$ vs. noncycling period). The percentage of *S. aureus* infections caused by MRSA declined from 67% to 36% *(279)*.

Contact Precautions for MRSA-Colonized or MRSA-Infected Patients Current guidelines and other recommendations for prevention of transmission of MRSA in acute care facilities recommend the use of Contact Precautions for patients colonized or infected with MRSA (194,251,*252*) (Infection Prevention Working Party; *www.wip.nl/UK/free_content/Richtlijnen/MRSA%20hospital.pdf*). These recommendations are based on the large body of evidence (largely discussed earlier in this chapter) that MRSA is primarily transmitted from one person to another by direct or indirect contact.

Components of Contact Precautions include the use of personal protective equipment, physical separation of the patient from other patients, and, when possible, use of dedicated equipment that is not shared with others. The use of a protective gown and gloves is intended to reduce the risk or severity of contamination of a healthcare worker's hands and clothing and thus reduce the risk of transient or persistent carriage of MRSA by the healthcare worker with its associated risk of subsequent transmission to others. The gown and gloves should be donned prior to entering the patient's room and removed prior to leaving the room. In addition to gown and gloves, some guidelines for preventing MRSA transmission in healthcare facilities recommend the use of surgical masks *(253)* (Infection Prevention Working Party; *www.wip.nl/UK/free_content/Richtlijnen/MRSA%20hospital.pdf*). Surgical masks may serve as physical barriers to reduce the risk of inadvertent contact transmission of MRSA to the anterior nares by a healthcare worker's contaminated gloves and may potentially prevent direct deposition of airborne droplets containing *S. aureus* onto the mucous membranes of the anterior nares and oropharynx. Although the anterior nares is the most common site of *S. aureus* carriage in humans, airborne dispersal of *S. aureus* is thought to occur in only a minority of healthy nasal carriers *(280)*. It has been demonstrated, however, that viral upper respiratory infection and respiratory allergies can substantially increase airborne dispersal of *S. aureus* from some nasal carriers *(239,281,282)*. These so-called cloud babies and cloud adults including healthcare workers, have been implicated in outbreaks of *S. aureus* infection in hospital patients *(239,283,284)*. In some experimental studies of "cloud adults," the use of a surgical mask has reduced airborne dispersal of *S. aureus* by up to 75%. In other studies, the use of a surgical mask was not associated with a reduction in the amount of *S. aureus* dispersed into the air. Thus, if masks are not a routine component of the precautions implemented for the care of patients with MRSA, consideration may be given to the use of masks when caring for MRSA patients with upper respiratory tract infections or allergies that may increase the risk for airborne dissemination of the microorganism.

In addition to the use of personal protective equipment by HCP and others who enter the patient's room, Contact Precautions should also include placement of the MRSA-colonized or MRSA-infected patient in a single room, if feasible. In settings in which a sufficient number of single rooms are not available, patients at greatest risk of transmission of MRSA (e.g., patients with uncontrolled drainage from an infected wound, patients with upper respiratory tract infection) should be given priority for placement in a single room. When a single room is not available, cohorting the patient with another patient with MRSA, preferably of the same genotype or similar antibiotic susceptibility profile, is a reasonable alternative. If a patient with MRSA must share a room with another patient(s) who is not MRSA colonized or MRSA infected, the roommate should ideally be selected from among patients at lower risk of MRSA acquisition and/or lower risk of invasive infection or complications from infection if transmission occurs.

A final intervention that can be considered part of Contact Precautions is dedication of noncritical patient care equipment, such as blood pressure cuffs and stethoscopes, for use with the MRSA patient. Limiting use of the equipment to a single patient reduces the risk of transmission of MRSA to other patients through contact with contaminated equipment. It may not be feasible, however, to dedicate some equipment (e.g., portable electrocardiogram machines) for use with an individual patient. When equipment that has been used for a patient on Contact Precautions must be used for other patients, thorough cleaning and appropriate disinfection prior to its next use can reduce the risk of exposure of other patients.

In LTCFs, implementation of Contact Precautions, and some other strategies that are commonly implemented in acute care hospitals, is associated with a number of challenges. In addition to facility-specific challenges, such as a limited number of single rooms, Contact Precautions may have a more pronounced psychosocial impact in the long-term care setting since these facilities serve not only as healthcare facilities but also as their residents' home. In recognition of these challenges, SHEA and the Association of Professionals in Infection Control and Epidemiology (APIC) have issued a guideline that is focused on infection prevention and control in the long-term care setting *(285)*. Because of the previously mentioned concerns, the guideline prioritizes implementation of Contact Precautions in LTCFs for those at greatest risk of transmitting multidrug resistant microorganisms, such as MRSA, to others, including those residents who are dependent upon HCP for their activities of daily living or whose secretions or drainage cannot be adequately contained. The SHEA/APIC publication provides an excellent review of the epidemiology and prevention of HAI in the long-term care setting.

Contact Precautions are often implemented in conjunction with other control measures, making it difficult to evaluate the individual contribution of Contact Precautions to the interruption of MRSA transmission. In addition, the impact of Contact Precautions in the clinical setting may be limited by poor adherence *(286)* and other factors, such as the presence of unrecognized reservoirs of MRSA (i.e., asymptomatic carriers of MRSA) for whom Contact Precautions are not implemented. Despite these complicating factors, there are data that suggest that Contact Precautions are effective in preventing transmission of MRSA. For example, during an MRSA outbreak in a neonatal ICU, MRSA transmission was found to be reduced 16-fold when colonized infants were cared for with the use of Contact Precautions (287). The effectiveness of Contact Precautions was also suggested in a more recent publication describing control of an outbreak of MRSA in a burn unit *(288)*. In that outbreak, because transmission of MRSA continued to occur despite high compliance with the use of

Contact Precautions for patients known to be colonized or infected with MRSA, empiric use of Contact Precautions for all patients was implemented. This was temporally associated with control of the outbreak and subsequent maintenance of a low MRSA incidence rate. This suggests that transmission of MRSA may have been reduced by preventing opportunities for transmission of MRSA from unrecognized MRSA carriers for whom Contact Precautions had previously not been implemented.

MRSA carriage can be quite prolonged persisting for more than a year in many patients *(289–292)*. In studies that have provided long-term follow-up of HA-MRSA-colonized patients, the median time to clearance has ranged from 8.5 to 40 months *(206,293)*. Factors that have been associated with prolonged carriage of MRSA include chronic skin lesions, the presence of foreign bodies (e.g., gastrostomy tubes, transcutaneous vascular access devices), and having more than one colonized body site *(289,290,293,294)*. Because prolonged carriage is common and asymptomatic carriers can serve as reservoirs for transmission of MRSA, Contact Precautions are typically recommended for the duration of hospitalization in which MRSA is detected (251). Similarly, it is recommended that Contact Precautions be implemented when a known MRSA-colonized patient is readmitted to the hospital. Because it is not possible to predict how long an individual patient will remain a carrier of MRSA, the patient's carriage status should be reassessed prior to discontinuing Contact Precautions. Obtaining samples from known sites of prior MRSA carriage and other common sites of carriage may be useful in assessing a patient's current MRSA carriage status. Obtaining negative results on three or more consecutive surveillance tests obtained in the absence of recent antimicrobial therapy is often considered to be sufficient evidence of clearance of MRSA carriage and indication for discontinuation of Contact Precautions (251).

Several studies have reported a variety of unintended, adverse consequences associated with the use of Contact Precautions *(295–298)*. A recent systematic review of the literature identified four main unintended consequences of Contact Precautions: less patient-healthcare worker contact, changes in systems of care resulting in delays and more noninfectious adverse events (including falls and pressure ulcers), increased symptoms of anxiety and depression, and decreased patient satisfaction *(299)*. In addition, some have found that patients on Contact Precautions have substantial knowledge deficits regarding the rationale for and the components of Contact Precautions, suggesting that insufficient education regarding isolation precautions is provided to these patients *(300)*. Although not all studies have found that patient care or patients' perception of their care is deleteriously affected by the implementation of Contact Precautions, it is important to recognize the potential for these unintended consequences of Contact Precautions to occur. These adverse consequences, however, do not necessarily represent unavoidable effects of the use of Contact Precautions but rather adverse effects due to the healthcare system failing to provide the same level of care to patients on Contact Precautions as provided to those who are not on Contact Precautions. This highlights the importance of ensuring that patients on Contact Precautions are given appropriate information and that they receive care that is equivalent to that received by other patients.

Ensure Cleaning and Disinfection of Equipment and Environment As discussed above, MRSA contaminates the patient's environment and patient care equipment, and exposure to this has been associated with acquisition of the microorganism. Thus, cleaning and disinfection protocols for environmental surfaces should be developed and implemented in healthcare facilities and guidelines have outlined such protocols *(215)*. Routine cleaning and disinfection of the patient environment with EPA-registered hospital disinfectants (e.g., quaternary ammonium compounds, sodium hypochlorite, iodophors, and phenolics) used according to manufacturer's directions (including amount of contact time) is recommended, and protocols should address daily cleaning and terminal cleaning, particularly paying attention to high-touch surfaces such as bed rails, overbed tables, bedside commodes, doorknobs, and sink handles (194). The goal of cleaning and disinfection of the patient care environment is to reduce or eradicate the microbial load in order to reduce the risk for transmission of epidemiologically important microorganisms. The effectiveness of environmental cleaning and disinfection depends on the frequency, the competence of the cleaning staff, as well as the type of cleaner or disinfectant *(225)*. With regards to MRSA, a recent prospective study reported the impact of an environmental cleaning program on the presence of MRSA on surfaces in the ICU. The presence of MRSA and VRE on ICU room surfaces during a 6-week baseline period where routine room cleaning consisted of using a hospital grade quaternary ammonium disinfectant applied according to national standards, was compared to that of a 6-month period where a cleaning intervention was implemented. This consisted of applying the disinfectant via immersion of the cleaning cloth into a bucket instead of via pour bottles, environmental staff education, and feedback regarding the effectiveness of cleaning. Qualitative cultures in 37 rooms at baseline revealed that 45% of them had at least one surface contaminated with MRSA or VRE. During the intervention period, cultures from 44 rooms revealed this had dropped to 27%. Multivariate analysis showed a significant association with reduced environmental MRSA and VRE contamination when cultures were used as the unit of analysis and data were clustered by room *(301)*. Other methods of environmental cleaning have also been shown to reduce MRSA in the environment including high-efficiency particulate air filtration, ultraviolet light, and gaseous decontamination using hydrogen peroxide vapor *(214,215,218)*.

Educate Healthcare Providers and Provide Data to Key Stakeholders Recent guidelines recommend that in order to have an effective control program for MRSA, healthcare worker behavior must be monitored and often modified (194,251). This would include activities such as compliance with hand hygiene, Contact Precautions, environmental disinfection, and active surveillance (194). In order to encourage behavior modification, an educational program should be developed and provided to HCP at all levels (194). This should be evidence-based, include a discussion about the local epidemiology of MRSA,

risk factors for acquisition and infection, how MRSA is transmitted, and the impact that MRSA has on patients and the healthcare system as well as measures for prevention and control. Additionally, data regarding the current compliance rates among different types of HCP should be discussed in the context of how it may relate to local rates or success. Because the healthcare system employs individuals at many levels of educational backgrounds, educational programs need to be presented at appropriate levels dependent on the intended audience. What is appropriate for physicians and nurses may not be appropriate for environmental services or laboratory personnel; however, each group has activities within the facility that will impact the ability to control and prevent MRSA.

The healthcare facility is responsible for ensuring proper support of an infection prevention and control program that works to effectively prevent HAI as well as transmission of epidemiologically important microorganism such as MRSA. This includes support to help properly train individuals to provide education to the providers within the facility. Additionally, senior leadership and administration personnel should develop a system of accountability to ensure that HCP and ancillary staff are competent to perform their job responsibilities as well as compliant with infection prevention and control measures.

Educate Patients and Their Families about MRSA Education of the patient and the patient's family about MRSA is also an important measure a healthcare facility should employ. This may serve not only to enhance the patient's knowledge regarding this important microorganism, but also may increase transparency within the facility, and may help alleviate patient fears regarding being placed into isolation (194,*302*). Newton and colleagues *(303)* conducted a small study to assess patients' perceptions of MRSA as well as the understanding of source isolation. When patients were identified as having an MRSA infection, they were placed into Contact Precautions and visited by an infection control nurse who provided the patient with verbal and written information regarding MRSA and source isolation. Nineteen of these patients agreed to participate in a semistructured interview. MRSA was perceived as an infective agent by the majority (15 of 19), many (6 of 19) attributed their acquisition of MRSA to the healthcare facility, and about half (10 of 19) considered their infection serious. The majority of patients (17 of 19) had little knowledge about the duration of their infection and few (4 of 19) understood why they were placed into isolation *(303)*. This highlights the importance of patient education and a recent paper by Noble provided an excellent example of a script for use by a nurse or other provider in order to communicate MRSA education effectively *(304)*. It includes general information about MRSA, colonization versus infection, the hospital's MRSA prevention program, the components of and rationale for Contact Precautions, and the risk of transmission to family and visitors while in the hospital and after discharge. Methods suggested to facilitate this education process include patient education sheets, patient education channels offered on closed circuit television, web site referrals, and videos. Examples of patient education materials appropriate for use within the hospital environment as well as upon patient discharge are available in several medical journals *(305,306)* as well as through online sources (http://www.shea-online.org/about/patientguides.cfm).

Advanced Practices for Preventing MRSA Transmission

Active Surveillance of Patients The rationale for conducting active surveillance testing for MRSA is based on the understanding that individuals colonized with the microorganism represent a large and important reservoir for spread to other patients and that colonized individuals have an increased risk for developing MRSA infection. Thus, the goals of active surveillance are to (a) identify patients colonized with MRSA in the hospital or other healthcare facility (who would otherwise go undetected unless they happened to have an infection) in order to employ Contact Precautions to halt patient to patient spread and/or to (b) identify patients colonized with MRSA in order to employ decolonization techniques to prevent infection. Active surveillance is recommended to be utilized in combination with other properly designed and executed infection prevention interventions including hand hygiene, Contact Precautions, environmental cleaning and disinfection, as well as prudent use of antimicrobials (Fig. 29-2) (194).

Active surveillance has been described for use under endemic as well as epidemic conditions and has been utilized for all patients admitted to a hospital or a healthcare facility (universal surveillance), or for a high-risk subset of patients (targeted surveillance). It is important to note that controversy exists regarding the effectiveness of active surveillance for prevention of MRSA transmission and infection. Much of this controversy stems from the fact that many of the reports describing active surveillance have been conducted at different types of healthcare facilities, under different circumstances, among different patient populations, in combination with different additional measures of control, as well as utilizing different culturing techniques and different measures of analysis. Recently published guidelines recommend to consider active surveillance in a facility where there is direct or indirect evidence of ongoing MRSA transmission despite adequate implementation of and adherence to hand hygiene, Contact Precautions for those known to harbor MRSA, and environmental cleaning and decontamination (194). Examples of ongoing transmission may include an unacceptably high or increasing prevalence or incidence of HA-MRSA infection or colonization or an increasing proportion of HA-*S. aureus* isolates that are resistant to methicillin. Additionally, CLSI recently released a document dedicated to the topic of surveillance for MRSA, which may serve as a guide for laboratorians, clinicians, epidemiologists, as well as healthcare administrators considering this practice of control (20).

A detailed review of active surveillance for MRSA is beyond the scope of this chapter; however, several recent, well-conducted studies regarding the impact of active surveillance deserve mention. Huang and colleagues assessed the effectiveness of four infection control measures; maximal sterile precautions for central line insertion, ABHR use, hand hygiene campaigns, and active surveillance, introduced over the course of 9 years into their 800-bed academic hospital. Active surveillance was targeted to ICU patients, conducted at the time of admission and then

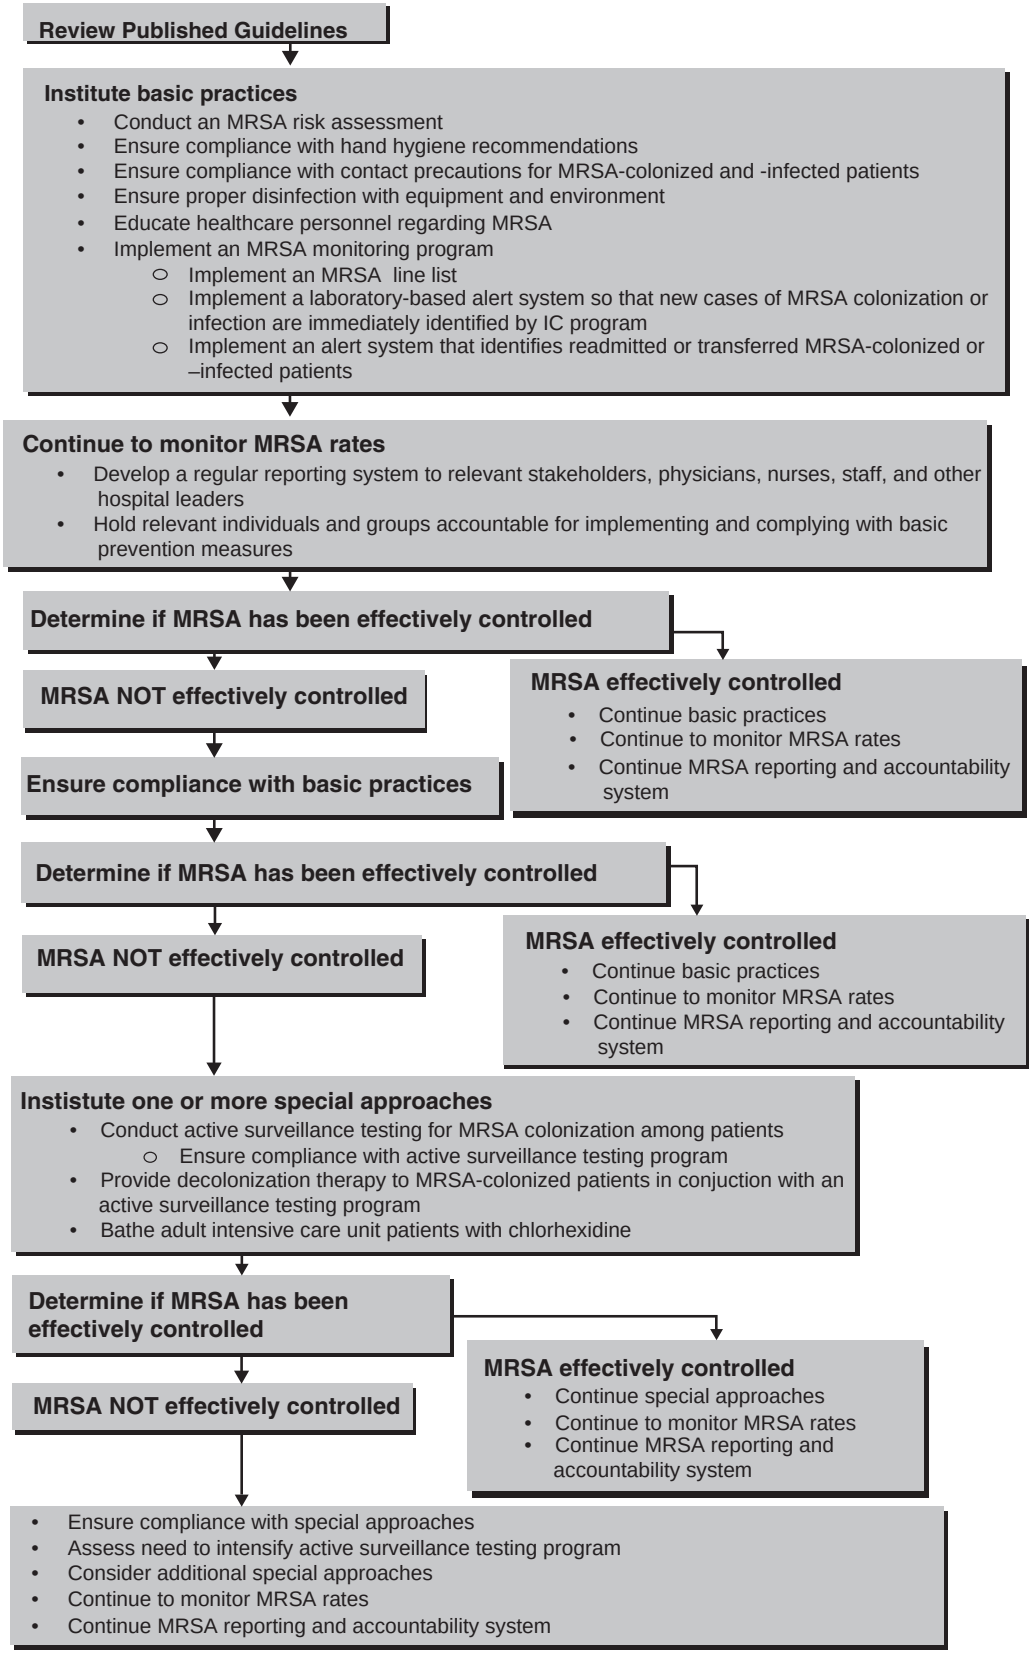

FIGURE 29-2 Approach to control and prevention of MRSA transmission. (Redrawn from Calfee DP, Salgado CD, Classen D, et al. Strategies to prevent transmission of methicillin-resistant *Staphylococcus aureus* in acute care hospitals. *Infect Control Hosp Epidemiol* 2008;29(suppl 1):S62–S80, with permission. Copyright © 2008 by The Society for Healthcare Epidemiology of America.)

weekly, and utilized routine culture methodology. MRSA patients were placed into Contact Precautions. Among all the interventions, only active surveillance was associated with a significant decrease in MRSA BSI not only in the ICU but also throughout the general hospital wards. Over the 16 months of active surveillance, MRSA decreased in the ICU by 75% and outside the ICU by 40% ($p = .007$ and .008, respectively). Additionally, there was a significant decrease in MRSA acquisition within the ICU from 43 per 1,000 patients at risk to 23 per 1,000 patients at risk ($p < .001$) *(307)*. In another study from a large Spanish tertiary care hospital, three different infection control measures were assessed with respect to the incidence of MRSA colonization and infection *(308)*. Contact Precautions for all MRSA patients found through clinical cultures were introduced initially followed by identification of high risk MRSA wards where admission and weekly surveillance cultures were conducted among patients and healthcare workers and finally more expanded active surveillance of MRSA patients readmitted as well as those from other healthcare facilities. Routine culture methodology was utilized and of note, MRSA patients received decolonization therapy. Using time series analysis, only after introducing more expanded surveillance was a significant reduction in MRSA achieved. The incidence of colonization or infection due to MRSA and the incidence of BSI due to MRSA decreased by 83% and 80%, respectively. The MRSA rate decreased from 0.56 cases per 1,000 patient days to 0.07 cases per 1,000 patient days, and this has been maintained for more than 8 years *(308)*. Targeted surveillance has also been shown to be effective in a community hospital system. West and colleagues demonstrated that active surveillance on admission and then weekly of ICU patients as well as high risk patients on general wards was associated with significant decreases in MRSA HAIs (BSIs and SSIs) and saved more than 1.5 million dollars over the course of 16 months *(309)*.

However, in a recent cluster-randomized trial, targeted surveillance of ICU patients and use of "expanded barrier precautions" was not effective in reducing the transmission of MRSA. Surveillance was performed in all participating ICUs but the results were only reported to providers in ICUs assigned to the intervention. In these intervention ICUs, MRSA-positive patients were cared for with Contact Precautions and all other patients were cared for with universal gloving until discharge from the unit or until the surveillance culture was reported as negative. The mean ICU-level incidence of MRSA colonization or infection per 1000 patient days at risk did not differ significantly between the intervention and control ICUs (16.0 and 13.5, respectively, p=0.39) and multivariable analysis showed no evidence of an intervention effect overall or a consistent effect over time. The authors concluded that although the intervention was not associated with significant reduction in MRSA, several factors could have contributed to this including, a prolonged turnaround time for reporting of surveillance results (5.2 days), less than optimal compliance with Contact precautions, and a brief intervention period (6 months) (309a).

Robiscek reported the results of an observational study comparing the rates of MRSA clinical disease at baseline, after introducing active surveillance on admission among ICU patients, and then after expanding to universal active surveillance. A rapid PCR method of identification of MRSA was utilized and all MRSA patients were offered decolonization therapy. The baseline MRSA rate was 8.9 per 10,000 patient days, fell only to 7.4 per 10,000 patient days during targeted surveillance of ICU patients, and then decreased significantly to 3.9 per 10,000 patient days after universal surveillance ($p < .001$) (310). Segmented regression found that the aggregate MRSA HAI disease prevalence density significantly decreased 69.6% compared to baseline during the period of universal surveillance ($p = .03$), and this was true for BSI, pneumonias, urinary tract infection (UTI), and SSI. Another recent report described the effect of a comprehensive "MRSA bundle" implemented across all acute care Veterans Affairs hospitals on HA-MRSA infections. The bundle consisted of universal surveillance for MRSA, Contact Precautions for MRSA colonized or infected patients, hand hygiene, and a change in the institutional culture. Compared to baseline, the rates of HA-MRSA infections in ICUs and non-ICUs significantly decreased with implementation of the bundle from 1.64 infections per 1000 patient days to 0.62 per 1000 patient days and from 0.47 per 1000 patient days to 0.26 per 1000 patient days, respectively (P<0.0001 for both) (310a). However, not all have had the same success utilizing universal surveillance. For example, Harbarth and colleagues conducted a prospective cohort study among surgical ward patients in a large Swiss teaching hospital to compare two MRSA control strategies in a crossover design. Rapid screening of all admissions of the nares, perineal area, catheter site, and skin lesions combined with standard infection control measures for MRSA patients was compared to standard infection control measures without surveillance. During the 9-month intervention period, the HA-MRSA infection rate was 1.11 per 1,000 patient days compared to that of 0.91 per 1,000 patient days ($p = .29$). Specifically, there was no decrease in SSI or in the rate of HA-MRSA acquisition. The authors concluded that a universal rapid MRSA admission screening strategy did not decrease HA-MRSA in a surgical department with endemic MRSA but low baseline rates of MRSA infection (311). Additionally, the authors stated that their conclusions were tempered by the fact that 57% of those who developed MRSA infection were known to be MRSA free on admission; thus, there was continued healthcare-associated spread. This could have been the result of poor compliance with standard infection control measures or could have been prevented by the addition of weekly cultures to identify these patients in order to employ control measures. Additionally, there was a delay of almost a day in obtaining the results despite using a rapid identification system, and there was a high colonization pressure incidence over the intervention phase (311).

Some have reported long-term control of HA-MRSA utilizing active surveillance as part of their MRSA prevention and control program *(312,313)*. For example, a large 1,200-bed tertiary care center in the Netherlands has utilized rigorous "search and destroy" approach for many years. This includes active surveillance for high-risk patients, pre-emptive isolation of high-risk patients pending surveillance results, and surveillance of healthcare workers caring for MRSA patients as well as other contacts when feasible. Strict isolation is also employed for any MRSA-positive patient. Over a 5-year period, the average number

of healthcare-associated transmissions was 6.7 per year and five episodes of MRSA bacteremia occurred (0.28 per 100,000 patient days per year) *(312)*. Another study reports the 15-year experience of 38 French hospitals, which have utilized active surveillance of high risk persons (ICU patients and contacts of MRSA patients) with a program of Contact Precautions, hand hygiene, and feedback to key stakeholders since 1993. In acute care facilities, the proportion of MRSA among *S. aureus* significantly decreased from 39.4% in 1993 to 21.6% in 2007 ($p < .001$), and in LTCFs the proportion decreased from 41.0% to 26.6% ($p < .001$). Additionally, in acute care facilities, the incidence of MRSA cases significantly decreased from 1.16 per 1,000 hospital days to 0.57 per 1,000 hospital days ($p = .001$), and this decrease was noted to occur in ICUs, surgical wards, and medical wards. The authors concluded that sustained decreases of MRSA could be obtained at the scale of a large hospital institution with endemic MRSA utilizing an aggressive MRSA control program that included active surveillance *(313)*.

Patient Population(s) to be Screened Selection of the patient population(s) to include in an active surveillance program should be based on the facility's MRSA risk assessment and other facility-specific characteristics (e.g., other infection prevention and control priorities, laboratory resources, information technology support, staffing). Facilities may choose to screen all patients (universal screening), patients with specific risk factors for MRSA carriage, patients admitted to high-risk or high-prevalence locations within the facility, or some combination of these patient populations. There are a number of advantages and disadvantages associated with each of these approaches. Among the screening strategies, universal screening will identify the most MRSA carriers but will also require the greatest amount of laboratory resources. By limiting screening to patients at increased risk of MRSA carriage, screening only those patients with identified risk factors, may optimize laboratory utilization (i.e., may have the fewest negative test results) and may identify a relatively large proportion of the entire population of MRSA-colonized persons *(314)*. Limitations of this approach include potential difficulties identifying which patients meet the screening criteria, especially in the absence of an integrated electronic medical record, and the inability to identify colonized patients who lack the risk factor(s) used in the selection process. Screening patients admitted to high-risk or high-prevalence locations is logistically easier than screening based on patient-specific factors and assessment of adherence to the screening protocol is straightforward. The major limitation of this approach is the inability to identify MRSA carriers admitted to other locations within the facility.

Laboratory Method for Screening As discussed in the earlier section on laboratory detection of MRSA, several methods are currently available for the detection of MRSA in surveillance specimens, including conventional culture-based methods, chromogenic agar-based methods, and molecular techniques. When determining which method of detection will be used in an MRSA active surveillance testing program, a number of factors should be considered. These factors include the test's performance characteristics (e.g., sensitivity and specificity), turnaround time, complexity, and cost as well as the laboratory's capabilities and resources and the volume of specimens to be processed. Culture-based methods have been used in most published descriptions of MRSA active surveillance testing programs. These methods are relatively simple and inexpensive. Results from conventional culture-based techniques, however, are not available for 48 to 72 hours. As compared with conventional culture methods, the recent introduction of chromogenic agars has simplified the laboratory procedure and reduced the turnaround time for culture results. Positive results may be available within 24 hours, and negative results are available within 48 hours.

PCR-based techniques have been demonstrated to be highly sensitive and specific for the detection of MRSA and, because these assays can provide results in as little as 2 hours, have the potential to allow for more rapid detection of MRSA-carriage than is possible with the use of culture-based methods. In clinical practice, however, it may not be practical to process all specimens at the time of receipt by the laboratory. Instead, specimens may be batched and processed during a limited number of runs each day, thus prolonging the turnaround time. Even under these constraints, one study found that when performed only once per day PCR was associated with significantly shorter turnaround times than chromogenic agar for both positive (median: 13.0 vs. 19.5 hours) and negative results (median: 16.5 vs. 42 hours) *(46)*. Reducing the time to a negative test result may be particularly valuable in healthcare facilities in which patients are empirically placed on Contact Precautions pending MRSA testing results. Although PCR-based testing has a number of potential advantages, including high sensitivity and negative predictive values and a rapid turnaround time, the cost of these assays is substantially higher than that of culture-based screening methods. These higher direct laboratory costs may potentially be offset by more effective use of isolation precautions and enhanced prevention of MRSA transmission *(315,316)*, but this has not been observed in all settings *(317)*. The clinical and economic benefits of rapid testing likely vary among populations and settings due to a variety of factors, including the prevalence of MRSA and adherence to infection prevention measures.

Management of Patients with Pending Results When planning an MRSA active surveillance program, a facility must determine how it will manage patients while awaiting the results of the surveillance test. The two major options are implementation of Contact Precautions only for those patients with a positive surveillance test and empiric implementation of Contact Precautions for all screened patients with discontinuation of precautions if the test is negative. The first option is used by the majority of active surveillance programs in the United States. This is likely because it is logistically simpler in many settings, particularly those in which the prevalence of MRSA is low. The major disadvantage of this approach is that it allows opportunities for MRSA transmission during the period between specimen collection and availability of a positive test result. Although this period for potential transmission from unrecognized sources may be minimized by the use of more rapid testing methods *(46)*, such as chromogenic agar or PCR, environmental contamination of the patient's

room has been shown to occur quickly, in many cases prior to the availability of screening test results, even with the use of rapid tests such as PCR *(318)*. Thus, if transmission of MRSA continues in a healthcare facility that is using this approach and another explanation for ongoing transmission cannot be identified, empiric use of Contact Precautions while awaiting the result of surveillance testing could be considered. In fact, empiric use of Contact Precautions has been associated with control of MRSA outbreaks in high prevalence settings *(288)*. The potential benefits of this approach should be considered in the context of the logistic difficulties and resource requirements associated with it. This approach may be logistically quite difficult in facilities or areas of facilities in which single rooms are scarce. In such settings, it may be reasonable to prioritize the available single rooms for those patients with proven infection or colonization with MRSA or other multi-drug resistant microorganisms or with other documented needs for a single room. Similarly, when the number of single rooms is insufficient, patients empirically placed in a single room who are subsequently found to have a negative screening test result will need to be relocated. Such relocations increase the resources needed for room cleaning and may interrupt patient flow in the facility. This approach may be most feasible in facilities or settings (e.g., some ICUs and some newer hospitals) in which a relatively large proportion of patient rooms are single rooms.

Active Surveillance among Healthcare Personnel As described above, testing HCPs for MRSA carriage has been useful in some outbreak investigations, leading to identification and elimination of presumed sources of MRSA transmission. One review of HA-MRSA outbreaks determined that 4.2% of 191 reported outbreaks were attributable to HCPs with MRSA infection and that an additional 1.6% of the outbreaks were attributable to HCPs who were asymptomatic carriers of MRSA *(319)*. The authors concluded that limiting screening to HCPs with evidence of active infection may be a more effective approach to identification of a healthcare worker source than screening all HCPs. A similar review, however, determined that a substantially larger proportion of HA-MRSA outbreaks was attributable to asymptomatic carriage of MRSA by HCPs *(132)*. Current recommendations for the prevention of MRSA transmission in acute-care hospitals from the CDC (251) and other groups (194,*252*) recommend screening HCPs for MRSA colonization if they are epidemiologically linked to new cases of MRSA or in the setting of ongoing transmission of MRSA despite active control measures, regardless of the presence or the absence of signs and symptoms of MRSA infection. In the Netherlands, a country with a very low prevalence of HA-MRSA, screening for MRSA carriage is conducted among HCPs who have had contact with an MRSA colonized or infected patient and those who have been hospitalized in or have worked in a hospital in a foreign country (Infection Prevention Working Party; *www.wip.nl/UK/free_content/Richtlijnen/MRSA%20hospital.pdf*). Routine screening for MRSA among HCPs outside of the outbreak setting, however, has not been included in guidelines and recommendations from countries in which MRSA is endemic within the healthcare system. This is likely due to a lack of strong data indicating that asymptomatic carriers of MRSA play a significant role in MRSA transmission in the endemic setting and a variety of logistic and financial considerations. When screening of HCPs is performed, whether in the outbreak or the endemic setting, specimens should be obtained prior to the beginning of a shift, rather than at the end of a shift, in order to better distinguish between transient and persistent carriage.

Routine Patient Bathing with Chlorhexidine Routine bathing of patients with a chlorhexidine soap has been the focus of recent reports designed to describe the effect of such on acquisition or transmission of MRSA and VRE *(320–322)*, infection rates due to MRSA and VRE *(320,321)*, as well as the incidence of CLABSI due to all microorganisms *(323–326)*. Its use is primarily based on the fact that colonized patients are at risk for developing infection, as well as serve as a reservoir for transmission of microorganisms to other patients via contamination of their surroundings and the hands of HCP. A variety of chlorhexidine products are available for patient bathing and manufacturers' directions should be followed, contact with the eyes and middle ear should be avoided, and the patient should be monitored for adverse skin effects such as fissures, rash, burning sensation, and itching (194). The use of chlorhexidine for routine patient bathing has been primarily studied in the adult ICU population, and primarily for CLABSI prevention *(320,321,323–325)*. For example, routine daily use of 2% chlorhexidine bathing was associated with a decrease in CLABSI in one study among patients of a 22-bed medical ICU by 61% (10.4 BSI per 1,000 patient days among those bathed with soap and water vs. 4.1 BSI per 1,000 patient days among those bathed with chlorhexidine; $p = .01$) *(325)*, and by 87% in another study among patients in a 21-bed medical ICU (5.31 BSI per 1,000 catheter days among those bathed with soap and water vs. 0.69 BSI per 1,000 catheter days among those bathed with chlorhexidine; $p = .006$) *(324)*. Another study among trauma ICU patients found that compared to baseline, when patients did not receive chlorhexidine baths, those bathed with 2% chlorhexidine were significantly less likely to acquire a CLABSI (8.4 vs. 2.1 per 1,000 catheter days; $p = .01$); although there was no difference in the overall rate of VAP between the two time periods, there was a significant reduction in MRSA VAP among patients bathed with chlorhexidine (5.7 vs. 1.6 infections per 1,000 ventilator days; $p = .03$) *(321)*. An additional study using time series analysis to evaluate the use of 2% chlorhexidine baths among patients in a long-term acute care hospital reported that compared to the preintervention period (soap and water baths), by the end of the intervention period (chlorhexidine baths), there was a net reduction of 99% in the CLABSI rate *(326)*.

Data also exist regarding the use of chlorhexidine baths for control of MRSA acquisition and transmission *(320–322,324,326)*; however, in some of these studies, this was not the primary outcome and as such, they were not powered to adequately assess effectiveness *(324,326)*. Climo and colleagues conducted a quasiexperimental multicenter trial where, among other outcomes, the incidence of MRSA colonization and BSI was assessed during a time period where all patients admitted to the participating ICUs received daily bathing with 4% chlorhexidine. The overall rate of MRSA acquisition decreased 32% (5.04 vs. 3.44 cases per 1,000 eligible patient days; $p = .046$), and the

risk of acquiring MRSA was significantly lower for patients bathed with chlorhexidine (p = .024). Furthermore, for patients who were in the ICU longer than 10 days, 4.37% of those bathed with chlorhexidine acquired MRSA compared to 9.93% of those bathed with soap and water (RR, 0.58; 95% CI, 0.351–0.968; p = .02). Time series analysis revealed that by the end of the intervention period there was a 25% decrease in the incidence of MRSA attributable to the use of chlorhexidine bathing. In this study, there was a low rate of MRSA bacteremia over the entire study period that prevented accurate comparisons *(320)*. Similarly, Evans and colleagues reported that during the time period where patients were bathed with 2% chlorhexidine, the rate of MRSA colonization significantly decreased (23.3 vs. 69.3 cases per 1,000 patient days; $p < .001$) and that protection against MRSA colonization was apparent 4 or more days after admission to the ICU. The probability of MRSA colonization was nearly threefold higher in the baseline period compared to the chlorhexidine bathing period (HR, 2.9; 95% CI, 1.4–4.5; p = .02) *(321)*. More often, the use of chlorhexidine baths has been studied as a component of a more comprehensive decolonization protocol, usually with intranasal mupirocin with or without systemic anti-MRSA antibiotic therapy, to eradicate MRSA colonization among patients in healthcare facilities or among patients who are scheduled to have elective surgery to prevent infection. These uses are discussed in the following section.

MRSA Decolonization Therapy for MRSA-Colonized Persons MRSA decolonization therapy has been studied as a means to eradicate, or at least transiently suppress, the MRSA carrier state to assist in prevention of transmission within a healthcare facility or to reduce the risk for MRSA infection among an MRSA-colonized patient. The optimal decolonization regimen has not been determined; however, most of the experience has been with topical administration of intranasal mupirocin with or without chlorhexidine bathing and occasionally with systemic antimicrobials directed toward MRSA.

The effectiveness of topical decolonization therapy on eradication of the carrier state has varied substantially from just 8% to 72.3% depending on the patient population under investigation *(327–329)*. For example, in a randomized, placebo-controlled study designed to evaluate the effectiveness (MRSA free at 30 days) of adding chlorhexidine body washes to nasal mupirocin and chlorhexidine mouth rinse among colonized university hospital and nursing home patients, the effectiveness was only 8% (4 of 48) *(328)*. Multivariate analysis revealed that colonization in the groin, perineum, or at more than one body site was associated with decolonization failure. Robicsek and colleagues reported the success of topical decolonization among colonized patients found through active surveillance in three hospitals in the Chicago area. In a group of 407 patients who were tested for recolonization at the time of a readmission, 47.8% of those who had received any amount of decolonization therapy were still MRSA-colonized compared to 63.2% of those who did not receive any therapy (p = .007) *(327)*. Residence in an LTCF, presence of a pressure ulcer, and high-level mupirocin resistance predicted persistent MRSA colonization. In another study where MRSA colonized patients received topical decolonization therapy and were followed with weekly surveillance cultures, a mean of 72.3% of patients had negative follow-up cultures *(329)*.

The addition of systemic antimicrobials to topical therapy has reported consistently higher decolonization rates ranging from 54% to more than 90% *(330–333)*. A recent prospective cohort study utilizing oral vancomycin and cotrimoxazole along with topical decolonization reported that decolonization was successful in 87% in the intention-to-treat group and in 98% among those in the on-therapy group. Of note, patients could receive repeated courses of therapy as needed if they remained MRSA positive *(331)*. Simor conducted a randomized controlled trial to assess the effectiveness of topical decolonization therapy accompanied by oral rifampin and doxycycline. At the time of 3-month follow-up, 74% who were randomized to therapy remained MRSA negative compared to 32% of those not treated (p = .0001); however, at 8 months only 54% remained MRSA free. Multivariate analysis revealed that mupirocin resistance at baseline was associated with decolonization failure *(333)*.

The use of MRSA decolonization therapy in conjunction with active surveillance has also been reported for prevention of MRSA transmission within a hospital *(322,330,334–337)*. Ridenour and colleagues reported on the use of decolonization therapy (topical only) among patients in a medical/coronary ICU found to be MRSA positive with active surveillance. Incident cases of MRSA colonization or infection decreased by 52% (8.45 vs. 4.05 per 1,000 patient days; p = .048), and no increase in chlorhexidine or mupirocin resistance was found *(334)*. A similar approach was utilized by Gould among ICU patients. By time series analysis, the proportion of patients with MRSA significantly decreased and the authors stated that treatment of 11 patients prevented one clinical case of MRSA *(337)*. Bowler et al. reported on the use of active surveillance and a more complicated decolonization protocol consisting of an initial phase of systemic antibiotics and topical therapy followed by a continuation phase of topical therapy during the first 5 days of the month. After 12 months of utilizing this approach, the prevalence of MRSA colonization in nursing homes decreased from 12% to 4% ($p < .001$), and the incident rate for HA-MRSA infection decreased from 0.64 to 0.32 per 1,000 patient days, ($p < .01$) *(330)*. Another recent prospective study utilizing time series analysis to assess the effectiveness of decolonization therapy and active surveillance on MRSA acquisition of an endemic and an epidemic strain in an ICU population reported an immediate 70% reduction in acquisition of endemic MRSA and an increase in the outbreak MRSA strain. Interestingly though, all of the outbreak strains tested revealed that they had the *qac*A/B gene conferring resistance to chlorhexidine compared to only 5% of the endemic strains *(322)*. Others have reported decreases in HA-MRSA infections with the use of decolonization therapy among neonatal ICU populations *(335)*, and among hospitalized adults *(327)*.

Decolonization therapy has also been used in certain MRSA-colonized patient populations in a direct attempt to reduce the risk of subsequent MRSA infection. This has been successful in preventing CLABSI among hemodialysis patients *(338)* as well as SSI for those undergoing cardiac and orthopedic procedures (*339–342*,343). A recent

Cochrane review found that mupirocin ointment applied to the catheter's exit site at the time of dressing change among colonized hemodialysis patients was protective against CLABSI (RR, 0.17; 95% CI, 0.07–0.43); however, no other decolonization agents such as topical chlorhexidine were studied *(338)*. Jog et al. conducted an observational cohort study of cardiac surgery patients. A rapid PCR test was used preoperatively to screen patients for MRSA colonization and carriers were treated with nasal mupirocin ointment and topical triclosan for 5 days, with single-dose teicoplanin instead of flucloxacillin as perioperative antibiotic prophylaxis. Compared to those who did not receive this decolonization therapy, those who did had a significant reduction in MRSA SSI (RR reduction, 0.77; 95% CI, 0.056–0.95) *(341)*. Rao and colleagues conducted a prospective observational study of patients undergoing elective total joint arthroplasty. Patients were screened preoperatively for *S. aureus* and carriers were decolonized with mupirocin ointment and chlorhexidine baths for 5 days before surgery. Those colonized with MRSA had vancomycin added to their preoperative prophylaxis. All 164 carriers (147 with MSSA and 17 with MRSA) completed the decolonization protocol and had no postoperative *S. aureus* SSIs at 1-year follow-up. In contrast, 1,330 concurrent control patients who did not undergo decolonization had 12 *S. aureus* infections (seven MSSA infections and five MRSA infections) *(342)*.

Widespread use of chlorhexidine to prevent colonization or infection has caused some to speculate on whether there is the potential for the emergence of resistant strains. This has been addressed only rarely in studies evaluating the effectiveness of chlorhexidine use with regards to MRSA control *(322,325)*. Increased minimum bactericidal concentrations (MBCs) to chlorhexidine is thought to occur due to strains with plasmid-borne *qac*A/B genes that code for multidrug efflux pumps. Such strains have two- to fourfold increases in these MBCs, although this seems to be well below the expected concentration of the antiseptic used to treat patients *(322)*. Beasdale reported that among 57 of 64 isolates available for chlorhexidine susceptibility testing, the median chlorhexidine minimum inhibitory concentration was slightly higher for isolates from patients bathed with chlorhexidine compared to those from patients bathed with soap and water (2 vs. 1 μg/mL; $p = .06$), and this was attributed to the less frequent recovery of highly chlorhexidine susceptible, gram-positive bacteria among patients bathed with chlorhexidine for prevention of BSI *(325)*. As mentioned above, Batra and colleagues reported failure to control MRSA using chlorhexidine due to a high prevalence of resistant strains. The authors cautioned the widespread use of chlorhexidine in areas where the prevalence of *qac*A/B is known to be high *(322)*.

As discussed above, decolonization therapy can be successfully utilized as a control measure for MRSA transmission and infection; however, a recent editorial on the subject described the emergence of both low-level mupirocin resistance mediated by a mutation in *ileS* gene and high-level mupirocin resistance mediated by the plasma-encoded *mupA* gene. The author suggested that institutions and investigators considering decolonization protocols with mupirocin should develop a strategy to monitor resistance *(344)*.

SUMMARY

MRSA is a common healthcare-associated pathogen that is capable of causing a variety of infectious disease syndromes often associated with substantial morbidity and mortality. The epidemiology of MRSA in healthcare has recently been further complicated by the emergence of MRSA as a common cause of community-associated infections. Several decades of research, observation, and experience have resulted in the development of a large body of knowledge regarding the pathogenesis, epidemiology, detection, and outcomes of MRSA infection. Similarly, much has been learned about preventing transmission of and infection with MRSA. Reductions in MRSA transmission have been associated with general infection control measures, such as hand hygiene, and with MRSA-specific preventive measures, including active surveillance to detect asymptomatic carriers of MRSA. Prevention of invasive MRSA infection has been associated with the implementation of interventions to prevent device- and procedure-associated infections (e.g., prevention of CLABSI through implementation of the "central line bundle") as well as interventions designed specifically to reduce the risk of MRSA infection among asymptomatic carriers of the microorganism (e.g., MRSA "decolonization" or "suppression" therapy). While numerous studies have demonstrated reductions in the burden of MRSA infection in individual healthcare facilities following the introduction of various preventive measures, data from several Northern European countries and, more recently, the United Kingdom and the United States (345,346) suggest that prevention of MRSA infections is also possible in larger populations. These observations highlight the value of continuing and expanding current efforts to prevent HAI, including those caused by MRSA.

CHAPTER 30

Coagulase-Negative Staphylococci

Wilma Ziebuhr and Ursula Flückiger

Coagulase-negative staphylococci primarily reside on the healthy human skin and mucosa, and as commensals they are considered to exhibit a low pathogenic potential. Indeed, coagulase-negative staphylococci rarely cause disease in immunocompetent individuals outside of hospitals. In recent decades, however, these bacteria have emerged as common causes of various healthcare-associated infections, preferentially in immunocompromised, long-term hospitalized, and critically ill patients *(1)*. Coagulase-negative staphylococci are regarded as bacteria associated with medical progress as the vast majority of infections are linked to the use of indwelling medical devices such as intravascular and intrathecal catheters systems, pacemaker electrodes as well as urinary tract catheters, and a range of other polymer and metal implants *(2)*. Until the 1970s, coagulase-negative staphylococci did not play a significant role as pathogens. In the National Nosocomial Infections Surveillance (NNIS) report of the Center for Disease Control and Prevention (CDC) in 1979, *Staphylococcus epidermidis*, the predominant coagulase-negative staphylococcal species, accounted for <4% of the pathogens causing healthcare-associated infections *(3)*. From the 1980s onward, this situation changed dramatically and, depending on the site of infection coagulase-negative staphylococci represent now common, if not the most common, healthcare-associated pathogens. Thus, the 2008 annual update of the National Healthcare Safety Network (NHSN) found coagulase-negative staphylococci among the 10 most common pathogens accounting for 84% of all healthcare-associated infections (15% coagulase-negative staphylococci; 15% *Staphylococcus aureus*; 12% *Enterococcus* species; 11% *Candida* species; 10% *Escherichia coli*; 8% *Pseudomonas aeruginosa*; 6% *Klebsiella pneumoniae*; 5% *Enterobacter* species; 3% *Acinetobacter baumannii*; and 2% *Klebsiella oxytoca*) *(4)*. In central-line-associated bloodstream infections (BSI), coagulase-negative staphylococci rank first (*5–7*,8), and second in surgical-site infections *(9)*. Healthcare-associated isolates of coagulase-negative staphylococci exhibit alarmingly high antibiotic resistance rates. In the United States, 89.1% of coagulase-negative staphylococci associated with healthcare-associated infections in intensive care units were found to be methicillin resistant *(10)*. In the United Kingdom and Ireland, methicillin resistance among coagulase-negative staphylococci ranges between 54% and 80% *(11)*, and similar figures have been reported for other countries as well *(12,13)*. As methicillin resistance is strongly associated with resistance against other groups of antibiotics, treatment of coagulase-negative staphylococcal infections is complicated and infections can be expected to increase morbidity and mortality rates and to contribute to the economic burden of healthcare-associated infections in general *(11,14,15)*.

Despite this striking overall impact on healthcare-associated infections, diagnosis of coagulase-negative staphylococcal infections often remains ambiguous and challenging. Due to the ubiquitous nature of coagulase-negative staphylococci as skin and mucosa colonizers, it is often difficult for clinicians to decide whether an isolate represents the causative agent of an infection or a non-specific contamination of a clinical specimen. Also, other than their highly pathogenic cousin *S. aureus*, coagulase-negative staphylococci are often regarded as relatively harmless bacteria and are not taken seriously enough as pathogens in daily routine to prompt immediate action. This may be due to the fact that, in comparison to many other bacterial pathogens, knowledge of coagulase-negative staphylococci virulence-associated factors, pathogenesis, genome evolution, and epidemiology was limited for a very long time. Most recent progress in genome research and molecular epidemiology, however, provided exciting novel insights into the biology of these bacteria. This chapter gives a synopsis on the most common coagulase-negative staphylococcal infections and summarizes, in addition to classical microbiological methods, recent trends in diagnosis, characterization, and typing of coagulase-negative staphylococci. A special emphasis is on the genomics and molecular pathogenesis of coagulase-negative staphylococcal infections as well as current concepts that might help to explain the establishment of these bacteria as successful healthcare-associated pathogens and their spread in hospital settings and beyond.

INFECTIONS CAUSED BY COAGULASE-NEGATIVE STAPHYLOCOCCI

Coagulase-negative staphylococci cause a variety of clinical infections, mainly in the presence of foreign material. Immunocompromised patients, particularly those with

severe neutropenia, are specifically at risk of bacteremia caused by these microorganisms (16). Several studies have demonstrated that colonization of the nasopharynx, rectum, or skin by coagulase-negative staphylococci precedes the development of bacteremia, and chemotherapy-induced breaks of the normal mucosa and skin barriers as well as placement of medical devices often represent typical entry sites for the bacteria *(17)*.

Bloodstream Infection due to Coagulase-Negative Staphylococci

In microbiological surveillance programs, coagulase-negative staphylococci belong together with enterobacteria and *S. aureus* to the most frequently isolated pathogens of BSI and to the leading microorganisms causing healthcare-associated BSI with 30% to 37% of all positive blood cultures being obtained in healthcare settings *(18–21)*. While in outpatients the isolation of coagulase-negative staphylococci is rarely of clinical significance, coagulase-negative staphylococci have emerged in the healthcare-associated setting as a major cause of healthcare-associated bacteremia, especially in immunocompromised patients who have indwelling or implanted medical devices. As coagulase-negative staphylococci and in particular *S. epidermidis* belong to the normal microflora of the skin, they are also often found as contaminants of blood culture specimens. The contamination rate of positive blood cultures is approximately 2% to 3%, and most contaminations are indeed due to coagulase-negative staphylococci *(22)*. To determine whether a coagulase-negative staphylococcal isolate represents a true pathogen causing bacteremia or contamination is often difficult and has also financial impacts. Thus, misdiagnosis of bacteremia due to contaminated blood cultures and subsequent unnecessary treatment of patients were shown to prompt estimated additional costs of $1,000 per patient *(23)*. To date, there is no single criterion with sufficient specificity to predict true bacteremia. Instead, several parameters such as more than one positive blood culture bottle, capability of coagulase-negative staphylococci to produce biofilm, time to positivity of samples, laboratory markers, and clinical signs of septicemia were proposed as predictive markers *(24–27)*. In this regard, fever or other signs of infection in conjunction with detection of coagulase-negative staphylococci in a blood culture sample are of notoriously unreliable discriminating value as presence of the bacteria might both be due to contamination and infection. Therefore, the time to sample positivity and the number of positive blood culture bottles represent better criteria to determine clinically significant BSI. Although some conflicting data have been obtained suggesting that the predictive value of the number of positive blood culture bottles is low *(28)*, most clinical studies use this criterion to discriminate between infection and contamination. Also, the time to positivity of blood culture samples might be helpful in this respect. Thus, it was found that a medium time to positivity of more than 22 hours had a positive predictive value of 87% for diagnosing a contamination *(24)*. This approach is particularly useful in neonates and preterm infants where it is not feasible to obtain more than one blood culture bottle for culturing. In general, blood cultures should be taken using aseptic techniques and, if a central line is present, paired cultures through the central line and through a peripheral vein should be taken (see below). The site and time of sampling should be recorded. Patients with clinical signs of infection, with multiple positive blood cultures and growth within <24 hours have a high likelihood of true bacteremia due to coagulase-negative staphylococci.

Catheter-Related Bloodstream Infections

CRBSI are by far the most common complication in immunocompromised, hospitalized patients. In the United States, each year more than 150 million intravascular devices are purchased and about 80,000 CRBSIs occur. Recently, guidelines for the diagnosis and management of these infections have been revised and published *(29)*. The sources of CRBSI are usually the insertion site, the hub, or both and coagulase-negative staphylococci are the leading pathogens causing CRBSIs *(30)*. Diagnosis of true bacteremia versus contamination in the presence of a central line is extremely difficult and requires a thorough workup. A mathematical model was established to calculate the predictive values for true bacteremia in blood cultures positive for coagulase-negative staphylococci in patients with central venous lines *(26)*. The positive predictive value is 98% if both blood cultures were obtained through a peripheral vein, and 96% if one sample is obtained through the catheter and the other by a vein, and only 50% if both bottles were sampled through the catheter. Thus, in the presence of a central line, it is important to draw blood culture through a peripheral vein (optimal 2×2, but at least 1×2 bottles) in order to diagnose a true BSI. To distinguish between intravascular catheter-associated bacteremia and bacteremia from other sources, the time to positivity from bottles drawn through the catheter and through a peripheral vein can be used. Nowadays, most clinicians take advantage of automated blood cultures systems and use a 2-hour cut-off differential time to positivity of blood cultures drawn from the periphery and the catheter to diagnose CRBSI. The catheter is regarded as the source of positive blood cultures when the catheter blood is positive two or more hours before the peripheral blood *(31)*. If the catheter is removed, a 5-cm segment of the tip should be sent for culture. Growth of more than 15 colony-forming units (CFU) from the catheter tip by semiquantitative (roll plate) culture or growth of more than 10^2 cfu from a catheter by quantitative (sonication) broth culture suggests catheter colonization. When there are positive blood cultures with a 2-hour differential time to positivity between the central line sample and the peripheral blood culture, the diagnosis of CRBSI can be established.

Endocarditis

Coagulase-negative staphylococci are more often found as causative microorganisms in prosthetic valve endocarditis (PVE) than in native valve endocarditis (NVE). However, the number of NVE due to coagulase-negative staphylococci is currently rising, as shown in a recent multicenter study where 8% of NVE were found to be due to these bacteria *(32)*. Patients with a history of healthcare contact are particularly at risk. Coagulase-negative staphylococcal endocarditis on native valves is found in patients receiving long-term hemodialysis or with pacemakers and/or implantable defibrillators, with long-term catheters or with

a history of a recent surgical procedure. Mortality is high (25%), which is probably also associated with the underlying chronic diseases in these patients *(32)*. In PVE, coagulase-negative staphylococci are isolated as causative pathogens in 15% to 40% of the cases. Infections are usually healthcare-associated and occur within 12 months of valve replacement *(33–35)*. Patients present with prolonged symptoms (>1 month) of weakness and low-grade fever. The modified Duke criteria are applied to diagnose infective endocarditis *(36)*, which include, among other factors, positive blood cultures and typical echocardiographic findings.

Infections of Cardiac Devices

Infections of cardiac electrophysiological devices (pacemakers, defibrillators) occur in up to 4% (reviewed in *(37)*) and are in 50% to 60% due to coagulase-negative staphylococci *(38,39)*. Patients present often with pocket site inflammation, mostly within 1 month of insertion but also delays of up to 2 years. Systemic symptoms may be absent. Diagnosis is based on tissue cultures of the pocket, cultures of the devices and multiple blood cultures. In many cases, successful treatment is only possible when the infected device is completely removed and a new device is inserted at a new site.

Sternum Osteomyelitis After Cardiac Surgery

Deep sternal wound infection (DSWI) is an infrequent but severe complication after cardiac surgery with reported incidence rates between 1% and 2% and mortality rates between 10% and 20% *(40–45)*. Clinical manifestations of DSWI are variable. Wound discharge, pain, tenderness, and sternal instability are the most common local signs, whereas fever, sepsis, and elevation of inflammatory parameters are less frequently reported. Most common causative microorganisms are coagulase-negative staphylococci and *S. aureus*, followed by gram-negative bacteria and fungi *(46–48)*. In a recently published study, the causative microorganism of DSWI was identified in 86% of superficial swabs, in 94% of deep swabs, and in 88% of sternal biopsies performed before empirical antibiotic treatment was started. In 60 patients from whom results both of superficial and deep swabs were available, agreement between both specimens was observed in 77% of patients with *S. aureus* and in 68% of those in which coagulase-negative staphylococci were detected *(49)*.

Prosthetic Joint Infections

Prosthetic joint replacement is increasingly used to relieve pain of osteoarthritis and to improve mobility. The average infection rate of joint prosthesis is about 2% (reviewed in (*37*)). Risk factors for infections are previous joint surgery, a perioperative wound complication, and rheumatoid arthritis, the latter being associated with infection rates of nearly 4% *(50)*. The most common microorganisms are coagulase-negative staphylococci, mostly *S. epidermidis* (30%–34%) and *S. aureus* (12%–23%), followed by mixed bacterial infections (10%), streptococci, and other microorganisms *(51)*. Infections associated with prosthetic joint replacement are classified as early (<3 months after surgery), delayed (3–24 months after surgery), or late onset (>24 months after surgery) *(52,53)*. Early- and delayed-onset infections are usually acquired during implantation. In contrast, late-onset infections are mainly due to hematogenous spread of virulent strains such as *S. aureus*, streptococci, or gram-negative bacilli and are rarely caused by coagulase-negative staphylococci. Infections due to coagulase-negative staphylococci can occur early or delayed and manifest with more subtle signs and symptoms. Early infections often present with a history of wound healing complications, purulent secretion at the incision site, and slightly elevated laboratory parameters of inflammation may occur. Delayed infection up to 24 months after surgery may present with persistent joint pain and/or signs of implant loosening, which may be difficult to distinguish from aseptic loosening or with a sinus tract *(51,54,55)*. The diagnosis of prosthetic joint infection is not uniformly established. Detection of coagulase-negative staphylococci may represent either contamination or a true pathogen. Growth of the same microorganism in two or more cultures of synovial fluid or periprosthetic tissues, short time to positivity, a positive Gram stain, the presence of inflammation on histopathological examination, or presence of a sinus tract may help to diagnose an infection *(53)*. Moreover, the recovery of microorganisms can be optimized by sonication of the prosthesis at the time of removal *(56)* and help to verify a true infection (see Chapter 65).

Other Infections

In general, all types of biomaterial or medical devices inserted across the skin or mucous membranes can become colonized and, thereafter, infected by coagulase-negative staphylococci. Thus, meningitis and encephalitis are the most serious complications associated with cerebrospinal fluid shunt implantation *(57–59)*. Other device-related infections that are often caused by coagulase-negative staphylococci and specifically *S. epidermidis* are peritoneal dialysis catheter-associated infections, infections of genitourinary prostheses, and infections of breast implants *(60)*. Since it is not rare nowadays that a patient has, at the same time, for example, a pacemaker, a hip prosthesis, and a vascular graft, it is anticipated that we will observe in the near future a significant increase in device-related coagulase-negative staphylococcal infections.

MICROBIOLOGY

The Genus *Staphylococcus* and Coagulase-Negative Staphylococcal Species

Microorganisms of the genus *Staphylococcus* are nonmotile gram-positive, spheroid bacteria that appear in irregular clusters. They are catalase-positive, lysostaphin susceptible, and have a G + C content ranging between 30% and 40%. Except for a few species that grow exclusively under anaerobic conditions, staphylococci are facultative anaerobes, capable of both aerobic and fermentative metabolism (61). The overall cell wall structure of staphylococci corresponds in general to that of other gram-positive bacteria with some notable characteristics. Thus, in staphylococci, the short peptides that crosslink the heteropolymer glycan chains of the murine, contain glycine residues, which are the targets of the endopeptidase lysostaphin *(62)*. Lysostaphin disrupts the staphylococcal cell wall specifically and the enzyme can therefore be used to distinguish staphylococci from other gram-positive cocci such as micrococci and streptococci (61). The cell wall of many

staphylococcal species is resistant to lysis by lysozyme that normally attacks the β-1,4-glycosidic bonds in the peptidoglycan chains. Lysozyme resistance in staphylococci was found to be based on O-acetylation of the muramic acid of the peptidoglycan, specifically in human pathogens such as *S. aureus*, *S. epidermidis*, and *Staphylococcus lugdunensis (63,64)*. Currently, the genus *Staphylococcus* comprises 47 species and 11 subspecies (Table 30-1). Classification of staphylococci is traditionally based on the production of coagulase, an enzyme that binds fibrinogen and mediates its conversion into fibrin, resulting eventually in blood plasma coagulation. In addition to the major coagulase-positive pathogen *S. aureus*, six other coagulase-positive species have been described that mainly play a role in veterinary medicine (Table 30-1) *(112)*. Among the 41 coagulase-negative species, *S. epidermidis* is the most common one with a broad pathogenic potential causing a wide variety of infections. Other coagulase-negative species involved in human disease are *Staphylococcus haemolyticus*, *Staphylococcus saprophyticus*, *Staphylococcus capitis*, *S. lugdunensis*, *Staphylococcus hominis*, *Staphylococcus warneri*, *and Staphylococcus schleiferii*. The natural reservoir of all staphylococci is the skin and the mucosa of humans and animals where the bacteria mostly reside as harmless and benign commensals. Some species were recovered from processed food or environmental samples and are traditionally used in food industry (e.g., *Staphylococcus carnosus*, *Staphylococcus piscifermentans*). In humans, microbial ecology of staphylococcal species varies individually and also depends on the body site. Thus, *S. aureus* prefers to colonize the anterior nares and the nasopharynx, but only 20% of healthy adults are permanently, and another 60% are transiently colonized by *S. aureus (113)*. In contrast, all human beings are persistently colonized by coagulase-negative staphylococcal species. *S. epidermidis* is the species that occurs in abundance. It colonizes preferentially the upper part of the body, including the nasopharynx, and constitutes over 50% of the resident staphylococci *(114)*. Other coagulase-negative species have adapted to distinct ecological niches and can be recovered from specific parts of the skin (e.g., *S. saprophyticus* from the perineum, *S. capitis* from the scalp, *Staphylococcus auricularis* from the external ear, *S. haemolyticus* and *S. hominis* from the axilla as well as the pubic and the perineal region, respectively).

Species Identification of Coagulase-Negative Staphylococci

In the early days of microbiological diagnostics all non-*S. aureus* staphylococci were referred to as *Staphylococcus albus*. Later, these isolates were differentiated into *S. epidermidis* and *S. saprophyticus*, a diagnosis that was mainly based on the novobiocin resistance of the latter. All other coagulase-negative species were subsumed as *S. epidermidis*, as the diversity of the genus was largely unknown at that time. Only upon introduction of phenotypic typing schemes in the late 1960s and early 1970s, the situation changed and a large number of novel species were identified in the following years *(75,82)*. However, coagulase-negative staphylococcus species definition was still reserved to specialized laboratories and was rarely performed in routine diagnostics. Nowadays, staphylococcal species determination is based on combinations of various phenotypic and genotypic tests that are widely available to most laboratories. However, depending on the clinical situation, an exact species determination is not always performed. A coagulase-negative species is only reported as such when the appropriate tests have been performed. All other isolates are referred to as "coagulase-negative staphylococci." Species identification in the routine laboratory

TABLE 30-2

Genotypic Methods for Species Identification of Coagulase-Negative Staphylococcal Species

	Target(s)	*Reference*

β-Subunit of RNA polymerase	*rpoB*	*(130,131)*

initiates with a variety of phenotypic tests, first of all to differentiate between coagulase-negative staphylococci and *S. aureus*. Slide-agglutination tests are performed to detect *S. aureus*–specific clumping factor, and other cell wall–associated proteins of *S. aureus*. As slide agglutination occasionally provides ambiguous results, the classical coagulase test mentioned above may be performed as well. Putative coagulase-negative staphylococcal species are then further examined for their colony morphology, growth requirements, oxidative and fermentative utilization of carbohydrates, novobiocin susceptibility, and various enzymatic activities (e.g., nitrate reductase, alkaline phosphatase, urease, ornithine decarboxylase, arginine dehydrogenase, etc.) (61). A variety of commercial test kits such as the API 20 Staph and API ID32 Staph systems (bioMerieux), the Staph-Zym (Rosco) or the Vitek system (bioMerieux) are available that combine detection of most of these phenotypic properties and allow for a rapid and convenient identification in the routine diagnostic laboratory. However, phenotypic tests have an inherent weakness as they rely on the expression of the phenotypic characteristic in question, and in coagulase-negative staphylococci these properties may vary within isolates belonging to the same species (115,*116,117*). Thus, DNA-based genotyping methods become increasingly important for an expression-independent species identification of coagulase-negative staphylococci *(118)*. These methods target highly conserved species-specific DNA loci and genes that are PCR-amplified and subjected to either DNA-fragment pattern comparison or DNA sequencing. PCR-based approaches include ribotyping, amplified-fragment-length-polymorphism (AFLP), and tRNA-locus-interspacer-length-polymorphism (tDNA-ILP) analyses (Table 30-2). DNA sequencing of amplified 16S rRNA DNA loci is the most common method for species identification across many bacterial genera *(122)*. Due to the close relatedness of some coagulase-negative staphylococcal species, the method may not have, in all cases, sufficient discriminatory power *(126)*. Therefore, DNA sequencing of a range of housekeeping genes has been implemented to complement 16S rRNA locus analysis (see Table 30-2 for details and references). In general, genotyping methods are considered to be superior to mere phenotyping for coagulase-negative *Staphylococcus* species definition. With the increasing availability and cost effectiveness of molecular techniques in diagnostic laboratories, accurate species identification of coagulase-negative staphylococci can be anticipated to become a routine procedure. This most welcome development in microbiological diagnostics will surely shed more light on the association of specific coagulase-negative staphylococcal species with distinct infection processes.

Antibiotic Resistance among Coagulase-Negative Staphylococci

Coagulase-negative staphylococcal isolates recovered from hospital-acquired infections are notoriously antibiotic resistant, and in many medical facilities multiresistance rates exceed those of *S. aureus*. Figure 30-1 exemplifies the steady increase of multiresistance rates among coagulase-negative staphylococci in Europe in the period from 1990 to 2007, and similar numbers have been reported from other countries worldwide *(10–12,132)*. The classical antistaphylococcal β-lactam antibiotic penicillin G, which inhibits cell wall synthesis by binding to penicillin-binding proteins, is practically no longer suitable to treat staphylococcal infections as approximately 90% of all isolates are nonsusceptible to the antibiotic. Penicillin G resistance is caused by enzymatic destruction of the antibiotic through a staphylococcal β-lactamase that is mostly plasmid encoded and now widespread among staphylococci. But resistance rates toward alternative antibiotics such as methicillin/oxacillin, gentamicin, macrolides, and fluoroquinolones are also alarmingly high (Fig. 30-1). The molecular and genetic basis of resistance against some of these compounds is briefly discussed here.

Methicillin Resistance Methicillin and oxacillin are β-lactam antibiotics that withstand the action of staphylococcal β-lactamases. They were introduced into clinical practice in the early 1960s to overcome β-lactamase-producing *Staphylococcus* strains. However, methicillin/oxacillin

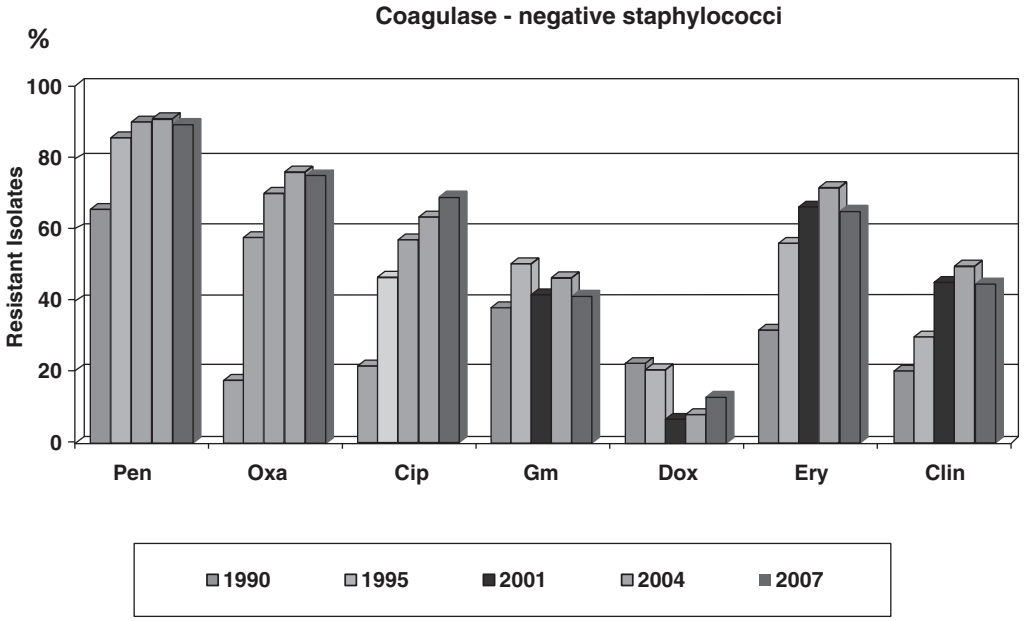

FIGURE 30-1 Antibiotic resistance development among healthcare-associated coagulase-negative staphylococci in Central Europe from 1990 to 2007. Oxa, oxacillin/methicillin; Cip, ciprofloxacin; Gm, gentamicin; Dox, doxycycline; Ery, erythromycin; Clin, clindamycin. (Data obtained from Antibiotic resistance situation among clinically relevant pathogens in Germany and Central Europe. Multicenter study report of the working group 'Susceptibility testing & resistance' of the Paul-Ehrlich-Society for Chemotherapy for the year 2007. [database on the Internet] 2009. Available at *http://www.p-e-g.org/ag_resistenz/main.htm.)*.

resistance emerged very soon, and resistance rates are nowadays as high as 70% to 90% among coagulase-negative staphylococci. Methicillin resistance is mediated by the *mecA* gene complex that is located on a unique molecular vector called the staphylococcal chromosome cassette (SCC*mec*) (133). *mecA* encodes the additional low-affinity penicillin-binding protein PBP2a that enables cell wall synthesis in the presence of β-lactam antibiotics. SCCmec cassettes represent large chromosomal DNA fragments that may harbor, in addition to *mecA*, a great variety of accessory genes, for example restriction modification systems, metabolic genes, integrated plasmids, transposons, insertion sequence (IS) elements, and many more. A characteristic feature of SCCmec cassettes is the presence of recombinase genes that confer mobility and mediate the site-specific integration of the elements into a highly conserved locus of the *Staphylococcus* chromosome (i.e., *orfX*). SCC*mecs* have an independent evolutionary history and eight major SCC*mec* types have been described to date (133,*134*). They are considered to be transferred into *S. aureus* from a coagulase-negative species *(135,136)*. However, the evolutionary origin of SSC*mecs*, the mechanism of SCC*mec* acquisition, and the factors that favor or limit their spread are still poorly understood. Interestingly, SCC cassettes cannot only carry *mecA* and mediate methicillin resistance. A number of SCCs has been identified that are devoid of *mecA*, but carry other genes instead *(135,137)*. Therefore, SCCs are regarded as effective vectors to spread useful genes among staphylococci *(138)*.

Aminoglycoside Resistance Aminoglycoside antibiotics inhibit protein synthesis by irreversible binding to the bacterial small ribosomal subunit (i.e., the 16S rRNA). Aminoglycoside resistance among coagulase-negative staphylococci is common (40%) and is mostly due to enzymatic inactivation of the antibiotic by acetyltransferases, adenylyltransferases, and phosphotransferases *(139)*. Table 30-3 lists the genes and enzymes that mediate aminoglycoside resistance in staphylococci. These determinants are often located on mobile genetic elements such as plasmids and transposons. The most widespread mechanism is resistance through the bifunctional phosphotransferase-acetyltransferase enzyme AAC(6)-APH(2) that confers resistance to a broad range of aminoglycoside compounds (Table 30-3). The corresponding *aacA-aphD* gene is located on composite transposon Tn*4001* that harbors two IS*256* copies at its ends. In *S. epidermidis*, Tn*4001* and IS*256* have been shown to be associated with biofilm formation in isolates obtained from device-related healthcare-associated infections *(141)*.

Macrolide-Lincosamide-Streptogramin Resistance Resistance toward the lincosamide clindamycin and the macrolide erythromycin among coagulase-negative staphylococci ranges between 20% and 70% and may vary by region. Although being structurally diverse, macrolide, lincosamide, and group B streptogramin antibiotics share overlapping binding sites on the large subunit of the bacterial ribosome, and are therefore often considered together. In addition to efflux pumps, inactivating enzymes, and point mutations, which are not discussed here, resistance against macrolides, lincosamides, and group B streptogramins is mainly mediated by rRNA methylases that modify the binding sites in the 23S rRNA molecule. In staphylococci, rRNA methylases are encoded by the *ermA*, *ermB*, *ermC*, *ermF*, and *ermQ* genes, most of them being located on plasmids and transposons *(142,143)*. The so called MLS_B cross-resistance

TABLE 30-3

Aminoglycoside Resistance Genes in Staphylococci (140)

Enzyme	*Gene*	*Localization (Plasmid/ Chromosome/Transposon)*	*Resistance Profile*
Adenylyltransferases

Bifunctional enzymes			
AAC(6′)-APH(2″)	*aacA-aphD*	Tn*4001*	Gentamicin, tobramycin, amikacin, netilmicin, kanamycin

phenotype depends on the expression status of the respective *erm* genes. In staphylococci, *ermA* and *ermC* can be expressed either constitutively or inducibly *(144,145)*. Constitutive expression results in cross-resistance against all three antibiotic classes. In contrast, strains with inducible *erm* expression display *in vitro* resistance to 14- and 15-membered ring macrolides, which also represent inducer molecules, while retaining susceptibility toward clindamycin and group B streptogramins. Although clindamycin is not able to induce *ermA* or *ermC* expression directly, exposure of *erm*-inducible staphylococcal isolates to clindamycin may result in complete MLS_B cross resistance both *in vitro* and *in vivo*. This phenomenon is attributed to the selection of preexisting constitutive *erm* mutants *(144)*. As clindamycin is an alternative drug for the treatment of some staphylococcal infections, detection of the inducible MLS_B resistance phenotype is of clinical relevance and should be performed when required by the D-test (Fig. 30-2) *(146)*.

Glycopeptide Resistance The glycopeptide antibiotics teicoplanin and vancomycin inhibit cell wall synthesis of gram-positive bacteria by interfering with the terminal D-alanine-D-alanine residues in the interpeptide side chains of the peptidoglycan. With the rise of multiresistance, glycopeptides gained significant importance in the treatment of infections due to gram-positive cocci in the late 1980s and 1990s. In enterococci, transmissible high-level glycopeptide resistance is a matter of concern in healthcare-associated isolates, and the resistance mechanism has been elucidated in molecular detail (*147*,148). Resistance in enterococci is mainly based on the modification of the glycopeptide binding site by replacement of one of the terminal D-alanine residue in the interpeptide side chain by D-lactate. The enzymes and regulators required for that process are transposon and plasmid encoded. Although being transferable from enterococci into staphylococci, high-level glycopeptide resistance through this mechanism is still rare among staphylococci *(149–152)*. However, some staphylococcal species exhibit an intrinsically diminished susceptibility toward glycopeptides, and in *S. aureus* and coagulase-negative staphylococci distinct subpopulations can develop intermediate resistance upon exposure to the antibiotics *(153–155)*. These intermediate or heterogeneous resistance phenotypes differ from the resistance mechanism described above for enterococci and are mainly attributed to an altered cell wall synthesis turnover and thickening of the peptidoglycan *(156,157)*. Glycopeptide resistance in coagulase-negative staphylococci was first reported in 1986 in *S. haemolyticus (158)*. *S. haemolyticus* displays often less susceptibility toward teicoplanin, while vancomycin is still effective. Glycopeptide resistance

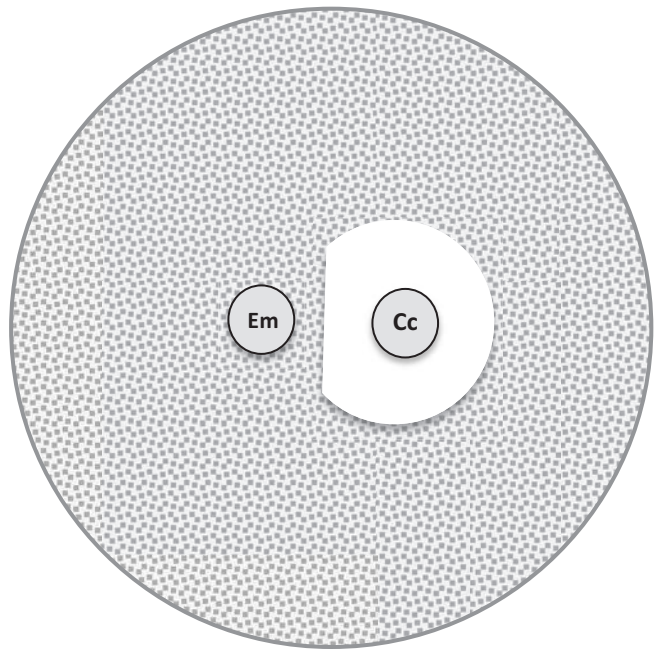

FIGURE 30-2 Scheme illustrating a positive D-test for detecting inducible MLS_B resistance in staphylococci. Erythromycin- and clindamycin-containing disks are placed onto an agar plate on which a staphylococcal strain was spread and grown overnight. Lack of an inhibition zone around the erythromycin disk indicates erythromycin resistance of the isolate. In case of clindamycin susceptibility, an O-shaped inhibition zone would be present around the clindamycin disk. However, the zone is blunted on the side facing the erythromycin disk where the diffusion zones of the two antibiotics meet. The typical D-shaped inhibition zone is due to the induction of clindamycin resistance by erythromycin in the colonies growing in this region. (Modified from Woods CR. Macrolide-inducible resistance to clindamycin and the D-test. *Pediatr Infect Dis J* 2009;28(12):1115–1118, with permission.)

has been reported for a number of other coagulase-negative staphylococcal species as well (e.g., *S. epidermidis*, *S. warneri*), and it is therefore necessary to perform careful antibiotic resistance testing to avoid treatment failure *(153,155,159,160)*.

TYPING OF COAGULASE-NEGATIVE STAPHYLOCOCCI

Typing of infectious agents aims at the elucidation of clonal relationships between single isolates of a species. It plays a major role in the detection of reservoirs of disease-associated bacteria and their transmission routes. Typing is therefore an indispensable tool in infection surveillance and outbreak control. In coagulase-negative staphylococci, due to the ubiquitous nature of the bacteria as commensals, typing is specifically important in order to distinguish between specimen contamination and true infection as well as for the recognition of outbreak situations. Repeated isolation of one and the same strain from various clinical samples or from different patients within a hospital unit makes it more likely that the isolate in question represents indeed the cause of an individual infection or an outbreak, respectively. Typing methods comprised in the past mainly classical microbiology approaches such as the comparison of antibiotic resistance patterns, the analysis of enzymes and metabolic properties as well as phage typing. However, in coagulase-negative staphylococci, these approaches proved to be unreliable and of insufficient discriminatory power. They were therefore largely replaced by genome-based molecular typing methods, which are briefly described here.

DNA Fingerprinting by Pulsed-Field Gel Electrophoresis

Pulsed-field gel electrophoresis (PFGE) is based on the comparison of DNA restriction fragment length polymorphism (RFLP) patterns of microorganisms upon separation in an agarose gel. For PFGE, the bacterial genome is fractionated into large DNA fragments through digestion by rarely cutting restriction enzymes, which is in contrast to classical RFLP comparisons where a high number of small DNA fragments are generated. In PFGE, the resulting large DNA molecules (usually 10–20) are separated in an agarose gel electrophoresis unit that allows for the separation of high-molecular weight DNA fragments by applying an alternating electric field (Fig. 30-3). PFGE has been established for a great variety of bacterial pathogens, including *S. aureus* and coagulase-negative staphylococci *(161,162)*. The method has an excellent discriminatory power and has been proven to be highly reproducible *(163)*. Using appropriate gel visualization and evaluation software, PFGE can also be employed to generate phylogenetic trees and to establish the relatedness of different strains *(164)*. A disadvantage

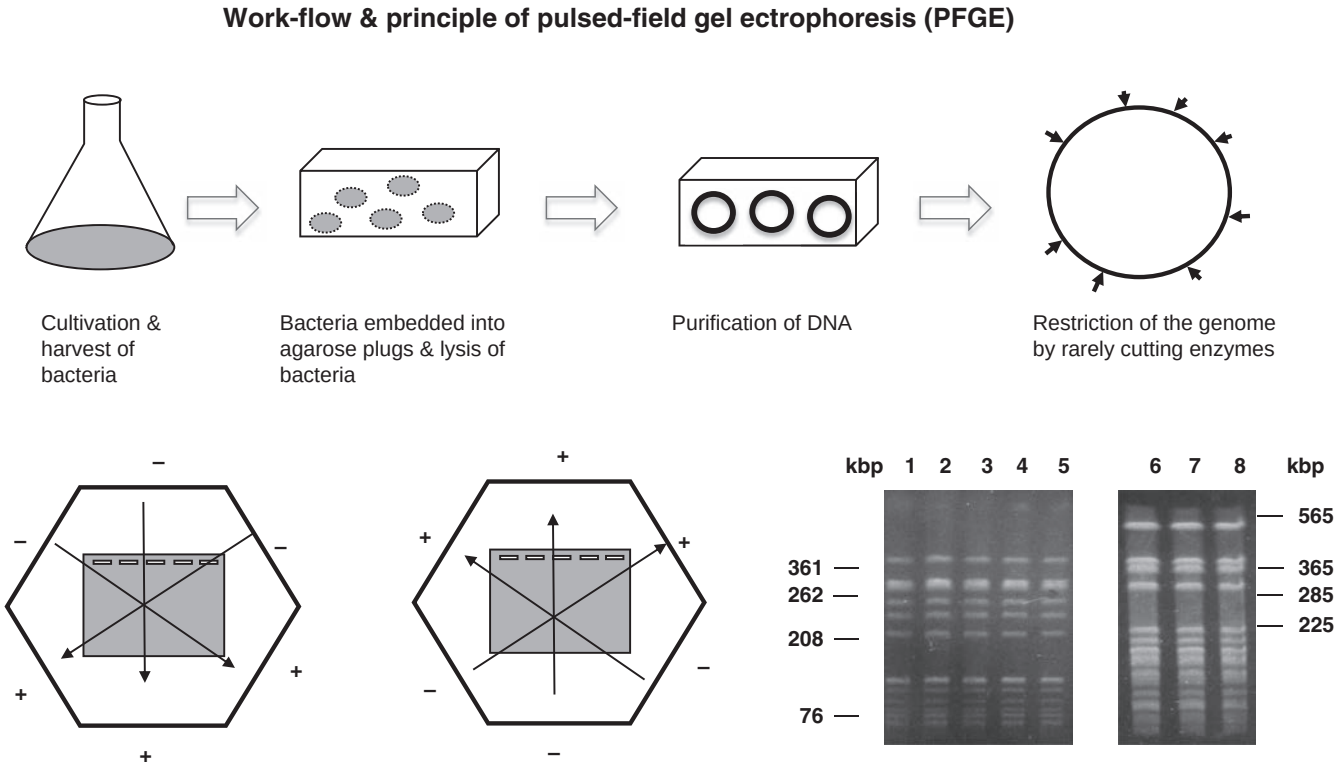

FIGURE 30-3 Principle and workflow of PFGE. Bacteria are grown, harvested, and subsequently embedded into agarose plugs. To mechanically stabilize the genomic DNA, the bacteria are lysed *in situ* within the plugs. The DNA is purified and restricted using rarely cutting restriction enzymes that provide 10 to 20 DNA fragments of a relatively large size (15–500 kbp). The agarose plugs are placed into an agarose gel and the DNA fragments are separated in a pulsed-field apparatus by applying an alternating (pulsed) electric field. Results can be visualized by ethidium bromide staining of the DNA under UV light.

of the approach is that it is technically demanding and relatively time consuming. Moreover, as with all gel-based visual typing methods, data storage and comparability over time and between laboratories is difficult. Although still being the gold standard for local outbreak control and surveillance, PFGE is therefore increasingly complemented or replaced by nucleotide sequence–based methods that generate more portable data formats.

Multilocus Sequence Typing

Multilocus Sequence Typing (MLST) analyzes nucleotide sequence variations in a set of housekeeping genes (usually seven) and identifies strains by their unique allelic profiles (165). For this purpose, the housekeeping genes are PCR-amplified and subjected to nucleotide sequencing. Sequences that differ at least in one nucleotide from a reference sequence are regarded as an allele that is numbered. Most importantly, identical alleles get identical numbers resulting in an unambiguous assignment of a nucleotide sequence. Applying the procedure to all seven housekeeping genes provides an allelic profile as a numeric code, which can be compared to that of other isolates. Allelic profiles are numbered as well and assigned as sequence types (ST). Allele definition does not consider the number of nucleotide exchanges, and no weighting is performed of a single nucleotide difference that arose from a point mutation or multiple sequence variations that might have been generated by a single recombination event or through the accumulation of multiple point mutations. In fact, the relatedness of strains is determined by the pairwise comparison of allelic profiles using the BURST (Based Upon Related Sequence Type) or eBURST algorithms *(166)*. Allelic profiles being very similar and differing in a maximum of two loci are likely to be derived from a common ancestor and displayed in a dendrogram. The ST exhibiting the highest number of single locus variants (SLVs) within a dataset is defined as the common ancestor and placed into the center of the dendrogram, while SLVs and DLVs (double locus variants) appear in a second and third circle or line, respectively, emanating from the center (Fig. 30-4). Related STs displayed in this way are called a clonal complex (CC), which is often named according to its common ancestor. MLST has proven to exhibit a high discriminatory power and is, facilitated by the recent technical progress in high-throughput sequencing, widely used for strain typing. The data are portable and primers, protocols, allele sequences and profiles held in publicly approachable databases (e.g., www.mlst.net), which can be queried online via the internet. MLST schemes have been established for numerous human pathogens including *S. aureus* and *S. epidermidis (167–169)* (Fig. 30-5). The technique has turned out to be an excellent tool not only for tracking the geographical and temporal spread of hypervirulent and antibiotic-resistant strains, but also for the population and evolutionary analysis of pathogenic bacteria *(172,173)*.

Multiple Loci Variable Number of Tandem Repeat Analysis

Multiple loci variable number of tandem repeat (VNTR) analysis (MLVA) is a typing method based on the length analysis of tandem repeat DNA sequence stretches present in most bacteria and also eukaryotes *(174)*. VNTRs

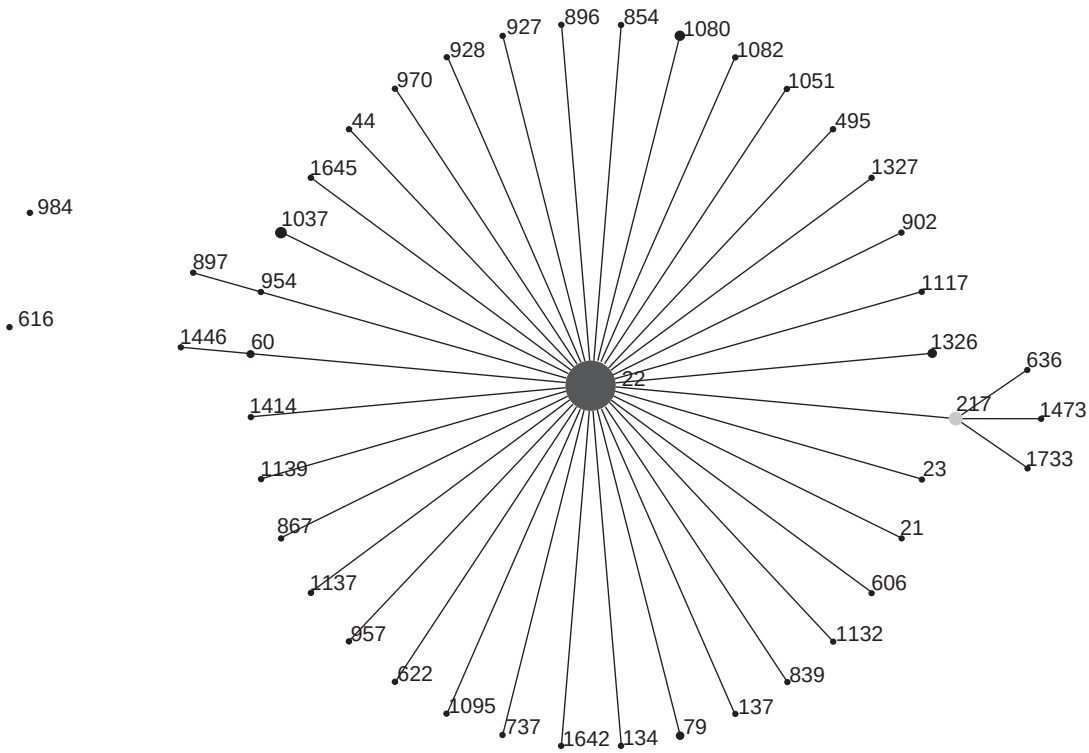

FIGURE 30-4 Example of an eBURST dendrogram. The figure was generated using the *S. aureus* MLST dataset on www.mlst.net by employing the eBURSTv3 algorithm available on this website. CC22 of *S. aureus* is shown with sequence type ST22, the common founder, being placed in the center of the diagram. Numbers represent STs and lines emanating from the center and from the circles display SLVs of the respective ST (see text for details). Circle diameters represent the number of isolates within the dataset that exhibit a particular ST.

FIGURE 30-5 MLST alleles used in two different *S. epidermidis* MLST typing schemes. The respective allelic profile of the most widespread healthcare-associated epidemic *S. epidermidis* clonal lineage (170,*171*) is shown when applying the scheme suggested by Wisplinghoff et al. *(169)* (ST27) and Thomas et al. *(168)* (ST2), respectively.

are usually scattered around a bacterial genome and they have been proven to be suitable for strain identification and typing in many human pathogens. In staphylococci, VNTRs typically occur in genes encoding surface-associated proteins carrying repeat units that mediate interactions with host matrix proteins. Thus, MLVA schemes for *S. aureus* and *S. epidermidis* preferentially target cell wall–associated protein genes, but other tandem repeat units such as the CRISPR loci (clustered regularly interspaced short palindromic repeat) would be adequate for MLVA as well. In the *S. epidermidis* MLVA scheme, currently five gene regions containing tandem repeats and the *mecA* gene are amplified in a multiplex PCR reaction *(175)*. The resulting PCR fragment patterns are resolved and displayed using microcapillary electrophoresis and are automatically assessed by computer-aided cluster analysis. The approach was demonstrated to have a similar discriminatory power as PFGE or MLST *(176)*. A major advantage of the technique is that it only comprises a single (multiplex) PCR reaction and does not require subsequent DNA sequencing. The computer-based pattern analysis makes the data portable, albeit data comparison between laboratories is not that convenient as with the MLST approach. Nevertheless, the technique is rapid and cost efficient and might therefore be suitable for the high-throughput analysis of large numbers of isolates in the routine laboratory.

SCCmec Typing

Although SCCmec typing does not represent a method suitable for strain identification, it will be discussed here as the classical typing methods described above are often complemented by the determination of SCCmec types detectable in clinical staphylococcal isolates. As already mentioned in the antibiotic resistance paragraph of the chapter, SCCmec elements consist of conserved and variable DNA regions encoding methicillin and other antibiotic resistance traits, the *ccr* mobility genes and so called J regions encoding accessory functions. Obviously, a great (unidentified) variety of SCC elements with and without the methicillin resistance conferring *mecA* gene do exist, specifically among coagulase-negative staphylococci *(177)*. For the routine praxis, a typing scheme has been implemented for eight major SCCmec types that carry *mecA* and are common among *S. aureus* and coagulase-negative staphylococci *(134,178–181)*. SCCmec elements typically consist of region J1 forming the left end of the element, followed by the recombinase complex *ccr*. Region J2 separates *ccr* from the *mec* gene complex, while region J3 borders the element at the right end, giving rise to the overall structural organization J1-*ccr*-J2-*mec*-J3. Typing is performed by a multiplex PCR reaction using 10 primer sets that target regions, which are, alone or in combination, specific for each of the SCCmec types. The resulting PCR amplification patterns are visualized either by classical agarose or automated capillary gel electrophoresis, the latter approach making the data more portable. SCCmec multiplex PCR typing is constantly evolving and updates with new primer sets targeting newly identified SCCmec types are continuously added to the typing scheme.

GENOMICS

Deciphered Coagulase-Negative Staphylococcal Genomes

With the recent progress in sequencing technology, bioinformatics, and database management, genome sequencing of microbes has become widely available and is currently revolutionizing the field of bacteriology and our understanding of infectious diseases in general. So far, representatives of all notable human bacterial pathogens have been sequenced, and from some species genome sequences of a number of several strains have been identified *(182)*. Thus, in July 2010, the genome sequences of as much as 64 distinct *S. aureus* strains were available in established databases (http://www.ncbi.nlm.nih.gov). The number of available coagulase-negative staphylococcal genomes is considerably lower, but constantly growing as well. Genome sequencing projects are completed for the most common coagulase-negative staphylococcal pathogens *S. epidermidis*, *S. haemolyticus*, *S. saprophyticus* as well as for the apathogenic species *S. carnosus*. Incomplete or provisional genome sequences exist currently for *S. hominis*, *S. capitis*, *S. warneri*, and *S. lugdunensis (183)*. Staphylococcal genome sequences represent a unique source of information. They provide a basis for molecular typing of strains and epidemiology, but give also invaluable insights into mechanisms of genome evolution, similarities and differences between strains and species, and the resulting molecular pathogenesis of coagulase-negative staphylococcal infections. The main characteristics of some coagulase-negative staphylococcal genomes are summarized in the following paragraphs.

Staphylococcus Epidermidis *S. epidermidis* was the first coagulase-negative staphylococcal genome to be sequenced and analyzed *(184)*. To date, two finished and another five incomplete genomes are available for the species *(184,185)*. The two completely sequenced strains

comprise *S. epidermidis* ATCC 12228, which is a commensal isolate widely used as a reference strain for antibiotic susceptibility testing, and *S. epidermidis* RP62A, a pathogenic isolate originally obtained from a blood culture associated with a catheter-associated septicemia *(186)*. *S. epidermidis* RP62A is also known as ATCC 35984 and serves as a reference strain for biofilm production among coagulase-negative staphylococci *(187)*. Whole genome analysis of both strains revealed a genome size of approximately 2.499 Mbp for ATCC 1228 and 2.616 Mbp for RP62A, respectively. Variation in genome size and gene content is mainly due to the insertion of a *Bacillus* prophage in *S. epidermidis* RP62A and differences in terms of other mobile elements such as genomic islands (see below), transposons, and ISs. Direct comparison of the *S. epidermidis* RP62A and ATCC 12228 sequences indicates over a broad extent a very uniform overall genome organization, except a region around the origin of replication. This DNA region is inverted in RP62A and harbors, in addition to the insertion site for the SCC*mec* elements (i.e., *orfX*), a number of genes involved in adhesion and biofilm formation. Most strikingly, the *ica* gene complex, involved in polysaccharide intercellular adhesin (PIA)-mediated biofilm formation, is present in the RP62A strain at the left-hand border of the inverted region, while this gene cluster lacks in ATCC 12228. *Ica* operon-mediated biofilm formation has been associated with invasive *S. epidermidis* isolates and was suggested as a discriminating marker between pathogenic and commensal isolates, at least in device-associated BSI (*141*,188,189–*193*). In both genomes, a number of genomic islands were detected that carry resistance or virulence-associated traits. Genomic islands are understood as genetic elements on the bacterial chromosome that have been acquired by horizontal gene transfer. They often differ in their GC content from the surrounding DNA, carry mobility genes, and are inserted in highly conserved regions of the chromosome such as tRNA loci. Most genomic islands are derived from mobile genetic elements. Thus in *S. epidermidis*, the νSe1 and νSe2 genomic islands originate from integrated plasmids. νSe1 was detected in RP62A and encodes a cadmium resistance gene complex, while νSe2 is a large DNA fragment specific to ATCC 12228 carrying among others two surface-associated proteins, which suggests specific interactions of this strain with host structures. A third island, νSeγ, is present in both *S. epidermidis* genomes at the same site and encodes β1 phenol soluble modulins (PSMs), which are known to interact with the human innate immune system *(194)*. The two strains differ with respect to their SCCmec islands. While strain RP62A harbors an SCCmec type II cassette, *S. epidermidis* ATCC 12228 contains an unusual SCC element (named SCC*pbp4*) that encodes, instead of the *mec* complex, the penicillin-binding protein gene *pbp*4 *(137,185)*. Compared to *S. aureus*, *S. epidermidis* does not carry superantigen and toxins genes, which might explain the more subacute and chronic course of *S. epidermidis* infections. However, the species contains a range of genes encoding proinflammatory cytolysins and other secreted exoenzymes such as lipases, esterases, and proteases, which are likely to be involved in invasion, evasion of host defense, and recruitment of nutrients through the destruction of host structures. A surprising result of the *S. epidermidis* genome sequencing project, however, was the strong evidence for an ongoing horizontal gene transfer across species and even genus borders. Thus, *S. epidermidis* RP62A was found to contain the *cap* operon that encodes a poly-gamma-glutamate (PGA) capsule and represents a major virulence factor in *Bacillus anthracis*. Presence of the *Bacillus* phage SPβ and detection of identical SCCmec cassettes both in *S. epidermidis* and *S. aureus* are further hints that coagulase-negative staphylococcal genomes are shaped by the uptake and incorporation of foreign DNA.

Staphylococcus Haemolyticus *S. haemolyticus* ranks second after *S. epidermidis* as a coagulase-negative staphylococcal species associated with BSIs and is capable of causing a wide range of infections including peritonitis, septicemia, otitis, and urinary tract infections. The species is known for its intrinsic and acquired antibiotic resistance, and as a consequence it seems logical that its genome sequence was revealed shortly after that of *S. epidermidis (195)*. Genome sequencing was undertaken in strain *S. haemolyticus* JCSC1435, a highly glycopeptide-resistant isolate that frequently generated mutants that had spontaneously lost resistance and metabolic traits upon subcultivation in antibiotic-free medium. The *S. haemolyticus* JCSC1435 genome size is similar to that of *S. epidermidis* and *S. aureus*, and a large proportion of open reading frames were identified that are conserved in their sequence and gene order in all three species. Differences were mainly detected in a region around the origin of replication. This region, named the "oriC environ," corresponds to the region around the origin of replication described above for *S. epidermidis* and contained most of the species-specific genes of *S. haemolyticus*. For example, genes encoding *S. haemolyticus*-specific metabolic pathways (e.g., mannitol utilization) are located in that region. Also, a putative capsule synthesis gene cluster, likely to be involved in pathogenesis, was detected in the oriC environ. Other putative virulence-associated genes such as three *S. haemolyticus*-specific hemolysin genes, a number of cell wall-associated adhesin genes, and PGA capsule synthesis enzyme genes are scattered around the genome. *S. haemolyticus* harbors, like *S. epidermidis*, a number of genomic islands that carry mostly genes of so far unknown function. Intact integrase genes on the islands point to a possible mobility of these structures. A characteristic and unexpected feature of the *S. haemolyticus* genome, however, is the unusually high number of mobile genetic elements. Thus, the genome carries two prophages, two integrated and another three free plasmids, three transposons, five genomic islands (including SCCmec) and, most notably, as much as 82 IS elements from which 60 were found to be intact and active. The complex mobile genetic elements (i.e., phages, plasmids, transposons, SCCmec) mostly carried antibiotic resistance genes, which explains the multiresistance phenotype of the isolate. The IS elements, however, which only encode functions for their own mobility, are suggested to play a role in the observed genome instability of the isolate *(195)*.

Staphylococcus Saprophyticus *S. saprophyticus* is a coagulase-negative staphylococcal species commonly involved in uncomplicated urinary tract infections, preferentially in young female outpatients. Genome sequencing of

the type strain ATCC 15305 revealed some specific features and mechanisms that shaped this species as a uropathogen *(196)*. Thus, *S. saprophyticus* has a number of additional sets of transporter systems involved in osmoprotection, which probably evolved by paralogue expansion *(196)*. Staphylococci are relatively salt tolerant, which is accomplished by the import of osmoprotective compounds such as proline, choline, and betain. The additional genes in *S. saprophyticus*, which were both chromosomally and plasmid-encoded, are likely to reinforce this mechanism and enable the bacteria to survive under the high ion conditions in urine. Also, the urease activity identified in the species might help the bacteria to thrive in this very special environment *(197)*. Other staphylococcal species harbor a great variety of cell wall–anchored adhesins, which interact with host matrix proteins and mediate adhesion to tissues and surfaces (198,*199*). In *S. saprophyticus*, only one such protein was predicted *(196)*, and this adhesin exhibited hemagglutination and adherence to human bladder cells suggesting again a highly specialized adaptation of the species to its environment *(200–203)*. Like the other staphylococcal genomes, *S. saprophyticus* harbors a range of mobile genetic elements, but their number is considerably lower than that of *S. haemolyticus*. Thus, *S. saprophyticus* ATCC 15305 contains one prophage, two complete IS elements and nine putative transposases as well as two SCC cassettes, one genomic island encoding streptomycin resistance, and two free plasmids carrying some of the osmoprotecting genes discussed above. Interestingly, the two SCC cassettes do not harbor *mecA*, but encode a capsule gene cluster and a restriction modification system, respectively.

Staphylococcus Carnosus In contrast to other coagulase-negative staphylococci, *S. carnosus* is a completely apathogenic species. The bacterium is classified as a GRAS (generally regarded as safe) microorganism and used as meat starter culture in dry sausage production and as a cloning vehicle for gram-positive bacteria *(204)*. Genome analysis of strain *S. carnosus* TM300 is an interesting project, not only because of the importance of the bacterium for the food industry, but also for understanding staphylococcal genome organization and pathogenesis by comparing the *S. carnosus* genome with those of pathogenic staphylococcal species. The *S. carnosus* TM300 genome is of similar size as other coagulase-negative staphylococcal genomes, but somewhat smaller than the *S. aureus* genomes *(205)*. *S. carnosus* encodes a series of metabolic pathways that obviously play a role when the bacterium is employed as a meat starter culture (e.g., nitrate/nitrite reduction, various sugar degradation pathways, osmoprotection systems, etc.). *S. carnosus* harbors also an *oriC* environ, which is inverted in comparison to *S. aureus* and carries some of the species-specific genes, while other genes of this class are scattered around the genome. The most intriguing feature, however, is that the *S. carnosus* genome does not contain intact mobile genetic elements such as plasmids, transposons, SCCs, IS elements, or any other repetitive sequence stretches. Lack of these elements is attributed to a relative stability of the *S. carnosus* genome and a low tendency for horizontal gene exchange with other bacteria. In addition to one prophage, only one genomic island with an integrase-like gene was detected, while other putative genomic islands only stood out as such by an aberrant GC content and integration into tRNA loci.

Mobile Genetic Elements of Coagulase-Negative Staphylococci

Mobile genetic elements are indispensable structures of nearly all bacterial genomes. They are characterized by their ability to move between different strains as well as between bacteria of various species and even genera. Mobile genetic elements in bacteria comprise plasmids, bacteriophages, transposons and IS elements, as well as genomic islands such as SCC elements or pathogenicity islands, carrying virulence factors. Mobile genetic elements often encode antibiotic resistance, metabolic or virulence-associated genes whose acquisition might be of benefit for the recipient bacterium. Therefore, horizontal gene transfer by mobile genetic elements has a major impact on enhancing the biological fitness of bacteria, but also contributes to the generation of genetic diversity within a species and the evolution and adaptation of the bacterial genome. Coagulase-negative staphylococci harbor a great diversity of mobile genetic elements. Table 30-4 lists a range of selected staphylococcal mobile genetic elements.

Plasmids The class I to III plasmids occur both in *S. aureus* and coagulase-negative staphylococci and confer resistance not only to antibiotics, but also to heavy metal ions or other toxic compounds *(206)*. Especially the large complex class II and III plasmids play an important role in the development of multiresistance in staphylococci. However, staphylococcal plasmids do not only carry resistance genes. They may also encode metabolic factors useful for the adaptation under specific external conditions as exemplified by two plasmids detected in *S. saprophyticus* that mediate salt tolerance *(196)*.

Genomic Islands Plasmids occasionally integrate into the bacterial chromosome where they can lose their replicative function and become a stabilized and integral part of the chromosome and form genomic islands such as νSe1 and νSe2 in *S. epidermidis*. The same applies to bacteriophages. All coagulase-negative staphylococcal genomes sequenced so far harbor at least one prophage, some of them likely to be defective. In *S. aureus*, prophages gave rise to the evolution of pathogenicity islands, which represent genomic islands carrying toxin and superantigen genes *(219,220)*. It is an intriguing feature of coagulase-negative staphylococci that they are devoid of toxin-encoding genomic islands. Instead, their phage-derived genomic islands carry antibiotic resistance genes or genes of so far unknown functions. Genomic islands often become hot spots for recombination events and the further uptake and integration of foreign DNA. The evolution of novel SCC elements, which obviously takes place preferentially within the coagulase-negative staphylococcal population, is a good example for the ongoing evolution of genomic islands in these bacteria *(138,221)*.

Transposons and IS Other important players in shaping staphylococcal genomes are transposons and IS elements (Table 30-4). Transposons and IS are DNA sequences capable of moving from one site within a genome to another.

While IS encode exclusively genes necessary for their own mobility, transposons encode additional factors as well, usually antibiotic resistance genes. Many transposons in staphylococci mediate resistance to standard antibiotics such as penicillin (Tn*552*), aminoglycosides (Tn*4001*, Tn*554*), trimethoprim (Tn*4003*), macrolides (Tn*554*), and tetracyclines (Tn*916*) (Table 30-4). More recently, large composite transposons have been described where one or more transposons along with IS elements and other DNA stretches have been inserted into another transposon forming new multidrug elements *(222–224)*. Most interestingly, these structures contain DNA fragments specific to both staphylococci and enterococci suggesting horizontal gene exchange between these bacteria.

IS-Mediated Genome Flexibility IS can be found in all three kingdoms of life and there is hardly any microorganism that is devoid of these elements. Coagulase-negative staphylococci harbor, with the notable exception of *S. carnosus*, a large number of various IS in their genomes (Table 30-4). IS exert a significant influence on expression of the genetic material and are important elements in genome organization. Thus, IS are capable of inactivating genes by active transposition to new insertion sites, but they can also trigger gene expression of neighboring genes through intrinsic promoter structures. In contrast to transposons, identical IS elements often occur in multiple copies within a bacterial genome, thereby influencing the genome structure more passively by their mere presence. Thus, multiple copies of the same IS form repetitive DNA sequence stretches that serve as crossover points for homologous recombination events. Depending on the orientation of two identical elements to each other, inversions or deletions of the enclosed DNA fragment will occur. The number of IS within a bacterial genome therefore also reflects the dynamics of the genetic material and its capacity for rearrangements and the generation of genetic diversity. *Staphylococcus* species differ to some degree with respect to the number and nature of IS elements residing in their genomes. *S. aureus* strains contain on average 10 to 20 IS, while this number is considerably higher in coagulase-negative species involved in infections. The highest number (i.e., 82 IS) can be found in *S. haemolyticus*, and the two *S. epidermidis* genomes sequenced so far harbor up to 54 IS copies. IS-mediated genome flexibility was recently suggested to play a role in the infection process, and specifically the IS*256* element detected in *S. epidermidis* RP62A and in other biofilm-forming isolates was shown to be involved in the generation of phenotypic and genotypic diversity. Details of this phenomenon are discussed in the "Pathogenesis" section of this chapter.

Mechanisms of Horizontal Gene Transfer and Its Limitation

Coagulase-negative staphylococci have an extraordinarily high capacity to exchange genetic material among each other and even across genus borders. This finding was rather unexpected and coagulase-negative staphylococci are now recognized as a genetic reservoir for the evolution and spread of novel antibiotic resistance and virulence-associated genes. Transformation, conjugation, and transduction are the main mechanisms of horizontal gene transfer in bacteria. Other than *Neisseria*, streptococci or *Haemophilus*, staphylococci are not naturally competent, which means that they are unable to be transformed by naked DNA directly. So, mechanisms of horizontal gene transfer are mainly restricted to conjugation and phage transduction.

Conjugation Conjugation is the transfer of genetic material by direct contact of a donor and a recipient bacterium, and conjugationally proficient staphylococcal plasmids are mobilized by this mechanism *(225)*. However, conjugation can also mediate the exchange of certain transposons. While classical transposons and IS only move within their host genome, the so called conjugative transposons can be mobilized to another cell *(226,227)*. They transpose from an insertion site by excising as a single-stranded circular DNA intermediate, which is then either inserted into another site of the genome or transferred to a new host bacterium in a similar manner like a conjugative plasmid. Conjugative transposons were first detected in gram-positive bacteria, but are widespread in many other bacteria as well. In staphylococci, members of the Tn*916* family are the most common conjugative transposons *(211)*. They have a significant capacity to accumulate accessory genes and to form composite transposons, making them important vectors for the dissemination of genetic material among a great variety of commensal and pathogenic bacteria *(223)*.

Transduction Another important mechanisms for the spread of antibiotic resistance and virulence genes is transduction by bacteriophages *(228)*. As outlined above, coagulase-negative staphylococci harbor a range of prophages inserted in their genomes. Once activated and entering the lytic cycle, bacteriophages can accidently pack or incorporate host genetic material and transfer it to another recipient cell. Due to their specificity for certain species and strains, staphylococcal phages were in the past widely used for strain typing *(229)*. More recently, a number of novel phages, mainly from *S. epidermidis*, have been identified and for some of them the genome sequence was established *(216,217)*. Interestingly, among coagulase-negative staphylococci and also in *S. aureus*, broad-host range phages were identified capable of infecting a number of various species *(218)*. In *S. aureus*, such phages were even shown to transfer superantigen genes into *Listeria* species, suggesting that phage transduction contributes more to horizontal gene transfer and genome evolution of pathogenic bacteria than originally anticipated *(230)*.

CRISPR Loci and Limitation of Horizontal Gene Transfer From the evolutionary point of view, intensive exchange of genetic material, as observed in coagulase-negative staphylococci, does not necessarily represent an advantage *per se*. There is also a certain risk for taking up too much or nonbeneficial DNA leading to the generation of less fit and nonviable variants. Classical factors of self-protection are restriction modification systems, which recognize and eventually degrade invading foreign DNA *(231)*. A range of restriction modifications systems are present in staphylococci, and some of them are localized on genomic islands such as SCC elements *(137)*. In addition to restriction modifications systems, *S. epidermidis* has adopted another fascinating mechanism to limit horizontal gene transfer and to prevent specifically the repeated uptake of elements that have already been acquired. Clustered, regularly interspaced, short palindromic repeat (CRISPR) loci were recently detected in the multiresistant clinical strain *S. epidermidis* RP62A. (232,*233*). CRISPR loci are widespread in bacteria and archaea *(234–236)*. In *S. epidermidis*, they were shown to confer acquired immunity against the invasion of phages and conjugative plasmids *(*232*,233)*. CRISPR-mediated immunity is based on sequence matches between the invading mobile DNA element and short spacer DNA stretches that separate the CRISPR repeats. These spacer regions are highly dynamic

and evolve rapidly upon contact with a novel mobile genetic element. The CRISPR repeats are regularly linked to a cluster of genes, *cas* (CRISPR-associated genes) encoding a sophisticated machinery of proteins involved in CRISPR adaptation and interference with invading DNA. The spacers along with parts of the conserved CRISPR sequence encode small untranslated RNAs that target the invading DNA in a sequence-specific manner by blocking it by direct base pairing *(237)*. The mechanism is regarded as a kind of adaptive immune system of bacteria, which acts as an important factor to limit the spread of antibiotic resistance traits.

Genome Evolution of Coagulase-Negative Staphylococci

Another result of the numerous *Staphylococcus* genome sequencing projects was the finding that coagulase-negative staphylococci have imbalanced genomes (*195,205*). All circular bacterial chromosomes exhibit two replicores: replicore 1 is the DNA strand spanning clockwise from the origin of replication *oriC* to *terC*, the terminus of replication, while replicore 2 spans counterclockwise the rest of the genome from *oriC* to *terC*. Replication of bacterial circular chromosomes initiates at *oriC* and runs in both directions. It terminates at *terC* where the two replication forks meet. In all *S. aureus* genomes sequenced so far and in many other genomes, *terC* is located 180 degrees from *oriC* ensuring that the two replication forks have to cover an equal distance until termination. Such genomes are called balanced genomes. In contrast, in all sequenced coagulase-negative staphylococcal genomes, *terC* significantly deviates from the 180-degrees position. The biological consequences of this imbalance for coagulase-negative staphylococci are currently poorly understood. However, it is hypothesized that genome imbalance is a result of the accumulation of exogenous DNA by horizontal gene transfer and its incorporation mainly into the *oriC environ* of the staphylococcal chromosome. The staphylococcal *oriC* environ is defined as the region around the *oriC* in which <45% of the genes encode common staphylococcal genes, and indeed, most of the species-specific as well as accessory genes of coagulase-negative staphylococci are localized in this region. It seems to be the most dynamic part of the staphylococcal chromosome in which the establishment of genetic diversity and delineation of strains and species are most likely to occur, however, at the cost of generating an imbalanced genome. It is tempting to speculate that the frequent inversions, deletions, and rearrangements observed in this region represent attempts to (re)establish the physical balance of the genome (*293*).

PATHOGENESIS

Infections due to coagulase-negative staphylococci are of typical opportunistic nature. They are favored when the fine-tuned balance between commensalism and pathogenicity is disturbed either by the presence of distinct bacterial virulence factors or by a transient or permanent weakness of the host defense. Indeed, coagulase-negative staphylococcal infections predominantly occur in immunocompromised patients and when the integrity of the skin barrier is disturbed. Often, the bacteria make use of indwelling medical devices such as intravenous catheters as vehicles to enter the host *(238)*. In the last decade, numerous studies were performed to identify bacterial factors that might help to distinguish commensal isolates from those being able to cause infections. In *S. epidermidis*, the most common coagulase-negative staphylococcal pathogen, two putative virulence-associated determinants were identified in invasive isolates. One is the *ica* gene cluster mediating polysaccharide-dependent biofilm formation and the other is presence of IS*256*, an IS element supposed to influence genome flexibility and adaptation of gene expression during an infection (*141*,188,*189–193*). The role of these and other factors in the pathogenesis of coagulase-negative staphylococcal infections will be discussed here.

Bacterial Factors Involved in Colonization and Biofilm Formation

As typical skin and mucosa commensals, coagulase-negative staphylococci have evolved surface structures mediating the contact to epithelial cells and matrix proteins of their hosts. MSCRAMMs (microbial surface components recognizing adhesive matrix molecules) are cell wall–associated proteins interacting with matrix proteins such as collagen, fibrinogen, vitronectin, and many others *(239)*. Most MSCRAMMs are covalently linked to the staphylococcal cell wall, and they have been detected in nearly all coagulase-negative staphylococcal species. MSCRAMMs are considered as key factors that guarantee the commensal lifestyle of the bacteria by maintaining contact to the host. As matrix proteins rapidly cover abiotic surfaces of indwelling medical devices, MSCRAMMs are also important for the colonization of implants and the initialization of device-associated infections by coagulase-negative staphylococci (198,*199*,*240*,*241*) (see Chapter 31). Initial attachment to a surface is often followed by the multiplication of the bacteria *in situ* and the formation of microcolonies. When growing into larger, mushroom-like structures with the development of channels for water, ion, and nutrient exchange, these microcolonies may give rise to the accumulation of a bacterial biofilm. Biofilms are, by definition, communities of microorganisms that stick to each other and/or to a surface, mostly by the production of a self-produced extracellular matrix *(242)*. The biofilm lifestyle has fascinating consequences for both the single bacterial cell and the population as a whole, and details of this phenomenon are discussed comprehensively elsewhere in this volume. Most strikingly, bacteria organized within a biofilm exhibit much higher resistance against antibiotics than their planktonically living peers *(243)*. In staphylococci, two different modes of biofilm formation have been described. Thus, biofilm formation can be accomplished by production of a PIA, a slimy matrix which is also known, according to its structure, as poly-*N*-acetylglucosamine (PNAG) *(244)*. The enzyme complex responsible for PIA/PNAG synthesis is encoded by the *icaADBC* operon (245). It is noteworthy that in *S. epidermidis* this gene cluster is preferentially found in epidemic, healthcare-associated clonal lineages, while it is rarely detectable in commensal *S. epidermidis* isolates recovered outside of medical facilities (*141*,170,188,*189–192*). The *ica* gene cluster has been detected in other staphylococcal species as well, but due to the low number of isolates analyzed no clear association

between presence of the genes and invasiveness has been deduced so far *(246–248)*. *S. epidermidis* biofilm formation can also be PIA/PNAG independent. Thus, *icaADBC*-negative strains have been described in which biofilm formation was found to be mediated by proteins such as the accumulation associated protein Aap and the biofilm associated protein Bap/Bhp, respectively *(249–252)*. More recently, it was shown that wall teichoic acids and extracellular DNA are also part of the biofilm matrix and contribute to biofilm formation, most likely as stabilizing factors through their polyanionic nature *(253–255)*.

Evasion of Host Defense

The formation of biofilms is one strategy to evade the host defense, as biofilms represent an efficient physical barrier for cells and soluble factors of the immune system. However, PIA/PNAG itself was also shown to have direct effects on the innate immune system by inhibiting phagocytosis and killing through polymorphonuclear leukocytes as well as by increasing resistance toward host-derived antimicrobial peptides (AMPs) *(256)* (see Chapter 31). Another exopolymer with similar effects is the PGA capsule of *S. epidermidi,s* which was demonstrated to protect from major components of the innate immune system as well and is obviously present in many coagulase-negative staphylococcal genomes *(257)*. Also, *S. epidermidis* is able to sense AMPs in the environment by dedicated signaling systems (*258*,259*,260*). AMPs are produced by eukaryotes and are in the first line of defense against many pathogens *(261,262)*. Staphylococci, notably coagulase-negative staphylococci, are known to be notoriously resistant to AMPs, which is accomplished by the upregulation of genes that decrease susceptibility to these peptides or facilitate their export from the staphylococcal cell *(263,264)*. Other small molecules interacting with the immune system are the PSMs, which are encoded by genomic islands or the *agr* quorum-sensing system (see below) *(194)*. PSMs were demonstrated to have proinflammatory and cytolytic effects on eukaryotes and one compound, the PSMγ (delta-toxin), is supposed to play a role in biofilm detachment and re-initiation of the process at other sites *(265–267)*.

Regulation of Gene Expression and Cross talk within the Ecological Niche

Successful establishment and survival of a bacterium within an ecological niche requires coordinated gene expression and adaptation according to nutrient supply, influence of the host immune system, and other external conditions. Staphylococci employ a number of various regulatory networks to accomplish this sophisticated task. Thus, staphylococcal gene regulators comprise, for example, alternative sigma factors such as SigB, which is involved in the control of stress response, numerous DNA-binding transcription factors, classical two-component signaling systems, and most interestingly, the quorum-sensing system Agr (accessory gene regulator) *(268)*. Agr is present in all staphylococcal species. It contains a two-component signal transduction system consisting of the sensor-histidine kinase AgrC and the response regulator AgrA as well as AgrD and AgrB responsible for the synthesis, export, and posttranslational modification of small pheromone peptides *(269)*. The Agr pheromone peptides vary in their sequence between staphylococcal species, and various subgroups have been detected within a single species *(270)*. Interestingly, these pheromones show self-induction of their own Agr system, while nonself-pheromones cross-inhibit expression of the locus *(271,272)*. The actual Agr effector molecule is a regulatory RNA (RNAIII) that interacts with the target mRNAs of Agr-controlled genes and that additionally encodes the PSM delta-toxin *(273–275)*. Agr is known to adapt staphylococcal physiology to postexponentially growth when nutrients start to become short in supply *(276)*. It activates a range of virulence-associated genes such as extracellular proteases, lipases, and other exoenzymes that might help to degrade host tissue structures and immune components. Moreover, it is involved in the general stress response of staphylococci, including the control of detoxifying enzymes *(276)*. Also, Agr seems to facilitate detachment of *S. epidermidis* biofilms most likely through the action of extracellular proteases and the detergent effect of delta-toxin *(265,277)*. Moreover, the system has a major impact on the central metabolism of staphylococci, thereby influencing indirectly staphylococcal physiology and biofilm formation (278). Agr-mediated quorum-sensing control of gene expression has therefore consequences for the protection from the innate immune system and metabolic adaptation of coagulase-negative staphylococci, but also for the mutual crosstalk of the bacteria on the skin and the suppression of unwanted neighbors and their displacement from the ecological niche (*269*,*279*).

Heterogeneous Gene Expression and Genome Instability as an Adaptive Strategy

Coagulase-negative staphylococci are known for their pronounced variability and heterogeneity, which can often be observed in clinical samples. Primary cultures from clinical specimens grown on agar plates frequently differ in colony morphology, size, color, hemolysis, and other properties suggesting, on first glance, a mixed bacterial population. Phenotypic differences may also affect the expression of metabolic traits, which in turn, hampers the correct identification of the species by metabolic tests. Other typical features subject to phenotypic and genetic instability are biofilm formation and methicillin resistance. Thus, early studies on *Staphylococcus* biofilm formation report a high variability of biofilm expression with the regular and spontaneous generation of biofilm-negative variants arising from a biofilm-forming population *(*188*,280)*. Alongside with biofilm formation, methicillin resistance was often found to be affected as well in such variants, and there is growing evidence to suggest that the IS element IS*256* plays a crucial role in these processes (*59*,281,*282*). IS*256* is present in multiple copies in the genomes of certain *S. epidermidis* clonal lineages preferentially associated with healthcare-associated infections, and the element is therefore regarded as a marker for invasive isolates. As IS*256* also forms the ends of composite transposon Tn*4001*, conferring aminoglycoside resistance, the element is detected in other multiresistant coagulase-negative staphylococcal strains and species as well (e.g., *S. haemolyticus*) *(283)*. When active, IS elements transpose from one insertion site within a genome to another, and IS*256* was shown to insert spontaneously into biofilm-associated genes and global regulators of staphylococcal gene expression (*141*,*190*,*193*,281,*284*). IS*256*

has also the capacity to activate the expression of genes through the formation of strong hybrid promoters when the element inserts into the neighborhood of genes and operons *(285–287)*. As a result, a heterogeneous bacterial population is generated in which virulence, metabolic, and antibiotic resistance genes are differentially expressed. It is tempting to speculate that the presence of IS*256* is an advantage in the infection process by facilitating the emergence of a variety of well-adapted variants that can readily cope with the very different environments on the skin and within the bloodstream, respectively. Biofilm formation seems to be particularly prone to variation and IS*256* was shown to impair *S. epidermidis* PIA expression by insertion into the *icaADBC* operon (281). The process is reversible and precise IS*256* excisions from an insertion site are mediated by an illegitimate recombination event that does not require the element's transposase *(288)*. While switch-off of PIA-production through IS*256* insertions occurs with a frequency of approximately 10^{-6} per cell, and generation, restoration of PIA-dependent biofilm formation by precise IS*256* excision was found to be an extremely rare event (10^{-11} per cell and generation). Interestingly, it was demonstrated that strains with a dysfunctional *ica* operon are able to induce biofilm formation, after repeated passages, by proteins (289). This ability to switch between different modes of biofilm formation obviously occurs *in vivo* and seems to play a critical role in pathogenesis. Thus, in a recently described clinical case of a fatal *S. epidermidis* septicemia, a number of consecutive isogenic isolates were obtained, which differed with respect to biofilm formation and oxacillin resistance (16). Isolates from the beginning of the infection produced a weak protein-mediated biofilm, while isogenic isolates from a later stage of the infection were strong PIA-expressing biofilm formers. It is generally thought that biofilm switching is of biological relevance in the highly dynamic course of a device-associated infection. Thus, PIA synthesis is known to be a costly, energy-, and resources-consuming process, which is not necessary and even detrimental when the bacteria live as commensals on the skin (290). In contrast, when the bacteria are translocated into the bloodstream, PIA production is required and indispensable for survival as the polysaccharide protects the bacteria efficiently from antibiotics and the action of the host immune system (291). The molecular mechanism of biofilm mode switching is currently poorly understood, and it remains to be investigated whether or not active IS*256* transpositions, into so far uncharacterized regulators controlling biofilm formation and/or the metabolism of the staphylococcal cell, are involved in this process.

In addition to active transposition, multiple genomic IS copies are supposed to serve as crossover points for homologous recombination events, and therefore to play an important role in genome flexibility and adaptation of bacterial genomes. In disease-associated *S. epidermidis* strains and in the course of an infection spontaneous IS*256*-mediated chromosomal DNA fragment deletions may occur that encompass, among many metabolic genes, the *ica* operon and large parts of the methicillin/oxacillin-resistance conferring SCC*mec* elements (16,*59*). *S. epidermidis* genome analyses indicates that both the *ica* genes and the SCC*mec* elements are colocated in a region of high recombination in the oriC environ of the chromosome suggesting a joint genetic instability of these traits *(292)*. This phenomenon is obviously not restricted to *S. epidermidis*, but has also been described in *S. haemolyticus*, a species that typically harbors a large number of IS elements in its genome *(293)*. Thus, upon drug-free passage of the multiresistant clinical isolate *S. haemolyticus* JCSC1435 large chromosomal rearrangements and deletions occurred, which were due to the action of multiple copies of IS*Sha1*, an IS that formed composite transposons, and which mediated the excision and self-integration of large chromosomal fragments in the oriC environ *(293)*.

Taken together, coagulase-negative staphylococci are highly versatile bacteria that can adapt their gene expression patterns very efficiently to rapidly changing environmental conditions. This flexibility is particularly pronounced in clinical isolates and recent research suggests that the number and activity of mobile genetic elements present in the genomes of coagulase-negative staphylococci play a crucial role in this process, which may critically determine pathogenesis, disease progression, and outcome of coagulase-negative staphylococcal infections.

MOLECULAR EPIDEMIOLOGY AND INFECTION CONTROL

Identification of Disease-Associated *S. Epidermidis* Clonal Lineages

Due to the ubiquitous nature of *S. epidermidis* as commensals, it was thought for a long time that any isolate residing on the skin of a patient can cause disease and that *S. epidermidis* infections are therefore likely to be polyclonal. In support of this idea, molecular typing by PFGE demonstrated indeed a striking diversity among *S. epidermidis* isolates *(294–297)*. However, at the same time, transmission of strains between patients, wards, and hospitals were also reported suggesting an epidemic spread of *S. epidermidis* strains *(298–303)*. These apparently conflicting data were even more difficult to interpret when it became clear that, as comprehensively described in this chapter, *S. epidermidis* genomes readily undergo rearrangements, sometimes with such aberrations being generated within an isolate in the course of one and the same infection (16,*59*,*304*,*305*). The high resolution power of the PFGE approach detects these genomic differences, suggesting a much higher degree of genetic diversity within the *S. epidermidis* population than genuinely present. The problem was eventually overcome by introducing MLST as a tool in *S. epidermidis* epidemiology. Thus, an MLST scheme introduced by Wisplinghoff et al. *(169)* revealed, for the first time, distinct related clones of *S. epidermidis* that were implicated in infections, but were recovered independently from patients in various geographic locations and over a long period of time. Employing the same MLST scheme, another study, which aimed at the clonal relatedness of biofilm-forming and non–biofilm-forming *S. epidermidis*, eventually revealed that the majority of disease-associated isolates belong to one sequence type, ST27, which was detected in various hospital settings in Europe and the United States (170). *S. epidermidis* ST27 strains were found to harbor in their

genomes the biofilm-mediating *ica* operon along with various SCC*mec* cassettes and multiple IS*256* copies. These findings were further backed and detailed by a more recent study, applying an improved MLST scheme to establish the overall population structure of the species *S. epidermidis* (*168*,*171*) (Fig. 30-5). MLST analysis of a representative collection of *S. epidermidis* isolates from various spatiotemporal and clinical origins revealed a high degree of genetic diversity within the species, but identified also nine epidemic clonal lineages that were disseminated worldwide. The most widespread clone was ST2, with isolates being identified in as many as 13 different countries on three continents. ST2 is the founder sequence type of CC2 and a particular high recombination frequency was recorded within this CC giving rise to further expansion of the clone *(171)*. Re-typing of the ST27 isolates identified in the study by Kozitskaya et al. 2005 revealed that ST27 corresponds to ST2 according to the revised MLST scheme (Kozitskaya and Ziebuhr, unpublished data) (Fig. 30-5). Using one or the other MLST schemes, ST2 (ST27) strains have meanwhile been detected in many geographic regions, suggesting that this clonal lineage is evolutionarily highly successful and able to disseminate worldwide (*169–171*,306–*308*). In general, *S. epidermidis* is now regarded as an epidemic species with a few well adapted clonal lineages emerging upon a background of a highly diverse and recombining population *(171)*. In the light of these findings, PFGE can still be regarded as the most appropriate and powerful tool for the short-term surveillance of *S. epidermidis* outbreak situations, but it has its limitations when it comes to long-term evolutionary analyses or the surveillance of the geographic dissemination of *S. epidermidis* clonal lineages. For these purposes, MLST, MLVA, or a combination of PFGE with other methods such as SCC typing are more suitable and recommended *(309)*.

Coagulase-Negative Staphylococci as a Reservoir of Antibiotic Resistance Genes

While occurrence of methicillin-resistant *S. aureus* (MRSA) in medical facilities immediately prompts action to contain their spread, there are hardly any infection control measures in place to fight methicillin-resistant *S. epidermidis* or methicillin-resistant coagulase-negative staphylococci. Numerous studies, however, demonstrate an ongoing evolution of novel SCC*mec* elements within the coagulase-negative staphylococcal population *(177,221,297,310,311)*. Notably, in *S. epidermidis* it was shown that epidemic, healthcare-associated clones readily acquire SCC*mecs* and that these acquisitions had occurred independently from each other many times *(171)*. Thus, among coagulase-negative staphylococci, a great variety of SCC elements can be found, many of them being novel, nontypable variants, suggesting that *S. epidermidis* and other coagulase-negative staphylococci are specifically prone to take up these mobile genetic elements (*169–171*). A recent study addressing the molecular epidemiology of commensal coagulase-negative staphylococci colonizing patients and staff in a nursing home with high MRSA colonization rates identified a great variety of novel SCC types (with or without *mecA*) among coagulase-negative staphylococci *(312)*. Most interestingly, many of these SCC elements were found to be shared with *S. aureus* strains recovered from the same nursing home. These and other data provide growing evidence that coagulase-negative staphylococci represent a reservoir and genetic background for the evolution of novel SCC*mec* elements and other resistance traits that might be transferable into *S. aureus*.

Prevention and Infection Control

The new insights gathered on genetics and epidemiology of coagulase-negative staphylococci during the last decade demonstrate that distinct isolates with very special properties have established in the hospital environment, causing the majority of infections. These isolates are characterized by multiresistance toward antibiotics, the ability to form biofilms on medical devices, and an extraordinary phenotypic and genetic flexibility and adaptation to changing external conditions. Moreover, these healthcare-associated multiresistant coagulase-negative staphylococcal populations have been recognized as a gene pool and reservoir for the evolution and spread of novel resistance genes which might be transferred into more pathogenic species such as *S. aureus*. At the moment, multiresistant and biofilm-forming coagulase-negative staphylococci are not targeted by any hospital infection control measures. However, in the light of the recent findings, it would be interesting to see whether consideration of these bacteria in future infection prevention plans could lower the number of device-associated infections by coagulase-negative staphylococci and, in the very long run, also decrease the burden of multiresistant *S. aureus* in medical facilities. Thus, studies would be desirable to detect biofilm-forming multiresistant coagulase-negative staphylococci in the environment of intensive care units, transplantation and cancer treatment centers, as well as other facilities with a high risk and incidence of coagulase-negative staphylococcal infections. Screening should specifically aim at strains colonizing the skin of staff and patients, and based on the experiences with MRSA control, it is tempting to speculate that a targeted "search and destroy policy" along with a meticulous hand hygiene regime might be effective to prevent individual infections and to stop the further spread of putative pathogenic strains within a medical setting.

CHAPTER 31

Mechanisms of Biofilm Formation in the Staphylococci

Paul D. Fey

As documented in other chapters of this text, both *Staphylococcus aureus* and *S. epidermidis* are a cause of significant infections in both the community and the hospital environment. Most likely due to their ability to colonize mucous membranes and skin of humans, data from the National Nosocomial Infection Surveillance (NNIS) system demonstrate that *S. aureus* and *S. epidermidis* are the most common cause of healthcare-associated infections including catheter-related infections *(1)*. One particularly onerous aspect of staphylococcal pathogenesis is the ability of most staphylococcal species to form biofilm on foreign medical devices (2). Despite the documented function of biofilm in the context of staphylococcal disease, our understanding of molecular mechanisms fundamental to biofilm formation is incomplete. It is clear that bacteria within a biofilm have a unique and heterogeneous metabolism compared to planktonic cells (3). Consequently, bacterial biofilms are inherently resistant to antibiotics and the innate immune system leaving clinicians little choice but to remove the infected device. Staphylococcal biofilm is defined as a heterogeneous mixture of cells, usually bound to a foreign body, encased in an extracellular matrix consisting of protein, extracellular DNA (eDNA), and polysaccharide (2,4). Recent data from a variety of investigators have clearly shown that extracellular matrix differs between strains; in fact, the composition of the extracellular matrix within a particular isolates biofilm may change depending upon the extracellular niche *(5–7)*. In an attempt to organize the data, this chapter will focus on the four identified stages of *S. aureus* and *S. epidermidis* biofilm synthesis (a) initial attachment, (b) accumulation, (c) maturation processes, and (d) dispersion. However, in some cases, particular factors clearly function in multiple stages of biofilm formation (i.e., initial attachment and accumulation). Particular biofilm components may have been studied in the context of either *S. aureus* or *S. epidermidis* biofilm, and this will be noted.

STAPHYLOCOCCAL ATTACHMENT TO A FOREIGN BODY

Both *S. aureus* and *S. epidermidis* have multiple factors that function to mediate adherence to foreign biomaterials. After insertion into a host, foreign medical devices are rapidly coated by serum proteins including fibrinogen, fibronectin, collagen, and vitronectin. Staphylococci have the capability to bind these serum proteins, and thus the biomaterial, through the interaction with MSCRAMMs (*M*icrobial *S*urface *C*omponents *R*ecognizing *A*dhesive *M*atrix *M*olecules) *(8–10)*. Although the number of MSCRAMMs encoded by a particular strain differs, *S. aureus* (~20) typically encodes more MSCRAMM-like proteins than does *S. epidermidis* (~12) *(8,11)*. MSCRAMMs have a common structure including a surface-exposed-binding domain, a cell wall-spanning domain, and a peptidoglycan-binding domain that is typically covalently attached through an LPXTG motif by sortase A *(12,13)*. *S. aureus* MSCRAMM examples include the fibronectin/fibrinogen/elastin-binding proteins FnBpA and FnBpB *(14)*, two unique fibrinogen-binding proteins ClfA and ClfB *(15,16)*, and the collagen-binding protein Cna *(17)*. Other staphylococcal MSCRAMMs found in both *S. aureus* and *S. epidermidis* include a family of proteins containing extensive serine-aspartate (SD) repeats *(8)*. One extensively studied MSCRAMM in *S. epidermidis* and *S. aureus* is SdrG, a molecule that binds fibrinogen through a "dock, lock, and latch" mechanism *(12)*. Evidence also suggests that (GehD), a cell wall-associated protein that does not encode an LPXTG motif, is a bifunctional enzyme that also binds collagen in addition to its activity as a lipase *(18)*.

In addition to binding specifically to serum proteins, staphylococci, especially *S. epidermidis,* have the unique ability to bind plastic polymers (e.g., catheters). Heilmann and colleagues found this binding property is linked to the autolysin AtlE in *S. epidermidis (19)*. It was subsequently shown that *atlE* mutants of *S. epidermidis* were less virulent in a rat vascular catheter model *(20)*. Further work demonstrated that both AtlE bind vitronectin whereas a separate autolysin, Aae, binds fibrinogen, fibronectin, and vitronectin in a dose-dependent manner *(19,21)*. Thus, autolysins of staphylococci have the ability to bind both polymers (through an unknown mechanism) and serum proteins. Somewhat complicating the interpretation of the autolysin mutant phenotype, however, is the recent finding of the importance of bacterial extracellular DNA (eDNA) in the establishment of a staphylococcal biofilm *(22,23)*. eDNA provides structure that is important for both initial adherence and biofilm accumulation; thus, bacteria that are unable to lyse effectively (*atlE* or *aae* mutants) would be defective in eDNA release and thus be less adherent.

Thus, autolysins may have multiple roles in biofilm formation including the release of eDNA, initial adherence to polymers, and specific binding to serum proteins.

STAPHYLOCOCCAL BIOFILM ACCUMULATION

Defining the multiple mechanisms of staphylococcal biofilm accumulation and its clinical relevance has been an extremely exciting avenue of recent investigation. Recent data have suggested that *S. epidermidis* biofilm accumulation is mediated mostly by polysaccharide intercellular adhesin (PIA) and is sensitive to polysaccharide-dispersing enzymes such as dispersin B but resistant to proteases, whereas the converse is true for *S. aureus* biofilms *(24)*. However, there is increasing evidence demonstrating that clinical isolates of *S. epidermidis* produce proteinaceous biofilms (i.e., accumulation associated protein [Aap]) *(5)*. Furthermore, antibodies against PIA (or PNAG; poly-*N*-acetyl glucosamine) are protective in animal models of *S. aureus* infection suggesting expression of PIA/PNAG *in vivo (25)*. Therefore, the available data suggest that multiple proteins and PIA/PNAG may function to mediate biofilm accumulation within staphylococci, and their expression may depend on the nutritional state of the bacterium and/or niche. It is unknown whether the expression of these unique accumulation molecules exhibits any clinical significance in regards to clinical management of the biofilm-mediated infection or whether the metabolism differs in a PIA/PNAG-dependent biofilm in comparison to a proteinaceous-sensitive biofilm. Understanding these and other questions is fundamental to the rational design of new antibiotics and/or biofilm inhibitors. This section will summarize the molecules known to mediate biofilm accumulation; transcriptional regulation of these determinants will be discussed if known.

Polysaccharide Intercellular Adhesin/ Poly-*N*-Acetylglucosamine

Staphylococcal biofilm accumulation has been most well studied in the context of polysaccharide intercellular adhesin (PIA) or poly-*N*-acetylglucosamine (PNAG) synthesis. PIA is a β-1,6 linked poly-*N*-acetylated glucosamine and its synthesis is directed by enzymes encoded by the *icaADBC* operon (26,27). An identical molecule has been identified from *S. aureus* and is termed PNAG *(28,29)*. All four open reading frames (ORFs; *icaA*, *icaD*, *icaB*, and *icaC*) are required for PIA/PNAG synthesis *(30,31)*. Utilizing UDP-*N*-acetylglucosamine as a substrate, IcaAD acts as an *N*-acetylglucosaminyl transferase; IcaC, a membrane protein, most likely functions to transfer the growing polysaccharide outside of the bacterium to the cell wall. IcaB is a secreted deacetylase that functions to deacetylate PIA/PNAG; 15% to 43% of glucosamine residues are deacetylated *(29,32)*. Vuong and colleagues found that a 1457 *icaB* mutant was unable to form functional biofilm and exhibited reduced virulence in a foreign body infection model demonstrating the importance of deacetylation in PIA/PNAG-mediated biofilm accumulation *(33)*. Utilizing *icaADBC* mutants, several studies have demonstrated the importance of PIA in virulence of *S. epidermidis* using relevant animal models of infections; these studies found that PIA-deficient strains of *S. epidermidis* 1457 and O-47 have reduced virulence in comparison to isogenic PIA positive strains (*20,34,35,*36). Furthermore, PIA/PNAG inhibits neutrophil-dependent killing and mediates biocide resistance *(37,38)*. However, it is important to note and as will be detailed below, multiple clinical strains of *S. epidermidis* do not encode the *icaADBC* operon (*39–41*,42,*43*) and, even when encoded, *icaADBC* can be highly repressed (unpublished observations from the author). Similarly, most studies have found *icaADBC* encoded in almost all *S. aureus* isolates *(30,39,44)*, but the operon is highly repressed and is dispensable for biofilm formation *in vitro (39,45–48)*. However, *icaADBC* expression is upregulated in *S. aureus* during infection demonstrating that *icaADBC* expression is strain dependent and contains multiple layers of transcriptional and/or translational regulation *(47,49)*. Transcriptional regulation of *icaADBC* is very complex and published reports have documented 14 unique direct or indirect regulatory elements (Fig. 31-1).

σ^B—The first regulatory element identified as a member of the *icaADBC* regulon was σ^B, the alternative sigma factor in staphylococci *(50)*. Insertion of Tn*917* into the *S. epidermidis* 1457 *rsbU* gene, a positive regulator of σ^B expression, led to significantly decreased biofilm and PIA synthesis. Further work demonstrated that σ^B functions in an indirect manner to repress expression of *icaR,* a transcriptional repressor of *icaADBC (51)*; inactivation of

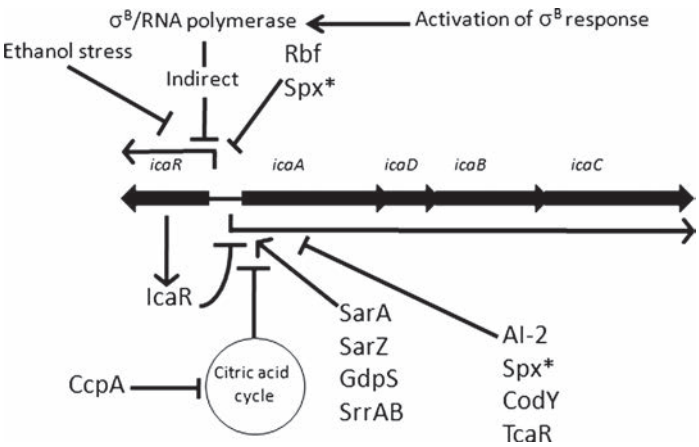

FIGURE 31-1 *icaADBC* regulatory circuit. Regulatory proteins known to function as activators of either *icaADBC* or *icaR* transcription are indicated with an *arrow*. Those that are known to repress transcription of *icaADBC* or *icaR* are indicated by a *blunt arrow*. (*) Spx is known to repress *icaR* transcription in *S. aureus* but represses *icaADBC* in *S. epidermidis*.

σ^B led to increased expression of IcaR and thus, decreased *icaADBC* transcription *(52,53)*. Ethanol pressure is also known to repress *icaR* transcription, however, this regulatory pathway is σ^B independent *(54)*.

IcaR/TcaR—icaR, a member of the TetR family of transcriptional regulators, is divergently transcribed from *icaADBC* (Fig. 31-1) and negatively regulates *icaADBC* transcription *(51)*. IcaR functions as a dimer and binds cooperatively to a 28-bp region upstream of *icaADBC (55)*. Cerca and colleagues recently found that in *S. aureus*, in contrast to *S. epidermidis*, *icaR* transcription is SarA and σ^B dependent, and IcaR is not required for activation of its own transcription suggesting that *S. aureus* and *S. epidermidis* regulate *icaR* transcription differently *(56)*. Utilizing the *ica* promoter region as a target in pull-down assays, Jefferson and colleagues identified a second regulator, TcaR, which has recently been shown to bind specifically to three separate regions in the *icaADBC* promoter region *(57,58)*. Interestingly, similar to IcaR, antibiotics bind to TcaR and inhibit their binding to the promoter region thus activating *icaADBC* transcription and PIA/PNAG production *(55,57)*.

Rbf—Rbf (*R*egulator of *B*iofilm *F*ormation) was first identified as a locus that regulated biofilm formation in response to glucose and sodium chloride in *S. aureus (59)*. Rbf has homology to the AraC/XylS family of transcriptional regulators and functions in an indirect manner to regulate *icaADBC* transcription by repressing *icaR* transcription *(60)*. As predicted, inactivation of *rbf* led to decreased virulence of *S. aureus* in a mouse model of foreign body infection due to decreased PIA/PNAG synthesis, although the effect was strain dependent *(61)*.

SarA/SarZ—The Sar family of DNA-binding proteins is a group of transcriptional regulators that function to activate or repress a large number of genes within the staphylococci, many of which are virulence genes including biofilm formation *(62)*. SarA has consistently been noted as a factor absolutely required for biofilm formation in both PIA/PNAG-dependent and PIA/PNAG-independent biofilms in *S. aureus* and *S. epidermidis (52,63–67)*. SarA is a positive regulator impacting *icaADBC* transcription in an *icaR*-independent manner *(65,66)*, although its function in regulating biofilm formation in PIA/PNAG biofilms is not clear but may involve protease production *(64)*. Furthermore, SarZ also acts as a positive activator of *icaADBC* transcription in *S. epidermidis* apparently independent of SarA *(68)*, although others have observed a relationship between SarA and SarZ expression and their interaction on biofilm formation in *S. aureus (69)*.

GdpS—The synthesis of cyclic dimeric GMP (c-di-GMP) is an important signaling molecule and regulator of biofilm formation in multiple Gram-negative bacteria *(70)*. However, only one protein in staphylococci, GdpS, contains a conserved GGDEP domain (diguanylate cyclase motif) *(71)*. Inactivation of *gdpS* resulted in a loss of biofilm formation and *icaADBC* transcription in media supplemented with sodium chloride; however, no c-di-GMP activity was detected in staphylococci suggesting that GdpS regulates biofilm formation in a c-di-GMP-independent pathway *(71)*. Further work has found that GdpS functions to regulate other virulence factors in *S. aureus* including proteases, fibrinogen-binding proteins, and protein A *(72)*.

SrrAB—Early studies on staphylococcal biofilm formation found that *icaADBC* transcription was induced when both *S. aureus* and *S. epidermidis* were grown under anaerobic conditions *(46)*. Later studies tied this observation to SrrAB, a two-component regulatory system homologous to ResDE in *Bacillus subtilis (73)* that is hypothesized to respond to environmental oxygen *(74)*. Studies from Ulrich and colleagues indicated that *icaADBC* transcription and PIA/PNAG synthesis in an *srrAB S. aureus* mutant was not induced under anaerobic growth conditions in an IcaR-independent manner *(74)*. In addition, the *srrAB* was less resistant to PIA/PNAG-mediated resistance to nonoxidative host response *(74)*. Induction of *icaADBC* in *S. aureus* grown under anaerobic conditions further suggests a function of PIA/PNAG in host resistance to the innate immune response.

Spx—Regulation of protein degradation in the staphylococci is mediated in part by ClpXP *(75)*. Two separate studies have indicated that ClpXP protease functions to regulate biofilm formation in both *S. aureus* and *S. epidermidis (75,76). clpX/clpP* mutants accumulate the transcriptional regulator Spx, known to function in multiple metabolic processes in *B. subtilis* including thiol homeostasis *(77)* and organosulfur metabolism *(78)*. Two recent studies have published conflicting data (see Fig. 31-1) demonstrating that accumulation of Spx in *clpXP* mutants increased *icaADBC* transcription through an IcaR-dependent process in *S. aureus (79)*; however, overexpression of Spx in *S. epidermidis* decreased *icaADBC* transcription in an IcaR-independent manner *(80)*. Further work is required to determine if the observed phenotype differences between *S. aureus* and *S. epidermidis* in regards to Spx are strain-dependent differences or conserved aspects within the species.

AI-2—It is proposed that the quorum-sensing molecule AI-2, which is synthesized from *S*-adenyolsylmethionine by LuxS, functions as a bacterial interspecies communication molecule. Multiple Gram-negative and Gram-positive species encode *luxS,* which was first identified as a locus required for bioluminescence in *Vibrio harveyi (81)*. However, the function of LuxS in the staphylococci is not known. Studies by Xu and colleagues found that insertional inactivation of *luxS* caused increased transcription of *icaADBC* and biofilm concomitant with an increase in metastatic disease as measured by a rat catheter model *(82)*. Microarray studies recently demonstrated that *luxS* mutants of *S. epidermidis* were deficient in amino acid, nitrogen, nucleotide, and carbohydrate metabolism *(83)*.

Central metabolism—Several early reports found that biofilm synthesis is regulated or induced by several environmental conditions such as anoxic growth conditions, iron limitation, glucose concentration, and subinhibitory concentration of antibiotics leading Somerville and colleagues to hypothesize that PNAG/PIA synthesis was linked to tricarboxylic acid (TCA) cycle activity *(46,84–87)*. Inactivation of aconitase led to increased *icaADBC* transcription and PIA synthesis suggesting that derepression of *icaADBC* is mediated by regulatory proteins that respond to the metabolic status of the bacterium *(88)*. Two global regulatory proteins involved in the carbon and the nitrogen metabolism cycles in Gram-positive bacteria are CcpA and CodY; both are linked to the TCA cycle (89). Seidl and colleagues demonstrated that an allelic replacement mutant of *ccpA* in

S. aureus increased *icaADBC* and PIA transcription; it was postulated that this was due to repression of the TCA cycle (*citA* and *citB*) *(90)*. Furthermore, CodY, which detects nutrient status of the bacterium by binding branched chain amino acids and GTP, represses *icaADBC* transcription under nutrient replete conditions *(91,92)*. Therefore, although the direct relationships regulating *icaADBC* transcription have not been identified in all cases, PIA/PNAG synthesis is linked to the metabolic status of the cell including TCA cycle activity and the regulatory circuit governed by CcpA and CodY.

Biofilm-Associated Protein

As previously mentioned, an increasing amount of evidence supports the notion that many clinical isolates of both *S. epidermidis* and *S. aureus* produce proteinaceous accumulation molecules and do not produce a detectable amount of PIA/PNAG. Biofilm-associated protein (Bap) was first identified as a proteinaceous adhesin that functioned in biofilm accumulation *(93)*. An orthologue exists in *S. epidermidis* and is termed Bhp *(11)*. Bap is closely linked to *S. aureus* isolates obtained from a bovine source and is quite rare in human isolates *(94)*; a recent study found that *bap* was not found in 262 *S. aureus* clinical isolates from various human and animal sources *(95)*. Depending on the study, *bhp* is encoded in approximately 15% to 45% of *S. epidermidis* human isolates *(5,96). bap* is associated with a pathogenicity island in *S. aureus* termed SaPIbov2, but *bhp* does not seem to be encoded on a mobile element in *S. epidermidis* RP62A *(11,94,97)*. Transcriptional analyses have shown that *bap* transcription is SarA and σ^B dependent in *S. aureus*, and formation of a Bap-dependent biofilm is sensitive to the σ^B-dependent proteases Aur and SspA that are overexpressed in a σ^B mutant *(98,99)*.

Accumulation-Associated Protein/ *Staphylococcus aureus* Surface Protein G

Aap (encoded by *S. epidermidis*) and its *S. aureus* orthologue *S. aureus* surface protein (SasG) are LPXTG proteins containing an N-terminal A domain and a B domain containing a variable number of 128-bp repeats *(100–103)*. SasG and Aap have no known binding affinity for extracellular matrix proteins; however, biofilm accumulation is mediated by Zn^{2+}-dependent dimerization utilizing the B domains of bacteria within the immediate vicinity of one another *(104)*. Furthermore, the A domain is known to bind specifically to corneocytes *(105)*. Interestingly, Aap is secreted in a nonfunctional form and is further processed by both host and bacterial proteases into a fibrillar protein *(100,103)*. Although Aap-dependent biofilms have been isolated from clinical *icaADBC*-negative *S. epidermidis* isolates *(5)*, the function of Aap in a PIA-dependent biofilm is unknown. Sun and colleagues found that inhibition of Aap by polyclonal antibodies in *S. epidermidis* RP62A inhibited a PIA/PNAG biofilm by 87% suggesting a function for Aap in both PIA/PNAG-dependent and PIA/PNAG-independent biofilms *(106)*. In addition, although the *aap* gene is found in approximately 90% of *S. epidermidis* isolates, recent data demonstrate that a functional Aap protein cannot be detected in some isolates when the gene is present *(96,107)*.

Extracellular Matrix-Binding Protein

Through enrichment experiments, Christner and colleagues isolated a biofilm-positive variant (1585v) of the PIA/PNAG negative *S. epidermidis* strain 1585 that produced a 460-kDa truncated isoform of Embp *(108)*. Extracellular matrix-binding protein (Embp) in strain 1585v was able to bind fibronectin but also mediates the accumulation phase of biofilm synthesis in addition to inhibition of phagocytosis *(108)*. Although most strains of *S. epidermidis* encode Embp, it is unclear how many clinical isolates of *S. epidermidis* express the appropriate isoform that is able to mediate biofilm accumulation.

Fibronectin-Binding Proteins A and B

The discovery demonstrating that FnbpA and FnbpB function to mediate *S. aureus* biofilm accumulation was reported independently by two laboratories *(109,110)*. Accumulation required both FnbpA and FnbpB and was independent of their ability to bind extracellular matrix proteins *(109)*. FnbpA and FnbpB accumulation was stimulated by mildly acidic growth media (due to glucose catabolism) or sodium citrate and is thus linked to TCA cycle activity *(109,110)*. Shanks et al. also determined that sodium citrate stimulation of biofilm accumulation was *icaADBC* independent, and, in fact, repressed *icaADBC* transcription as would be predicted by work from Sadykov et al. *(88,110)*.

Protein A (Spa)

Utilizing proteomic techniques, protein A was identified as an essential component of proteinaceous *S. aureus* biofilm *(111)*. Surprisingly, protein A-mediated accumulation was not dependent on anchoring of protein A to the cell surface as exogenously added protein A stimulated biofilm development *(111)*. Furthermore, competition studies indicated that protein A proficient wild-type strains (*S. aureus* Newman) outcompeted the *S. aureus* Newman *spa* mutant in a mouse foreign body infection model further demonstrating the fundamental role of Spa in proteinaceous biofilm accumulation *(111)*.

STAPHYLOCOCCAL BIOFILM MATURATION

Maturation is the most understudied aspect of biofilm development within the staphylococci. It is clear, however, that biofilm is composed of multiple metabolic niches with unique nutrient and oxygen concentrations (3). For example, using pulse-labeled DNA, oxygen probes, and green fluorescent protein (GFP) labeling experiments, Rani and colleagues found that *S. epidermidis* biofilms consisted of aerobically growing cells, cells that were utilizing fermentation to acquire ATP, dormant, and dead cells *(112)*. Several microarray studies have confirmed these data demonstrating that, in comparison to *S. aureus* or *S. epidermidis* growing under exponential phase, bacteria growing within a biofilm exhibit traits of microaerobic or anaerobic metabolism including amino acid catabolism *(45,113,114)*. In addition, microarray studies have indicated that additional genes are induced as a biofilm matures in flow cell systems (authors' unpublished data). Two genes induced

in a staphylococcal biofilm that have been studied include the arginine–ornithine transporter ArcD and succinate dehydrogenase (*sdhCAB*) *(115,116)*. Although a striking biofilm phenotype was not observed or reported when allelic replacement experiments were performed with both *arcD* or *sdhCAB,* the data strongly suggest that amino acids are utilized as a carbon source within biofilms. ArcD is part of the arginine deiminase operon that catabolizes arginine to form ATP and ammonia; succinate dehydrogenase functions within the TCA cycle that is required for catabolism of many amino acids. Further work is required to determine if inhibition of biofilm maturation processes is a viable target for antibiofilm treatment modalities.

STAPHYLOCOCCAL BIOFILM DISPERSAL

Similar to biofilm maturation, bacterial dispersal from staphylococcal biofilms is not well understood, but models are beginning to emerge. The difficulty in obtaining a model is due to the plurality of biofilm accumulation molecules (e.g., PIA/PNAG, Aap, eDNA, etc.). Detachment from *S. epidermidis* PIA/PNAG-dependent biofilms is accessory gene regulator (*agr*) dependent as *agr* mutant biofilms are thicker and *agr* activity has been detected on the surface of both *S. aureus* and *S. epidermidis* biofilms *(117,118)*. The detergent-like activity of phenol-soluble modulins and δ-toxin has been proposed to detach PIA/PNAG-mediated *S. epidermidis* biofilms; phenol-soluble modulins and δ-toxin are *agr*-dependent virulence factors *(119)*. A functional *agr* system is required for functional detachment of *S. aureus* proteinaceous biofilms where addition of autoinducing peptide (AIP; *agr* quorum sensing peptide) causes dramatic biofilm detachment (120). It is hypothesized that activation of *agr* on the outer surface of the biofilm activates transcription of certain proteases (e.g., Aur metalloprotease and SplABCDEF serine proteases) and nucleases that function to degrade the proteinaceous accumulation molecules including the eDNA (120,121).

CONCLUSIONS

An emerging theme in staphylococcal biofilm biology is the multitude of adherence and accumulation molecules that are used to form functional biofilms. Two recent reports found that both *S. aureus* and *S. epidermidis* clinical isolates have the ability to alternate between PIA/PNAG and proteinaceous biofilms *(6,7)*. These data suggest that staphylococci with particular accumulation molecules are selected under certain conditions/niches. Further investigation of biofilm development and maturation should yield novel antimicrobial therapies effective against all aspects of biofilm development (e.g., attachment, accumulation, maturation, and dispersion).

CHAPTER 32

Streptococci

Kent B. Crossley

Microorganisms of the genus *Streptococcus* were a major cause of healthcare-associated infection in the preantibiotic era. During the last half-century, they have been associated with occasional outbreaks of infection in hospitals.

The most frequent streptococcal species encountered as causes of healthcare-associated infections are group A β-hemolytic streptococci (*Streptococcus pyogenes*) (GABHS), group B β-hemolytic streptococci (*Streptococcus agalactiae*) (GBS), and *Streptococcus pneumoniae*. This chapter discusses healthcare-associated infections caused by these microorganisms and by other streptococci (e.g., group C and G streptococci). Healthcare-associated infections caused by enterococci are considered in Chapter 33.

Streptococci were first described in material recovered from wound infections by Billroth in 1874 and 5 years later by Pasteur in the blood of a patient with puerperal sepsis *(1)*. Until the introduction of sulfonamides, streptococci (particularly GABHS) were common causes of healthcare-associated infection. Puerperal sepsis was a major concern in the first third of the 20th century *(2)*. The mortality rate from bacteremic group A streptococcal infections at Boston City Hospital in the 1930s was 72% *(3)*.

Although antimicrobials have markedly reduced the frequency of these infections, streptococci continue to cause healthcare-associated disease. In a recent study of bloodstream infections, 10.3% were caused by Streptococci. *S. pneumoniae* accounted for half followed by GABHS and viridans Streptococci in decreasing frequency *(4)*.

GROUP A β-HEMOLYTIC STREPTOCOCCI

GABHS are relatively uncommon causes of healthcare-associated infection *(5)*. A review of invasive GABHS infections in Ontario between 1992 and 2000 found that 12.4% were healthcare-associated *(6)*. Surgical site and postpartum infections accounted for two-thirds of these cases. Interestingly, 70% of the hospital outbreaks involved nonsurgical, nonobstetric patients (7). Of severe cases of GABHS disease in Europe in 2003 to 2004, 4.3% were noted to be healthcare-associated (8). GABHS tend to cause small outbreaks of burn wound, puerperal, and neonatal infection that persist and that are difficult to evaluate and control.

GABHS may be serogrouped on the basis of protein antigens, designated as M and T antigens. For the last decade, sequencing of the *emm* gene, which specifies filamentous M protein, has been more widely used *(9)*. This method has also been used for large population-based studies *(10)*. Random amplified polymorphic DNA (RAPD) and pulse field gel electrophoresis are also occasionally used *(11)*.

Surgical Site Infection and the Epidemiology of GABHS Infection

GABHS are common causes of community-acquired pharyngitis and skin infection. These microorganisms may also be carried in the throat, on the skin, and in the rectum and vagina of asymptomatic people *(12–15)*. Somewhat <1% of normal individuals have positive anal or vaginal cultures for group A streptococci *(14,16)*. Anal carriage in children with group A β-hemolytic streptococcal pharyngitis appears to be somewhat more frequent; in one study, 6% of children with documented GABHS pharyngitis had the same microorganisms recovered from anal swabs *(13)*.

Wu et al. *(12)* reported that 12.3% to 18.4% of hospital employees with pharyngitis had throat cultures positive for GABHS. It is curious that, despite frequent carriage of this microorganism in the respiratory tract of healthcare workers, very little healthcare-associated transmission from this source has been documented. Only five small outbreaks of infections appear to be directly the result of pharyngeal carriage of GABHS *(17–21)*. In one of these outbreaks, the same strain that infected the patients and an anesthesiologist was also recovered from a member of the physician's family *(17)*.

Although GABHS may be carried on unbroken skin *(15)*, outbreaks resulting from cutaneous sources in healthcare workers have primarily been traced to individuals with clinically evident infection. Bisno et al. *(22)* described a patient who developed GABHS bacteremia from an intravascular catheter inserted by a physician who had an identical *Streptococcus* isolated from a healing wound on the dorsum of his hand. Mastro et al. *(23)* reported an outbreak of 20 postoperative surgical site infections that occurred over 40 months. This outbreak was eventually traced to an operating room technician who had the identical type of GABHS cultured from psoriatic lesions on his scalp. This individual worked in the operating rooms only before operations were performed.

Asymptomatic rectal or vaginal carriage of GABHS is the most commonly reported source of outbreaks of healthcare-associated surgical site infection. Schaffner et al. *(24)* described an outbreak that resulted from anal carriage of streptococci by an anesthesiologist. His throat culture was negative, but an M nontypeable group A *Streptococcus* similar to that recovered from nine patients with infection was cultured from an anal swab. McKee et al. *(25)* reported an outbreak of 11 cases of infection associated with a medical attendant who was a rectal carrier. The same microorganism was also cultured from two of four family members. In this study, after the carrier exercised in an 8-ft by 11-ft examining room, settle plates yielded GABHS. A similar outbreak involving four patients was reported by Richman et al. *(26)* and resulted from carriage by a surgeon. Kolmos et al. *(21)*, in a review of surgical site infections causally tied to healthcare workers, noted that anal carriage appeared to be associated with rectal ulcers, hemorrhoids, and other rectal pathology.

Viglionese et al. *(27)* described an outbreak of postpartum infections traced to an obstetrician who was an anal carrier of GABHS. Of 34 patients delivered vaginally by this physician, 6 (18%) were infected. The obstetrician was treated with penicillin, rifampin, and hexachlorophene; surveillance cultures were negative 1 week, 1 month, and 3 months later. Subsequently, however, four additional cases occurred 14 months after the end of his treatment, and he was again found to be colonized with the same microorganism. One additional case occurred during the next 19 months. This is the only published report that suggests recurrent outbreaks might be caused by one healthcare worker who continues to carry or becomes recolonized with the same GABHS. We have had a similar experience with a vaginal carrier of GABHS. After treatment with erythromycin and rifampin, additional infections occurred, and she was found again to be colonized. Some experts recommend use of settle plates as a sensitive method to assess ongoing shedding of GABHS by carriers during an outbreak *(28)*.

Vaginal carriage has been documented as a source of surgical site infections less often than rectal carriage. Berkelman et al. *(29)* reported postoperative surgical site infections that occurred on two occasions, 5 months apart, associated with a nurse with both vaginal and rectal carriage of GABHS. (In this case, the two outbreaks involved serologically different streptococci.) Stamm et al. *(16)* reported another outbreak involving 18 patients. The source was a nurse with vaginal colonization with GABHS.

Based on evidence presented by Berkelman et al. *(29)* and Mastro et al. *(23)*, it seems most likely that aerosolization of GABHS with motion or activity followed by contamination of the surgical site is the usual mode of transmission. In the outbreaks described by Stamm et al. *(16)* and Schaffner et al. *(24)*, cases occurred in operating rooms adjacent to the one in which the source employee worked. Rutishauser et al. *(30)* reported two patients who developed streptococcal toxic shock after exposure to a surgeon who had nasal (but not pharyngeal) GABHS colonization. An outbreak involving three patients (two of whom died) was reported to be associated with a surgeon believed to be colonized with GABHS *(31)*. A recent outbreak of 28 cases of GABHS infection was associated with care from a hospital wound care team. Although vaginal, rectal, and pharyngeal cultures of members of the team were negative, cases recurred a year later and a carrier was then identified *(32)*.

Nearly all of the approximately 20 reported outbreaks of GABHS surgical site infection have been small, relatively chronic, and associated with an infected or colonized healthcare worker who is not immediately identified as the source. Occasional outbreaks not associated with an identified source have been reported. Webster et al. *(33)* described an outbreak of infection in seven patients on a plastic and maxillofacial surgery ward and in one patient on an adjacent psychiatric ward in London. The source of the outbreak was unclear, and it ended with the closure of the unit before its move to a new building.

GABHS may also be recovered from dust in the environment, and it is possible (but unlikely) that microorganisms disseminated by a carrier could contaminate hands or other surfaces and then be transmitted to a patient.

There are several reported outbreaks in which clusters of healthcare employees have acquired GABHS in an outbreak. Ramage et al. *(34)* reported three patients and six nurses who had developed infection; the nurses (three of whom were not cultured) all had developed pharyngitis. Kakis et al. (35) described transmission of the identical GABHS strain to 24 healthcare workers. Transmission occurred within 25 hours following exposure to this individual, and all 24 healthcare workers developed symptoms of pharyngitis within 4 days of contact with the source patient.

Two recent reports document transmission from a patient with pneumonia to two nurses (36) and from a patient with necrotizing fasciitis to a respiratory therapist who developed pneumonia and toxic shock syndrome *(37)*. A 2006 report noted transmission from a patient with necrotizing fasciitis to two operating room staff; both developed pharyngitis *(38)*. The last two papers recommended more careful infection control precautions when caring for patients with large open wounds infected with GABHS.

Although a very uncommon event, foodborne GABHS illness may occur. A recent Japanese report described an outbreak among students at a university hospital. After eating boxed lunches, some 65% of the group had GABHS isolated from a throat culture (39).

Burn Wound Infection

GABHS were important pathogens in burn units before the introduction of routine penicillin prophylaxis for patients with thermal injuries. They continue to cause occasional burn wound infections and outbreaks.

In 1984, Whitby et al. *(40)* reported an outbreak that began in a burn center and eventually spread to involve an intensive care unit in an associated hospital. Of the eight patients in the burn unit who were colonized with GABHS, two developed clinical evidence of infection and one additional patient became bacteremic. The outbreak apparently resulted from admission of a patient who carried GABHS in his pharynx. Burnett et al. *(41)* described an outbreak involving four patients, six relatives of the index case, and four staff members in Sheffield. The source was a child with burns who had streptococcal pharyngitis. GABHS infection developed in four nurses (cellulitis in two, a facial pustule and an infected whitlow in one each). The outbreak was

controlled by treatment with penicillin V. In the index case, the burn wounds did not clear with oral antibiotic therapy alone but were cured after mupirocin was applied to the burn wounds. The authors believed that the use of short-sleeved isolation gowns was related to the occurrence of the lesions on the forearms of two of the nurses. Allen and Ridgway *(42)* reported a small outbreak of *S. pyogenes* infection in a burn unit in Liverpool. The source was apparently GABHS pharyngeal colonization in a patient admitted to the burn unit. The outbreak persisted despite treatment of cases and careful hand washing. Prophylaxis of all uninfected patients on the unit and all new admissions with penicillin V, 500 mg each day, terminated the outbreak.

Two papers have questioned the need for prophylaxis of GABHS in patients with burn wound infection. Sheridan et al. compared two cohorts of children (treated in 1992–1994 and 1995–1997, respectively) with and without penicillin prophylaxis *(43)*. There was no difference in the frequency of GABHS infection during the two time periods. Bang and others did a similar study and reached a similar conclusion *(44)*.

Puerperal and Neonatal Infection

The communicable nature of puerperal fever was well understood by 1840 *(45,46)*. The careful observations of Alexander Gordon in Aberdeen and Semmelweis in Vienna made prevention possible *(47)*. Semmelweis noted that an obstetric service staffed by midwives had little puerperal infection. On an adjacent ward, the service run by physicians (who also participated in autopsies on patients who had died) experienced three to five times the number of infections. He also observed that, in hospitals in which obstetric units were distant from autopsy rooms (and here he compared Dublin and Vienna), puerperal infection was uncommon. In May 1847, he introduced chlorine water hand rinses to the first obstetric clinic in Vienna and documented a dramatic decrease in the frequency of puerperal infections *(48)*.

Despite the significant reduction in the occurrence of these infections through hand washing, major outbreaks were relatively common until effective antimicrobials became available *(2)*. Isolated outbreaks of puerperal infection caused by GABHS have continued to occur. Data from the Active Bacterial Core surveillance program from 1995 to 2000 suggest about 220 cases of GABHS postpartum infection occur annually in the United States. Clusters of infections caused by microorganisms of the same *emm* types suggested common source outbreaks occurred (49). Most outbreaks are small (i.e., one or two cases). While postpartum infections account for only about 2% of invasive GABHS infections in the United States, 3.5% of healthy women with GABHS postpartum infections die of their infection (49).

Van Beneden and others recently assessed knowledge of obstetricians and gynecologists about prevention and management of healthcare-associated GABHS infections *(50)*. Of the respondents, >70% were unaware of Centers for Disease Control and Prevention (CDC) recommendations. Most (86%) reported not routinely culturing postpartum infections.

Small outbreaks of infections in newly delivered neonates are also well recognized. Studies published in the last 30 years include an outbreak caused by a tetracycline-resistant strain of GABHS that was isolated from both adults and neonates *(51)*. The outbreak was terminated by closing the implicated ward and administering penicillin prophylaxis or treatment to all of the mothers and infants. Tancer et al. *(52)* reported an outbreak involving 11 infants, 2 postpartum mothers, 3 nurses, and another hospital employee. This outbreak was temporally related to episodes of pharyngitis in a newly delivered mother and an elevator operator in the maternity wing of the hospital. Neither of these individuals was cultured. Ogden and Amstey *(53)* described five patients with puerperal GABHS infection. These cases were characteristic of the clinical presentation of puerperal GABHS infection. All of the mothers experienced uterine tenderness and then developed fever spikes associated with recovery of these microorganisms from the lochia. McGregor et al. *(54)* reported a similar-sized outbreak. A labor room nurse had mild eczema on her hands, and these lesions grew GABHS and *Staphylococcus aureus*. The microorganism was serologically identical to that recovered from the patients. In two studies, evidence has suggested that outbreaks were related to contamination of inanimate objects. In one, a handheld showerhead was seen as a possible route of transmission; in the other, use of a communal bidet was implicated *(55,56)*. GABHS were shown by Claesson and Claesson *(55)* to remain viable on a metal surface for more than 9 days.

Outbreaks of GABHS infection also have involved neonates. In these episodes, microorganisms have primarily contaminated the umbilicus. Transmission between infants has apparently occurred with nursing care. In the two outbreaks described by Geil et al. *(57)*, penicillin was administered to all of the infants in the nursery on both occasions. This regimen was successful in the first of their two outbreaks. However, in the second outbreak, it was not successful without the additional application of bacitracin ointment to the umbilical stumps of the infants. Bygdeman et al. *(58)* reported an outbreak in Stockholm in which 67% of infants had umbilical colonization with GABHS. Pharyngitis was documented among family members of neonates. Five of sixty-nine mothers who had nose and throat cultures for GABHS yielded this microorganism. Presumably, this outbreak resulted from introduction of an epidemiologically virulent strain by a mother or healthcare worker. Transmission at the time of delivery could also have been responsible, although the authors did not perform vaginal or rectal cultures.

An outbreak described by Isenberg et al. *(59)* involved 10 newborn infants over a 2-month period. Nineteen percent of the infants in the nursery were found to be carriers of streptococci. Again, umbilical infection was most frequent. Only 1 of the 10 infected infants had GABHS isolated from throat cultures.

Infections Associated with Nursing Homes

GABHS has been reported to cause outbreaks of infection in various healthcare settings notably in facilities for the elderly *(60–62)*. Over the last 20 years, a number of outbreaks of GABHS infections have been reported in long-term care units (LTCF) in the United States. These reports have occurred during a period in which GABHS disease has been caused by strains of apparent increasing virulence *(63,64)*.

The CDC described outbreaks in four nursing homes during the winter of 1989 to 1990, each in a different state *(65)*. Infection occurred in 18 residents, with slightly over half [(10 of 18 (56%)] of the residents dying. Pneumonia and cutaneous infection were most common. Culture surveys to identify pharyngeal carriage in each of the four nursing homes revealed that 11 of 312 residents (3.5%) and 4 of 297 staff members (1%) had asymptomatic pharyngeal carriage of GABHS. These isolates were found to be the same serotype as the strains causing infection in each of the homes. The outbreaks were controlled following antimicrobial prophylaxis or therapy (Fig. 32-1).

Data about long-term care facility (LTCF) associated GABHS infection from the Active Bacterial Core surveillance program from 1998 to 2003 were recently reviewed (66). Invasive GABHS infections were six times more common among LTCF residents when compared with community-living elderly. Death was also 1.5 times more frequent among the LTCF residents. Bacteremia without a focus, pneumonia, and cellulitis were the most common infections in both groups of patients.

A review of invasive GABHS infection in Minnesota for the years 1995 to 2006 found that 7% of cases occurred in nursing home residents. Of the 134 cases, 34 were part of 13 clusters of infection (67). In two of these outbreaks, 2.7% and 6.2% of throat cultures from staff grew GABHS. In the same facilities, 5.9% and 4.5% of throat cultures of residents were positive. Carriage rates documented in a Georgia outbreak were 9% among staff and 10% among residents (68).

A more recent LTCF outbreak in Georgia involved six cases that occurred in a 104-bed facility in March and April 2004. As also documented in the other Georgia outbreak, presence of nonintact skin was associated with this cluster. Although 16.5% of residents carried the implicated strain, only 2.4% of employees were colonized with this microorganism. These authors suggested the importance of training both employees and visitors in hand hygiene and infection control *(69)*.

Another outbreak occurred in a Nevada nursing home in late 2003 *(70)*. The authors reported that about a third of employees did not always wash their hands between patient contacts.

Schwartz and Ussery *(71)* reviewed reports to the CDC of invasive GABHS infections in nursing homes and described five other outbreaks that were primarily associated with noninvasive infection. Outbreaks of noninvasive disease tended to last longer, were associated with more cases, and characteristically involved patients who were more physically impaired than those infected in the invasive outbreaks.

In all of these nursing home outbreaks, there was no clear proof that healthcare workers were sources of the microorganism. (The positive pharyngeal cultures suggest possible introduction of these microorganisms, but obviously the healthcare workers might have been colonized by exposure to the nursing home patients.) In two of the nursing home outbreaks investigated by the CDC, extensive environmental culturing yielded only one positive culture for GABHS. This would suggest that these microorganisms are uncommonly transmitted by fomites *(65)*.

Critical Care Units

Several outbreaks of GABHS have been described in intensive care units in teaching hospitals. In a review of clusters of GABHS, Schwartz et al. *(72)* describe family and healthcare-associated clusters and outbreaks within nursing homes. All five healthcare-associated clusters reported to the CDC occurred in intensive care units. The index patient in each had streptococcal toxic shock syndrome.

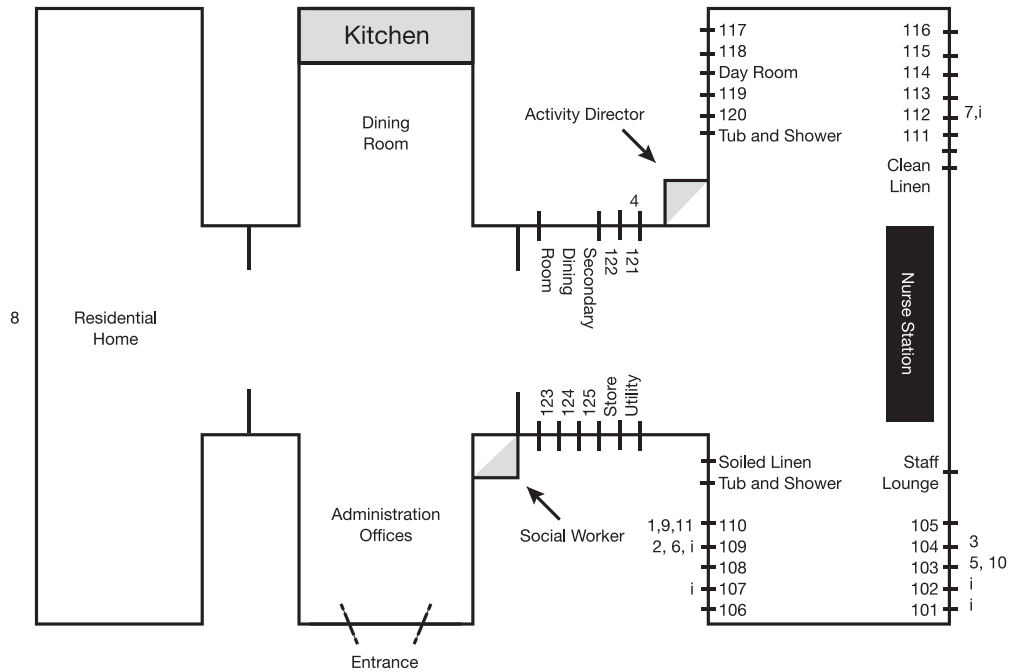

FIGURE 32-1 Distribution of cases of GABHS infection in a North Carolina nursing home. Spatial clustering of infections in one wing of the nursing home is evident. (Adapted from Auerbach SB, Schwartz B, Williams D, et al. Outbreak of invasive group A streptococcal infections in a nursing home. Lessons on prevention and control. *Arch Intern Med* 1992;152:1017–1022.)

Types of infections included cellulitis, paronychia, and pharyngitis. In three of the four outbreaks in which the causal microorganisms were typed, a serotype M1 strain was identified. This serotype has often been associated with invasive infection and the streptococcal toxic shock syndrome *(73,74)*.

Lannigan et al. *(75)* described a cluster of five cases that followed the admission of a patient with necrotizing fasciitis to a Canadian hospital. The microorganism was serotype M1. Two nurses developed cellulitis (superimposed on underlying dermatitis), and three patients had GABHS isolated from endotracheal secretions. Both of the isolates from the nurses and one of the three isolates from endotracheal secretions were the same M and T type as the index patient's microorganism; in two of the patients, sputum isolates were not typed. Transmission by contamination of the nurses' hands seemed most likely. A similar outbreak, involving two patients with isolates of the same M and T type, occurred following admission of a patient with facial cellulitis to an intensive care unit *(76)*. The two patients who acquired the microorganism had endotracheal tubes in place and developed pneumonia and bacteremia.

A recent outbreak involving two healthcare workers that developed febrile pharyngitis was described by Chandler et al. *(38)*. Both individuals had prolonged contact with the open wound of a patient with GABHS pharyngitis and necrotizing fasciitis in an operating room.

Control of Infections in Hospitals and Long-Term Care

Whether a GABHS outbreak occurs in an acute care hospital or a nursing home (and no matter the types of infection), much of the process of evaluation and control is the same (Table 32-1). Most outbreaks of GABHS are small; a single case that is apparently healthcare-associated should warrant an investigation.

After developing appropriate case definitions, determining the time course of the outbreak, and examining basic epidemiologic data, it is appropriate to look for patients or healthcare workers who might be carrying GABHS. Rectal and/or vaginal carriage is at least as frequent as pharyngeal carriage. Use of settle plates may be very helpful in determining if colonized staff continued to shed microorganisms *(28)*. Penicillin alone has not been effective in eliminating pharyngeal, rectal, or vaginal colonization in a number of carriers. Recommendations for chemoprophylaxis from CDC are summarized in Table 32-2 (77). (See also Chapter 8.)

Prompt culturing and treatment of individuals who have clinical manifestations of streptococcal infection is appropriate. Although penicillin remains uniformly effective against GABHS, resistance to alternative agents (e.g., the macrolides or tetracycline) occurs in 10% to 15% of isolates. Before erythromycin is used in place of penicillin to treat a carrier or for prophylaxis, susceptibility of the isolate to this drug should be determined. In some settings—especially in long-term care—antibiotic treatment has been given to all of the patients on a ward or a unit. Although this has not been done in a controlled fashion, outbreaks have usually ended after this intervention *(71,78)*.

In settings other than operating rooms, GABHS infections are occasionally spread by the respiratory route or, more often, by contamination of hands of healthcare workers. Appropriate infection control intervention will, therefore, require emphasis on careful hand washing. Interruption of respiratory spread (by use of a mask) in individuals who are known or suspected to be infected or colonized with GABHS before antibiotic administration is also necessary. In acute care hospitals, these are relatively easy interventions, but in nursing homes, limited hand washing facilities and infection control resources may make it difficult to take appropriate control steps. Most homes do not pay employees when they are ill. Thus, workers with streptococcal pharyngitis or cutaneous infections may often be providing care while they are infectious.

Especially when patients are infected with large numbers of microorganisms (e.g., burn wound infections), control may require awareness of the potential of airborne transmission and the possible (although unlikely) role of fomites. GABHS are very resistant to desiccation, and reports of infections in operating rooms adjacent to those in which colonized surgeons or anesthesiologists have worked indicate that airborne transmission may occur *(24,26,29)*.

TABLE 32-1

Steps in the Management of an Outbreak of GABHS Infection

More than one case of apparent institutionally acquired infection should initiate an outbreak investigation
Develop case definitions (*definite* infection if culture positive for GABHS, *probable* if symptoms and signs compatible with streptococcal infection but no culture done)
Examine susceptibility of isolates and treat cases appropriately
Make an effort to determine likely sources for the outbreak by examining data about contacts between patients and healthcare workers
Attempt to identify healthcare workers and patients who might be sources (by examining for dermatitis and by asking about skin infections and sore throat)
Do vaginal, rectal, and pharyngeal cultures (and cultures of areas of dermatitis) of healthcare workers or patients who may be potential sources
Arrange for serotyping of isolates
Isolate apparent sources and patients until appropriately treated (see text)
Reculture source of outbreak at 1 week and at 1 and 3 months after treatment

GROUP B β-HEMOLYTIC STREPTOCOCCI

S. agalactiae (β-hemolytic streptococci belonging to Lancefield group B) was originally described as a cause of mastitis in cattle *(79)*. Since the mid-1960s, GBS have become a common cause of puerperal and neonatal

TABLE 32-2

Recommended Regimens for Elimination of Asymptomatic Group A Streptococcal Colonization

Drug	*Dosage(s)*	*Comment(s)*
BPG plus rifampin	BPG. 600,000 U i.m. in 1 dose for patients weighing <27 kg or 1,200,000 U i.m. in 1 dose for patients weighing ≥27 kg; rifampin; 20 mg/kg/d po (max. daily dose, 600 mg) in 2 divided doses for 4 d	Not recommended for pregnant women because rifampin is teratogenic in laboratory animals. Because the reliability of oral contraceptives may be affected by rifampin therapy, alternative contraceptive measures should be considered while rifampin is being administered
Clindamycin	20 mg/kg/d po (max. daily dose, 900 mg) in 3 divided doses for 10 d	Preferred for healthcare workers who are rectal carriers of GAS[a]
Azithromycin	12 mg/kg/d po (max. daily dose, 500 mg/d) in a single dose for 5 d	Pregnancy category B: human data reassuring (animal positive) or animal studies show no risk[a]

All regimens are acceptable for nonpregnant persons who are not allergic to penicillin, BPG, benzathine penicillin G; GAS, group A streptococci; max., maximum.

[a]Clindamycin or azithromycin is acceptable for persons allergic to penicillin. If administered to healthcare workers implicated in an outbreak or to their colonized household contacts, susceptibility testing should be performed.

(From The Prevention of Invasive Group A Streptococcal Infections Workshop Participants. Prevention of invasive Group A streptococcal disease among household contacts of case patients and among postpartum and postsurgical patients; recommendations from the CDC. *Clin Infect Dis* 2002;35:950–959.)

infections, some of which are healthcare-associated *(80)*. In one recent population-based study, 22% of GBS infections were healthcare-associated *(81)*. Other studies suggest that about 25% of cases of GBS infections manifest ≥48 hours after hospital admission. Although there are no recent studies, data suggest that between 46% and 70% of *S. agalactiae* bacteremias are healthcare-associated *(82–84)*.

Recently published papers have made it clear that invasive Group B Streptococcal infection is increasingly frequent among nonpregnant adults. This appears to be particularly true of older patients and those with chronic underlying diseases (e.g., diabetes or conditions associated with immunosuppression) (85).

Group B streptococci may be subdivided into nine types on the basis of immunospecific carbohydrates *(86)*. Type I may be further divided into Ia and Ib. Type II is most commonly associated with early-onset disease (usually characterized by meningitis occurring shortly after birth). Type III has been isolated largely from blood cultures of infants taken more than 10 days after birth *(87,88)*. Use of this type of identification has been of help in documenting healthcare-associated transmission of these microorganisms.

Epidemiology and Transmission in the Hospital

Group B streptococci are carried within the gastrointestinal tract *(89,90)* and may colonize the urinary tract and the vagina. Rates of colonization vary depending on the number of cultures, the sites sampled, and whether an enrichment medium is used. Studies suggest that 20% to 25% of women carry GBS genitally during pregnancy *(91,92)*. Among infants, Ferrieri et al. *(93)* showed that the external ear was the most commonly colonized site, with nose, umbilicus, and rectum also often yielding GBS.

It has been repeatedly demonstrated that a significant proportion of infants who are colonized with group B streptococci acquire their microorganisms by healthcare-associated transmission and not from their mothers *(94)*. Easmon et al. *(95)* reported that 36% of infants who acquired GBS did so through healthcare-associated routes. (The other 64% of infants who were colonized in this study acquired infection from their mothers.) These authors and others have noted that healthcare-associated acquisition of this microorganism is associated with colonization at fewer sites and by smaller numbers of microorganisms *(96)*. Presumably, infants contaminated by maternal routes may, thus, be at greater risk for development of infection. Easmon et al. *(95)* showed that at 6 weeks after discharge from the hospital, colonization was present in only 10% of babies who were colonized with GBS during their hospitalization but whose mothers were not. In contrast, infants who were positive for GBS and whose mothers were also culture-positive with the same microorganism during hospitalization were five times as likely to be carriers at 6 weeks (52% vs. 10%).

Easmon et al. *(95)* compared the frequency of transmission in an obstetric unit with that in a neonatal intensive care unit (NICU). In the obstetric unit, 38 of 107 (36%) colonized babies acquired the microorganism from a nonmaternal source versus only 2 of 23 (9%) in the NICU *(95)*. This suggests that more careful attention to infection control measures in the NICU may be associated with a reduction in the frequency of healthcare-associated transmission of GBS *(97)*.

Group B streptococcal carriage among healthcare workers is relatively common *(98)*. In one study, the carriage rate ranged from 6% to 50% in serial prevalence surveys of NICU staff *(95)*. Eighty-eight percent of the carriers had the microorganism recovered from perianal swabs; pharyngeal carriage (or simultaneous carriage at both sites) accounted for the remainder. Despite rather frequent colonization of healthcare workers, documented transmission of identifiable strains of GBS to patients is rare. Easmon et al. *(95)* reported that a pediatrician apparently transmitted a group III phage type 11 strain to four babies on whom he did well-child examinations.

The bulk of cases of group B streptococcal infection acquired in the hospital appear to have occurred because of transient hand contamination of healthcare workers *(99)*. GBS have also been reported to contaminate devices and cause infection in this manner. Davis et al. *(100)* found group B streptococci in pressure transducer domes. The authors were able to correlate colonization with use of intrauterine transducers and documented a reduction in colonization following sterilization of domes after each maternal use.

Puerperal and Neonatal Infections

The frequency of healthcare-associated infections in neonates caused by group B streptococci is unclear. Although reported as a common cause of bacteremia and pneumonia in the past *(101)*, recent studies have not made the same observations. Two European studies of healthcare-associated infections in NICUs (one in Denmark and another in the Netherlands) did not identify any Group B streptococcal infections (102,*103*).

Only a small proportion of newborns colonized with GBS will develop clinical infection. Two syndromes in neonates have been associated with GBS infection. One is an infection of sudden onset developing within the first few days of life (early onset) and characterized by meningitis or pneumonia, often with bacteremia. The mortality rate is high, and serious sequelae in survivors of central nervous system disease are common. All three of the major serogroups are recovered with approximately equal frequency. Important risk factors associated with this syndrome include premature labor and prolonged rupture of membranes *(104)*.

The other type of neonatal infection occurs characteristically 3 to 4 weeks after birth (late onset) and is associated with a lower mortality rate. Meningitis is the most common manifestation, and sequelae are often frequent and serious. Approximately 90% of cases of late-onset disease are caused by type III microorganisms.

Although GBS neonatal infection is relatively common, recognizable outbreaks are not often described. In part, this must be because of the difficulties in distinguishing maternally acquired from healthcare-associated disease. Macfarquhar et al. (105) described an epidemic of late-onset infection occurring in five infants in an NICU. No nursery personnel carried the same types as was recovered from the patients.

In adults, GBS infections may be encountered in women following delivery. Surgical site infections in women who have had a Cesarean section and endometritis are most common. Evidence suggests that these infections are particularly common in immunocompromised women *(106)*.

Group B streptococci may also be encountered as causes of healthcare-associated urinary tract infection, pneumonia, or meningitis. GBS have been associated with intravenous line infection and have been described as the cause of a small outbreak of infections associated with arthroscopy *(107)*. The exact route of infection in this outbreak was unclear. GBS infection has been reported following cardiac catheterization and, in the one case reported, was felt to be associated with multiple puncture sites made to gain vascular access *(108)*. Burn wound infection has also occurred *(109)* as has hemodialysis catheter–related infection *(110)*.

One recent study has documented a series of Group B streptococcal prosthetic hip infections. Thirty infections were reported; 27 were thought to have been hematogenous. Treatment failure was noted to be frequent because of the ages and underlying diseases of the infected patients (*111*,112).

The most serious GBS infections are acquired maternally. For this reason, extensive efforts have been made during the past 25 years to reduce or eliminate acquisition of GBS at the time of delivery. The most popular strategy employs screening cultures and subsequent administration of antibiotics such as ampicillin during labor (113). Antibiotic administration is especially indicated in women who are at high risk for serious GBS infection or for delivering a child who is likely to be infected *(98)*. Data from the CDC suggest that a significant decline in early-onset GBS disease has occurred in recent years *(114)*.

Healthcare-associated acquisition of GBS infection is primarily a result of transmission on the hands of healthcare workers, enabling microorganisms to be spread between infected mothers or infants and other mothers or neonates. Thus, hand washing is perhaps the most important mechanism for preventing transmission of this microorganism within the hospital (see also Chapter 52).

OTHER HEALTHCARE-ASSOCIATED (NONENTEROCOCCAL) STREPTOCOCCAL INFECTIONS

Pneumococci

S. pneumoniae is a well-recognized cause of healthcare-associated infection. The first probable outbreak was described in 1903 *(115)*. A recent analysis examined the etiology of pneumonia as reflected in a large US database with information from some 59 hospitals for the period between January 1, 2002 and December 31, 2003 (116). The paper reported that 16.6% of community-acquired pneumonia was caused by *S. pneumonia*; 5.8%, 3.1%, and 5.5% of pneumococcal pneumonia cases were classified as ventilator-associated, hospital-acquired, and healthcare-associated, respectively, in origin.

A study compared 37 patients with healthcare-associated pneumococcal bacteremia (first positive blood culture performed >72 hours after admission in a patient who did not have a clinical syndrome compatible with infection on admission) with controls. Respiratory and hematologic malignancy, anemia, chronic obstructive pulmonary disease (COPD), and coronary artery disease were significantly associated with healthcare-associated pneumococcal bacteremia. There was also a strong association with death within 7 days of the date of the initial blood culture; the mortality rate was 40.5% compared with 1.2% for controls *(117)*.

Recent papers about healthcare-associated *S. pneumoniae* have emphasized the place of this microorganism as a cause of infection in compromised patients. An 8-year review of pneumococcal bacteremia from two large Spanish teaching hospitals found that 10.6% of cases were healthcare-associated. Most patients had significant underlying illness to include malignancy, COPD, heart

failure, renal failure, cirrhosis, and HIV infection *(118)*. Pneumonia was the primary infection in 70% of these patients. Nearly half of these bacteremic patients died. In a cancer center, 16/135 episodes of pneumococcal bacteremia were healthcare-associated (119). Pneumococcal pneumonia and bacteremia have also been recently noted to occur on occasion in burn patients *(120)*. A recent study of healthcare-associated bacterial pneumonia in HIV infected patients in Milan reported *S. pneumoniae* accounted for 21% of cases and was exceeded in frequency by only *Pseudomonas aeruginosa* and *S. aureus* (121).

Changes in the prevalence of *S. pneumoniae* serotypes and antibiotic resistance patterns are continuing to evolve both in the community and in the healthcare settings (122,123). Drug-resistant pneumococci were recovered from patients with healthcare-associated pneumonia more often than with community-acquired pneumonia in a study from Barcelona *(124)*. In a study that examined patients with levofloxacin-resistant *S. pneumoniae*, two-thirds were healthcare-associated. Age, nursing home residence, COPD, number of hospitalizations, and exposure to fluoroquinolones correlated with infection or colonization with the resistant pneumococcal strains *(125)*.

Fluoroquinolone-resistant isolates of *S. pneumoniae* have been documented as causes of at least two difficult-to-eradicate outbreaks of infection in long-term care facilities *(126,127)*. These microorganisms are significantly more often recovered from residents of long-term care units than from community-living elderly. In a nursing home outbreak of multidrug-resistant pneumococci, 17/74 (23%) of asymptomatic residents and 2/69 (3%) employees had nasopharyngeal carriage of these microorganisms *(128)*. Recent use of antibiotics was associated with both nasopharyngeal colonization and the development of clinical disease. In another study, more than 5 days of therapy with an oral β-lactam antibiotic in low dose has been found to be significantly associated with nasal carriage of resistant pneumococci *(129)*. Prolonged outbreaks have also been described in acute care hospitals. In the largest of these studies, 36 patients had the same strain of antibiotic-resistant *S. pneumoniae* cultured in an outbreak that persisted for 2 years. The patients were elderly and 89% had COPD. The outbreak ended after patients were treated with ceftriaxone and rifampin *(130)*.

Nursing home outbreaks caused by both antibiotic-susceptible and multidrug-resistant strains of *S. pneumoniae* are well documented *(128,131)*. Immunization programs and use of prophylactic antibiotics have usually effectively terminated these episodes. This reinforces the need for widespread routine immunization with pneumococcal vaccine among the institutionalized elderly.

Primary methods of prevention of healthcare-associated pneumococcal infection should include immunization of susceptible individuals *(132)*. Careful hand washing is also needed. Transmission of pneumococci by contaminated respiratory therapy equipment has been documented, and appropriate disinfection is needed *(133)*. A healthcare-associated central venous line infection in an infant also has been described *(134)*. In both acute care hospitals and long-term care facilities, recent use of antibiotics has been associated with development of clinical disease.

Miscellaneous Microorganisms

Group C and G Streptococci Streptococci belonging to Lancefield group C and group G may be associated with pharyngitis, pneumonia, and cellulitis. The microorganisms are often β-hemolytic and may be confused with Lancefield group A streptococci *(135,136)*. Both Group C and Group G streptococci are usually speciated as *Streptococcus dysgalactiae* subspecies equisimilis. Some streptococci that are in these Lancefield groups may be strains of *Streptococcus anginosus* (137).

Group C streptococci have been recognized as causes of puerperal infection and of surgical site infection *(138)*. In an outbreak of two postoperative surgical site infections, a surgeon was found to carry the microorganism in his nose and rectum. Administration of topical bacitracin and orally administered penicillin and vancomycin ended the carrier state. This outbreak shares many characteristics with outbreaks of group A streptococcal infection. Teare et al. *(139)* described an outbreak of 33 cases of puerperal infection in three hospitals in Britain caused by group C streptococci. Environmental contamination was documented. The outbreak strain carried M protein antigen.

Efstratiou *(140)* reported outbreaks of infections noted in a laboratory-based study of 749 strains of group C streptococci (*Streptococcus equisimilis*) and 2,348 strains of group G streptococci that were referred to the public health laboratory at Colindale, United Kingdom, over a 6-year period. Ten outbreaks were reported (Table 32-3). These included pharyngitis, cutaneous infection, and puerperal sepsis. Except for pharyngitis, all of these clusters were in hospitals or nursing homes (most pharyngitis outbreaks occurred in schools).

Group G streptococci were much more frequent causes of outbreaks. Forty-one institutions in Great Britain reported outbreaks in the 6-year period. Group G streptococci were associated with outbreaks in three burn units, where they were found to occasionally colonize the nose and pharynx of staff members and were isolated from the environment. Most outbreaks of group G streptococci reported in this study involved skin and soft tissue. Twelve puerperal outbreaks were reported; in two hospitals, the implicated serotype was isolated from bath water, toilet seats, and showers in the maternity ward. In each of the reports of puerperal fever caused by group G streptococci, none of the babies born to infected mothers had invasive disease. Haynes et al. *(141)* reported an outbreak of puerperal fever among 15 mothers that was associated with contamination of automated douches. Although group G streptococci may be recovered from the pharynx of up to 25% of normal individuals *(135)*, group C streptococci also may be recovered from a few normal individuals (3%) *(142)*. Group G streptococci appear to be increasingly frequently associated with cellulitis and other skin and soft tissue infection (143,*144*).

Streptococcus Viridans *Streptococcus milleri* and other viridans streptococci have become important causes of infection in immunocompromised patients in recent years. These microorganisms have been associated with bacteremia, endocarditis, cellulitis, abscesses (subcutaneous, intra-abdominal, and intracranial), and other infections *(145)*. Seven of eighteen bacteremias with *S. milleri* in

TABLE 32-3

Presumptive Healthcare-Associated Outbreaks of Group C and Group G Streptococci in A 6-Year Period[a]

Location	*Source*	*Number of Isolates*	*T-type*
Group C			
Pharyngitis			
Hospital A	Throat (staff)		
	Foodborne	146	204
Skin sepsis			
Hospital B—ward	Skin	4	PT1058
Hospital C—geriatric ward	Pressure sores	3	305

Puerperal sepsis			
Hospital E—maternity unit patients	Vagina	29	204
—maternity unit staff	Throat	8	204
Group G			
Skin sepsis			
22 outbreaks	Skin, wounds, ulcers	119	Varied
Puerperal infection			
12 outbreaks	Perineum, throat, vagina	104	Varied

[a]Outbreaks are presumptive, and no detailed epidemiologic data are provided.
(From Efstratiou A. Outbreaks of human infection caused by pyogenic streptococci of Lancefield groups C and G. *J Med Microbiol* 1989;29:207–219, with permission.)

one recent study were healthcare-associated *(146)*. Other studies do not report the proportion of cases that were healthcare-associated. Two recent papers stress a relationship to stem cell transplantation and to the administration of cytosine arabinoside (147,*148*). It is noteworthy that isolates of *S. viridans* recovered from healthcare-associated bloodstream infection are often antibiotic resistant even when the patient does not have a hematological malignancy *(149)*.

S. viridans has also been reported to cause pseudobacteremia. Church and Bryant *(150)* reported an outbreak in which a phlebotomist did not wear gloves and had eczema involving her hands. Skin scrapings from her hands and fingernails grew this microorganism and contaminated blood cultures.

CHAPTER 33

Enterococcus Species

Emily K. Shuman and Carol E. Chenoweth

Compared with other Gram-positive cocci such as *Staphylococcus aureus* and *Streptococcus pyogenes*, enterococci have been viewed as relatively avirulent, endogenous microorganisms with little potential for human infection. Despite their apparent lack of virulence, enterococci have emerged as important healthcare-associated pathogens (1,2,*3*). The enterococci possess several characteristics that allow them to survive and cause serious infections. They are intrinsically resistant to many commonly used antimicrobial agents, and they have considerable ability to acquire antimicrobial resistance through exchange of genetic elements with other Gram-positive cocci. They are hardy microorganisms and can survive in the environment and on the hands of healthcare personnel. These factors have allowed the enterococci to flourish and spread from patient to patient in healthcare settings (1,2,*3*).

ETIOLOGIES

Microbiologic Features and Taxonomy of Enterococci

Enterococci are catalase-negative, Gram-positive, facultative anaerobic cocci that classically belonged to the Lancefield group D streptococci. In the mid-1980s, they were officially classified, based on DNA–DNA and DNA–RNA homology, into their own genus (2,*4*,5). Their characteristic biochemical features include the ability to grow in the presence of 6.5% NaCl and at extremes of temperature (range of 10–45°C) and pH (up to 9.6). They share the ability to hydrolyze esculin in the presence of 40% bile salts with the remaining members of the group D streptococci. The ability of enterococci to hydrolyze L-pyrrolidonyl β-naphthylamide has been used as part of a rapid screening method for enterococci in the laboratory (2,5). Although other Gram-positive microorganisms (e.g., *Lactococcus, Aerococcus*, *Gemella*, *Leuconostoc*, *Lactobacillus*) may show one or more of the previously listed characteristics, these microorganisms are rarely isolated from clinical infections. Therefore, these classic physiologic tests are still useful for initial identification of enterococci in clinical laboratories (2,5).

There are five recognized groups of enterococci, with a total of 33 species *(4)*. Most species can be identified with conventional techniques using a combination of biochemical and morphologic characteristics, such as motility and pigmentation (2,5). The most clinically important species of enterococci are listed with their distinguishing biochemical features in Table 33-1. *Enterococcus faecalis* remains the major human pathogen, accounting for approximately 60% of clinical isolates of enterococci. *Enterococcus faecium* is the second most commonly isolated species, now accounting for about 30% of enterococcal clinical isolates (2,5). With the emergence of vancomycin resistance, the relative proportion of *E. faecium* in clinical isolates has been increasing. In 2006 to 2007, *E. faecium* represented 46% of enterococcal isolates from healthcare-associated infections (6). *Enterococcus gallinarum*, a motile strain of enterococcus that also exhibits intrinsic vancomycin resistance, has been associated with outbreaks of healthcare-associated infection *(7,8)*.

Typing Methods

Early epidemiologic studies of healthcare-associated enterococcal infections were limited by a lack of typing methods. Biochemical tests and antibiograms were insufficient because enterococci rarely exhibit enough variation to allow for adequate strain differentiation. Total plasmid DNA analysis, with or without restriction enzyme digestion, was used in many studies to type enterococci *(9–11)*. However, these techniques have been uniformly replaced by newer methods for bacterial typing.

Pulsed-field gel electrophoresis (PFGE) or contour-clamped homogeneous electric field electrophoresis of restriction enzyme-digested genomic DNA has been the dominant method used for typing enterococci *(12–15)*. Enterococci have a relatively low guanine plus cytosine content of DNA, which, when digested with *sma*1 (a restriction enzyme seeking G-plus C-rich sequences), yields diverse, easily interpreted patterns. These techniques produce high-resolution, reproducible bands, which allow confident interpretation *(12,14,15)*.

Newer methods of typing for enterococci have recently been applied. Ribotyping is a reproducible means of differentiating enterococcal strains, and automated systems have been developed for rapid typing. However, the reliability of the automated systems in comparison to other typing systems for enterococci has not been determined *(15)*. Amplified fragment length polymorphism has been used

as a newer method of typing enterococci. This method is fast, reproducible, and appears to discriminate enterococcal strains well enough for the recognition of hospital outbreaks *(16)*. Recently, a multilocus sequence typing scheme has been developed and compared with PFGE. This method appears promising for use in global epidemiologic analysis of *E. faecalis* and *E. faecium*, in addition to use in local outbreak investigations *(14)*.

ANTIMICROBIAL RESISTANCE IN ENTEROCOCCI

Enterococcal infections are a therapeutic challenge because of the intrinsic resistance of enterococci to many antimicrobials. In addition to their intrinsic resistance, enterococci have a remarkable ability to acquire antimicrobial resistance genes (2,*17*). Enterococci with high-level resistance (HLR) to multiple antimicrobials have become endemic in many institutions *(18–20)*. As humans enter an era of decreased antimicrobial effectiveness, it becomes imperative to develop appropriate infection control procedures to decrease the transmission of these microorganisms in healthcare settings.

Intrinsic Resistance

Most enterococci are inherently resistant to many antimicrobials, as shown in Table 33-2. The gene coding for intrinsic resistance resides on the chromosome and confers resistance to cephalosporins and penicillinase-resistant penicillins, clindamycin, low levels of aminoglycosides, and trimethoprim-sulfamethoxazole (TMP-SMX) (1,2,*3*,21). Most clinical isolates of enterococci are inherently tolerant to all β-lactams and glycopeptides and are typically not killed by concentrations of antimicrobials many times higher than the minimum inhibitory concentration (MIC). The relative resistance to β-lactam antimicrobials is due to low affinity of the penicillin-binding proteins of enterococci for these antimicrobials. The MICs of *E. faecalis* to penicillin average 2 to 8 μg/mL, which is approximately

TABLE 33-2

Characteristics of Antimicrobial Resistance in Enterococci

Antimicrobial	*Characteristic*
Intrinsic resistance	
Penicillins	Relative resistance, tolerance
Cephalosporins	Diminished affinity for PBPs 4, 5, 6
Clindamycin	Low-level resistance
Aminoglycosides	Low-level resistance
Trimethoprim/ sulfamethoxazole	*In vivo* resistance
Quinupristin/dalfopristin (*E. faecalis*)	Possible efflux
Acquired resistance	
Macrolides	Transposon, plasmid-mediated
Tetracyclines	Transposon, plasmid-mediated
Lincosamides	High-level, plasmid or transposon
Chloramphenicol	Transferable acetyltransferase activity
Aminoglycosides	High-level, plasmid or transposon
Penicillin (without β-lactamase)	Altered PBPs
Penicillin (with β-lactamase)	Transposon, plasmid-mediated
Vancomycin	Plasmid- or chromosome-mediated
Quinolones	Plasmid-mediated
Quinupristin/dalfopristin (*E. faecium*)	Drug inactivation, ribosomal mutation, efflux
Linezolid	Ribosomal mutation
Daptomycin	Mechanisms not yet fully understood
Tigecycline	Mechanisms not yet fully understood

PBP, penicillin-binding protein.

10 to 100 times greater than those for most streptococci (21). *E. faecium* strains are even more resistant, with MICs of 16 to 32 μg/mL and higher (21).

In addition, all enterococci exhibit resistance to low concentrations of aminoglycosides (MIC = 8–64 μg/mL for gentamicin). This resistance trait appears to be due to a decreased uptake of the drug. Even in the presence of low-level aminoglycoside resistance, aminoglycosides may be used in combination with a cell-wall active agent (i.e., a penicillin or vancomycin) to achieve synergistic killing (21,*22*). The combination of an aminoglycoside with a penicillin or vancomycin is required for reliable bactericidal therapy for the treatment of serious enterococcal infections (21,*22*).

Enterococci are intrinsically resistant to TMP-SMX because they are able to use exogenous folates to bypass the inhibitory effects of TMP-SMX. *In vitro* susceptibility testing is unreliable in enterococci because media used in these tests do not contain thymidine or folates (2). Animal studies confirm that TMP-SMX is ineffective *in vivo* despite apparent *in vitro* susceptibility *(23,24)*.

Acquired Resistance

High-Level Aminoglycoside Resistance HLR to streptomycin and gentamicin was first identified in the 1970s *(25)*. Over the next decade, the prevalence of these resistant strains increased dramatically in diverse geographic areas *(25,26)*. HLR (MICs >2,000 μg/mL) confers resistance to the synergistic killing normally observed with combinations of cell-wall active agents and an aminoglycoside *(25)*.

HLR to aminoglycosides in enterococci occurs primarily through acquisition of genes encoding aminoglycoside-modifying enzymes; these resistance genes are usually found on a transferable plasmid (21). Streptomycin is inactivated by an enzyme that adenylates its 6-hydroxyl position *(25)*. A second mechanism of streptomycin resistance confers HLR (MICs up to 128,000 μg/mL) through ribosomal resistance *(25)*.

HLR to gentamicin in most clinical isolates is mediated by a bifunctional aminoglycoside-modifying enzyme with 6′-acetyltransferase and 2″-phosphotransferase activity. The presence of this enzyme confers HLR to gentamicin, tobramycin, kanamycin, amikacin, sisomicin, and netilmicin *(25)*. The gene encoding for HLR to gentamicin has a DNA sequence homologous to the gene-conferring gentamicin resistance in *S. aureus (26,27)*, and has been localized to transposons found on conjugative plasmids and chromosomes, which has allowed spread to multiple unrelated strains of enterococci *(11,28,29)*. Additional gentamicin resistance genes encoding other 2″-phosphorylating enzymes have been identified in clinical isolates *(26,30)*. Arbekacin may have synergistic activity against enterococci with HLR to aminoglycosides *(31)*.

HLR to gentamicin does not always correlate with HLR to streptomycin; therefore, screening for HLR to both streptomycin and gentamicin is important *(26)*. There are several screening methods currently available, but the disk method and the single-concentration agar plate method are most reliable for detecting high-level aminoglycoside resistance in enterococci and are recommended by the Clinical Laboratory Standards Institute (CLSI) (formerly the National Committee for Clinical Laboratory Standards) *(32)*. Disks containing 120 μg of gentamicin generate a zone of 15 mm or less in strains with HLR to gentamicin. For streptomycin, disks containing 300 μg give rise to zones of 12 mm or less in HLR strains *(7)*. Automated susceptibility testing is now also being used to screen for high-level aminoglycoside resistance in enterococci *(33)*.

β-Lactam Resistance Penicillin resistance in enterococci occurs through two distinct mechanisms (21,*34–36*). The most common mechanism of penicillin resistance occurs primarily in *E. faecium* and correlates with increased amounts of a low affinity penicillin-binding protein (21,*34,35*). A large, multicenter study of enterococcal bloodstream isolates reported that only 12.5% of *E. faecium* isolates were susceptible to penicillin *(37)*. In the United States, ampicillin resistance is highly associated with vancomycin resistance in *E. faecium (37–39)*, but in Sweden an outbreak of ampicillin- and quinolone-resistant *E. faecium* was identified *(40)*. *In vitro* penicillin or ampicillin susceptibility generally predicts susceptibility to imipenem *(41)*. However, imipenem-resistant, ampicillin-sensitive *E. faecium* have been identified *(42)*.

Since 1981, numerous centers have reported β-lactamase-producing strains of enterococci *(10,36,43)*. The β-lactamase gene has been localized to transferable plasmids or to the chromosome in some isolates *(36)*. The β-lactamase gene in enterococci is homologous with the *S. aureus* β-lactamase gene and has features suggesting that it resides on a transposon similar to *S. aureus* transposon Tn4201 *(44)*. Routine susceptibility tests may not reliably detect β-lactamase-producing strains *(43)*. Several β-lactamase tests, including nitrocefin disks, have been used to successfully identify β-lactamase production *(36)*.

Vancomycin Resistance Vancomycin-resistant enterococci (VRE), first detected in Europe in 1988, have increased in prevalence dramatically in the United States (1,*45*,46,47) and worldwide *(48,49)*. There are several phenotypes and genotypes for vancomycin resistance in enterococci, and some of these phenotypes have been studied in detail (Table 33-3). *vanA* and *vanB* are the most predominant phenotypes in clinical isolates of VRE (1,*45*,47). All phenotypes code for alternate biosynthetic pathways that alter the D-ala-D-ala cell wall precursors that normally bind vancomycin. *vanA*, *vanB*, and *vanD* genes code for D-ala-D-lac ligases *(50,51)*, whereas *vanC* and *vanE* genes code for D-ala-D-ser ligases *(52)*.

vanA strains exhibit high-level, inducible resistance (MICs >64 μg/mL) to both vancomycin and teicoplanin *(53)*. The *vanA* trait is carried by a gene cluster located in a transposon, Tn*1546 (54)*. The transposon is usually found on a plasmid, which is transferable to other Gram-positive cocci. This accounts for the presence of *vanA* genes in widely heterogeneous strains of enterococci *(37,55)*. Although *vanA* is usually found in *E. faecium* and *E. faecalis*, it has been identified in *E. gallinarum* and other enterococcal species *(45)*. In addition, there have now been nine reported cases of infection with *vanA*-mediated vancomycin-resistant *S. aureus* in the United States *(56,57)*.

vanB strains have variable resistance to vancomycin (MICs 16 to >1,000 μg/mL) but in general remain susceptible to teicoplanin. The genes that code for *vanB* trait are

TABLE 33-3

Characteristics of Phenotypes of Glycopeptide-Resistant Enterococci

	Phenotype					
Characteristic	***vanA***	***vanB***	***vanC***	***vanD***	***vanE***	***vanG***

ND, not done.

very similar to *vanA* genes, are usually found within large mobile elements located on the chromosome, and can be transferred to other enterococci. The *vanC* phenotype is typically found intrinsically on the chromosome of motile species of enterococci, *E. gallinarum* (*vanC-1*) and *E. casseliflavus* (*vanC-2* and *vanC-3*) *(58–60)*. These strains are moderately resistant to vancomycin (MICs, 8–16 μg/mL) but remain susceptible to teicoplanin. The resistance in these isolates is not inducible or transferable *(58,59)*.

The *vanD* phenotype has constitutive intermediate resistance to vancomycin and low-level resistance to teicoplanin *(51,61)*. *vanE* resistance is nontransferable and confers a low-level resistance phenotype *(62,63)*. The *vanG* phenotype has moderate-level resistance to vancomycin (MIC = 16 μg/mL), has no resistance to teicoplanin, and is negative by polymerase chain reaction (PCR) for *vanA*, *vanB*, *vanC*, or *vanE (64)*. Vancomycin-resistant strains of enterococci that are dependent on vancomycin for growth have been identified from clinical isolates *(65–67)*.

Many laboratories have difficulty detecting vancomycin resistance when the MICs are less than 64 μg/mL *(68)*; however, HLR can be detected more readily *(69)*. The agar screen test using 6 μg/mL of vancomycin in brain–heart infusion agar is a simple, sensitive, confirmatory test and is recommended by CLSI *(7,68)*. Automated susceptibility testing of isolates is also commonly performed *(70)*. Heteroresistance to vancomycin, confirmed by presence of the *vanA* gene by PCR, has been identified recently in a clinical isolate *(71)*. PCR assays have been developed for identification of VRE isolates and are now commonly used *(72)*.

Resistance to Newer Antimicrobials *E. faecalis* is inherently resistant to the combination antimicrobial quinupristin/dalfopristin, with MICs of 4 to 32 μg/mL *(73,74)*. This is thought to be a species characteristic and may be related to an efflux mechanism *(74)*. *E. faecium* does not have inherent resistance, and most strains of *E. faecium* remain susceptible to quinupristin/dalfopristin (75). Mechanisms of resistance to quinupristin/dalfopristin in *E. faecium* include inactivation by enzymes, structural or conformational alterations in ribosomal target binding sites, and efflux of the antimicrobial out of cells (75,*76*).

Linezolid, an oxazolidinone, has activity against most enterococci, including VRE *(77)*. However, linezolid resistance was reported in isolates from 9 of 501 patients treated with linezolid during the manufacturer's compassionate use program and was related to ribosomal mutations *(78)*. Although large prevalence studies reveal near universal susceptibility of enterococci to linezolid *(79)*, healthcare-associated outbreaks of linezolid-resistant strains of VRE have occurred *(18,20)*.

Daptomycin, a new cyclic lipopeptide antimicrobial, also has activity against most enterococci, including VRE *(80)*. Enterococcal isolates have been almost universally susceptible to daptomycin in large surveillance studies *(81,82)*. However, sporadic cases of resistance have been reported in patients with and without prior exposure to daptomycin *(83–86)*. Resistance mechanisms have not been fully elucidated. Proposed mechanisms include decreased ability to adequately disrupt cell membrane potential, physical changes in the bacterial cell wall, protein binding leading to low serum concentrations, and chromosomal mutations *(83,85,86)*.

Tigecycline is a new broad-spectrum glycylcycline antimicrobial that is active against most enterococci, including VRE *(87)*. Tigecycline is closely related to the tetracycline class of antimicrobials but overcomes common resistance mechanisms associated with this class, including efflux pumps and ribosomal protection *(87)*. Thus far, surveillance studies have demonstrated nearly universal susceptibility of enterococci to tigecycline *(88)*. There is one reported case of resistance, in which tigecycline-resistant *E. faecalis* was isolated from the urine of a patient after prolonged therapy with tigecycline *(89)*. The mechanism of resistance was not fully elucidated in this case but was not related to tetracycline-resistance mechanisms.

EPIDEMIOLOGY OF HEALTHCARE-ASSOCIATED INFECTIONS

Descriptive Epidemiology

The prevalence of enterococci in healthcare-associated infections has increased over the past three decades. In current reports from the National Healthcare Safety Network (NHSN) at the Centers for Disease Control and Prevention (CDC), enterococci rank as the third most common cause of all healthcare-associated infections hospital wide (6). In data from January 2006 through October 2007, enterococci accounted for 16% and 15% of healthcare-associated bloodstream infections (BSIs) and UTIs, respectively, and for 12% of all healthcare-associated infections (6).

At the same time their prevalence has increased, the enterococci have also developed increased antimicrobial resistance. One institution reported its first clinical isolate of high-level gentamicin-resistant enterococci in 1981, but, by 1989, 20% of clinical isolates were high-level gentamicin-resistant and, by 1992, 23% of nonurinary isolates were highly resistant to gentamicin (90). Other institutions noted a similar increase in prevalence of high-level gentamicin-resistant isolates; some centers reported that 50% to 55% of clinical isolates exhibited HLR *(9,91)*. In a recent survey of more than 8,000 enterococcal isolates, 14% to 32% of enterococcal strains were gentamicin resistant, and 30% to 46% were streptomycin resistant, with variations reflected by geographic area *(92)*.

Even more dramatic has been the continued increase in the prevalence of VRE in the United States (6,*45*,46). Between January 2006 and October 2007, the NHSN reported that 36% of enterococcal isolates from healthcare-associated infections were vancomycin resistant (6). *E. faecium* were more frequently vancomycin resistant (79%) compared with *E. faecalis* (7.5%) (6). Rates of VRE vary between geographic areas and institutions *(92)*. Other areas of the world report lower prevalence of VRE than the United States (*45*,46,*92*). Latin America reports 0% to 4% VRE, whereas Europe reports 1% to 3% VRE (*45*,46,*92*). The prevalence of VRE in Canada may have increased in recent years, with VRE accounting for 6.7% of enterococcal isolates in a recent study *(93)*.

Reservoirs

Enterococci are normal inhabitants of the human gastrointestinal tract. *E. faecalis* is found in concentrations of 10^5 to 10^7 colony-forming units (CFUs)/g of feces in 80% of hospitalized patients. *E. faecium* is recovered in smaller amounts in 30% of adult patients (2,*3*,90). Other parts of the gastrointestinal tract such as the oropharynx and hepatobiliary tract may also harbor enterococci (90,*94*). The gastrointestinal tract of hospitalized patients is the major reservoir for resistant enterococci *(10,95–100)*. Rectal colonization was found in 100% of patients with VRE BSI and may persist for years after identification *(100–103)*. Prolonged colonization has been associated with prolonged hospitalization, ICU care, and antimicrobial use *(96,102)*. In addition, higher density colonization by VRE has been associated with use of antianaerobic antimicrobial regimens *(95)*.

Enterococci may also colonize the gastrointestinal tract of healthcare personnel, as illustrated by an outbreak of a β-lactamase-producing enterococcus on an infant/toddler ward, where the resistant strain was isolated from 8 of 33 personnel *(10)*. Healthcare personnel colonization with VRE is uncommon, but a recent study showed that 12 of 228 healthcare personnel carried VRE *(104)*. In addition, identical strains of VRE were identified in household members of two colonized healthcare personnel *(104)*. Antimicrobial therapy may place healthcare personnel at risk for colonization with VRE *(105)*. The significance of colonization of healthcare personnel with VRE in the transmission of VRE has not been defined.

Other major sites of colonization that are reservoirs for enterococci in hospitalized patients include skin, wounds, and chronic pressure ulcers *(101,106)*. In patients with VRE BSI, 86% were found to have VRE colonizing their skin in the inguinal or the antecubital fossa areas *(97)*. Enterococci, when present in wounds, are usually found in mixed culture (2,90). Asymptomatic women may also carry enterococci in high numbers in their vagina, and more than 60% of men in the hospital may carry enterococci in their perineal or meatal areas (2,90,107).

Enterococci are also hardy microorganisms, which allow them to survive well on environmental surfaces *(13,104)*. Resistant enterococci have been cultured from environmental surroundings of infected or colonized patients in many studies *(9,10,100,108–113)*. Heavy contamination of the surrounding environment is more likely to occur when the patient has diarrhea or is incontinent *(100,112,114,115)*. Medical equipment may also become contaminated with resistant enterococci and serve as a reservoir for these microorganisms. In one notable outbreak of infection resulting from VRE, the epidemic strain was cultured from electronic thermometers within the ICU *(116)*. VRE has since been found to contaminate electronic ear thermometers, blood pressure cuffs, patient gowns and linens, fabric seat cushions, beds, bed rails, bedside tables, and commodes *(13,100,109,112,117,118)*. Recent studies showed that ICU patients are more likely to acquire VRE if prior room occupants were VRE-positive, demonstrating the role of environmental contamination in VRE transmission *(113,119)*.

Residents of long-term care facilities may serve as a reservoir for introduction of resistant enterococci into the hospital *(13,106,120)*. Rectal VRE colonization of patients in a single long-term care facility increased from 9% in December 1994 to 22% in January 1996 *(13)*. In another hospital where VRE has become endemic, it was found that 45% of patients admitted to the hospital from long-term care facilities were colonized with VRE *(106)*. VRE colonization at admission was associated with the presence of a pressure ulcer and prior use of antimicrobials *(106)*.

In Europe, VRE colonization of nonhospitalized people was identified in the early 1990s. Evidence suggested that foodborne VRE may lead to human colonization in the community setting *(121,122)*. Avoparcin, a glycopeptide used as a food supplement in animals, was identified as an important factor in the emergence of VRE in the community setting *(121,122)*. Use of avoparcin has now been banned in many countries, but VRE colonization of animals has persisted at lower rates, likely due to horizontal transfer of resistance determinants, environmental contamination, and use of other antimicrobials in animal feed *(123)*. One study demonstrated that persons who ingested meat products contaminated with antimicrobial-resistant

enterococci developed transient intestinal colonization with VRE *(124)*. In the United States, avoparcin has not been approved for use as a food additive; however, resistant enterococci have been found in the community *(125,126)*. In 200 patients admitted to a community hospital, 10 patients were colonized with enterococci with HLR to aminoglycosides, and two patients were colonized with ampicillin-resistant enterococci *(125)*. VRE colonization of outpatients without hospital exposures is rare in the United States *(125–127)*, but person-to-person transmission of VRE has been reported in the household setting *(128,129)*. Virginiamycin, a streptogramin similar to quinupristin/dalfopristin, has been used in animal feed since 1974 in the United States. A large proportion of chicken sold in the United States was contaminated with quinupristin/dalfopristin-resistant enterococci *(130)*. At this point, persons living in the community are not a major reservoir for VRE or other resistant enterococci, but the potential for increased dissemination in the community is concerning.

Modes of Transmission

Early studies suggested that enterococci isolated from sites of infection were from the host's own gastrointestinal tract (107). Since the emergence of antimicrobial resistance and more sophisticated molecular typing tools, numerous studies have shown that person-to-person spread of enterococci is a significant mode of transmission in healthcare settings *(9,10,39,43,91,112,131)*. Zervos et al. *(91)* used total plasmid content and a high-level gentamicin-resistance marker, which was uncommon at that time, to show exogenous acquisition of enterococci. Since the emergence of VRE, the understanding of the spread of enterococci within healthcare settings has become more complete. The most important method of spread of VRE and other resistant enterococci is through transient carriage on the hands of healthcare personnel *(10,13,107,112,132)*. Regional dissemination of VRE has resulted from interfacility transfer of colonized patients *(133,134)*.

Recent studies suggest that the environment may have a role in the transmission of resistant enterococci (*100,108–111,113–117*,135). Medical equipment used on multiple patients should be considered a possible route of patient-to-patient transmission. Resistant enterococci heavily contaminate environmental surfaces in both acute care and extended care facilities *(10,13,91,100)*. It has been shown that hands and gloves of healthcare personnel become contaminated with VRE after contact with patients' environments, suggesting that environmental contamination may be an intermediate step in person-to-person transmission of VRE via healthcare personnel *(136)*.

Risk Factors for Enterococcal Infections

Early studies examining risk factors for the development of enterococcal UTIs identified urinary tract instrumentation or catheterization; other genitourinary pathology; and the previous use of antimicrobials, especially cephalosporins, as significant risk factors (107,*137*). Most patients who became colonized with resistant enterococci had a history of serious underlying illnesses, being bedridden, or having had prior surgery (*9*,90,*91*).

Risk factors for acquisition of VRE include serious underlying disease or debilitation *(138,139)*, organ transplantation *(140–145)*, chronic kidney disease *(138,139,146)*, malignancy *(147,148)*, prolonged hospital stay *(147,149–151)*, intrahospital transfers *(149)*, diarrhea *(118)*, and enteral feedings *(152,153)*. Residence in an ICU setting has been a major risk factor for acquisition of VRE *(147,151)*. However, VRE has increased steadily in frequency in non-ICU settings (154). Recent studies highlight the importance of colonization pressure (defined as the proportion of other patients colonized) or proximity to VRE-colonized patients (including prior room occupants) as significant risk factors for acquisition of VRE *(103,119,152,153,155,156)*. Changes in gastrointestinal function, resulting from either oral medication or gastrointestinal bleeding, may affect the risk of colonization with VRE. A recent retrospective case–control study on the effect of oral medication on acquisition of VRE identified presence of central lines and use of vancomycin or antacids as independent risk factors for VRE colonization *(157)*. Interestingly, gastrointestinal bleeding or use of hydrocodone with acetaminophen protected against colonization (Table 33-4).

TABLE 33-4

Major Risk Factors for Colonization with VRE

Risk Factor	*References*
Underlying disease or debilitation	*(138,139)*
Organ transplantation	*(140–145)*
Chronic kidney disease	*(138,139,146)*
Malignancy	*(147,148)*
Prolonged hospital stay	*(147,149–151)*
Intrahospital transfers	*(149)*
Diarrhea	*(118)*
Enteral feedings	*(152,153)*
Colonization pressure	*(103,152,153,155,156)*
Antimicrobial use	
Multiple antimicrobials	*(151)*
Antianaerobic antimicrobials	*(98,153,157,161,162)*
Vancomycin	*(138,149,158)*
Cephalosporins	*(96,148,149,151,152,163)*

Previous antimicrobial therapy is the most consistent risk factor for colonization with resistant enterococci *(95,139,147–150,152,158,159)*. The acquisition of gentamicin-resistant enterococci has been associated with previous treatment with cephalosporins or aminoglycosides *(9,91)*. Imipenem was found to significantly predispose to acquisition of ampicillin-resistant enterococci *(160)*. VRE colonization has been associated with use of multiple antimicrobials *(151)*, antianaerobic antimicrobials *(98,153,157,161,162)*, vancomycin *(138,149,158)*, and cephalosporins *(96,148,149,151,152,163)*.

PATHOGENESIS OF HEALTHCARE-ASSOCIATED INFECTIONS CAUSED BY ENTEROCOCCI

Generally, enterococci are human commensals and have minimal pathogenic potential in the normal host. However, in the immunocompromised patient or when invasive

procedures are performed, enterococci are common opportunistic pathogens. The increase in prevalence of enterococci in healthcare-associated infections is more related to the accumulation of antimicrobial resistance than to inherent pathogenicity in enterococci (6,*17*,*164*).

Hemolysin has been identified as a potential virulence factor in enterococci (2,*165*). Patients with BSI caused by hemolytic, gentamicin-resistant *E. faecalis* were shown to have a fivefold increased risk of death compared with patients with nonhemolytic, gentamicin-susceptible strains *(165)*. It is unclear from this study whether the increased mortality was due to the presence of hemolysin or an aminoglycoside-resistant phenotype.

Other potential virulence factors include production of enterococcal surface protein (Esp), aggregation substances (Agg), or gelatinase (2,*17*,*164*,*166*,*167*). One study noted that hemolysin and Agg were found more frequently in blood isolates and isolates from liver transplant recipients, whereas Esp was found more frequently in fecal isolates. The authors speculated that hemolysin and Agg may be associated with infection, whereas Esp is associated with colonization and spread *(167)*. Recently, however, among 398 enterococcal BSI isolates, 64% of isolates produced gelatinase, 32% carried the *esp* gene, and 11% produced hemolysin. There was no association of these putative virulence markers with 14-day mortality *(166)*. More studies will be necessary to further define true virulence factors in enterococci.

CLINICAL MANIFESTATIONS OF HEALTHCARE-ASSOCIATED INFECTIONS CAUSED BY ENTEROCOCCI

Urinary Tract Infection

In young healthy women, enterococci cause <5% of UTIs. However, in persons who have had urinary catheterization or instrumentation, have urinary tract pathology, or have received antimicrobials, the proportion of UTIs associated with enterococci increases dramatically (6,*137*,*168*,*169*). Morrison and Wenzel *(137)* found an increase in the rate of UTIs caused by enterococci from 12.3 to 32.2 cases per 10,000 patient discharges. According to the most recent data from the NHSN, enterococci are the third most common cause of catheter-associated UTIs, accounting for 15% of such infections (6).

Risk factors for enterococcal UTI are urinary tract instrumentation, catheterization, and genitourinary tract pathology (107,*137*,*169*). The previous use of antimicrobials, especially cephalosporins, has also been associated with enterococcal UTI (*137*,*169*). One study showed a parallel rise in healthcare-associated enterococcal UTI and in cephalosporin use in a single hospital *(137)*. Prior antimicrobial use was found to be more frequent in patients with enterococcal UTI than in controls in a rehabilitation facility with a high rate of enterococcal UTI *(169)*. Little has been published about specific risk factors for VRE UTI.

Early studies suggested that enterococci associated with UTIs were predominantly from the patients' own gastrointestinal tract. Patients found to be colonized with enterococci later developed enterococcal UTI with microorganisms identical to their previously cultured enterococci (107). More recent studies suggest that direct crossinfection is not the predominant source of enterococci in UTIs *(169)*. However, fecal microorganisms of hospitalized patients may be altered through the acquisition or selection of hospital-specific strains *(97,168)*.

The clinical manifestations of UTI caused by enterococci are indistinguishable from those of UTIs caused by other microorganisms. The spectrum of disease ranges from asymptomatic bacteriuria to bacteremic pyelonephritis. Mortality resulting from enterococcal UTI in the absence of BSI is low (see Chapter 20) (107,*137*,*168*,*169*). In a study of 97 evaluable patients with VRE bacteriuria, 37 patients were colonized with VRE, 21 had asymptomatic bacteriuria, and 13 patients had symptomatic UTI. The status of 27 patients was not ascertainable *(168)*. Patients with symptomatic UTI were more likely to have malignancy *(168)*.

Bloodstream Infection

The incidence of BSI resulting from enterococci has increased over the past three decades (6,170). Maki and Agger (170) cited a threefold increase in healthcare-associated enterococcal BSI in their hospital between 1970 and 1983. In their study, healthcare-associated BSIs accounted for 77% to 78% of enterococcal BSIs (170). Recent data indicate that enterococci are the second most common cause of healthcare-associated BSIs, accounting for 16% of central line-associated BSIs (6).

Enterococcal BSI is associated with prolonged hospitalization, malignancy, neutropenia, urethral catheterization, intravascular lines, recent surgery, biliary tree complications, and major burns (see Chapter 25) (*142*,170,*171*,*172*). Prior antimicrobial therapy is also associated with enterococcal BSI. In particular, use of a cephalosporin, imipenem, aztreonam, or ciprofloxacin has been shown to predispose to BSI (170,*172*,*173*). In children, the most common predisposing factors for enterococcal BSI are central lines, gastrointestinal lesions, and pulmonary infiltrates *(174)*.

As the prevalence of VRE has increased, BSIs due to VRE have increased (6,*175*,*176*). VRE account for 36% of enterococci isolated from central line-associated BSIs (6). BSI resulting from VRE has been associated with severity of illness *(177,178)*, underlying disease (especially hematologic malignancy with receipt of chemotherapy) *(175,178,179)*, human immunodeficiency virus (HIV) infection *(180)*, liver transplantation *(180)*, prolonged hospitalization *(171,181)*, corticosteroid use *(177)*, drug abuse *(180)*, acute and chronic kidney disease *(175,182)*, central line *(171)*, indwelling bladder catheter *(182)*, hyperalimentation *(171)*, and previous gastrointestinal colonization with VRE *(183)*. Prior exposure to antimicrobials, especially vancomycin, has been a consistent risk factor for VRE BSI *(177,178,182,183–187)*. Antimicrobials with antianerobic activity (e.g., clindamycin, metronidazole, and carbapenems) and *Clostridium difficile* infection have also been associated with increased risk of VRE BSI *(171,184,188,189)*.

Risk factors for VRE BSI in high-risk patient populations have been assessed. In patients undergoing liver transplantation, VRE BSI was associated with coinfections with other pathogens and biliary complications requiring repeat laparotomy *(141,142)*. VRE BSI in patients with malignancy has been associated with vancomycin use *(182,189,190)*, neutropenia *(190)*, *C. difficile* infection *(188)*, diabetes mellitus *(182)*, or gastrointestinal procedures *(182)*.

Recurrence of VRE BSI in patients with cancer has been associated with prolonged gastrointestinal colonization *(103,191)*.

In secondary enterococcal BSI without endocarditis, the urinary tract is the most common source of BSI, accounting for 19% to 43% of cases (170,*172*). Other major sources of enterococcal bacteremia include hepatobiliary tract and intra-abdominal infections (90,170,*172*). Soft tissue infections are another major source of BSI, with 15% to 30% of BSIs arising from these sites (170,*172*). It is not surprising, given the nature of common sources of BSI, that enterococcal BSI is frequently polymicrobial. Enterococci are associated with other bacteria in 25% to 46% of BSI cases (90,170,*172*).

The clinical manifestations of enterococcal BSI are influenced by whether enterococci are isolated alone or as part of a polymicrobial BSI. When caused solely by enterococci, BSI is typically an indolent disease, frequently characterized by fever only. Signs of local infection may be minimal. BSI is rarely associated with disseminated intravascular coagulation or shock. VRE are more likely than vancomycin-susceptible enterococci to occur as the sole isolated blood pathogen *(171,181)*. Polymicrobial BSI and VRE BSI are much more likely to be associated with the development of shock (50%), thrombocytopenia, or disseminated intravascular coagulation (30%) (170). Multiple studies have indicated higher rates of sepsis and shock, refractory infection and serious morbidity, and increased length of stay and hospital costs in patients with VRE BSI *(175,180,181,183,192–194)*.

Overall mortality of enterococcal BSI has been estimated to be 30% to 76% (170,*172*,*177*,*180*,*181*,*183*,*192–195*), with an attributable mortality of 7% to 37% *(181,195)*. Mortality resulting from polymicrobial BSI was two times higher than mortality associated with BSI resulting from enterococci alone *(184)*.

Whether vancomycin resistance increases mortality resulting from enterococcal BSI is still unclear. Some studies show no increased mortality with VRE BSI when compared with BSI caused by vancomycin-susceptible enterococci *(178,194,196)*. However, a growing number of studies, including a recent meta-analysis, have found that vancomycin resistance is an independent risk factor for death in patients with enterococcal BSI (*177*,*180*,*181*,*183*,*193*,*195*,197). Mortality resulting from VRE BSI is associated with severe underlying disease, hematologic malignancy, presence of shock, and liver failure *(177,181,192)*. Treatment with effective antimicrobial agents within 48 hours independently predicts survival from VRE BSI *(177)*.

Endocarditis

Enterococci are the third most common cause of endocarditis, accounting for 5% to 20% of cases of native valve endocarditis *(198,199)*. Patients with enterococcal endocarditis are predominantly men, with an average age of 56 to 59 years. In women, enterococcal endocarditis occurs during the childbearing years. A source of enterococci is usually not found; however, in many cases the genitourinary tract is implicated. Mandell et al. *(198)* found that 50% of men with enterococcal endocarditis had a previous history of enterococcal UTI or genitourinary tract instrumentation and that 43% of women had a history of childbirth or a genitourinary tract procedure in the preceding 3 months. Patients with underlying valvular heart disease are at greatest risk for developing enterococcal endocarditis *(198,199)*; however, 42% of patients in the Mandell et al. *(198)* series had no underlying heart disease.

Although endocarditis resulting from enterococci occurs more commonly in the community setting, healthcare-associated endocarditis also occurs (170,*200*). In a recent series, 26% of cases of enterococcal endocarditis were healthcare-associated, and patients with healthcare-associated infection had significantly higher mortality *(200)*. There are now multiple cases of endocarditis due to VRE reported in the literature, all of which have been healthcare-associated (201). The vast majority of patients with VRE endocarditis had significant underlying comorbidities, including chronic kidney disease with receipt of hemodialysis and transplantation. Many of these patients were treated successfully using newer antimicrobial agents.

Intra-abdominal and Pelvic Infections

The clinical manifestations of enterococcal intra-abdominal infections are similar to infections caused by other microorganisms. Enterococci are usually found in mixed culture when isolated from intra-abdominal infections *(202)*. Nichols and Muzik *(202)* found that enterococci were rarely isolated in postoperative infections after penetrating abdominal trauma unless there was gastrointestinal perforation and the patient received broad-spectrum cephalosporins. Others have found an increased prevalence of enterococci in intra-abdominal infections from a hepatobiliary source (90,*143*). In reviews of enterococcal BSI, intra-abdominal sites are often the source of BSI (170,*172*). When enterococcal BSI arises from an intra-abdominal site, the mortality is high with rates more than 40% (170,*172*).

Patients undergoing orthotopic liver transplantation (OLT) are at high risk of developing intra-abdominal infections resulting from enterococci, in particular VRE *(140–145)*. Enterococcal BSI, including VRE BSI, is more likely to occur following OLT if hepatobiliary surgical complications and infection occur *(141,142,144)*. In one series, 14 of 34 patients with VRE infection following OLT had an intra-abdominal site of infection *(141)*. In another study, 23 of 27 infections with VRE had an intra-abdominal site. Risk factors for VRE infection in this patient population include biliary complications requiring re-exploration, prolonged ICU stay, and administration of vancomycin preoperatively *(144)*. A recent study demonstrated that patients who acquired VRE colonization after transplantation had higher mortality than noncolonized recipients *(203)*.

Skin and Soft Tissue Infections

Enterococci are rarely isolated in pure culture from skin and soft tissue infections. However, they are identified frequently in mixed surgical site infections, diabetic foot ulcers, pressure ulcers, and burns (2). Enterococci accounted for 9.3% of isolates from a recent large international surveillance study of skin and soft tissue infections *(204)*. In several studies of enterococcal BSI, skin and soft tissue infections were identified as the source of bacteremia in 15% to 30% of cases (90,170,*172*). Infected burn wounds have been found to be a significant source of enterococcal BSI; BSI secondary to burn wounds is associated with a high mortality rate (170,*172*).

Neonatal and Pediatric Infections

Enterococci account for approximately 5% of bacteriologically confirmed cases of neonatal BSI *(205)*. Risk factors for enterococcal sepsis in neonates include low birth weight, prolonged nonumbilical central line, bowel resection or other abdominal surgery, prolonged hospitalization, and treatment with cephalosporins *(206,207)*. The development of enterococcal meningitis in neonates and older children has been associated with anatomic central nervous system defects or prior neurologic procedures, especially ventriculoperitoneal shunts (see Chapter 27) *(208,209)*.

Although VRE colonization and infection are less common in children than in adults, outbreaks of VRE have been described in neonatal and pediatric patients *(207, 210–212)*. Risk factors for VRE colonization and infection have included neutropenia, vancomycin use, and broad-spectrum antimicrobial use *(210–212)*. Overall, prospective prevalence studies have shown wide variability in colonization rates in pediatric populations, ranging from 0% to 50% *(213–216)*.

Other Miscellaneous Infections

Outside the neonatal setting, enterococci are a rare cause of meningitis. Risk factors for enterococcal meningitis include prior neurologic procedures, especially ventriculoperitoneal shunts *(209,217)*. Other risk factors include enterococcal UTI, endocarditis, and the immunocompromised state *(209)*. Other unusual infections associated with enterococci include endogenous endophthalmitis, arthritis (including prosthetic joint infection), or osteomyelitis *(218,219)*. Enterococci are rarely implicated as the cause of lower respiratory tract infections, although there have been reports of enterococcal pneumonia occurring in patients with advanced age, multiple comorbidities, and underlying immunosuppression *(220)*. Many of these patients developed empyema requiring surgical drainage.

Impact of Vancomycin Resistance on Patient Outcome

Recent matched case–control studies confirm that infections with VRE decrease survival, increase length of stay, and significantly increase costs of hospitalization *(161, 221–223)*. In one institution, hospital costs for a patient with VRE were $52,449 compared with $31,915 for controls *(161)*. Similarly, VRE infection was associated with an attributable ICU cost of $33,251 and increased length of hospital stay of 22 days *(224)*. In addition, patients identified as carrying VRE waited significantly longer for placement into long-term care facilities when compared with matched controls, requiring an average of 2.5 requests for placement *(225)*.

PREVENTION AND CONTROL OF HEALTHCARE-ASSOCIATED INFECTIONS CAUSED BY ENTEROCOCCI

As antimicrobial resistance in enterococci increases in prevalence and therapeutic options become more limited, the prevention of emergence and spread of resistant enterococci is imperative. Although most outbreaks of VRE have been controlled with strict application of isolation precautions, a multidisciplinary approach is recommended for continued prevention and control of multidrug-resistant enterococci.

Decreasing Risk of Colonization

Numerous studies have emphasized the role of previous antimicrobials as a risk factor for colonization and infection resulting from enterococcal species *(226–230)*. Therefore, a key element for decreasing the risk of colonization with resistant enterococci is to limit the injudicious use of antimicrobials that select for their growth (*162*,*226*,*230*,231). Some hospitals have effectively used restriction of vancomycin to help control outbreaks of VRE *(226,230)*. Vancomycin use has been closely linked to central line-associated BSI rate and prevalence of methicillin-resistant *S. aureus (232)*. Feedback of specific prescriber use of vancomycin with benchmarking data has resulted in decreased vancomycin use and decreased VRE prevalence *(228)*.

In addition, formulary restriction of cephalosporins may be important in decreasing the risk of colonization with enterococci, including VRE *(230)*. However, one institution had an increase in VRE colonization while restricting vancomycin and cephalosporins and noted that clindamycin restriction may be an important component of an antimicrobial stewardship program for controlling VRE *(162)*. Although recommendations for antimicrobial stewardship have been outlined, many hospitals do not have stewardship programs that fully meet the recommendations (233,*234*).

Along with selective use of antimicrobials, another necessary measure to decrease infection resulting from enterococci is to reduce the use of invasive devices whenever possible. Urinary catheterization predisposes to enterococcal UTIs (107,*137*). In addition, central line use has been recognized as a risk factor for the development of enterococcal bacteremia (170). Finally, attempts should be made to eliminate the modifiable risk factors for colonization and infection with resistant enterococci as mentioned previously (Table 33-4).

Interruption of Transmission

Early identification of patients infected and colonized with antimicrobial-resistant enterococci is an important step in interrupting transmission of these microorganisms (*157*,231,*235*,*236*). Active screening for VRE colonization, when used with other infection control measures, has been found to be effective in decreasing prevalence of VRE colonization and infection *(236,237)*. In addition, active surveillance and control has been shown to be cost-effective for hospitals *(235,238–240)*. For active surveillance for gastrointestinal VRE colonization, perirectal swabs have been effective in most studies *(235,241–243)*; however, false-negative results may occur in patients with low-density colonization *(244)*. Some have used passive surveillance through routine laboratory culturing or culturing stool samples sent for *C. difficile* studies to identify and control VRE colonization *(111,245,246)*. However, passive reporting may underestimate the prevalence of VRE *(247)*. Therefore, the Society for Healthcare Epidemiology of America (SHEA) now recommends obtaining active surveillance cultures for high-risk patients at the time of admission and at periodic time intervals (e.g., weekly) thereafter (231).

High-risk patients typically include ICU patients and may include patients with a history of previous hospitalization or other known risk factors for VRE colonization *(248)*. It is essential that hospital microbiology laboratories use accurate screening methods for VRE and have a system for quickly reporting these microorganisms so that appropriate precautions may be instituted (5,231).

Isolation precautions with private rooms, gowns, and gloves have been used and recommended for the prevention of transmission and control of VRE (231,249). However, in a hospital with a high rate of endemic VRE, the addition of gown use did not decrease acquisition of VRE when compared with glove use alone *(250)*. Several studies support the Healthcare Infection Control Practices Advisory Committee (HICPAC) guidelines for control of VRE and indicate that gowns have an added benefit to the use of gloves in the ICU setting (249,*251*,*252*). Isolation precautions have been successful, for the most part, in ending epidemics as long as all reservoirs have been identified and eradicated. Cohorting of colonized patients, in addition to isolation precautions, have been used in outbreak situations to help control transmission of VRE *(253)*.

Hand hygiene is a key element in controlling spread of resistant enterococci (231,249,254). Gloves reduce hand carriage of VRE but do not completely prevent contamination of hands *(255)*. In one study, 5 of 17 healthcare personnel were found to have VRE on the hands after glove removal, emphasizing the importance of hand hygiene after removal of gloves *(255)*. Use of alcohol hand rub is now generally recommended for hand hygiene (254). In an *in vitro* study of the efficacy of various hand disinfectants against enterococci, propanol-based compounds were found to be highly effective *(256)*. At one institution, the incidence of VRE colonization or infection decreased after introduction of alcohol hand rub for hand hygiene *(257)*.

Elimination of Reservoirs

Patients harboring resistant enterococci in their gastrointestinal tract are the major reservoirs for transmission within hospitals, but healthcare workers may also carry enterococci. Eradication of enterococci from human carriers has been problematic *(101,258,259)*. During an outbreak of β-lactamase-producing gentamicin-resistant enterococci, a 14-day course of oral vancomycin and rifampin, based on the isolate's antimicrobial susceptibilities, was used to eradicate carriage in a nurse *(10)*. Eradication of VRE from the intestinal tract has been attempted with several oral antimicrobial regimens with little success *(97,258–260)*. Ramoplanin, a nonabsorbable glycolipopeptide with bactericidal activity against VRE, was successful in temporarily suppressing VRE in the gastrointestinal tract of colonized patients. However, the suppressive effects were lost by 3 weeks after discontinuing treatment *(259)*. In this study, repopulation of the intestinal tract with VRE within 7 days of discontinuing ramoplanin represented relapse with a genotypically similar isolate of VRE *(98)*.

While eradication of VRE from the gastrointestinal tract may not be possible, skin represents another important reservoir for VRE that may be more easily addressed. A recent study demonstrated that daily bathing of ICU patients with the antiseptic chlorhexidine lowered the rate of VRE acquisition and BSI *(260)*.

In many studies, the environment surrounding infected patients had become heavily contaminated with enterococci (*10*,*91*,*100*,135,*261*). Noncritical medical equipment, such as thermometers, stethoscopes, and blood pressure cuffs, should be dedicated to a single VRE colonized patient (231). If equipment must be used on multiple patients, it should be disinfected after each use (231). Other authors have incorporated a thorough cleaning of the environment into control measures during an epidemic *(262)*. More recently, it has been shown that enforcement of routine environmental cleaning reduces environmental contamination with VRE and patient acquisition of VRE *(263,264)*. Enterococci, including VRE, appear to be susceptible to disinfectants routinely used in hospitals *(265)*. Screening for environmental contamination may be performed, when applicable, through use of Rodac imprints or use of swabs with enrichment broth *(111,242)*.

CHAPTER 34

Enterobacteriaceae

Stephanie R. Black, Marc J.M. Bonten, and Robert A. Weinstein

The family Enterobacteriaceae comprises a wide array of gram-negative bacilli whose reservoirs include soil, water, plants, and the gastrointestinal tracts of humans and animals. As a group, Enterobacteriaceae are the most frequent bacterial isolates recovered from inpatient and outpatient clinical specimens *(1)*. In 2006 to 2007, Enterobacteriaceae accounted for 21% of pathogens isolated from all infection sites in the Centers for Disease Control and Prevention (CDC) National Healthcare Safety Network (NHSN) Surveillance System, the successor to the CDC's National Healthcare-associated Infections Surveillance (NNIS) System (2).

OVERVIEW

Microbiologically, all members of the Enterobacteriaceae are facultative anaerobes that, with few exceptions, ferment glucose, reduce nitrate to nitrite, and are oxidase negative *(3)*. Several approaches to classifying the Enterobacteriaceae have been used over the years, including phenotypic subgroupings *(4)*, DNA-relatedness studies *(5)*, and a combination of the two methods *(6)*. A summary of a current classification is presented in Table 34-1 *(7)*.

For identification of aerobic gram-negative bacilli, many hospital microbiology laboratories now use automated rapid identification systems rather than conventional biochemical testing *(3)*. Of particular importance to infection control is the ability to determine in the microbiology laboratory whether healthcare-associated infections are due to the spread of a single species. This requires the ability to type strains by classic or newer molecular methods (Table 34-2) *(8)*. Pulsed-field gel electrophoresis (PFGE) has been the most widely used method of genotyping, and for small sets of isolates empiric guidelines have been formulated to interpret chromosomal DNA restriction patterns produced by this method *(9)* (see Chapter 102). These guidelines have been validated for some species *(10)*. Currently though, PCR-based (multiple-locus variable number tandem repeat Analysis [MLVA]) and sequence-based methods (multiple-locus sequence typing [MLST] and whole genome sequencing) have become the standard.

As the use of invasive devices, broad-spectrum antibiotics, and immunosuppressive agents has increased in hospitals, the Enterobacteriaceae, particularly *Escherichia coli*, have become somewhat less prevalent, and gram-positive microorganisms, especially staphylococci and enterococci, more prevalent as causes of healthcare-associated infection. In 1999 and in 2006 to 2007 CDC data, the major device-associated infections, that is, central-line–associated bloodstream infections (CLABSIs), catheter-associated urinary tract infections (CAUTIs), and ventilator-associated pneumonia (VAP), were each caused most often by the same four pathogens, respectively (2,*11*); the one exception was that for VAP, in the 2006 to 2007 data, *Acinetobacter baumannii* tied *Enterobacter* spp. as the third most frequent pathogen (2).

To illustrate the changing overall role of Enterobacteriaceae in the pathogenesis of healthcare-associated infections, Table 34-3 presents NNIS data from 1980 to 1982 and 1990 to 1996 and NHSN data from 2006 to 2007. Comparisons between NNIS and NHSN need to be made with caution due to differences between the two systems (e.g., NHSN includes units outside of intensive care, has no minimum hospital size requirement for participation, and has a greatly expanded hospital base due to mandated use in many states for public reporting purposes). The percentage of pathogens recovered from healthcare-associated infections that were Enterobacteriaceae declined from 42% in 1980 to 1982 to 29% in 1990 to 1996, and continued to trend down to 21% for 2006 to 2007, primarily because of less frequent recovery of *E. coli*. This trend is apparent and continues in all major infection sites. For example, Enterobacteriaceae accounted for 18% of the 14,424 isolates causing bloodstream infections (BSIs) in the 1990 to 1996 NNIS data, but accounted for only 10% of the 21,943 isolates causing BSIs in the 1992 to 1999 data *(11)* and for 12.4% of 11,428 isolates from CLABSIs in 2006 to 2007 (2). Selected data from other recent multicenter healthcare-associated surveillance systems are shown in Table 34-4.

Although the overall percentage of healthcare-associated infections due to the Enterobacteriaceae has declined, Enterobacteriaceae remain important healthcare-associated pathogens. They have been implicated in almost a third (34%) of all healthcare-associated urinary tract infections (UTIs), in nearly a fifth (18%) of all SSIs, in up to 12% of all BSIs, and in 23% of all VAP. Overall, *E. coli*, *Klebsiella pneumoniae*, *Enterobacter* spp., and *K. oxytoca* were the most common healthcare-associated pathogens from the family Enterobacteriaceae and together accounted for about one-fifth of all healthcare-associated isolates in 2006 to 2007 (2).

Enterobacteriaceae discussed in the text are highlighted.
(Adapted from Bruckner DA, Colonna P, Bearson BL. Nomenclature for aerobic and facultative bacteria. *Clin Infect Dis* 1999;29:713–723.)

Though Enterobacteriaceae comprise a slightly smaller portion of healthcare-associated infections than in the past, the alarming increase in antimicrobial resistance, particularly to carbapenem antibiotics and the presence of resistance cassettes on transmissible genetic elements, compels healthcare professionals to understand the pathogenesis, infection control, and preventive measures to limit their spread.

PATHOGEN-SPECIFIC FACTORS IN THE PATHOGENESIS OF HEALTHCARE-ASSOCIATED INFECTIONS CAUSED BY ENTEROBACTERIACEAE

Multiple factors are involved in the pathogenesis of infection caused by Enterobacteriaceae. As discussed below, a variety of pathogen-specific factors, device-related factors, and host factors act together to determine the likelihood of infection. The virulence of the microorganism (i.e., the ability to invade and cause disease) relates to both pathogen factors and to the immune status of the patient.

Adhesion

Bacterial adhesion is a highly specific phenomenon that leads to attachment of bacteria to mucosal surfaces and, thus, to colonization and potentially to bacterial overgrowth and tissue invasion. Adhesins may also function as invasins, promote biofilm formation, and transmit signals to epithelial cells leading to inflammation *(19,20)*. Among Enterobacteriaceae, adhesion is mediated by both fimbrial and nonfimbrial adhesins (Table 34-5) that are encoded on plasmids and on the bacterial genome, forming "pathogenicity islands" *(21)*. The locus for enterocyte effacement on the chromosome encodes the virulence types necessary for attachment and effacement of *E. coli* to enterocytes *(22)*. The *E. coli* fimbrial adhesins are among the most studied and the best characterized of the bacterial adhesins.

P fimbriae anchor bacteria to uroepithelial cells *(29)* and are found in strains that cause pyelonephritis in adults and children *(30–32)*. The symbol P was chosen because P-fimbriated *E. coli* were a frequent cause of pyelonephritis and because glycolipids were receptors for P fimbriae and antigens in the P blood group system *(33)*. Compared to non–P-fimbriated strains of *E. coli*, isolates with P fimbriae can adhere to specific receptors on human colonic epithelial cells (leading to colonization), spread more easily to the urinary tract, have a better ability to persist in kidneys and bladders, and enhance the inflammatory response *(33)*.

A relation between adherence and virulence has been demonstrated. Among *E. coli* strains from patients with different forms of UTIs, *in vitro* adherence to uroepithelial cells was found in 80% of the patients with pyelonephritis, 40% to 50% of the patients with acute cystitis, and 20% of the patients with asymptomatic bacteriuria *(33)*. Studies of bacteremia secondary to urosepsis have shown that *E. coli* strains that cause urosepsis in healthy patients almost always have P fimbriae, whereas *E. coli* urosepsis in immunocompromised patients is less often due to such P-fimbriated strains *(30–32)*. In a study of fimbrial types found in respiratory isolates from intensive care

Note: These judgments represent the views of Maslow et al. *(10)*; many systems remain incompletely evaluated, and characteristics may vary when the systems are applied to different species.
(Modified from Maslow JN, Mulligan ME, Arbeit RD. Molecular epidemiology: application of contemporary techniques to the typing of microorganisms. *Clin Infect Dis* 1993;17:153–164.)

unit (ICU) patients with presumed healthcare-associated pneumonia, P fimbriae were found in approximately half of the *E. coli* respiratory isolates *(34)*. This rate is higher than the rate of P fimbriation commonly found in fecal isolates (14–16%) and, thus, raises the question of how the presence of this adhesin may be advantageous to strains causing pulmonary infection *(34)*. Another study looked at the role of the *papG* class II gene, a P-fimbrial structural allele causing uroepithelial attachment of *E. coli*, and the pathogenesis of *E. coli* bacteremia in upper UTIs and ascending cholangitis. The authors found a significant difference between the presence of the virulence factor, *papG* class II, in bacteremic patients with upper UTI compared to bacteremic patients with ascending cholangitis and to controls *(35)*.

Cranberry juice consumption may offer protection against P-fimbriated strains of *E. coli* by the action of cranberry proanthocyanidin (condensed tannin), which inhibits P-fimbriated *E. coli* from adhering to uroepithelial cells *(36)*. A randomized controlled study with 50 women per arm compared drinking 50 mL of cranberry juice concentrate daily for 6 months to drinking 100 mL of lactobacillus GG 5 days a week for 1 year, compared to controls. The authors found an absolute risk reduction for recurrent UTI of 20% in the group that drank cranberry juice *(37)*.

S fimbriae are present on many *E. coli* strains that cause infant meningitis. The presence of binding sites for S fimbriae on blood vessels in the central nervous system (CNS) and on epithelial cells of the choroid plexus and of the ventricle of the infant rat brain provides a model for the pathogenesis of neonatal *E. coli* meningitis *(38)*. The binding affinity of S fimbriae for vascular endothelium and epithelium of the choroid plexus and the ventricles decreases after the neonatal period in rats, paralleling the decrease in susceptibility to *E. coli* meningitis *(39)*. S fimbriae also allow *E. coli* to bind to intact endothelial cells *(38,40)* and thus may be an important virulence factor for septicemia. When isolates of *E. coli* that caused a variety of invasive bacterial infections were compared to fecal isolates in healthy children, P fimbriae and S fimbriae were predominant in *E. coli* isolates causing invasive disease *(41)*.

Type I pili have been associated with uropathogenic *E. coli* (UPEC). Type I pili facilitate entry of UPEC into bladder epithelial cells, with subsequent exfoliation *(42)*. The ability of UPEC to invade and persist in bladder epithelial cells has been suggested as an explanation of recurrent UTIs.

Type IV pili have been identified in enteropathogenic *E. coli*, which frequently cause childhood diarrhea in developing countries. Type IV pili are known as bundle-forming pili (BFP) and are critical to the full virulence of these bacteria *(43)*. Mutants without these pili could not attach to epithelial cells *in vitro* and were relatively benign when fed to human volunteers. These pili facilitate bacterial bundling into rope-like filaments that attach to epithelial cells; subsequently, the clumped bacteria disperse to cause infection *(43)*.

In addition to Type 1 pili and P fimbriae, the Dr adhesion family of UPEC has been associated with pyelonephritis in pregnant women *(44)*. The Dr adhesin family includes a fimbrial adhesin and nonfimbrial adhesins and is termed Dr for the blood group antigen, a common receptor for this family of adhesins *(45)*. Dr adhesins are associated with bacterial persistence in the urinary tract and facilitate invasion of the bladder and kidney tissue and binding

(Data from CDC and refs. 2, *12*, and *13*.)

to decay accelerating factor, a host protective protein that prevents autologous complement mediated damage (*46*,47). Currently, it is unknown if this group of adhesins is expressed during UPEC-associated CAUTIs.

Autotransporter (AT) proteins are another group of adhesins associated with UTI virulence *(48)*. Antigen 43 (Ag 43), a bacterial surface AT protein, has been identified in UPEC and enteropathogenic *E. coli (48)*, though not specifically in CAUTI. Antigen 43 confers characteristic surface properties such as autoaggregation and promotes bacterial biofilm formation, and the Ag 43a variant recently has been shown to promote long-term persistence in the urinary bladder in mouse models of UTI *(49)*. These autotranporters may be future targets for novel vaccines against gram-negative pathogens *(50)*.

The role of adhesins in the pathogenesis of infection caused by other Enterobacteriaceae is not well characterized. Type 1, 3, and 6 fimbriae have been found in *Klebsiella*, but their function as virulence factors remains largely unknown *(51,52)*. The majority of respiratory isolates of *K. pneumoniae* and *K. oxytoca* from ICU patients with presumed healthcare-associated pneumonia have been shown to express type 3 fimbriae and a mannose-resistant, *Klebsiella*-like (MR-K) hemagglutinin *(34)*. Multidrug-resistant *K. pneumoniae* strains from a variety of healthcare-associated infections have been found to colonize the human intestinal tract through a plasmid-encoded 29,000-dalton surface protein *(51)* that facilitates adherence to gastrointestinal epithelium. Type 3 fimbriae also are commonly found in *Klebsiella* isolates associated with human UTIs *(51)*. An MR-K fimbria has been isolated in *Providencia stuartii* and appears to be related to adherence to genitourinary catheters *(53)*. Cell adhesins that allow attachment to exfoliated uroepithelium *(54–56)* have been found in *Proteus* spp. as well. Nonfimbrial adhesive factors also are being characterized in the Enterobacteriaceae *(57,58)*. An R-plasmid encoded nonfimbrial adhesive factor has been isolated from strains of *K. pneumoniae* responsible for a variety of healthcare-associated infections *(57)*.

Capsules

The bacterial capsule, which is well characterized for *Klebsiella* spp., *E. coli*, and *Salmonella typhi*, can partly protect the microorganisms against the bactericidal effect of serum and against phagocytosis *(57,59,60)*. However, most of the Enterobacteriaceae do not possess a substantial bacterial capsule and do not have serum resistance. In a prospective observational study from six United States university teaching hospitals evaluating the incidence and the risk factors for the development of endocarditis in bacteremic patients with prosthetic cardiac valves, a significant proportion of cases of new endocarditis were due to gram-negative aerobic bacilli, often when a portal of entry was found *(61)*. This study suggests that the previous hypothesis that endocarditis was unlikely in the presence of gram-negative bacteremia, presumably because gram-negative bacilli are

serum susceptible or if a portal of entry is identified, may not be correct.

A capsule, when present, can also directly suppress the host immune response *(62)*. In invasive *E. coli* disease in children, K1 and K5 capsules are found most commonly *(41)*. It has been suggested that these capsules are more virulent, because they are structurally similar to human antigens, and therefore may be spared by or elude specific host defense mechanisms. The size of the capsule and the rate of capsule polysaccharide production appear to influence bacterial virulence *(62)*.

Iron Chelators

The ability of some gram-negative bacteria to acquire iron for growth becomes an important factor in many gram-negative infections. Almost all the iron in the human body is bound to various proteins such as hemoglobin, myoglobin, and transferrin, thereby limiting the availability of free iron for utilization by bacteria. Some Enterobacteriaceae contain low molecular weight, high-affinity iron chelators called siderophores. The chelator permits the bacteria to scavenge iron from the host for growth purposes.

Aerobactin is an iron-chelating bacterial siderophore associated with increased virulence in *E. coli (63)* and *Klebsiella (64,52)*. In Enterobacteriaceae, the catechol enterobactin is the most commonly occurring iron-chelating siderophore but does not appear to be associated with increased bacterial virulence *(64,65)* possibly because enterobactin is more antigenic than aerobactin and causes a strong antibody response in the host that diminishes enterobactin's ability to take up iron *(65)*.

Yersinia enterocolitica 1B, *Y. pseudotuberculosis*, and *Y. pestis* have been found to contain chromosomal gene sets designated high-pathogenicity islands (HPIs) that are involved in the synthesis, transport, and regulation of the siderophore yersiniabactin. This HPI has also been found in other genera including *E. coli*, *Klebsiella*, *Citrobacter*, and *Enterobacter (66–68)*. *Y. enterocolitica* has increased virulence in patients receiving desferrioxamine therapy, presumably because *Yersinia* can use desferrioxamine to meet some of its growth requirements more effectively in these patients *(69,70)*.

Another method by which bacteria may acquire iron is hemolysis. Hemolysins are cytotoxic proteins encoded by chromosomal or plasmid genes. The chromosomal

localization seems to be predominant for *E. coli* causing extraintestinal infections, whereas hemolysins are usually carried on plasmid genes in *E. coli* strains from veterinary sources. Hemolysins are cytotoxic for erythrocytes, and *in vitro* for polymorphonuclear leukocytes, monocytes, and isolated renal tubular cells. These proteins contribute to virulence in intraperitoneal infection models, but their role in ascending UTIs is uncertain. Hemolysin production is frequent in pyelonephritic clones of *E. coli*, but does not enhance bacterial persistence in kidneys and bladders *(33,41)*.

Other Pathogen Factors and Tropisms

Other virulence factors, such as bacterial motility *(71)*; the ability to grow in alkaline pH; the ability to colonize skin (especially hands) of healthcare workers; the ability to produce urease, which catalyzes hydrolysis of urea in the urine and increases urinary pH *(72)*; and the ability to produce biofilms *(73)*, contribute to the ability of various members of the Enterobacteriaceae to produce disease, especially in healthcare settings. Enterobacteriaceae liberate numerous toxins, endotoxin being one of the most lethal, which contribute to bacterial virulence (Table 34-5). The role of endotoxins in healthcare-associated infection is no different from their role in community-acquired infection. Finally, some virulence factors have been associated with worsened patient outcome, although precise mechanisms of tissue injury are unknown. For example, a minor outer membrane protein (molecular weight of 32,000) is found more often in strains of *Citrobacter koseri* causing neonatal meningitis and abscess than in strains of *C. koseri* from other body sites *(74)*. Evidence from an infant rat model suggests that strains of *C. koseri* with this outer membrane protein can produce more extensive histopathologic changes within the brain *(75)*.

Infections by several species of Enterobacteriaceae have been associated with specific devices, materials, and/or procedures because of increased device affinity or specific tropisms. For example, *Proteus mirabilis* is an urease-producing bacterium that has been associated with bacteriuria and obstructed urinary catheters in patients with long-term indwelling bladder catheters *(76)*. Urease catalyzes the hydrolysis of urea in the urine, thus alkalinizing it; this permits the formation of struvite and carbonate-apatite stones or sludge or concretions within the catheter lumen, leading to catheter obstruction. Other members of the

CFA I, II, colonization factor antigen I, II; HC, hemorrhagic colitis; HUS, hemolytic-uremic syndrome; LT, long-term; MR-K, mannose-resistant *Klebsiella*-like hemagglutinin; UTI, urinary tract infection.

Enterobacteriaceae family, including *Morganella morganii*, *K. pneumoniae*, *P. vulgaris*, and *P. stuartii*, also produce urease. Although no association between bacteriuria and catheter obstruction has been demonstrated for these microorganisms *(76)*, some, such as *P. stuartii*, are very commonly associated with long-term bladder catheterization. An MR-K hemagglutinin has been identified in *P. stuartii* that increases adherence to catheter material *(53)*.

The cell-surface characteristics of *K. pneumoniae* may also play a role in increased adherence to ventriculoperitoneal shunts. For example, when a multiresistant strain of *K. pneumoniae* was compared to its spontaneous *in vitro* antibiotic-susceptible derivative, the derivative was more adherent to the surface of ventriculoperitoneal catheters *(58)*. Genetic studies suggested that the absence of a plasmid-mediated outer membrane protein led to increased adherence to the ventriculoperitoneal shunt surface.

Enterobacter sakazakii has been associated with several neonatal outbreaks and sporadic cases of sepsis, meningitis, and diarrhea *(77–81)*. No environmental source for *E. sakazakii* has been identified *(81)*. Most outbreaks have been associated with either intrinsic or extrinsic contamination of powdered milk substitute. *E. sakazakii* has been isolated from powdered infant formula produced in 13 different countries by multiple manufacturers *(79,82)*, suggesting that this microorganism has the propensity to contaminate such products. *In vitro* studies show that *E. sakazakii* survives better than *E. cloacae* in infant formula *(77)*.

Y. enterocolitica has a well-documented association with blood transfusion–related sepsis *(83,84)*. Apparently, blood donors with asymptomatic gastrointestinal infection with *Y. enterocolitica* and transient bacteremia at the time of blood donation are the most common source of such cases *(85)*. The environment of cold stored red blood cells favors the

growth of *Y. enterocolitica* more than the growth of other, more likely contaminants (e.g., skin flora from donors) since *Y. enterocolitica* survives better than most bacteria at refrigeration temperatures. In addition, progressive hemolysis of stored blood may provide an ongoing supply of iron for *Yersinia's* growth. Virulent strains of *Yersinia* can also grow in calcium-free media such as that produced by citrate chelation of red blood cells for storage. Serotype 0:3 has accounted for the majority of cases of transfusion-related *Yersinia* sepsis. This serotype shows a persistent resistance to the bactericidal effect of serum at cold temperatures and has a growth–response curve that is directly related to the iron content of the culture medium *(86)*.

Enterobacter spp. and *Citrobacter* spp. thrive in aqueous environments and may cause healthcare-associated bacteremia by their ability to grow in infusion fluids *(87)*. *Enterobacter* spp. can fix nitrogen, allowing for replication in nitrogen-deficient fluids, and have been shown to have more rapid replication than *E. coli*, *Klebsiella*, *Pseudomonas*, or *Proteus (88)* in dextrose-containing solutions.

Examples of Genetics of Some Virulence Factors

R-plasmids, commonly found in Enterobacteriaceae, are also associated with bacterial virulence. They carry genes encoding virulence factors, such as adhesive factors *(57)*, enterotoxins, and hemolysins *(89)*. Plasmids code for outer membrane proteins for various Enterobacteriaceae. In *Y. enterocolitica*, a 70-kb plasmid codes proteins of the outer membrane that are associated with resistance to complement-mediated opsonization, to neutrophil phagocytosis, and to bactericidal activity of human serum *(90)*. Similar plasmids have been isolated in *Y. pseudotuberculosis* and *Y. pestis*. Two soluble plasmid-mediated antigens, V and W, have been isolated from virulent strains of *Y. pestis*, *Y. pseudotuberculosis*, and *Y. enterocolitica (90)*. Because plasmids are also important determinants of antimicrobial resistance, they may allow pathogens to link drug resistance and virulence determinants, which may be transferred together to other species.

Temporal Evolution of Antibiotic Resistance

The increasing prevalence of antibiotic-resistant Enterobacteriaceae has contributed to the difficulty in treating healthcare-associated infections (2,*91*,92). Antibiotic resistance often is related to excessive or widespread use of a particular antibiotic *(93)*. For example, aminoglycoside and cephalosporin resistance in *Klebsiella* has been correlated with exposure to and intensity of use of these drugs *(94,95)*. Mechanisms of antibiotic resistance in the Enterobacteriaceae include enzyme production that can inactivate or modify the drug (e.g., β-lactamase production), diminished permeability of antibiotics, and altered antibiotic target sites. Bacteria may acquire these mechanisms of resistance spontaneously via chromosomal mutation or via transfer of plasmids or transposable genetic elements from other bacteria *(96)*. Genes that determine resistance to different classes of antibiotics may occur on a single plasmid so that use of one antimicrobial can lead to resistance to other classes of antibiotics.

Common mechanisms of β-lactam antibiotic resistance include chromosomal mutation, which is frequent and offers a bacterial survival advantage during antibiotic therapy. This is the mechanism of resistance found in Enterobacteriaceae, such as *Enterobacter*, *Serratia*, indole-positive *Proteus*, and *Citrobacter*, which carry chromosomal genes that encode a type 1 β-lactamase *(96,97)*. These bacteria can undergo single-step mutations to constitutive high-level β-lactamase production. Thus, initially susceptible strains of *Enterobacter* and other Enterobacteriaceae may develop spontaneous resistant mutants to broad-spectrum cephalosporins during 20% to 50% of courses of therapy *(98)*. These AmpC enzymes may be present on plasmids and therefore, transmissible to other species such as *E. coli* and *Klebsiella* (99,*100*). The AmpC β-lactamase hydrolyzes cephamycins and oxyimino-β-lactamases (or third-generation cephalosporins) (101). AmpC enzymes are not inhibited by β-lactamase inhibitors such as clauvulanic acid, a characteristic that distinguishes them from extended-spectrum β-lactamases (ESBLs) (102).

Enterobacteriaceae have responded to the widespread use of β-lactam antibiotics with inactivation of these drugs by a variety of β-lactamases (such as TEM-1, TEM-2, and SHV-1 β-lactamases), which are typically plasmid-encoded *(96)*. These resistances were overcome by the pharmaceutical industry development of second- and third-generation cephalosporins and combinations of β-lactam antibiotics with β-lactamase inhibitors. However, in 1982, the first Enterobacteriaceae with resistance to broad-spectrum cephalosporins, such as cefuroxime, cefotaxime, and ceftazidime, were isolated in Europe *(103,104)*. These ESBLs arose by point mutations, which arose in the face of widespread use of antibiotics. ESBLs differ in only one or a few amino acids from the original TEM-1, TEM-2, and SHV-1 β-lactamases and are also plasmid-mediated *(96)*. Hundreds of ESBLs have been identified (101,*105–108*). Although the first ESBLs were reported from Europe, they have spread to most continents during the last two decades (*109*,110). Some of these ESBLs are highlighted in Table 34-6. *Klebsiella* spp. and *E. coli* have been the primary carriers of ESBLs in North America and Europe (111,112). ESBL profiles differ dramatically between the United States and Canada and between North America and Europe (111,112). Large surveillance studies have shown various rates of ESBL production depending on geographic location, on whether surveillance relied only on phenotypic data or used confirmatory microbiologic testing, and on which patient care areas were assessed (i.e., ICU vs. other wards) (Table 34-7).

While the healthcare-associated pathogen distribution remains similar *(11,116)*, increasing antibiotic resistance among Enterobacteriaceae infections is a major cause of concern in healthcare facilities. CDC reported that from 1998 to 2002 to 2003, there was a 47% increase in the rate of resistance to third-generation cephalosporins among *K. pneumoniae* recovered from healthcare-associated infections in ICU patients *(91)*. In addition, comparing 1986–2003 to 2006–2007, among pathogens causing device-associated healthcare-associated infections (HAIs) (2), resistance to extended-spectrum cephalosporins increased among healthcare-associated *E. coli* (6% vs. 6–11%) and *K. pneumoniae* (21% vs. 21–27%) isolates, and resistance to carbapenems increased among *Pseudomonas aeruginosa* (21% vs. 25%). Among all HAIs, while resistant gram-positive species represent the four most common antimicrobial-resistant pathogens, *P. aeruginosa* isolates resistant to

fluoroquinolones, carbapenems, and β-lactam/β-lactamase inhibitor combinations represent the fourth, fifth, and sixth most common resistant pathogens, respectively. *K. pneumoniae* resistant to third-generation cephalosporins, *E. coli* resistant to fluoroquinolones, and *A. baumannii* resistant to carbapenems also are prominent causes of CLABSI, CAUTI, and VAP (Table 34-7).

In a surveillance study of 35,790 isolates (more than 50% of which were respiratory) from United States, ICUs in 43 states and the District of Columbia demonstrated decreasing susceptibility of gram-negative bacilli (including *Enterobacter* spp. and *Klebsiella*) to ciprofloxacin from 86% in 1994 to 76% in 2000 *(117)*. This decline coincided with increased national use of fluoroquinolones measured by sales of pharmaceuticals to retail stores and healthcare facilities. Resistance to ciprofloxacin was associated with crossresistance to other classes of broad-spectrum antimicrobial agents, including aminoglycosides, carbapenems, and third-generation cephalosporins *(117)*. CDC data from 2006 to 2007 show that among Enterobacteriaceae, resistance to fluoroquinolones, as well as to extended-spectrum cephalosporins and carbapenems, was higher than noted in surveillance studies from the late 1990s; fluoroquinolone-resistance rates for *E. coli* from CLABSIs, CAUTIs, and VAP were 30.8%, 24.8%, and 22.7%, respectively (Table 34-7).

Epidemiology of Selected β-Lactamases

Spread of multidrug-resistant *E. coli* clonal group A (CGA), was described initially in London, England, in 1986 *(118)* and has now been reported in cohorts of women with UTIs in California, Minnesota, and Michigan. This CGA *E. coli* accounted for almost 50% of community-acquired UTIs that were resistant to trimethoprim-sulfamethoxazole *(119)*. This clone also has been associated with the development of pyelonephritis *(120)* and anecdotally in a renal transplant patient from Buffalo, New York, with pneumonia and bacteremia who had taken trimethoprim-sulfamethoxazole prophylactic therapy *(121)*. In a study of 103 women with symptoms of cystitis and a positive urine culture, 15% had trimethoprim-sulfamethoxazole–resistant *E. coli*. In this small study, independently associated risk factors for having a pathogen resistant to trimethoprim-sulfamethoxazole

included travel (within 3 months to Asia, S. America, Canada, or Europe) and Asian race. Prior exposure to the antibiotic and having a child in daycare were not associated with resistance *(122)*.

The burden of antibiotic-resistant pathogens has led to increased awareness of colonization with ESBLs in nonoutbreak and in community settings. In Spain, the rate of ESBL-producing isolates in fecal samples from hospitalized patients and outpatients increased significantly from 0.3% and 0.7% respectively, in 1991, to 11.8% and 5.5%, respectively, in 2003; and 3.7% of healthy volunteers, with no history of antibiotic use or hospitalization within 3 months, were colonized. In 1991, ESBL-producing isolates included *E. coli*, *Klebsiella*, and *Citrobacter*, whereas in 2003, all ESBL producers were *E. coli*. CTX-M and SHV enzymes were detected in outpatients, while TEM enzymes were limited to inpatients; the genetic diversity among isolates suggested horizontal transfer of genetic structures such as plasmids, transposons, or integrons, rather than clonal dissemination *(123,124)*.

CTX-M β-lactamases have become the predominant ESBL family in Europe, Africa, Asia, South America, and North America and are now beginning to be reported in the United States (125–127). CTX-M isolates emerged from the rarely pathogenic commensal genus, *Kluyvera*, and are typically associated with greater activity against cefotaxime than ceftazidime, though some are capable of hydrolyzing ceftazidime *(128)*. The phenotype for CTX-M isolates often demonstrates resistance to multiple antibiotics, including aminoglycosides, tetracyclines, sulfonamides, and fluoroquinolones, due to other genes present on the $bla_{\text{CTX-M}}$ plasmid (110,*129*).

CTX-M have been identified largely in community settings, primarily among patients with *E. coli* UTIs (125,130). *E. coli*–producing CTX-M enzymes have been identified in domestic animals, food products, sewage, and stool samples from healthy volunteers *(131,132)*. In the United Kingdom, many patients with community-onset CTX-M UTIs were elderly individuals who have multiple underlying illnesses and history of exposure to a hospital setting within the prior 3 years (126). In a study of 311 nonhospitalized patients with community-acquired UTI by ESBL-producing bacteria, multivariate analysis revealed independent risk factors associated with UTI included prior hospitalization

or antibiotic treatment within 3 months, age over 60 years, diabetes, male gender, *K. pneumoniae* infection, and prior use of second- or third-generation cephalosporins, quinolones, or penicillin *(133)*.

Fecal samples from 294 residents from 16 nursing homes in Ireland demonstrated multidrug-resistant *E. coli* in 40% of specimens (a rate that was 40 times that in the community). Half of these carriers had no history of hospitalization in the prior 1.5 years and only 13.5% had known history of ESBL colonization or infection. Half of the isolates carried the CTX-M-15 enzyme. Multivariate analysis showed independent host risk factors including days of fluoroquinolone use and UTI *(134)*.

Resistance to carbapenems has become more prevalent in Enterobacteriaceae, especially *K. pneumoniae* and *E. coli*. Dissemination of these resistant pathogens, which are common etiologies of healthcare-associated and community infections, is of particular concern because there are few antibiotic choices for treatment and none are orally available. Carbapenem-resistant Enterobacteriaceae (CRE) may be due to three carbapenemases including metallo-β-lactamases, *K. pneumoniae* carbapenemases, and oxacillinases *(135,136)*. The New Delhi metallo-β-lactamase (NDM-1) has been identified in *K. pneumoniae* and *E. coli* and has become widespread in India and Pakistan (137). NDM-1 has been identified in European, North American travelers who have sought medical care in India, due to lower cost and shorter waiting times for surgical procedures, termed "medical tourism" *(138,139)*. NDM-1 isolates have spread clonally, the common mode of spread, and have also spread by dissemination of a plasmid encoding the NDM-1 sequence into multiple species of Enterobacteriaceae. "Plasmid outbreaks" may allow for more rapid transfer of resistance when plasmid recipient bacteria are well adapted to their environment with efficient person-to-person spread. Plasmid rearrangement may lead to accumulation of resistance mechanisms. The NDM-1 gene confers resistance to fluoroquinolones, aminoglycosides, and β-lactams, including carbapenems, but remains sensitive to tigecycline and colistin *(136)*.

In addition, the Verona integron–encoded metallo-β-lactamase (VIM) carbapenemase has been identified in a returning US traveler who had a diarrheal illness on a Mediterranean cruise ship and was hospitalized in Greece, where VIM resistance mechanism has been previously identified (140).

K. pneumoniae carbapenemases (KPCs), KPC-1 to KPC-7, confer resistance or decreased susceptibility to almost all β-lactams (141), leaving few therapeutic options to treat infected patients, and are the most common mechanism of carbapenem resistance among Enterobacteriaceae in the United States *(142)*. Enterobacteriaceae that produce KPCs were first reported in 1996 from *K. pneumoniae* isolated in North Carolina *(143)*. KPC isolates were next recognized in New York City where molecular analysis revealed that 78 of 95 *K. pneumoniae* isolates from 10 acute-care hospitals belonged to one ribotype, suggesting crosstransmission *(144)*. By 2004, 24%, and by 2006, 38% of *K. pneumoniae* isolates from Brooklyn or other New York hospitals were KPC positive (145,*146*). KPCs may have spread from the United States to Israel, where KPC-2 and KPC-3 clones have caused outbreaks in Tel Aviv hospitals *(147)* and Athens *(148)*. The U.S.- and Israeli-derived isolates are genetically linked, suggesting spread by travelers and patients *(149)*.

KPC enzymes have spread to other Enterobacteriaceae including *E. coli*, *S. cubana*, *E. cloacae*, *P. mirabilis*, and *K. oxytoca* in up to 20 US states (141). KPCs have been identified in S. America, China, and less commonly in Europe, related to regional epidemics. Spread of KPCs occurs via large plasmids and transposons (141). *In vivo* transfer of bla_{KPC} carrying plasmids between two Enterobacteriaceae species has been documented *(150)*. KPC detection is challenging due to heterogeneous expression of β-lactam resistance and poor detection by automated systems due to variable levels of carbapenem resistance and low inocula. Screening tests to detect KPC-producing *Enterobacter* spp. by resistance to ertapenem have been reliable, but a confirmatory test is necessary because ertapenem resistance may arise from ESBL or AmpC production with outer membrane defects. Confirmatory testing may include modified Hodge test (though this will also detect other carbapenemases) or the disc diffusion method with ertapenem substrate and 3-aminophenyl boronic acid as an inhibitor that allows differentiation of KPC-type β-lactamase from other enzymes (141).

CDC data from 2006 to 2007 show 4% to 11% of *K. pneumoniae* healthcare-associated isolates were resistant to carbapenems, with the highest percentage of resistance seen in isolates from CLABSIs. New York hospitals have contributed disproportionately to the percentage of resistance isolates, based on a statewide resistance rate of approximately 21%; however, even when New York state hospitals are excluded from the CDC data, the resistance rate to carbapenems among *K. pneumoniae* was approximately 5%, representing increasing carbapenem resistance in many geographic regions (2).

Chapters 85 and 86 discuss antibiotic resistance in more detail.

EPIDEMIOLOGY OF HEALTHCARE-ASSOCIATED INFECTIONS CAUSED BY ENTEROBACTERIACEAE

Reservoirs/Sources

The primary reservoirs for the Enterobacteriaceae are water, soil, and the human gastrointestinal tract *(3)*. Oropharyngeal and gastrointestinal colonization of hospital patients is common. Intestinal carriage of Enterobacteriaceae is associated with increased risk of infection. For example, the gastrointestinal tract is an important reservoir in outbreaks of healthcare-associated *K. pneumoniae* UTIs. A prospective study examining the role of intestinal colonization with multiply resistant *K. pneumoniae* demonstrated that 14 of 31 patients who became intestinal carriers of *K. pneumoniae* developed clinical infections with the same serotype, whereas only 11 of 101 patients who were not intestinal carriers developed clinical disease *(151)*.

In outbreaks of multidrug-resistant *P. mirabilis*, gastrointestinal carriage of the epidemic strain by susceptible patients has been shown to be an important reservoir for outbreak development and propagation *(152)*. In one study, approximately 75% of patients with healthcare-associated *Proteus* infections were intestinal carriers of the microorganism *(153)*. In contrast, the major reservoir of *P. rettgeri* has been

the urinary tract *(154)*, and in one study of 2,693 fecal isolates tested, no *P. stuartii* microorganisms were isolated *(155)*.

Many of the members of the family Enterobacteriaceae have a propensity for certain environments and reservoirs. *Serratia* thrives in moist environments. It frequently contaminates solutions and hospital equipment *(156,157)*. Its human reservoirs are the urinary and the respiratory tracts, primarily in patients subjected to devices such as indwelling bladder catheters *(156)* or endotracheal tubes *(158)*. The gastrointestinal tract may be the primary reservoir in infants and children but is an uncommon reservoir of *Serratia* in adults.

Enterobacter spp. thrive in moist environments and have been found contaminating the environment *(159)*, distilled water and humidifiers *(160)*, and infusion fluids *(161,162)*. Enterobacter also may be found in low numbers in the intestinal flora of 40% to 80% of healthy outpatients *(163)*. Multiple studies have shown increased rates of rectal colonization by Enterobacter after patient use of cephalosporin antibiotics *(163–165)*. *E. cloacae* is found more frequently than *E. aerogenes* and more often leads to clinical disease *(163)*.

C. freundii is the most prevalent *Citrobacter* microorganism found in stool and is an occasional cause of gastrointestinal disease (gallbladder, peritonitis) *(166,167)*.

Long-term acute-care facilities (LTACHs) and nursing homes serve as reservoirs and amplifiers of multidrug-resistant pathogens. LTACHs were initially created to care for, and thus ease the burden of Medicare spending for, difficult-to-wean patients from acute-care ICUs (168). LTACH patients usually have multiple significant comorbidites; often have multiple invasive devices, such as a central venous catheter or urinary catheters; and may require total parenteral nutrition—all of which place LTACH patients at high risk for healthcare-associated infections.

Host and Related Factors Controlling Colonization

Host factors are important in controlling the extent of colonization with Enterobacteriaceae, as discussed below. Host factors are also important in determining the susceptibility of the host to developing disease. Bacterial virulence factors tend to be associated with disease in patients with normal immunity, whereas bacteria without these virulence factors often can only cause disease in patients with diminished immunity (e.g., the very young and the very old), in patients with abnormal anatomy (e.g., hydronephrosis), or in patients whose mucosal barriers are breached by invasive devices. Site-specific infections and host factors are discussed briefly here and in the site-specific chapters.

A number of studies have shown that the patient's endogenous oropharyngeal flora is a common source of Enterobacteriaceae that cause infection in the hospitalized patient *(169–171)*. Oropharyngeal colonization with these bacteria is uncommon in healthy subjects, but increases with severity of underlying diseases or the presence of other risk factors for infection *(172)*. Many patients are colonized with potentially pathogenic Enterobacteriaceae before admission to the hospital *(173–175)*. These bacteria may increase in colony counts under selective pressures of antibiotic use in the ICU *(173,176)* or with increased duration of hospitalization *(177,178)*.

Oropharyngeal colonization with gram-negative bacteria is an important risk factor for the development of healthcare-associated pneumonia. In the early 1970s, 23% of patients with oropharyngeal colonization developed healthcare-associated pneumonia as compared to only 3% of the patients without colonization *(179)*. Similar findings were reported 25 years later; in multivariate risk factor analysis, oropharyngeal colonization with Enterobacteriaceae was the most important risk factor for the development of VAP *(177)*, and the risk of gram-negative pneumonia was estimated to be approximately eight times greater in patients with gram-negative bacillary oropharyngeal colonization *(172)*.

In contrast to oropharyngeal colonization, intestinal colonization with Enterobacteriaceae is universal in healthy subjects and hospitalized patients. However, intestinal colonization with resistant *E. coli* strains has been shown to increase with length of hospital stay. Approximately 30% to 40% of patients admitted to the hospital become colonized with hospital flora, including antibiotic-resistant Enterobacteriaceae, within 48 hours of admission. This rate of colonization increases in critically ill patients *(172)*. Although there is an association between an increased duration of antibiotic exposure and the likelihood to acquire colonization (and infection) with antibiotic-resistant Enterobacteriaceae, effects of modulation of antibiotic exposure on these resistance levels are not straightforward, and most studies suffered from methodological insufficiencies *(180)*. In a randomized crossover study in two ICUs in the Netherlands, a 40% reduction in β-lactam use (at the cost of a 243% increase in fluoroquinolone use) failed to reduce acquisition rates with cephalosporin-resistant Enterobacteriaceae but was associated with higher acquisition of cephalosporin-resistant Enterobacteriaceae with coresistance to the fluoroquinolones *(181)*.

Gastric pH The stomach is usually not colonized with gram-negative bacteria. However, in critically ill patients, gastric colonization frequently occurs and its incidence increases with time *(182,183)*. Gastric colonization with gram-negative bacteria has been assumed to be an important risk factor for the development of VAP. According to the hypothesis of the gastropulmonary route of infection, bacteria colonizing the stomach will subsequently colonize the oropharynx and be aspirated into the lower respiratory tract *(184,185)*. However, the relevance of the gastropulmonary hypothesis has been debated, since several studies failed to show an important role of gastric colonization in the pathogenesis of VAP *(186–188)*. Therefore, intragastric acidity influences gastric colonization, but whether this influences respiratory tract colonization and infection remains uncertain.

Fibronectin In normal hosts, fibronectin, a glycoprotein, is present on oral epithelial cells and facilitates adherence of gram-positive bacteria. It has been observed that loss of fibronectin uncovers cellular-binding sites and leads to increased rates of oropharyngeal colonization by gram-negative bacilli. One hypothesis to explain the loss of fibronectin is that salivary protease secretion, which degrades fibronectin, is increased in critically ill patients *(189,190)*.

Hormonal Modulation of Colonization Very little is known about the relationship between hormones and colonization. It has been observed that recurrent UTIs

occur in many postmenopausal women. Investigators have hypothesized that lack of estrogen leads to diminished colonization of the vagina by lactobacilli. Normally, lactobacilli adhere to uroepithelial cells and have been shown to exclude the adherence of *E. coli*, *K. pneumoniae*, and *P. aeruginosa (191)*. The absence of lactobacilli appears to result in increased vaginal pH (>4) and increased rates of colonization by Enterobacteriaceae, especially *E. coli*. In one study, intravaginal estriol administration resulted in increased colonization by lactobacilli, decreased vaginal pH, decreased Enterobacteriaceae colonization, and significantly reduced incidence of recurrent UTI in postmenopausal women *(192)*.

Biliary Tract and Urinary Tract Obstruction Colonization and stasis facilitate the development of acute cholangitis and UTI. Wang et al. *(35)* examined the role of *E. coli* virulence factors and host factors in patients with *E. coli* bacteremia who met clinical and radiographic criteria for acute cholangitis or upper UTI. The authors found that obstruction was an important host factor leading to bacteremia (100% of those with acute cholangitis and bacteremia were obstructed; 31% of those with upper UTI were obstructed). The most common causes of biliary obstruction included choledocholithiasis, cholangiocarcinoma, ampullary carcinoma, and pancreatic head tumor, and the causes of urinary tract obstruction included nephrolithiasis, ureteral tumor, neurogenic bladder, benign prostatic hypertrophy, and uterine tumor.

Neutrophil Elastase Neutrophil elastase (NE) is the first neutrophil factor that targets bacterial virulence proteins. In neutrophils with inactivated NE, *Shigella* escapes from phagosomes, increasing bacterial survival. NE cleaves virulence factors in *Shigella*, *Salmonella*, and *Yersinia (193)*.

Modes of Transmission and Outbreaks of Enterobacteriaceae

Enterobacteriaceae are primarily spread in the hospital from person to person via the hands of healthcare personnel or from environmental reservoirs to patients (Fig. 34-1). These modes of transmission have been documented in multiple outbreaks of healthcare-associated UTIs due to *Klebsiella*, *P. rettgeri*, and *Serratia*, as well as in multiple neonatal intensive care unit (NICU) outbreaks due to the Enterobacteriaceae. The majority of studies commonly cited in discussions of the epidemiology of healthcare-associated infections caused by the Enterobacteriaceae are analyses of common source (Table 34-8) or person-to-person outbreaks. Thus, most of the data characterizing the epidemiology of Enterobacteriaceae are derived from retrospective studies of epidemic strains.

Many healthcare-associated outbreaks caused by Enterobacteriaceae that produce ESBLs have been reported *(215–218)*. Most outbreaks occurred in special care wards such as ICUs and oncology wards; *K. pneumoniae* was involved in almost all outbreaks; and extensive use of third-generation cephalosporins, mostly as monotherapy, frequently was a risk factor *(217–220)*. Some outbreaks were caused by the spread of a single ESBL gene among multiple genotypes of Enterobacteriaceae *(217,220,221)*, although horizontal spread of bacteria with ESBLs has been described as well *(222,223)*. As with methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant enterococci (VRE), environmental contamination may contribute to the epidemiology of Enterobacteriaceae containing ESBLs *(223,224)*. Situations of endemicity of colonization with ESBL-producing Enterobacteriaceae have been reported *(225–228)*. For example, in Chicago, ceftazidime resistance due to TEM-10 has been endemic among multiple strains of *K. pneumoniae* and *E. coli*; the prevalence of these strains was especially high in nursing home patients *(225)*. In addition, ESBL-producing Enterobacteriaceae were already endemic in a French ICU in 1990; the risk for patients to acquire these bacteria was 4.2% in the first week of stay in the ICU and increased to 24% by the fourth week, and most cases of colonization were caused by the same strain type *(226)*.

A regional outbreak of KPC-producing *K. pneumoniae* that affected multiple facilities, including tertiary care and community hospitals and nursing homes, appeared to have spread from a single LTACH *(229)*. Infections due to KPC microoganisms tend to occur in immunocompromised patients and those with invasive devices *(230,231)*. Risk factors associated with acquisition of KPC pathogens include prolonged hospitalization, stay in ICU, immunosuppression, and exposure to multiple antibiotics *(230,232)*. Prior antibiotic regimens did not necessarily

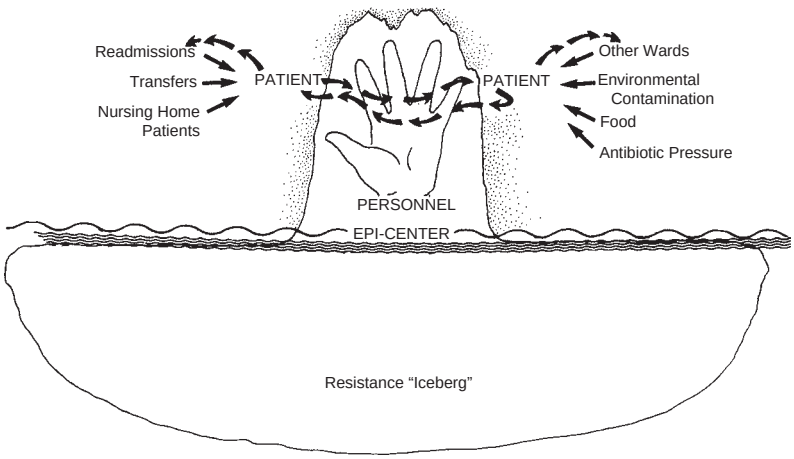

FIGURE 34-1 Infection control "iceberg," depicting the epidemiology of infections in hospitals, emphasizing the often unrecognizable colonization of patients with antibiotic-resistant Enterobacteriaceae and other potential pathogens (e.g., other gram-negative bacilli, MRSA, VRE). S. marcescens (213)	Tracheal aspirates	5	Contaminated unmedicated liquid soap	Exposure to central or percutaneous venous catheters; longer exposure to endotracheal intubation housing in room with contaminated soap dispenser	Resistant to amoxicillin, amoxicillin/clavulanate, cefalotin cefamandole, colistin
K. pneumoniae (214)	Blood, urine, respiratory perfusion needle (colonization)	10	Contaminated rinse solution (tap water) for neonatal aspiration tubing	Mucus aspiration performed at birth or on arrival in the emergency department	Resistant to quinolones, cefotaxime, ceftazidime, gentamicin, and TMP/SMX; SHV-2 and CTX-M15 ESBL identified

CSF, cerebrospinal fluid; ICU, intensive care unit; NA, not available.

include a carbapenem, but all patients were exposed to either another β-lactam or a fluoroquinolone *(230)*.

Over the past decade, CTX-M enzymes have caused numerous healthcare outbreaks in Europe. CTX-M-15 has been the dominant enzyme in Hungarian, Spanish, and Scandinavian outbreaks. Most outbreak isolates were from UTIs or BSIs *(216,233,234)*.

TYPES OF HEALTHCARE-ASSOCIATED INFECTIONS CAUSED BY ENTEROBACTERIACEAE

Urinary Tract

UTIs are the most common healthcare-associated infection in the United States. Approximately 35% of the pathogens associated with healthcare-associated UTIs are members of the family Enterobacteriaceae. *E. coli* is the leading pathogen, implicated in 21% of all CAUTIs (NHSN data 2006–2007) (2). *K. pneumoniae* is the fifth leading cause of healthcare-associated UTIs and is recovered from 8% of cases. *Enterobacter* spp. are ranked sixth and are recovered from 4% of cases (Table 34-9).

In 2005, CDC began collecting data on device-associated infections. Healthcare-associated UTI is now reported as CAUTI. Criteria for defining CAUTI may be found at http://www.cdc.gov/nhsn/library.html. For 2006 to 2008, NHSN acute-care hospitals reported pooled mean CAUTI rates from 0 to 14.4 infections per 1,000 urinary catheter days (235); so, Enterobacteriaceae cause approximately 5 infections per 1,000 catheter days.

Risk factors for healthcare-associated UTIs usually are host- and device-related rather than pathogen-related, with the presence of a urinary catheter being most important. The catheter predisposes to UTIs in several ways. It offers a possibility for bacteria to enter the bladder along external or internal surfaces of the catheter and for development of a biofilm that can protect bacteria from antibiotics and host defenses; adhesion to mucosal surfaces will be facilitated; the catheter may blunt adequate antibacterial polymorphonuclear leukocyte function; and catheter drainage is frequently imperfect,

[a]CDC NHSN 2006 to 2007 data reports device-associated hospital-associated infections from 912 ICUs (88% of 1,040 reporting units) and 128 non-ICUs (12% of 1,040 reporting units). Of 8,579 CAUTIs, 6,778 (79%) were from ICUs and 1,801 (21%) were from non-ICUs.
NA, not available.
(Data from refs. 2, *11, 12* and *13*; data from 1980 to 1982 and 1990 to 1996 represent the hospital-wide component, and data from 1992 to 1999 the ICU component of the National Healthcare-associated Infections Surveillance (NNIS) system.)

leading to residual urine volumes in the bladder *(236)*. In multivariate analysis, nine independent risk factors for catheter-associated bacteriuria were found: duration of urinary catheterization, absence of use of a urinometer, microbial colonization of the drainage bag, diabetes mellitus, absence of antibiotic use, female gender, indications for other than surgery or output measurement, abnormal serum creatinine, and errors in catheter care *(237)*. Other risk factors reported include any urinary tract or catheter obstruction to flow (e.g., prostatic hypertrophy or stones) and periurethral colonization *(236,238)*. In the presence of urinary catheters with or without obstruction, relatively nonvirulent microorganisms can cause infection *(30–32)*. For instance, P fimbriae, the most important virulence factor in non–CAUTIs, were found in only 10% of *E. coli* strains recovered during febrile episodes of CAUTIs *(236)*. The incidence of new-onset bacteriuria is approximately 5% to 10% per day during the first week of catheterization. The prevalence of bacteriuria increases during the first month of catheterization until virtually all patients have bacteriuria *(239)*.

Routes of entry of bacteria into the bladder vary for catheterized men and women. Approximately 70% of bacteriuria cases in women occur as a result of periurethral entry of Enterobacteriaceae that have colonized the perineum *(240,241)*. In men, because the urethral passage is longer, the primary route of bacterial entry presumably is through the catheter lumen *(238,241)*. Although periurethral colonization in men does occur, transient hand carriage of pathogens by personnel leading to crossinfection may have a greater role in healthcare-associated UTIs in men *(238)*. Broad-spectrum antibiotics alter flora, increasing colonization with resistant Enterobacteriaceae and thus increasing the likelihood of UTI with these strains. In two studies, *E. coli* and *Proteus* accounted for a progressively smaller, and *Serratia* and *Pseudomonas* a progressively greater, proportion of healthcare-associated UTIs as length of hospitalization and catheterization increased *(242,243)*.

Antimicrobial resistance has continued to pose an increasing challenge over the past decade. NHSN data from 2006 to 2007 demonstrate that approximately one-quarter of CAUTI are caused by fluoroquinolone-resistant *E. coli*. For CAUTI due to *K. pneumoniae*, approximately 20% were resistant to third-generation cephalosporins and 10% were resistant to carbapenems (2) (see also Chapter 20).

Pulmonary

The second most common site of healthcare-associated infection is the lungs *(244)*. The pathogenesis of healthcare-associated pneumonia most often involves the patient's aspiration of oropharyngeal contents, or inoculation of contaminated material directly into an endotracheal tube *(245)*. Duration of ventilation and oropharyngeal colonization with Enterobacteriaceae are important risk factors for pneumonia *(177)*. Oropharyngeal colonization with Enterobacteriaceae can also occur via exogenous contamination from respiratory therapy equipment and from patient-to-patient spread of bacteria on the unlearned hands of personnel (see also Chapter 22).

Respiratory tract infections outnumber symptomatic UTIs in the ICU. The May 2007 Extended Prevalence of Infection in Intensive Care (EPIC II) 1-day worldwide point prevalence study included 14,414 patients in 1,265 ICUs from 75 countries; 7,087 patients were considered to be infected. Respiratory infection accounted for 64% of infections and represented the most common site of infection in each of seven participating regions around the world. Sixty-two percent of the infections were due to gram-negative pathogens, of which *Pseudomonas* spp. (20%) and *E. coli* (16%) were the most common isolates *(246)*.

Approximately 23% of VAP episodes were due to Enterobacteriaceae in the 2006 to 2007 NHSN summary of antimicrobial-resistant healthcare-associated pathogens (2). *Enterobacter* spp., along with *A. baumannii*, were the third (each 8.4%) leading cause of VAP after *S. aureus* and *P. aeruginosa* (24.4% and 16.3%, respectively) (Table 34-10).

For individual pathogens, highest percentages are found for *S. aureus* and *P. aeruginosa,* but as a group Enterobacteriaceae still represent an important proportion of pathogens, especially when VAP is diagnosed after 4 days of mechanical ventilation (late-onset pneumonia). At that time, most patients have respiratory tract colonization with these pathogens. In contrast, early-onset pneumonia (i.e., diagnosed within 4 days of ventilation) is more frequently caused by streptococci and *Haemophilus influenzae*. These community-acquired bacteria colonize the upper respiratory tract at the time of intubation. However, in a comparison of patients with early-onset pneumonia, defined as occurring within 96 hours of ICU admission (n = 235 patients [56%]) to late-onset pneumonia (n = 185 patients [44%]) in a medical ICU and a surgical ICU from a teaching hospital, *Enterobacter* spp. represented 10% of isolates from both groups, *K. pneumoniae* represented 5.5% and 6.5%, respectively, *E. coli* was found in 2.6% and 1.6%, respectively, and *Citrobacter* represented approximately 1% of each *(247)*. These data and more recent studies have challenged the notion that early-onset VAP reflects community-acquired pathogens.

Surgical Site Infections

Approximately 17% of incisional SSIs involve Enterobacteriaceae (NHSN 2006–2007) (2). *E. coli* accounts for 10% and *Enterobacter* spp. account for 4% of pathogens recovered from incisional surgical site infections (Table 34-11). The pathogens isolated from surgical site infections vary primarily with the type of surgery performed. In surgical procedures involving clean-contaminated, contaminated, and dirty fields, the pathogens isolated reflect the normal endogenous flora of the resected organ *(248,249)*. Antibiotic prophylaxis may permit selective overgrowth of antimicrobial-resistant Enterobacteriaceae.

Enterobacteriaceae have been associated with extrinsic contamination of devices and solutions used perioperatively, leading to surgical site infections. For example, *Serratia marcescens* has contaminated saline solutions, leading to surgical site infection after breast reconstruction with silicone mammary prostheses *(250)*, and has contaminated reusable electrocardiogram bulbs, leading to postoperative sternal and leg incision infections in cardiac surgery patients *(251)* (see also Chapter 21).

In NHSN data, 23% of *E. coli* from SSIs were resistant to fluoroquinolones; in these data, *E. coli* was the fifth most common pathogen after the gram-positive pathogens MRSA, VRE, and ARE, and *A. baumannii* (2).

Diarrhea

Although *Salmonella*, *Shigella*, *Yersinia*, *E. coli*, *Citrobacter*, and *Enterobacter* all have been implicated as healthcare-associated diarrheal pathogens, the Enterobacteriaceae are uncommon causes of healthcare-associated diarrhea. Healthcare-associated infectious diarrhea due to Enterobacteriaceae usually represents exogenously acquired disease. The mode of transmission is either the fecal-oral route by crossinfection or common source infection secondary to contaminated food or medicine. Patients may have indirect contact with an infectious patient either by sharing a room or a bathroom or via the hands of hospital personnel *(162,252,253)*.

Salmonella infections are the most common of the healthcare-associated diarrheal diseases due to the Enterobacteriaceae. Between 10% and 30% of the reported cases of *Salmonella* infection in the United States occur in institutions (hospitals, nursing homes, custodial facilities) *(254,255)*. Healthcare-associated infection with *Salmonella* is more common in developing countries *(256,257)*. Fifty percent of healthcare-associated cases of salmonellosis in the United States occur in newborn nurseries and pediatric wards *(255,258)*.

Sources of *Salmonella* in healthcare-associated outbreaks include other patients and contaminated foods, especially eggs, and devices. In the past, contaminated egg products, hospital eggnog *(259)*, and raw eggs used in the preparation of mayonnaise *(260)* have led to large outbreaks of healthcare-associated diarrhea. The routine availability of pasteurized egg products should eliminate this problem in US hospitals. The mayonnaise outbreak that occurred in 1989 was the largest healthcare-associated outbreak of *S. enteritidis* in US history, with 404 (42%) of 965 inpatients in a single hospital affected, resulting in nine deaths *(260)*.

Contaminated devices, rectal thermometers *(261)*, gastroscopes *(262)*, and rubber tubing of oropharyngeal suction devices *(263)* all have been associated with healthcare-associated *Salmonella* infection. Soiled linens have been reported as a source of healthcare-associated *Salmonella* infection in laundry workers in both hospital and nursing home outbreaks of *Salmonella* gastroenteritis *(264–266)*.

(Data from refs. 2, *12*, and *13*.)

Neonatal outbreaks generally are associated with infant-to-infant spread, presumably on the hands of hospital personnel, from an index patient who acquired the infection at delivery from the mother.

The correlation of specific serotypes and sources should be considered when *Salmonella* is isolated in the hospital. For example, *S. choleraesuis* has been associated with pork products, *S. cubana* with carmine dye, *S. dublin* with beef products, and *S. pullorum* with poultry products.

Healthcare-associated transmission of *Shigella* has been reported *(267,268)*, and termed "asylum dysentery" in the early 1900s *(269)*. An outbreak of *Shigella dysenteriae* type 1 occurred at a chronic care psychiatric facility in Durban, South Africa, involving 10 patients, 4 of whom died. The infection in the index case was thought to be community-acquired. Strict adherence to infection control measures (cohorting, hand hygiene, and restriction of food supplies brought in from outside the hospital) resulted in control of the outbreak. The high mortality rate was attributed to late recognition of the etiologic agent and failure to treat with appropriate antimicrobials *(268)*.

E. coli is a serious healthcare-associated enteric pathogen for newborn infants and young children. The commonest scenario is crossinfection and environmental contamination from an infected child with diarrhea due to an enteropathogenic *E. coli*. Asymptomatic carriers also are an important cause of epidemics. Although most healthcare-associated enteric disease is due to enteropathogenic *E. coli*, there has been one large hospital nursery outbreak due to enterotoxigenic *E. coli (270)*. Enterohemorrhagic *E. coli* has been reported in several healthcare-associated outbreaks *(271–275)*. Transmission has been attributed to person-to-person spread, environmental contamination, and contaminated lettuce *(276)*.

There have been at least four reports of healthcare-associated transmission of *Y. enterocolitica* diarrhea *(277–280)*. The mode of transmission is similar to that of the other enteric pathogens, with indirect contact spread from patient to patient via shared fomites and via the hands of personnel. A retrospective analysis of *Yersinia* infections in one hospital revealed 18 infections over 4 years; 5 infections appeared to be healthcare-associated *(280)*. In most of these cases, a patient admitted with *Y. enterocolitica* gastroenteritis appeared to be the source of crossinfection. *Y. enterocolitica* is a rarely recognized enteric healthcare-associated pathogen, perhaps because it is difficult to isolate in the laboratory, because clinicians do not have a high index of suspicion for *Yersinia* as a pathogen, and because many patients may not be symptomatic *(281)*. The outbreaks that have been reported to date have been small, and it is likely that such outbreaks may be missed easily.

Antimicrobial resistance has been a problem seen in cases of healthcare-associated diarrhea infections. *S. enterica* serotype Livingstone with the CTX-M-27 enzyme caused a diarrhea outbreak in Tunisia during 2002 in 16 heavily antibiotic-treated neonates; 3 developed bacteremia and 2 died. Isolates also were resistant to aminoglycosides and sulfamethoxazole/trimethoprim *(282)*. Fluoroquinolone-resistant *S. enterica* serotype Schwarzengrund resulted in 11 ill patients at two nursing homes and an acute-care facility in Oregon during 1996 to 1998. Prior fluoroquinolone use was associated with infection in four of five nursing home residents at one facility. Transmission likely occurred patient to patient or through contaminated surfaces *(283)*.

Bacteremia

As a group, Enterobacteriaceae account for approximately 13% of healthcare-associated BSIs (NHSN, 2006–2007) (2). *K. pneumoniae*, *E. coli*, and *Enterobacter* spp. are the most common Enterobacteriaceae causing such bacteremias (Table 34-12). For 2006 to 2008, NHSN acute-care hospitals reported pooled mean CLABSI rates from 0 to 5.5 infections per 1,000 catheter days (235); so, Enterobacteriaceae cause approximately 0.66 infections per 1,000 catheter days. In a Spanish multicenter study, *K. pneumoniae*, *E. coli*, *and E. cloacae* accounted for 5.6%, 2.5%, and 1.9%, respectively, of 590 cases of healthcare-associated bacteremia *(284)*.

Approximately half of *E. coli* bacteremias are healthcare-associated. The most common portal of entry of infection for both community-acquired and healthcare-associated *E. coli* bacteremia is the urinary tract *(285,286)*. The overall mortality rate from *E. coli* bacteremia is approximately 20% *(284,285)*. Bacteremias that originate outside the urinary tract tend to have a worse outcome.

The majority of bacteremias due to *Enterobacter* spp., primarily *E. cloacae* and *E. aerogenes*, are healthcare-associated. Several large series of cases of bacteremia due to *Enterobacter* spp. report that 67% to 84% of the bacteremias were healthcare-associated *(285,287–290)*. Approximately one-third of these cases are polymicrobial. Major portals of entry for *Enterobacter* spp. in bacteremic patients include the lung, surgical sites/skin wounds, the urinary tract, and central

(Data from refs. 2, *11, 12,* and *13*; data from 1980 to 1982 and 1990 to 1996 represent the hospital-wide component, and data from 1992 to 1999 the ICU component, of NNIS.)

venous lines, in descending order of frequency *(287–292)*. The use of devices (e.g., endotracheal tubes, Foley catheters) and the prior use of antibiotics appeared to be associated with increased risk of *Enterobacter* bacteremia. Mortality rates of 24% to 69% have been reported *(284,287–290)*.

Large series that describe *Klebsiella* bacteremia report that approximately one-half to three-quarters of these bacteremias are healthcare-associated *(293–297)*; up to 25% of these cases are polymicrobial *(293,294)*. Major portals of entry include the urinary tract and the lung, although in some series the gastrointestinal tract and the intravenous catheters were major sites of primary infection (*293,294,297*,298). Patients with pneumonia as a primary source of bacteremia tend to have a worse outcome (*293,295,297*,298). In children, *Klebsiella* bacteremia has been reported in outbreaks in the NICU *(299)*. Widespread colonization of the gastrointestinal tract and respiratory tract with *Klebsiella* has been documented in these outbreaks, as has hand carriage of these strains by hospital personnel. Overall mortality rates for healthcare-associated *Klebsiella* bacteremia vary from 21% to 55% (*284,293,296,297,300*,301).

Bacteremia due to *Citrobacter* spp. is primarily a healthcare-associated infection *(302,303)*. It occurs most frequently in elderly or very young patients, with initial sites of infection in the urinary tract, gastrointestinal tract, and wounds, in decreasing frequency of occurrence. *C. koseri* is frequently associated with genitourinary or intra-abdominal disease, and *C. freundii,* the most prevalent *Citrobacter* spp. found in stool *(166,303,304)*, is associated with gallbladder disease and peritonitis. Bacteremia with *Citrobacter* is commonly preceded by instrumentation at the site of the primary infection. Mortality rates from *Citrobacter* bacteremia are high (~50%) and are related to severity of the patient's underlying medical condition *(303)*.

One series of bacteremias due to *Serratia* reported that 82% were healthcare-associated 23% had polymicrobial bacteremia. The portal of entry was unknown in 64% of patients. Clinical syndromes included primary bacteremia (in two-thirds of patients), pneumonia, UTI, thrombophlebitis, and surgical site infection. Mortality rates attributable to *Serratia* bacteremia have been reported from 32% to 41% *(305,306)* (see also Chapter 19).

Rates of antimicrobial-resistant BSIs have been studied extensively for Enterobacteriaceae. Studies have shown an added burden of BSI caused by resistant Enterobacteriaceae and an association with increased mortality. A retrospective study at a 997-bed tertiary care center in the Netherlands quantified changes in incidence of healthcare-associated bacteremias caused by antibiotic-susceptible and antibiotic-resistant pathogens in adults admitted for >48 hours during 1996 to 2005. Of 1785 cases of healthcare-associated bacteremia, 538 (30.1%) were caused by Enterobacteriaceae. The proportion of antibiotic-resistant pathogens causing healthcare-associated bacteremia increased from 3% to 8% from the first 5 years to the second 5 years of the study. These increases were most pronounced for amoxicillin-resistant *Enterococcus faecium* (from 12% to 31.5%) and for multidrug-resistant Enterobacteriaceae (from 0.7% to 4.7%). The incidence density (daily risk of healthcare-associated bacteremia measured as the number of healthcare-associated bacteremias per number of patients who were admitted for at least 2 days before acquiring healthcare-associated bacteremia) of highly resistant microorganisms increased on average by 26.1% annually, compared to an increase of 3% per year of susceptible pathogens. Though there was no increase in the overall burden of healthcare-associated bacteremia from Enterobacteriaceae, the ratio of increased incidence densities of resistant to susceptible Enterobacteriaceae was 38. Antibiotic-resistant pathogens did not replace episodes of less resistant pathogens, but rather added to the existing burden of healthcare-associated bacteremia *(307)*. ESBL-producing Enterobacteriaceae bacteremia was the subject of a meta-analysis in which 16 studies were reviewed through April 2006 and found an association with increased mortality and delay in effective therapy in ESBL-associated bacteremia, though studies lacked controls for confounding variables *(308)*.

A single-center Spanish tertiary care facility prospectively reviewed 4,758 episodes of *E. coli* bacteremia from 1991 to 2007, 29% of which were healthcare-associated acquisition. Fluoroquinolone-resistant strains were identified in 1,300 (27%) of cases and third-generation cephalosporin-resistant strains were present in 211 (4%), of which 84% were isolated after 2001. Independent risk factors for infection with an antibiotic-resistant strain included healthcare-associated acquisition, urinary catheterization, and previous treatment with the implicated antibiotic to which the pathogen had become resistant, fluoroquinolones, or β-lactam therapy, respectively. The most common source for healthcare-associated fluoroquinolone-resistant bacteremia was a central-line catheter (51%). Common sources for healthcare-associated ESBL bacteremia were skin/soft tissue infection (13%) and catheter-related (11%). Overall, 9% of patients died; risk for death was associated with shock at presentation and inappropriate empiric antimicrobial therapy *(286)*.

Increasingly, ESBL-producing *Klebsiella* are causing bacteremia *(309,310)*. In a retrospective study of 162 *K. pneumoniae* isolates, 44 (27.2%) were ESBL producing. In a multivariate analysis, risk factors for ESBL-producing *Klebsiella* bacteremia, compared to non–ESBL-producing strains, included presence of a biliary drainage catheter, prior antibiotic therapy, and healthcare-associated acquisition of bacteremia. Mortality attributable to *Klebsiella* bacteremia did not differ significantly between the two groups (23.3% vs. 20% in ESBL producers vs. nonproducers, respectively) *(309)*. *K. pneumoniae* resistant to carbapenems has emerged as one of the most concerning antimicrobial-resistant pathogen threats over the past decade. A matched retrospective historical cohort study of carbapenemase-resistant *K. pneumoniae* bacteremias in an Israeli tertiary university teaching hospital found a crude mortality rate of 71.9% and an attributable mortality rate of 50% in 32 case-patients from 2005 to 2008. The mortality risk ratio was 3.3 (95% CI, 2.9–28.5) for case-patients. Case-patients were more likely than patients without bacteremia to require ICU care, ventilator support, and use of a central venous catheter (301).

Central Nervous System Infections

Healthcare-associated CNS infections occur primarily in neurosurgical patients, neonates, and patients undergoing procedures that penetrate the CNS *(311)*. A review of gram-negative bacillary meningitis showed that 69% of the cases occurred in postneurosurgical patients, with the majority (70%) of infections due to *E. coli (312)*. A descriptive review of

55 adult cases of *Klebsiella* meningitis over 13 years found that "spontaneous" meningitis occurred in 80% and postneurosurgical meningitis occurred in 20% of patients. Underlying conditions in the patients with spontaneous meningitis included diabetes mellitus (70%), alcoholism (30%), and chronic otitis media (17%). Other less common underlying diseases included neoplasm, stroke, nasopharyngeal carcinoma, and end-stage renal disease *(313)*.

In a study of 171 cases of pediatric healthcare-associated meningitis from 1992 to 2007, 9.5% were due to Enterobacteriaceae. The most common isolates were *E. coli* in nine (50%) patients, *K. pneumoniae* in three (16.7%), and a patient each had *E. cloacae*, *C. freundii*, *P. mirabilis*, and *S. enteriditis*. Risk factors included neonatal age, low birth weight, head trauma, and neurosurgery. Mortality in the patients with healthcare-associated meningitis due to Enterobacteriaceae was significantly greater than was mortality in the entire cohort of 171 patients: 29.9% versus 15.1%, respectively *(314)*.

In neonates, the most common etiologic agent of gram-negative bacillary meningitis remains *E. coli*. The K1 strains are the etiologic agents in most cases *(75)*. Unusual pathogens associated with outbreaks of neonatal meningitis include *C. koseri*, *S. marcescens*, and *E. sakazakii*. *C. koseri* has been reported to cause meningitis and CNS abscess in both preterm and full-term infants. One cluster of healthcare-associated neonatal *C. koseri* meningitis cases was found to be due to hand carriage of this strain by a nurse with dermatitis. Removal of the nurse from the unit resulted in decreased rates of neonatal colonization with *C. koseri* and no further clinical cases of *C. koseri* sepsis and meningitis *(315)*. During reported outbreaks of *C. koseri* infections in nurseries, rates of fecal and umbilical carriage are high (50% to nearly 100%), yet few infants acquire clinical disease *(316)*. One case of *C. koseri* brain abscess has been reported in an adult following a community-acquired *C. koseri* UTI *(317)*. A case of multiple brain abscesses in association with bacteremia has been reported with *S. paratyphi* B in an infant *(318)*.

S. marcescens meningitis occurs primarily in neonates, particularly in premature infants requiring ICU care. Most of these infants have multiple invasive catheters and have received a prior course of antibiotics *(319)*. Notable features of *Serratia* meningitis in infants include a propensity for progression to ventriculitis, a frequent lack of cerebrospinal fluid pleocytosis and of hypoglycorrhachia (present in only 50% of cases), the development of *Serratia* meningitis despite receiving therapy for *Serratia* bacteremia, concurrent soft tissue infection or UTI with *Serratia*, and a high mortality rate (>45%) *(319)* (see also Chapters 27, 49, and 52).

PREVENTION AND CONTROL OF HEALTHCARE-ASSOCIATED INFECTIONS DUE TO ENTEROBACTERIACEAE

Hand Hygiene

The importance of hand hygiene cannot be overemphasized. Hand transfer of the Enterobacteriaceae between patients by healthcare personnel has been implicated in numerous outbreaks of healthcare-associated infection *(320)*. It is felt that most endemic infections also are transmitted by the hands of healthcare workers *(321)*. In most studies, the Enterobacteriaceae are only transient hand flora; *Acinetobacter* is usually the only gram-negative bacillus found consistently in hand cultures. For example, *Klebsiella* has been shown to survive on the hands for about 2 hours *(322)*. In one study, however, approximately 60% of people demonstrated endemic hand carriage of gram-negative bacilli, primarily the Enterobacteriaceae *(323)*. In that study, healthcare workers with hand dermatitis carried gram-negative bacilli more frequently and in greater numbers than other healthcare workers *(324)*. The investigators also found that continuous hand carriage (over 3–6 weeks) was common. In an epidemic in an NICU, a nurse with hand dermatitis was found to be the reservoir for the epidemic strain of *C. koseri (315)* .

Observations of hand-washing behavior in university hospital ICUs have found compliance rates ranging from 28% to 41% *(325)*. Strategies such as increasing the number of sinks and installing automated sinks have not been shown to improve hand-washing compliance and have had little effect on infection rates *(326–330)*. Efficacy of specific hand-cleansing agents in preventing horizontal pathogen transmission has not been studied extensively. Based on efficacy of hand degerming, ease of use, and salutary effect on the condition of the hands of healthcare workers, alcohol-based hand rubs are now recommended for hand hygiene between patient contacts *(331)* (see Chapter 91).

Other Conventional Methods of Infection Control

Conventional infection control methods are summarized in Table 34-13. Barrier precautions, when used aggressively,

TABLE 34-13

Examples of Conventional Infection Control Policies[a]

Identify reservoirs
Colonized and infected patients
Environmental contamination; common sources
Halt transmission among patients
Improve hand washing and asepsis
Barrier precautions (gloves, gowns) for colonized and infected patients
Eliminate any common source; disinfect environment
Separate susceptible patients
Close unit to new admissions if necessary
Halt progression from colonization to infection—examples of site-specific measures
Discontinue nonessential devices
Extubate and remove nasogastric tube
Position patients to decrease risk of aspiration
48-h (or less frequent) ventilator circuit tubing changes
Proper removal of ventilator tubing condensate
Proper endotracheal suctioning technique
Antisepsis bathing of patients
Modify host risk
Treat underlying disease and complications
Control antibiotic use

[a]See Chapters 17 to 27 for more detailed site-specific control measures.
(Adapted from Baine WB, Gangerosa EJ, Bonnet JV, et al. CDC news. Institutional salmonellosis. *J Infect Dis* 1973;128:357.)

have successfully prevented the healthcare-associated spread of multiply resistant Enterobacteriaceae and have reduced ICU infection rates *(332,333)*. The institution of barrier precautions (primarily gloving) resulted in a sustained 87% reduction in gentamicin-resistant Enterobacteriaceae in one hospital *(332)*. Even with the use of gloves, hand washing should be emphasized, as studies have shown that up to 50% of hands were contaminated after glove removal *(334)*. Use of gloves and gowns has been shown to reduce the incidence of healthcare-associated infections in the pediatric ICU as well *(335,336)*.

Elimination of common reservoirs of infection and proper care of invasive monitoring equipment are also important in prevention of healthcare-associated infection due to the Enterobacteriaceae. A variety of invasive devices have been implicated as sources of epidemic infections (Table 34-8). Care of all invasive devices should include removal of the device as soon as a patient's clinical condition permits and careful asepsis during use.

The environment is usually not a major source or vector in infections with Enterobacteriaceae. Contamination from environmental reservoirs that may come into contact with patients has been the cause of healthcare-associated outbreaks. These outbreaks have called attention to reservoirs that may warrant special care (Table 34-8).

Because broad-spectrum antibiotic therapy alters patients' microflora and may lead to colonization and to infection with multiply resistant microorganisms, restriction of broad-spectrum antibiotics has been cited as an important infection control measure *(93,337)*. Resistance rates generally diminish with antibiotic restriction, although most studies introduce several control measures simultaneously, making assignment of causality difficult.

With regard to infection control, two aspects are instrumental when attempting to control outbreaks of ESBL-containing Enterobacteriaceae or to prevent healthcare-associated epidemics *(93,337)*. First, as for all other healthcare-associated pathogens, enforcement of compliance with infection control measures is of key importance. Reinforcement of hand hygiene compliance *(338,339)*, glove use *(338)*, barrier precautions *(339,340)*, and appropriate room disinfection *(220)* have reduced the spread of resistant bacteria. A limited and rational use of broad-spectrum antibiotics, such as third-generation cephalosporins, is the second strategy to prevent and control outbreaks with these bacteria. ESBL genes can be transferred easily to other bacteria and even other bacterial species, especially in the presence of antibiotic pressure. In three studies, the use of ceftazidime was a risk factor for infection with ESBL-containing microorganisms *(217,218,340)*. Discontinuation of empiric ceftazidime and reduction of ceftazidime use in combination with barrier precautions resulted in a decline of resistant isolates, but they were not completely eradicated *(218,220)*. In a smaller outbreak in a pediatric cancer ward, no further cases of infection with resistant strains were detected after a change of empirical therapy from ceftazidime to a combination of amikacin, azlocillin, and nafcillin *(217)*. An outbreak of gentamicin-resistant Enterobacteriaceae (85 isolates comprising eight species) on neurology and neurosurgery wards was controlled following restriction of broad-spectrum β-lactams, cephalosporins, gentamicin, tobramycin, quinolones, and cotrimoxazole. Only after addition of the antibiotic restriction policy to infection control measures already in place (barrier precautions, educational sessions, and new hand hygiene products) did the incidence of multidrug-resistant Enterobacteriaceae decrease to half of the preintervention phase *(341)*. An experimental approach would be to use intestinal decontamination by nonabsorbable antibiotics, as a temporary adjunct to strict hygienic and antimicrobial control measures, to eradicate colonization with multiresistant bacteria *(342)*.

Efficacy of screening for multidrug-resistant Enterobacteriaceae in the absence of an outbreak was studied in patients admitted for organ transplantation. Of 287 patients (75% of whom underwent liver or kidney transplant), 69 (24%) were colonized with multidrug-resistant Enterobacteriaceae; 6 (9%) of 69 colonized patients developed clinical infections. These six isolates were all unique by PFGE. Of 995 other transplant ward patients who underwent passive clinical culture surveillance for multidrug-resistant Enterobacteriaceae, 12 (1.2%) were noted to be colonized; no clinical infections were detected in these patients. Typing of isolates included PFGE, plasmid, and integron analysis. There was no patient-to-patient transmission detected. The authors demonstrated a large cost for surveillance cultures and concluded that in a setting where multidrug-resistant Enterobacteriaceae are endemic, surveillance of clinical isolates was adequate for infection control purposes *(343)*.

Surveillance rectal cultures were part of an enhanced infection control program (among six total added measures) to limit spread of carbapenem-resistant *K. pneumoniae* in a New York City hospital. The mean number of new patients with positive cultures for KPCs per 1,000 patient days per quarter decreased significantly from 9.7 ± 2.2 before the intervention to 3.7 ± 1.6 after the intervention, though there was no decrease in the mean numbers of patients per quarter with cultures demonstrating other multidrug-resistant microoganisms. The investigators speculated that their intervention failed to control carbapenem-resistant *Acinetobacter* or *Pseudomonas* because these microoganisms frequently colonize the respiratory, rather than the gastrointestinal, tract, thereby trumping the value of rectal surveillance cultures, which had led to identification of 10 of 37 patients with carbapenem-resistant *K. pneumoniae (344)*.

Control and/or Eradication of Colonization

Conventional approaches to control of healthcare-associated infection due to the Enterobacteriaceae as outlined above are not always successful, in part because of lack of compliance. But even when compliance is total, endogenous oropharyngeal or rectal carriage of Enterobacteriaceae may create an "iceberg" effect (Fig. 34-1). Thus, conventional infection control methods aimed at reducing crossinfection may not work, because many patients arrive at the hospital already colonized. Studies have shown that isolation, barrier nursing, and strict antibiotic policies reduce rates of crossinfection and crosscolonization, but overall rates of infection, especially pneumonia, may be unchanged *(345)*. Thus, antibiotic prophylaxis has been studied repeatedly since the 1950s as a method to decrease rates of healthcare-associated infection, particularly pneumonia.

Early trials of systemic antibiotics in the 1950s showed no decrease in the risk of pneumonia and, furthermore, showed increased risk of gram-negative bacilli overgrowth

and increased risk of pneumonia, skin infection, and bacteremia *(346,347)*. Two later studies addressed the issue of systemic intravenous prophylaxis to prevent early-onset VAP. In one study, 570 patients were randomized to receive either 24 hours of penicillin G, cefoxitin, or no antibiotics, and the incidences of early-onset VAP were 6% in patients with and 7% in patients without antibiotics *(348)*. In the other study, two dosages of intravenous cefuroxime 12 hours apart after intubation resulted in a reduction in the incidence of early-onset VAP from 36% to 16% in comatose ICU patients *(349)*.

In the 1970s, use of topical antibiotics, either aerosolized polymyxin or endotracheal aminoglycosides, delivered directly to the site of potential infection, was studied as prophylaxis of gram-negative pneumonia. Use of polymyxin led to decreased rates of pneumonia but to increased rates of colonization with polymyxin-resistant *Serratia*, *Proteus*, and *Flavobacterium (350,351)*. Use of an endotracheal aminoglycoside, gentamicin, was also associated with decreased rates of pneumonia but with increased rates of colonization by gentamicin-resistant *Providencia* spp. *(352)*. Neither regimen had any effect on overall mortality rates.

More recently, topical application of chlorhexidine has been used to reduce bacterial colonization in the oropharynx as a way to prevent VAP, as a presurgical skin preparation, and for impregnation of devices and dressings *(353)*. Chlorexidine gluconate (2%)–impregnated cloths have demonstrated effectiveness in reducing CLABSIs in MICU patients *(354)*. Antiseptic solutions including iseganan, chlorhexidine, and povidone iodine have been proposed to achieve oropharyngeal decolonization and minimize promotion of antimicrobial resistance *(355)*. A double-blind RCT in noncardiothoracic ICUs using 2% of chlorhexidine compared to chlorhexidine and colistin against placebo showed a reduction in VAP with a 65% reduction for chlorhexidine-treated patients and 55% reduction for chlorhexidine/colistin-treated patients, the latter of which provided better decolonization of gram-negative microorganisms *(356)*. Daily baths with 2% chlorhexadine impregnated wipes were part of a bundled strategy (including point-prevalence surveillance, environmental culture, cleaning evaluation with powder detectable by ultraviolet light, cohorting colonized patients and healthcare providers, and staff education) which led to control of a monoclonal outbreak of KPC-3 producing *K. pneumoniae* in a 20-bed SICU (356a). A similar bundled strategy including daily bathing with 2% chlorhexidine gluconate controlled horizontal spread of KPC-producing *K. pneumoniae* at a long-term acute care hospital, despite continued admission of patients harboring KPC-producing pathogens *(229)*.

Novel experimental approaches to reducing bacterial adherence and biofilm formation on urinary catheters include devices to sense bacterial encrustation, application of biofilm inhibitors, hydrophilic coating or nutrient-scavenging materials on catheter surfaces, and use of low-energy surface acoustic waves *(47)*.

Selective Decontamination Selective decontamination of the digestive tract (SDD) has been investigated extensively as a method of pneumonia prophylaxis for ventilated patients in the ICU. SDD uses nonabsorbable antibiotics to eliminate potential gram-negative pathogens from the oropharynx and the gastrointestinal tract. The antibiotics chosen for SDD spare normal anaerobic flora that may help limit intestinal overgrowth by SDD-resistant gram-negative bacilli. The typical SDD regimen utilizes a sticky paste or gel mixed with polymyxin, an aminoglycoside, and an antifungal agent for topical oropharyngeal decontamination. The same antibiotics are also put into solution for gastric and intestinal decontamination. Some regimens also use systemic antibiotic therapy for the first few days to treat incubating community-acquired pneumonia. The effects of SDD (or selective oropharyngeal decontamination [SOD]) on infection rates and patient outcome are addressed in Chapter 22.

The most recent (and largest) trial on SDD was a crossover trial using cluster randomization in 13 ICUs of differing size and teaching status compared the effectiveness of SDD to SOD versus standard care over a 6-month period with the primary end point of mortality at 28 days. The SDD regimen included 4 days of intravenous cefotaxime and oropharyngeal/gastric topical application of tobramycin, colistin, and amphotericin B. The SOD regimen included only the topical application combination with no systemic antimicrobial therapy. The crude mortality in each group at day 28 for standard, SOD, and SDD was 27.5%, 26.6%, and 26.9%, respectively. In a random-effects logistic-regression model with covariates including age, sex, APACHE II score, intubation, and medical specialty, the odds ratio for 28-day mortality compared to standard care was 0.86 (95% CI, 0.74–0.99) for SOD and 0.83 (95% CI, 0.72–0.97) for SDD, respectively. These odds correspond to an absolute reduction in mortality at day 28 for SOD: 2.9% and SDD: 3.5% (357). SDD was, as compared to standard care and SOD, associated with a significantly reduced incidence of ICU-acquired bacteremia caused by Enterobacteriaceae.

The development of antibiotic resistance is the most feared complication of SDD. Initial studies in the 1980s showed no problems with overgrowth of resistant gram-negative bacilli. Now that gram-positive bacteria are re-emerging as important healthcare-associated pathogens in the last 2 decades, increased colonization rates with antibiotic-resistant gram-positive cocci, especially staphylococci and enterococci, have been reported from some ICUs using SDD *(342,358–362)*. Thus, ICUs with endemic or epidemic MRSA or enterococcal infection should avoid SDD. The crossover trial in 13 Dutch ICUs comparing SDD and SOD to standard care included monthly point-prevalence assessments with surveillance rectal swabs and endotracheal aspirates or throat swabs from all ICU patients (whether participating in the study or not) and did not find evidence of the emergence of antimicrobial-resistant pathogens or increased rates of *Clostridium difficile*. However, the study period may not have been long enough to determine the effect of the interventions on resident flora (357). In a separate analysis, the ecological effects of SDD and SOD were analyzed in time, by comparing point-prevalence rates of gram-negative bacteria resistant to certain marker antibiotics during the months of SDD and SOD to the months before and after intervention. For rectal carriage, lowest point-prevalence rates were observed during SDD, but rates rapidly increased after SDD, most notably for ceftazidime-resistant gram-negative bacteria. And for respiratory

tract carriage, point prevalence rates were lowest during SDD and SOD, but during these periods a steady increase in resistance, again most notably for ceftazidime-resistance, was observed *(363)*. Therefore, the clinical benefits of both interventions (as observed in units with low prevalence rates of antibiotic resistance) must be carefully balanced against the ecological effects on antibiotic resistance.

SDD may also be a useful short-term control measure for outbreaks of multiply resistant gram-negative bacilli when conventional infection control methods fail. Intestinal decontamination with orally administered nonabsorbable antibiotics (neomycin, polymyxin E, nalidixic acid) has successfully controlled ICU outbreaks of multiresistant Enterobacteriaceae (mainly *Klebsiella* and *Enterobacter*) *(342)* and of multiresistant *Klebsiella (364)*. In one outbreak, intestinal colonization with resistant strains decreased from 19% to 3%, and infection rates decreased from 9% to 0%. The infection rate for nonresistant strains was unchanged.

SDD may be of arguable benefit in reducing the risk of gram-negative pneumonia in a select patient population (e.g., ventilator patients with acute trauma or postoperative patients), although it is unclear whether the benefit of SDD reflects systemic antibiotic use as much as it does topical antibiotic use. Although there is accumulating evidence that SDD and SOD may decrease ICU mortality, these provocative results should be confirmed in various ICU settings and the relative importance of the individual components of SDD should be evaluated. Based on decreased mortality with SOD and SDD regimens demonstrated in the Dutch study (357), the SOD regimen may be preferable to the SDD regimen to avoid systemic antibiotic prophylaxis therapy, and the risk of increasing antimicrobial resistance. Oropharyngeal decontamination with antiseptic agents (chlorhexidine) could be an alternative to the antibiotic paste regimen and needs further study. Moreover, more studies should determine the relative benefits of SDD in specific patient populations (i.e., medical, surgical, or trauma) or subgroups of patients with different levels of illness. Nevertheless, SDD may increase the risk of colonization and infection with antibiotic-resistant gram-positive microorganisms, such as staphylococci and enterococci, in some ICUs, so that units having problems with such strains should avoid SDD. SDD has contributed to outbreak control in a few ICUs with epidemics of multiply resistant Enterobacteriaceae that had not been controlled by conventional methods.

Other Strategies Immunoprophylaxis has also been studied as an alternative approach to infection prevention in the ICU. Clinical studies have suggested that immunization of high-risk ICU patients with plasma from volunteers immunized with *E. coli* J5, a mutant in which core lipid A determinants are exposed *(365)*, failed to lower the infection rate but did prevent gram-negative shock.

Intravenously administered immunoglobulin reduced the infection rate when given prophylactically to selected high-risk patients in a surgical ICU in one study *(366)*, but did not reduce patient mortality. Prophylactic intravenous administration of immunoglobulin has been shown not to reduce the healthcare-associated infection rate in very low birth weight infants *(367)*. Passive immunization with intravenous hyperimmune globulin, derived from donors immunized with a 24-valent *Klebsiella* capsular polysaccharide plus an 8-valent *P. aeruginosa* O-polysaccharide–toxin A conjugate vaccine, was tested in 725 ICU patients and compared to albumin administered to 667 patients. Although there was some evidence that passive immunization decreased the incidence and the severity of vaccine-specific *Klebsiella* infections (from 2.7–1.2% and from 1.0–0.3%, respectively), the reductions were not statistically significant. Moreover, patients receiving hyperimmunoglobulin had more adverse reactions *(368)*.

Passive systemic vaccination with immune sera to bacteria-specific adhesins may be another approach for the future. Sera from animals vaccinated with adhesins from type 1 pili (FimH) inhibited UPEC from binding to human bladder cells *in vitro*. Immunization with FimH almost completely reduced *in vivo* colonization of the bladder in a murine cystitis model, and levels of immunoglobulin G to FimH could be detected in the urine samples of these mice *(369)*.

Less invasive and colonization-resistant devices are needed. These may very well be the most useful aids in controlling healthcare-associated infection by Enterobacteriaceae *(370,371)*.

CONCLUSION

Enterobacteriaceae, in part due to the increasing prevalence of antimicrobial-resistant strains, remain problem pathogens for healthcare facilities. Although the distribution of healthcare-associated pathogens continues to see a predominance of gram-positive bacteria at the end of the first decade in the 21st century, healthcare-associated infections due to the Enterobacteriaceae, especially strains that carry chromosomal- or plasmid-mediated antibiotic-resistance elements, still heavily impact infection control and treatment decisions. So, as the epidemiologic pendulum continues to swing, Enterobacteriaceae remain a challenging healthcare-associated and clinical problem.

The control of healthcare-associated infections due to the Enterobacteriaceae begins with our understanding of the basic epidemiology of these pathogens. Infection control measures including antiseptic-based decolonization and targeted active surveillance continue to be explored. The collaboration of public health and healthcare facility personnel at acute and long-term facilities is crucial to exploring regional epidemiologic patterns of spread and implementing measures to identify colonized and infected patients and to contain, reduce, and possibly eradicate transmission of these pathogens. Strides are being made in the development of safer and less invasive devices and surgical procedures and in our understanding of ways to control colonization and prevent invasive disease. And, as is said for most healthcare-associated infections, we must continue to make healthcare workers' adherence to hand hygiene a quality indicator (372).

CHAPTER 35

Nonfermentative Gram-Negative Bacilli

Valentina Stosor, Alan R. Hauser, and John P. Flaherty

Nonfermentative gram-negative bacilli are a diverse array of microorganisms that have evolved in aquatic environments, have minimal growth requirements, and differ substantially in virulence. Included in this category are *Pseudomonas aeruginosa*, other *Pseudomonas* species, and genera such as *Stenotrophomonas*, *Acinetobacter*, *Burkholderia*, *Flavobacterium*, and *Achromobacter*. During the last half-century, nonfermentative gram-negative bacilli have become significant healthcare-associated pathogens because of the many reservoirs they inhabit in hospitals and the resistance of these microorganisms to commonly used antibiotics. Furthermore, the virulence of *P. aeruginosa* and its frequency as a healthcare-associated pathogen have been important factors impelling increased use of antipseudomonal β-lactam antibiotics and quinolones as presumptive therapy where *P. aeruginosa* is a potential pathogen.

MICROORGANISM CHARACTERISTICS

Pathogenicity

Like other bacterial pathogens, nonfermentative gram-negative bacilli must successfully navigate through a series of critical steps to cause disease. After entering the host, bacteria attach to host cells, breach host barriers, access nutrients to proliferate, evade local host defenses, and in some cases spread to regional or distant sites *(1)*. To accomplish these tasks, bacteria produce a number of cell-associated and secreted virulence determinants in a tightly regulated manner. Pathogenesis has been studied most extensively in *P. aeruginosa*, and this bacterium will be used as a model in our discussion of pathogenesis. However, it should be noted that each of the nonfermentative gram-negative bacilli has evolved its own unique set of pathogenicity factors and accomplishes the difficult process of causing infection by a different means.

Regardless of the type of infection, bacterial attachment to host epithelial cells is typically a prerequisite to the pathogenesis of bacterial disease. Attachment of *P. aeruginosa* (formerly *P. pyocyanea*) is accomplished by a number of surface structures including type IV pili (or fimbriae), flagella, lipopolysaccharide, and lectins. Of these, type IV pili have received the most attention as adhesins *(2)*. These polar filaments are composed of repeated monomers of the protein pilin and bind to the GalNacβ(1-4)Gal moiety of asialylated glycolipids found on epithelial cells *(3)*. Disruption of pilus biosynthetic genes results in decreased virulence in animal models of acute pneumonia *(4,5)*.

Despite producing a number of adhesins, *P. aeruginosa* attaches to the apical surface of intact epithelial cells quite poorly *(6)*. *P. aeruginosa* is thus blocked at this very early step in the pathogenic process, an observation that likely explains why healthy individuals are rarely infected with this ubiquitous bacterium. However, in a host in which skin and mucosal surfaces are disrupted by endotracheal intubation and mechanical ventilation, burn wounds, corneal abrasion, indwelling catheters, or cytotoxic chemotherapy, *P. aeruginosa* has all the virulence machinery necessary to proceed through the remaining steps of pathogenesis and to cause severe infection. Injury of epithelium leads to the loss of polarized distribution of cellular ligands for *P. aeruginosa*. In particular, heparin sulfate proteoglycans normally found only on the basal–lateral surface of epithelial cells are redistributed to the apical surface following tissue damage *(7)*. These proteoglycans are avidly bound by *P. aeruginosa* adhesins and allow this bacterium to efficiently bind to the apical surface of damaged epithelium.

Once *P. aeruginosa* bacteria successfully bind to a surface (living or inert), they are capable of forming biofilms under appropriate conditions. Biofilms are communities of microbes embedded in an organic polymer matrix at an air–solid or liquid–solid interface. The extracellular matrix of biofilms formed by *P. aeruginosa* consists of exopolysaccharides, proteins, and extracellular DNA. In particular, three exopolysaccharides play an important role in biofilm formation and maintenance: Psl, Pel, and alginate *(8)*. The extracellular matrix confers partial resistance to the host immune response by inhibiting antibody coating, phagocytosis, and intracellular killing by leukocytes *(9–12)*. Thus, even in individuals with normal cellular and humoral immune function, biofilm-related infections are rarely resolved by the host defense mechanisms *(9)*. Unfortunately, biofilms are also quite resistant to eradication by antimicrobial agents. Although the reasons for this are unclear, three mechanisms have been proposed. First, antimicrobial agents may diffuse slowly through the extracellular matrix of a biofilm, resulting in subinhibitory concentrations within the biofilm interior *(13,14)*. Second, bacteria in certain regions of the biofilm may assume a metabolically or otherwise inactive state

that allows persistence in the presence of antibiotics *(15)*. Third, zones of biofilms may accumulate waste products and have low oxygen tensions, conditions that antagonize the activity of some antibiotics *(16)*. More recently, it has been shown that mutations and horizontal transfer of genetic material occur more frequently during a biofilm mode of growth *(17,18)*. All these processes could contribute to the ability of *P. aeruginosa* biofilms to develop antimicrobial resistance and to persist despite antibiotic therapy. *P. aeruginosa* biofilms play important roles in the pathogenesis of central venous catheter–related infection, urinary catheter cystitis, contact lens–associated corneal infection, lung infection in cystic fibrosis, and ventilator-associated pneumonia (VAP) *(9)*. In these infections, antibiotic therapy typically eliminates the symptoms caused by the planktonic cells released from the biofilm but fails to kill the biofilm itself. As a result, biofilm infections typically show recurring symptoms until the sessile population of bacteria along with the infected catheter or prostheses is removed.

Once a focus of infection is established, *P. aeruginosa* employs its broad spectrum of metabolic pathways to utilize nutrients available within the host. One such essential nutrient is iron, which is tightly sequestered by a number of host factors. *P. aeruginosa* secretes two siderophores named pyoverdin and pyochelin to access these cellular stores *(19)*. Both are pigmented diffusable molecules that chelate iron in the environment and then transport it into the bacterium via specific outer membrane receptors. The yellow-green fluorescence of pyoverdine is sometimes apparent in wounds and dressings, allowing a presumptive diagnosis of *P. aeruginosa* infection to be made *(20)*. Interestingly, *P. aeruginosa* has the ability to hijack and utilize siderophores secreted by other microrganisms *(21)*.

After overcoming the initial obstacles to infection, *P. aeruginosa* employs a number of secretion systems to export toxic factors into the host environment. These factors function to impair host immune components or disrupt host barriers to facilitate dissemination. Here we will review each of these secretion systems in turn.

Type I secretion is a relatively simple three-component mechanism used by gram-negative bacteria to export a dedicated factor from within the bacterium to the extracellular environment. *P. aeruginosa* uses such a system to export alkaline protease, an enzyme that cleaves components of the complement cascade and the extracellular matrix *(22,23)*. Animal models of keratitis and burn infections have demonstrated that alkaline protease plays an important role in the pathogenesis of these infections *(24)*.

A number of *P. aeruginosa* virulence factors are exported by a type II secretion system, which similarly functions to move bacterial proteins across the inner and outer bacterial membranes. *P. aeruginosa* factors secreted by this system include exotoxin A, phospholipase C, and elastase. Exotoxin A is a secreted adenosine ribosyltransferase that inhibits protein synthesis in eukaryotic cells by modifying the structure of elongation factor-2 *(25)*. Exotoxin A is produced by most clinical isolates of *P. aeruginosa* and has potent local and systemic effects. These include necrosis of soft tissues into which sublethal doses are injected *(26)* and shock and hepatocellular necrosis following systemic administration *(27)*. Although experimental models of local infection have not consistently shown enhanced virulence of *P. aeruginosa* isolates that produce exotoxin A *(28,29)*, studies of bacteremic infection in humans suggest an important role *(30,31)*.

Elastase, a metalloprotease that accounts for the majority of the proteolytic activity of *P. aeruginosa*, cleaves elastin as well as a number of other host factors. One such factor is syndecan-1, a heparin sulfate proteoglycan found on the surface of respiratory mucosal cells *(32)*. It has been postulated that *P. aeruginosa* utilizes the shed portion of cleaved syndecan-1 to protect itself from host defenses *(32)*. Animal models support a pathogenic role for elastase, especially in the lung *(33)*.

P. aeruginosa produces two phospholipase C enzymes, sometimes referred to as Plc-HR and Plc-N. These enzymes can degrade surfactant in the lung and cause tissue destruction *(34)*. Mutants with disruptions in the genes encoding these phospholipases were defective in virulence in a mouse burn model *(35)*.

All *P. aeruginosa* strains also encode a type III secretion system, although this system appears to not function in some isolates. The type III secretion system uses a complex secretion/translocation mechanism to move toxins (called effector proteins) directly from the bacterium into host cells. Four effector proteins have been identified in *P. aeruginosa*: ExoS, ExoT, ExoU, and ExoY. ExoS and ExoT are related proteins that have ADP-ribosyltransferase and GTPase-activating protein activities. These activities are directed against a number of host proteins and are thought to inhibit phagocytosis, disrupt epithelial barriers, and cause apoptosis *(36,37)*. ExoU is a potent phospholipase that causes rapid necrotic cell death of a number of cell types, including neutrophils during acute pneumonia *(38–40)*. ExoY is an adenylate cyclase that elevates intracellular cyclic adenosine monophosphate levels *(41)*. ExoU and ExoS have been shown to be important virulence factors in several animal models *(40,42)*. Type III secretion itself has been associated with worse clinical outcomes in patients with VAP and bloodstream infection *(43,44)*.

P. aeruginosa does not harbor a type IV secretion system and the relationships between this bacterium's type V secretion systems and virulence have not been examined in detail. Recently, however, examples of a newly described type VI secretion system have been found in *P. aeruginosa* (45,*46*). One such system, designated H1-T6SS, has been shown to secrete three substrates: Tse1, Tse2, and Tse3 *(47)*. Work is ongoing to determine whether this secretion system is directed against eukaryotic microorganisms such as humans or competing bacteria, or both *(47)*.

P. aeruginosa produces a number of additional factors that have been implicated in disease pathogenesis, including rhamnolipids, pyocyanin, and leukocidin. The reader is referred to several recent reviews for more detailed information on these factors and *P. aeruginosa* pathogenesis in general *(48,49)*.

As would be expected, complex, integrated, and overlapping regulatory networks are required to ensure that many *P. aeruginosa* virulence determinants are activated at the appropriate time and place during infection. One such regulatory system is cyclic-diguanylate. This second messenger molecule is synthesized from guanosine triphosphate by diguanylate cyclases and degraded by

phosphodiesterases. Interestingly, more than 30 of these enzymes are believed to be encoded by the *P. aeruginosa* genome, suggesting complex regulation of this second messenger *(50)*. Cyclic-diguanylate levels within the bacterium, to a large extent, control biofilm formation by regulating matrix production and adhesion *(51,52)*.

A more global regulatory system employed by *P. aeruginosa* is quorum sensing. Quorum sensing allows bacteria to detect the density of their own species and alter their gene expression patterns to take advantage of this density. Small diffusible signal molecules called autoinducers are secreted by *P. aeruginosa*. At a specific cell density, the concentration of these molecules becomes sufficient to activate transcriptional regulator proteins and induce gene transcription. *In vitro*, quorum-sensing systems modulate expression of 6% to 10% of the genes in the *P. aeruginosa* genome *(53,54)*. *P. aeruginosa* produces several autoinducers, but two small acyl-homoserine lactone molecules referred to as PAI-1 and PAI-2 have been most extensively studied *(55)*. PAI-1 activates the LasR protein, which enhances the transcription of extracellular virulence factors including alkaline protease, exotoxin A, and elastase. The formation of a normal, dense biofilm is also dependent on the synthesis of PAI-1 (*56*,57). The autoinducer molecule PAI-2 binds RhlR and initiates transcription of several different genes involved in a variety of adaptations including biofilm formation. A further indication of the complexity of regulation is that the Las system itself regulates the Rhl system. *P. aeruginosa* strains with inactivated quorum-sensing systems demonstrate significantly diminished virulence in animal models of infection *(58)*.

Another global regulatory system used by *P. aeruginosa* consists of RetS and LadS. These two proteins are reciprocally activated hybrid sensor kinases/response regulators that form a molecular switch priming *P. aeruginosa* for either an acute (RetS) or a chronic (LadS) infection lifestyle. They activate downstream pathways that posttranslationally regulate a number of virulence determinants, including type III secretion, piliation, and a biofilm mode of growth *(59–62)*. Thus, RetS and LadS may sense environmental cues consistent with acute infection (e.g., VAP) or chronic infection (cystic fibrosis) and alter gene expression accordingly.

During pathogenesis, *P. aeruginosa* pathogenicity factors interact intimately with the host's immune system to cause pathology *(63,64)*. Key components of immunity to invasive infection are TLRs *(65)*, the inflammasome *(66,67)*, polymorphonuclear leukocytes *(68,69)*, and antibodies against the lipopolysaccharide cell wall *(70,71)*. A role for cellular immunity (in particular a Th17 response) is also suggested by reports of invasive pseudomonal infection in patients with cellular immune impairment *(72,73)* and is supported by experimental findings involving T cells *(74,75)*.

By most measures, *Stenotrophomonas maltophilia* (formerly *Pseudomonas maltophilia* and then *Xanthomonas maltophilia*) is not particularly virulent (reviewed in Ref. *76*). In the burned mouse model, inocula of 3×10^7 colony-forming units (CFU)/mL of *S. maltophilia* failed to establish lethal infection *(70)*. In contrast, only 2×10^2 CFU/mL of *P. aeruginosa* caused fatal infection in all the animals studied. Nevertheless, *S. maltophilia* can cause serious infection in compromised hosts. Genomic comparison of a clinical *S. maltophilia* isolate to an environmental isolate demonstrated that the clinical isolate encoded a unique filamentous hemagglutinin, a protein that functions as an adhesin in other bacteria, and a type IV pilus *(77)*. *S. maltophilia* also produces or carries genes encoding a number of putative virulence determinants, including protease, elastase, DNase, lipase, fibrinolysin, and zonula occludens toxin *(78–80)*. The latter is similar to an enterotoxin produced by *Vibrio cholerae*. Consistent with the production of these factors, *S. maltophilia* was cytotoxic toward a number of mammalian cell lines *(81)* and lethal in a *Caenorhabditis elegans* infection model *(82)*. Particularly, significant protease and elastase production was identified in a clinical isolate of *S. maltophilia* from a leukemic patient with bacteremia and ecthyma gangrenosum, mimicking both the clinical and virulence properties of *P. aeruginosa (83)*.

The *Burkholderia cepacia* complex group of bacteria was originally described in 1950 as a cause of soft rot in onions (Latin: *coepa*) and previously named eugonic oxidizer group 1, *Pseudomonas kingii*, *Pseudomonas multivorans*, *Pseudomonas P. alcaligenes* IVc, and *Pseudomonas cepacia*. More recently, they were given the name *B. cepacia*, but as these microorganisms were further characterized, it became clear that *B. cepacia* actually comprised a group of several related but distinct bacteria that have now been given species designations. Currently this group of bacteria is referred to as the *B. cepacia* complex and consists of more than 16 species *(84–87)* (reviewed in *88*). These bacteria are extremely versatile and capable of utilizing a wide variety of nutrients for growth. They thrive in natural water sources and can proliferate in tap or distilled water, presumably by utilizing trace elements and low concentrations of organic materials *(89–93)*. Like *S. maltophilia* bacteria, *B. cepacia* complex strains can cause significant disease in the compromised patient and produce a number of important virulence factors. The cable pilus, an adhesin, is used to tether bacteria to cytokeratin 13 on the surface of host cells *(94)*. *B. cepacia* complex bacteria can enter and survive intracellularly in cultured macrophages and pulmonary epithelial cells, which may provide a protected niche, allowing persistent infection *(95)*. Flagella are necessary for the invasion process, and mutants lacking functional flagella were defective in invasion *in vitro* and in lethality in a mouse model of chronic pulmonary infection *(96,97)*. *B. cepacia* complex bacteria also have a quorum-sensing system (CepIR), which is necessary for biofilm formation, secretion of putative toxins, and full virulence in a rodent model *(98,99)*. Interestingly, the *B. cepacia* complex quorum-sensing system also responds to autoinducers from *P. aeruginosa (100)*, demonstrating interspecies communication. Some strains within the *B. cepacia* complex contain a pathogenicity island named the cenocepacia island *(101)*. This island encodes a second quorum-sensing system (CciIR), metabolic pathways, and several transcriptional regulators. Mutations in specific portions of this island caused defects in bacterial persistence and inflammation in a rat chronic infection model *(101)*.

Acinetobacter, formerly classified as *Mima*, *Herellea*, *Moraxella*, *Neisseria*, *Bacterium*, *Alcaligenes*, *Achromobacter*, and *Pseudomonas*, is widely distributed in nature and is part of the normal flora of many animal species and humans

(*102*,*103*, reviewed in Ref. 104). By DNA hybridization, there may be as many as 17 species *(105)*, of which *Acinetobacter baumannii* is the most clinically relevant. *A. baumannii* is an uncommon pathogen *(106,107)* that usually infects immunocompromised or debilitated hosts and sometimes causes outbreaks in intensive care units (ICUs) *(108–110)*. A number of *A. baumannii* factors likely to be important in pathogenesis have been identified including siderophores for iron acquisition *(111,112)*, piluslike structures that facilitate adherence to host cells and biofilm formation *(113,114)*, and multiple quorum-sensing systems *(115)*. The sequencing of the *A. baumannii* genome identified a substantial number of genomic islands *(116,117)*, six of which were shown to enhance virulence in *C. elegans* and *Dictyostelium discoideum* models of infection *(117)*. The virulence-associated islands contained genes predicted to encode transcription factors, multidrug efflux transport systems, and a urease.

The pathogenesis or virulence properties of other nonfermenters have not been fully elucidated. *Sphingomonas paucimobilis* appears to have limited inherent virulence, but it does have endotoxin activity and produces alkaline and acid phosphatases and several esterases *(118,119)*. A report of *Shewanella putrefaciens* causing refractory ulcerative cellulitis and septic shock suggested possible exotoxin production *(120)*.

Resistance to Antimicrobial Agents

P. aeruginosa and other nonfermentative gram-negative bacilli are resistant to many common antibiotics, including first- and second-generation cephalosporins. Based on recent surveillance studies, piperacillin/tazobactam, carbapenems, piperacillin, ceftazidime, cefepime, and the polymyxins remain the most active antipseudomonal agents (104,*121–128*). Increased resistance across many classes of antimicrobial agents and multiclass drug resistance is a concerning trend exhibited by all the clinically important nonfermentative gram-negative bacteria *(121–123,129)*. Mechanisms of resistance to each class of antibiotics are diverse, and more than one mechanism may contribute to resistance to some antibiotics *(130)*. Antimicrobial resistance exhibited by the clinically important nonfermentative gram-negative pathogens is discussed below. Other nonfermenters that are less commonly encountered have varying antimicrobial susceptibility patterns *(127,131–134)*. Treatment of infections caused by these pathogens is typically guided by susceptibility testing of individual isolates.

For *P. aeruginosa*, inherent mechanisms such as outer cell membrane permeability factors and active drug efflux systems result in reduced susceptibility to many antimicrobial agents *(135,136)*. Efflux pumps play a role in reduced susceptibility to sulfonamides, tetracycline, macrolides, fluoroquinolones, penicillins, cephalosporins, meropenem, and even the aminoglycosides *(137)*. All *P. aeruginosa* inherently produce the AmpC β-lactamase that hydrolyzes penicillins and cephalosporins (*136*,138,*139*). In addition, acquired β-lactamases are responsible for penicillin, and first- and second-generation cephalosporin resistance *(136,139)*. Production of a number of extended-spectrum β-lactamases is reported with increasing frequency, resulting in resistance to advanced-generation cephalosporins, monobactams, and extended-spectrum penicillins, depending on the enzyme(s) present *(136,139)*. Changes in penicillin-binding proteins are a relatively uncommon mechanism of β-lactam resistance in *P. aeruginosa (130,135)*. Historically, reduced activity of carbapenems, when present, was attributed to reduced accumulation of the drug via downregulation of carbapenem-specific porin production *(137)*; however, carbapenemase production has been reported with increasing frequency *(124,140–142)*. Aminoglycosides are inactivated by enzymatic modification via the acquisition of plasmids carrying any of a number of such enzymes. The prevalence of fluoroquinolone resistance among *P. aeruginosa* is remarkably high *(121–123,128)*; mutations in the topoisomerase genes, *gyrA* and *parC*, are the genetic basis for such resistance *(143–146)* in addition to resistance caused by active efflux and membrane impermeability.

S. maltophilia demonstrates high-level resistance to many antimicrobial agent classes including the β-lactams, tetracyclines, and aminoglycosides *(127,147)*. As a rule, the carbapenems are hydrolyzed by a chromosomally encoded zinc-dependent β-lactamase possessed by most strains, thus rendering these agents ineffective for the treatment of *S. maltophilia* infections. The most reliable agents include trimethoprim/sulfamethoxazole, ticarcillin/clavulanate, and the newer generation fluoroquinolones such as levofloxacin, moxifloxacin, or gatifloxacin *(125,126,129,147–150)*. In addition, tigecycline demonstrates *in vitro* activity and polymyxin B has variable activity against *Stenotrophomonas (151,152)*.

B. cepacia complex strains are resistant to most antibiotics commonly used for treatment of gram-negative bacterial infections, including the extended-spectrum penicillins and aminoglycosides *(153)*. The most active antimicrobial agents are trimethoprim/sulfamethoxazole, the carbapenems, ceftazidime, and the fluoroquinolones (*127*,154). *Burkholderia* demonstrates *in vitro* susceptibility to tigecycline *(151)*. Most strains are resistant to polymyxin B *(127,152)*. Typically, serious infections are treated with combinations of antimicrobial agents.

Acinetobacter varies substantially in its susceptibility to specific antibiotics, and resistance has steadily increased over the last 3 decades (104,*123*,*124*,*128*,*140*,155). Multiple drug resistance has emerged (104), and outbreaks caused by *Acinetobacter* strains that are resistant to imipenem, ceftazidime, amikacin, and other routinely tested antibiotics are increasingly reported (156,*157–160*). The most appropriate therapy in such circumstances is unclear and should be guided by the results of antimicrobial susceptibility testing. Sulbactam exhibits antimicrobial activity against *Acinetobacter*, and thus, ampicillin–sulbactam may be considered for therapy *(105,157,161,162)*. Tigecycline possesses *in vitro* activity against *Acinetobacter (163)*, but data are limited regarding clinical efficacy and cases of tigecycline resistance have been reported *(164,165)*. The polymyxins, such as polymyxin B, colistin, and similar investigational peptides, demonstrate *in vitro* activity against *Acinetobacter* and *Pseudomonas* and offer a potential therapy for infections caused by strains that are resistant to all other agents *(157,166)*. Finally, there is limited data that support the use of combination therapy with agents such as colistin plus rifampin or colistin plus a carbapenem (104,*167*).

Antimicrobial resistance exhibited by the nonfermentative gram-negative bacilli creates an epidemiologic niche for these pathogens that facilitates colonization and

superinfection in antibiotic-treated patients. For example, multiple studies demonstrate that patients who receive antibiotics lacking anti-*Pseudomonas* activity are at risk for intestinal colonization *(168–171)* and bloodstream infections *(172)* caused by this bacterium. Similarly, administration of broad-spectrum antibiotics lacking activity against other nonfermentative gram-negative bacilli including *Acinetobacter* and *S. maltophilia* predisposes toward colonization and infection with these pathogens *(173–177)*.

Resistance to Biocides

Resistance to biocides is a feature of some nonfermentative gram-negative bacilli, most notably *P. aeruginosa* and *B. cepacia*. This problem was initially recognized in the 1950s when *Pseudomonas* contamination of dilute aqueous benzalkonium chloride was reported at several hospitals *(178,179)*. At these hospitals, the use of contaminated aqueous benzalkonium chloride to disinfect intravascular catheters and needles caused outbreaks of *Pseudomonas* bacteremia. The continued use of aqueous benzalkonium chloride alone or with other agents for antiseptic preparation of the skin or urethral meatus before catheter insertion resulted in further cases of bloodstream or urinary tract infection *(180–185)*. Most outbreaks involved aqueous benzalkonium chloride diluted in hospitals to an in-use concentration of 1:1,000; however, in several instances, *B. cepacia* was an intrinsic contaminant of commercially prepared swabs containing a 1:500 concentration of aqueous benzalkonium chloride *(183,186)*.

Other antiseptic preparations such as chlorhexidine *(187–190)*, chlorhexidine and cetrimide *(191,192)*, cetrimide *(193)*, hexachlorophene *(194)*, and green soap *(195)* have become contaminated with *Pseudomonas*, *Burkholderia*, *Ralstonia*, or *Stenotrophomonas*. While the presence of organic materials enhances survival of bacteria in these antiseptics *(178,193,196)*, *Pseudomonas* and related nonfermenters may proliferate substantially in antiseptics in the absence of such contaminants *(193,196)*. These bacteria may also contaminate phenolic disinfectants *(196–198)*. Even commercial preparations of poloxamer-iodine and povidone-iodine have become contaminated with *P. aeruginosa (199)* and *B. cepacia (200–202)*; in such reports, products from different manufacturers were implicated, and concentrations of free iodine, when tested, were sometimes in the same range as uncontaminated products *(201,202)*.

The susceptibility of *P. aeruginosa* and *B. cepacia* to commonly used antiseptics and disinfectants varies. Some strains are resistant to in-use dilutions of benzalkonium chloride, chlorhexidine, cetrimide, phenolic disinfectant, iodophor disinfectant, or quaternary ammonium disinfectant *(203–208)*. There are limited data regarding biocide resistance in other nonfermentative gram-negative bacteria. Two such studies examining *in vitro* susceptibility of *A. baumannii*, including multidrug resistant isolates, to biocides demonstrated no resistance to commonly used antiseptics such as chlorhexidine *(209,210)*. In contrast, *Acinetobacter* isolates possessing class 1 integrons were associated with both biofilm formation and resistance to biocides including benzalkonium chloride and chlorhexidine *(211)*.

It is evident that gram-negative bacteria may possess multiple intrinsic and acquired mechanisms for antiseptic and disinfectant resistance (212,213). *P. aeruginosa* and *B. cepacia* within biofilms are more resistant to biocides of all types, including antibiotics, than their free-living counterparts (9,*214–219*). Studies of iodophor contamination by *P. aeruginosa* and *B. cepacia* demonstrate the potential protective role of biofilm matrix *(220–222)*. The ways in which bacteria within a biofilm evade the actions of antimicrobials and disinfectants remain under investigation but appear identical to the mechanisms by which biofilms inhibit antibiotic activity. First, biofilms act as a permeability barrier to biocides (9,*215*,*223*). For example, *in vitro* resistance to povidone-iodine is mediated by the protective layering of *Pseudomonas* bacterial cells within a biofilm *(224)*. *In vitro*, higher concentrations of biocides can overcome this type of resistance *(225)*. Second, bacteria within a biofilm have slower growth rates that result in reduced efficacy of antimicrobials such as β-lactams.

Additional inherent and acquired mechanisms may allow evasion of biocide effects. The relative impermeability of the bacterial outer membrane may result in low-level resistance to hydrophobic compounds such as triclosan, and acquired alterations in bacterial outer membrane proteins may confer resistance to higher concentrations of such compounds (213,*216*,*223*,*226*). The expression of multidrug efflux pumps is another proposed mechanism of biocide resistance (*137*,213,*223*,*226–228*). Resistance of *Pseudomonas* species to other compounds such as phenols may be mediated by catabolic enzymes *(229–231)*. Plasmid-mediated resistance to silver has occurred in *Pseudomonas stutzeri (232)*.

Replication and Survival

Species of *Pseudomonas* and *B. cepacia* complex replicate in a wide range of moist environments because of their ability to obtain carbon and nitrogen from diverse substrates. Aliphatic amides or amino acids provide the source of both carbon and nitrogen. Alternatively, carbon may be derived from organic acids or esters of organic acids, whereas nitrogen is extracted from ammonium or nitrate. The range of substrates includes both antibiotics and germicides. For example, penicillin has served as a carbon source for *B. cepacia (233)* and *Pseudomonas fluorescens (234)*; chlorinated phenols were utilized by an isolate-designated *Pseudomonas* species B 13 *(235)*; and chlorhexidine and cetrimide were utilized by *B. cepacia (191)*. In addition, ammonium acetate–buffered benzalkonium chloride has supported the growth of *P. aeruginosa (236)*.

The minimal nutrient requirements of *P. aeruginosa* and *B. cepacia* complex permit their growth in tap water and distilled or deionized water up to concentrations of 10^5 to 10^7 CFU/mL *(185,237–239)*. Presumably, organic compounds absorbed in water from plumbing and storage systems are utilized as substrates. Naturally occurring pseudomonads in these minimal medium environments are more resistant to chemical inactivation by agents such as chlorine or iodine than are bacteria grown in enriched media *(191,201,237,238)*.

Pseudomonads are capable of prolonged survival in moist or dry environments. In laboratory studies, *P. aeruginosa* can survive in water for more than 300 days, on dry filter paper disks for up to 150 days, on hardened plaster of Paris bandages for at least 20 days, on plastics used in the hospital environment for up to 2 days, and in dried sputum for at least 5 days *(240–243)*. In the hospital environment,

P. aeruginosa was recovered from a dry floor 5 weeks after the ward was closed and from burn eschar tissue samples excised 8 weeks earlier *(244)*.

Acinetobacter demonstrates even better survival than *P. aeruginosa* under some conditions *(240,245–250)*. For example, *Acinetobacter calcoaceticus* survived an average of 9 days on a dry Formica surface compared with <1 day for *P. aeruginosa (247)*. Survival of *A. baumannii* at high colony counts for at least 16 weeks on dry surfaces has been shown using a strain initially isolated from dry environmental surfaces *(248)*. In addition, strains of *A. baumannii* survived on glass coverslips for an average of 27 days when incubated under conditions mimicking the hospital environment *(250)*.

B. cepacia achieved concentrations of 10^6 to 10^8 CFU/mL when inoculated into sterile 5% dextrose and normal saline solutions but appeared to exhaust its nutrient supply after 21 days of incubation *(251)*. *B. cepacia* did not multiply in 50% dextrose, 3% saline, or hyperalimentation solutions *(239)*. After prolonged storage of a contaminated solution of minimal inorganic salts containing benzalkonium chloride and ammonium acetate, cultures demonstrated viable *B. cepacia* after 14 years *(252)*.

DETECTION AND TYPING

P. aeruginosa grows readily on most standard laboratory media. For isolation from clinical specimens or sources with mixed flora, media that are selective for gram-negative bacilli, such as MacConkey or eosin–methylene blue agars, are utilized *(253,254)*. When culture surveillance of body sites or the environment is warranted, the detection of *P. aeruginosa* is facilitated by the use of selective media, and agar containing cetyltrimethylammonium bromide (cetrimide) is the most widely employed *(255–258)*. Other agents selective for *P. aeruginosa* include acetamide *(259)*, nitrofurantoin *(260)*, 9-chloro-9-(4-diethylaminophenyl)-10-phenylacridan (C-390) *(261–263)*, 1,10-phenanthroline *(264)*, C-390 and phenanthroline *(265)*, and 2,4,4-trichloro-2-hydroxydiphenyl ether (Irgasan) *(258)*. Before embarking on a culture survey with a selective medium, it is worthwhile to first confirm that the chosen medium inhibits competing species but not the strain(s) of interest. After isolation of bacteria on agar, characteristics that distinguish *P. aeruginosa* include a grapelike odor and production of a blue-green pigment (pyocyanin). Bacterial colonies exhibiting these features are definitively identified as *P. aeruginosa* by standard laboratory methods *(253,254)*.

Most nonfermenters also grow well on nonselective media and MacConkey agar *(266,267)*. For patients with cystic fibrosis, the isolation of *Burkholderia* species from culture is significantly enhanced by the use of selective media. *P. cepacia* agar and oxidation–fermentation polymyxin–bacitracin–lactose medium increase the yield of *B. cepacia* to three to four times that of MacConkey agar *(268,269)* and demonstrate evidence of growth 24 to 48 hours earlier *(270)*. *B. cepacia* selective agar, containing 1% lactose, 1% sucrose, polymyxin, gentamicin, and vancomycin, achieves better suppression of other respiratory tract pathogens than *P. cepacia* agar or oxidation–fermentation polymyxin–bacitracin–lactose while allowing the isolation of *B. cepacia (271,272)*. *S. maltophilia* has been misidentified as *B. cepacia* based on a false-negative DNase reaction. Because of the important clinical and prognostic implications in patients with cystic fibrosis, careful interpretation of such laboratory assays is essential *(273)*. Selective and differential media for the detection of *Acinetobacter* species, such as Leeds *Acinetobacter* medium, *Herellea* agar, and Holton's agar, were developed for use with clinical specimens and environmental testing *(267,274,275)*.

Because strain typing systems have become more sophisticated and accessible, epidemiologic investigations of *P. aeruginosa* are now more efficient and provide increasingly meaningful information. Early typing systems relied on phenotypic characteristics such as biochemical reactions, antibiotic susceptibility patterns, bacteriophage susceptibility, pyocin susceptibility, pyocin production, O serotype, and enzyme electrophoretic mobility. Because of the limited discriminatory power and sometimes cumbersome nature of such methods, these approaches have been largely replaced by DNA-based techniques *(276,277)*. Only serotyping, based on antigenic determinants on cell wall lipopolysaccharide (International Antigenic Typing System), remains a useful, widely available system *(276,278,279)*.

Plasmid profile analysis was among the first nucleic acid–based techniques applied to strain typing. This technique has been used infrequently *(280)*, and its interpretation is limited by the absence of plasmids in some strains and by potential transfer or spontaneous loss of plasmid(s) in others. Newer techniques have focused on chromosomal DNA (genotyping) to demonstrate genetic relatedness. Restriction endonuclease analysis of genomic DNA is the simplest approach and is useful as a screening tool *(279,281,282)*. Ribotyping has been employed successfully in epidemiologic investigations but is the least discriminatory of molecular methods *(281,283–287)*. A more precise approach is Southern blot analysis of chromosomal DNA in which restriction endonuclease fragments carrying a specific sequence are detected by a DNA probe. Probes encoding the exotoxin A gene have proven useful *(281,283,288–291)*, but not all *Pseudomonas* strains carry this gene. Probes encoding for phospholipase C or the pilin polypeptide also have been used alone or in combination with exotoxin A gene probes *(288,291,292)*. Restriction endonuclease analysis of genomic DNA using enzymes with infrequent recognition sites followed by pulsed-field gel electrophoresis (PFGE) has proven highly discriminatory in epidemiologic investigations involving *P. aeruginosa (255,281,293–297)*. This method is now considered the typing method of choice for *P. aeruginosa. P. aeruginosa* genotyping is also feasible by polymerase chain reaction (PCR) methodology such as random amplified polymorphic DNA analysis (RAPD) or enterobacterial repetitive intergenic consensus PCR *(285,292,298)*. Multilocus sequence typing (MLST), which involves the phylogenetic analysis of conserved regions of multiple housekeeping genes, is being investigated as a potential tool for the epidemiologic study of *Pseudomonas (299)*.

Similarly, for *B. cepacia*, the phenotypic typing methods *(300)* employed in the past are now considered unreliable (154). Ribotyping has documented patient-to-patient transmission *(301–303)*; however, PFGE and RAPD are now

the most commonly employed genotypic methods in epidemiologic investigations (154,*301–306*). Genotyping by repetitive extra-palindromic PCR is also reported *(307)*. MLST is emerging as a reliable and discriminatory tool to examine the global molecular epidemiology of *B. cepacia (308–311)*.

A variety of molecular techniques have been applied to the epidemiologic study of *A. baumannii*. Plasmid DNA electrophoresis and ribotyping both have limitations and thus largely have been replaced by PFGE or other PCR-based methods (104,*107*,*109*,*312–318*). The molecular epidemiology of *Acinetobacter*, particularly geographically remote clusters, can be undertaken with MLST *(319–320)*. Multilocus PCR followed by electron spray ionization mass spectroscopy is a rapid, high-throughput platform for MLST that is not widely available but has been successfully applied to the study of *Acinetobacter* and correlates with PFGE results *(321,322)*.

For other nonfermenters, older methods such as serotyping *(175,323)* and plasmid DNA electrophoresis *(313,314)* are sometimes helpful, and a variety of molecular techniques including ribotyping *(324)* and PCR-based systems *(325–333)* have been employed. However, PFGE of digested genomic or total DNA is most commonly used for molecular epidemiologic investigations, such as with *Stenotrophomonas (147,327,334–336)* and *Chryseobacterium (337,338)*.

CLINICAL AND EPIDEMIOLOGIC MANIFESTATIONS

Bacteremia

Bacteria may enter the bloodstream either because of microorganism virulence or because direct access is provided by contaminated intravascular devices or fluids. *P. aeruginosa* bacteremia usually arises by the former mechanism, whereas the latter mechanism accounts for most cases of bacteremia by other nonfermentative gram-negative bacilli.

The frequency of *P. aeruginosa* bacteremia largely depends on the population of patients studied. National statistics rank *P. aeruginosa* as the seventh leading cause of bloodstream infection, accounting for 4.3% of all bloodstream infections with an incidence of 2.1 per 10,000 hospitals admissions (155). At university teaching hospitals, the overall incidence has been about 10 cases per 10,000 admissions *(339,340)*. In patients with burn injuries or cancer, the incidence has been about 50 cases per 10,000 admissions *(341,342)*, and the incidence has exceeded 500 cases per 10,000 admissions in patients with acute leukemia *(342,343)*. The great majority of cases of *P. aeruginosa* bacteremia appears to be healthcare-associated.

The usual clinical picture of *P. aeruginosa* bacteremia is the same as that of bacteremia caused by other gram-negative bacilli. Fever is almost always present, except in infants, and tachycardia and hypotension are common findings *(342,344,345)*. Necrotizing skin lesions, called ecthyma gangrenosum, are considered pathognomonic of *P. aeruginosa* bacteremia *(346,347)*, but occasionally are seen in bloodstream infections by other pathogens, including *S. maltophilia* (83,*348*,*349*) and *B. cepacia (350)*. Ecthyma and other skin lesions were not uncommon in infected cancer patients treated in the 1950s and 1960s *(351,352)*, but are rare in later series *(342,344,345)*.

When present in the bloodstream of cancer patients, *P. aeruginosa* is virtually always the sole pathogen, and bacteremia is thought to arise from the alimentary tract. Gut colonization with *P. aeruginosa* has been associated with a risk of *P. aeruginosa* bacteremia exceeding 40% during neutropenia *(353–355)*. In other settings, about 20% of the cases of *P. aeruginosa* bacteremia are polymicrobial *(339,344,356)*. The most common primary sites of infection from which bacteremia arises are the urinary tract and respiratory tract *(339,340,344,356)*.

The outcome of *P. aeruginosa* bacteremia is poor, especially in neutropenic cancer patients. The mortality rate for these patients was about 90% until the 1970s, when it became common practice to administer combination therapy with gentamicin and carbenicillin presumptively for neutropenic fever *(343,351,357)*. Subsequently, the timely administration of more potent antipseudomonal antibiotics has lowered mortality rates below 40% *(358)*. In unselected patients at teaching hospitals, the mortality rate of *P. aeruginosa* bacteremia has remained about 40% to 50% *(349,359)* and exceeds that for other bacteria *(360)*. Some of this mortality can be attributed to the severity of underlying disease in patients with *P. aeruginosa* bacteremia. A matched cohort study of ICU patients with *P. aeruginosa* bacteremia reported an overall mortality of 62%, but an attributable mortality of only 15% *(361)*. Improved outcomes have been associated with resolution of neutropenia and the early use of appropriate antibiotics (*351*,*357–359*,*362*,363). Poor outcomes have been associated with inappropriate initial antimicrobial therapy (363,*364–366*). Historically, an emphasis was placed on the treatment of *P. aeruginosa* bacteremia with synergistic antibiotic combinations, typically an antipseudomonal β-lactam agent plus an aminoglycoside. Ongoing analysis suggests that combination therapy is no more effective than monotherapy, provided the single agent is not an aminoglycoside but is an antipseudomonal β-lactam with potent activity given at a suitable dosage *(364*,*365*,*367)*. Combination therapy may continue to have value as initial empiric therapy when the identity and the susceptibility profile of the infecting agent are unknown. In striking contrast to the life-threatening nature of most cases of healthcare-associated *P. aeruginosa* bacteremia, there are occasional examples of asymptomatic *P. aeruginosa* bacteremia *(368)* and of symptomatic intravenous catheter sepsis that resolves without specific antibiotic therapy *(369,370)*.

Cases of primary *P. aeruginosa* bacteremia occasionally have been linked to intravenous devices or infusion products that became contaminated during preparation in hospitals *(179*,*371–373)*. Bacteremia arising from contaminated endoscopes has been a more frequent problem (*374*,*375*,376), including episodes reported in association with endoscopic retrograde cholangiopancreatography *(377–380)*. Outbreaks of *P. aeruginosa* infection similarly have been traced to breaches in reprocessing of bronchoscopes (376) and cystoscopes *(381)*. In these cases, the onset of symptoms usually was a few hours to a few days after the procedure. Hemodialysis treatment also has been a source of *P. aeruginosa* bacteremia and has been associated with inadequate reprocessing of hemodialyzers

with benzalkonium chloride *(368,382)*, incorrectly diluted formaldehyde *(383)*, or contaminated dialysate waste drainage ports *(384)*.

In some centers treating neutropenic cancer patients, the overall incidence of *P. aeruginosa* bacteremia has declined *(385)*. However, other centers have reported outbreak or hyperendemic problems apparently linked to contamination of mouthwash *(386)*, environmental contamination *(355)*, or cross-transmission from patients *(171)*.

Pseudobacteremia due to *P. aeruginosa* contamination of blood culture specimens has been reported *(387,388)*. One outbreak of *P. aeruginosa* pseudobacteremia was traced to the use of contaminated disinfectant to clean blood culture bottles before use *(388)* (see also Chapter 9).

Although *P. aeruginosa* bacteremia is almost always life-threatening, bacteremia caused by other nonfermenting gram-negative bacilli is frequently self-limited. Outbreaks of *B. cepacia* complex bacteremia associated with common source exposure to contaminated fluids (89,*389–393*), including alcohol-free mouthwash *(394,395)*, skin moisturizer *(396)*, disinfectants *(186,202,397,398)*, or medical devices *(382–387,389–392,399,400)*, have been associated with significant morbidity, but there has been little or no mortality. Most reported cases of *B. cepacia* bacteremia have in common the direct introduction of contaminated material into the bloodstream. Pseudobacteremia due to *B. cepacia* has been reported rarely *(401)*.

S. maltophilia bacteremia generally arises secondary to respiratory tract or intravenous catheter–related infection in immunocompromised patients receiving broad-spectrum antibiotics. *S. maltophilia* bacteremia often occurs as a breakthrough infection *(402)*. Unlike *B. cepacia*, *S. maltophilia* bacteremia is often associated with signs and symptoms of sepsis and carries a mortality rate of 25% to 57% *(403–405)*. One case–control study reported an attributable mortality rate of 27% in patients with *S. maltophilia* bacteremia *(406)*. Mortality is increased when the patient is immunocompromised, the primary source is the lung, or antibiotic therapy is inappropriate *(402–405,407)*. Catheter-related bloodstream *S. maltophilia* infections respond well to early catheter removal; failure to remove the catheter is associated with a high risk of relapse (*408*,409,*410*). *S. maltophilia* has also been associated with outbreaks of pseudobacteremia *(411)*.

Acinetobacter species accounted for 1.5% of all healthcare-associated bloodstream infections in a survey of 49 US hospitals from 1995 to 1998 *(412)*. *A. baumannii* accounted for 86% of *Acinetobacter* isolates. *A. baumannii* bacteremia was more frequently observed in the ICU than bloodstream infections with other gram-negative bacilli (69% vs. 47%, respectively). *Acinetobacter* bacteremia has the potential to present as very low grade infection or as septic shock. Early reports emphasized the transient or benign nature of *Acinetobacter* bacteremia *(413–417)*. Bacteremia often cleared with removal of the associated intravenous catheter with or without antibiotic therapy. A report of catheter-related *Acinetobacter johnsonii* bacteremia described a similarly benign clinical course *(418)*. In other series, high fever, leukocytosis, and septic shock were present in 37% to 78% of cases, mortality rates ranged from 15% to 32%, and metastatic complications including endocarditis, septic thrombophlebitis, and intra-abdominal abscess were detected *(107,419–421)*. A case–control study of ICU patients with *A. baumannii* bacteremia found an overall mortality of 42%, but an attributable mortality of only 8%, reflecting the underlying severity of illness in patients with *Acinetobacter* bacteremia *(422)*. *Acinetobacter* infection tends to occur in patients with impaired host defenses. Almost all have intravenous catheters and are receiving broad-spectrum antibiotics *(107,413–421,423,424)*.

P. fluorescens is an important cause of transfusion-associated infection. This microorganism is psychrophilic (grows at 4°C) and utilizes citrate as a carbon source. Refrigerated citrate anticoagulated red blood cell units serve as an ideal growth medium. *P. fluorescens* can achieve peak concentrations of 10^6 to 10^7 CFU/mL within 1 week of storage at 4°C. Transfusion-related infection has been associated with severe illness and mortality rates exceeding 50% *(425–427)*. These infections are characterized by the sudden onset of fever, chills, and hypotension during red blood cell transfusion, and the source of infection has been confirmed by positive culture of untransfused blood. *P. fluorescens* bacteremia has also been associated with infusion of contaminated heparinized saline flush solution (428). In contrast to the high mortality rate reported with transfusion-related infection, there were no deaths among 80 cases reported, possibly reflecting a lower microorganism load in the infused flushes.

Bacteremia caused by *Ralstonia* (formerly *Pseudomonas*) *pickettii (189,361,420,421,423–427,429–441)*, other *Ralstonia* species *(442,443)*, *S. paucimobilis (118,438,443–448)*, *Pseudomonas* (formerly *Flavimonas*) *oryzihabitans (132)*, and *Rhizobium radiobacter* (formerly *Agrobacterium radiobacter* and *Agrobacterium tumefaciens) (449–452)*, *Ochrobactrum anthropi (453)*, or *P. stutzeri (454)* almost always results from either infusion of contaminated solutions or direct contact with contaminated ventilators or dialysis equipment. These infections have generally produced few symptoms, and many episodes of bacteremia have cleared without antibiotic therapy. Complications such as hematogenous infection of the central nervous system or bone have been reported rarely *(443)*, and catheter removal to resolve intravascular catheter–related bacteremia sometimes has been necessary *(448)*.

Pseudobacteremia has been reported with a variety of nonfermenting gram-negative bacilli including *O. anthropi (455)*, *Achromobacter xylosoxidans (456)*, and *P. oryzihabitans (457)*.

Pneumonia

Prior to the 1980s, *P. aeruginosa* was isolated from fewer than 10% of patients with healthcare-associated pneumonia (30,*458,459*). Thereafter, the proportion of cases attributed to *P. aeruginosa* nearly doubled, and *P. aeruginosa* has been the most common pathogen or the most common gram-negative bacterium isolated from patients with healthcare-associated pneumonia *(459–461)*. It remains uncertain whether detection of *P. aeruginosa* in sputum obtained by expectoration or tracheal aspiration necessarily indicates a causative role in lower respiratory tract infection since tracheal colonization may be present without causing pneumonia *(462)*. Nonetheless, *P. aeruginosa* has been the leading gram-negative pathogen in several studies in which selected patients underwent bronchial lavage or protected brush sampling *(463–466)*.

Factors that predispose to *P. aeruginosa* pneumonia include cystic fibrosis *(467–469)*, other underlying chronic pulmonary diseases *(462,468–471)*, mechanical ventilation *(470–472)*, and hematologic malignancies *(468,472)*. The pathogenesis of infection can involve microaspiration of microorganisms colonizing the oropharynx but more often appears to be due to direct contamination of the trachea with microorganisms from environmental or patient reservoirs *(473–476)*. Once initiated, *P. aeruginosa* infection of the lungs may progress to a necrotizing bronchopneumonia. Radiographically evident cavitation sometimes develops *(471,477)*, and pathologic features include diffuse small necrotic nodules, areas of hemorrhage, and vasculitis of small arteries *(288,470,471)*.

Survival of patients with *P. aeruginosa* pneumonia was infrequent prior to the 1980s, when potent antipseudomonal antibiotics became available *(468,472,478,479)*. Bacteremic pneumonia had an especially dismal prognosis. In later studies, survival rates have reached about 50% *(470,480,481)*. However, in patients with severe pneumonia, the prognosis remains poorest when *P. aeruginosa* is the bacterial pathogen isolated from initial respiratory tract cultures or blood cultures *(479–481)*. VAP also appears to have a worse prognosis when *P. aeruginosa* is the pathogen *(482,483)*. Specific problems in the treatment of *P. aeruginosa* pneumonia are recurrence, even after treatment for several weeks *(470)*, and emergence of resistance to the antibiotics used during treatment *(480,481)*. Even when potent antibiotics such as ciprofloxacin or imipenem–cilastatin have been used, resistance has emerged in more than one fourth of cases *(481)*.

During the 1960s and early 1970s, respiratory therapy equipment was recognized to be a potential source from which nonfermentative gram-negative bacilli could be introduced into the respiratory tract *(483–487)*. Contaminated nebulizers were the major problem and were shown in an experimental model to cause *P. aeruginosa* pneumonia in mechanically ventilated dogs *(487)*. Other devices that produce aerosols, such as room humidifiers *(488)* and oxygen humidifiers *(488,489)*, also have been identified as potential sources of pseudomonal respiratory infection. Investigations in specialized care units have shown that tracheal acquisition of *P. aeruginosa* sometimes is preceded by gastrointestinal tract colonization and that sources of *P. aeruginosa* include the inanimate environment and other patients *(476,490–496)*.

In cystic fibrosis centers, acquisition of *P. aeruginosa* is a significant concern. Contamination of the environment has been detected in some clinics *(242)* but not in others *(495,497)*. Where environmental contamination is minimized by routine or contact isolation precautions, transmission is infrequent *(497–499)*.

P. aeruginosa is a rare cause of community-acquired pneumonia. The clinical presentation is nonspecific, but the disease may be rapidly fatal. Patients with previous hospitalization or antimicrobial therapy and underlying pulmonary disease seem to be at highest risk *(500)*. In previously healthy persons with community-acquired pneumonia, *P. aeruginosa* should be considered in the differential diagnosis for anyone with a smoking history who presents with rapidly progressive pneumonia *(501)*.

B. cepacia complex is a rare pulmonary pathogen except in patients with cystic fibrosis or chronic granulomatous disease *(502)*. Epidemic recovery of *B. cepacia* from respiratory specimens has been reported when contaminated lidocaine, tetracaine, or cocaine was used in bronchoscopy or otolaryngology procedures, but pneumonia did not occur *(503–505)*. In one outbreak, there was no reported evidence of clinical illness among 18 patients with *B. cepacia* respiratory tract colonization despite instillation into the respiratory tract of 10 mL of contaminated anesthetic containing up to 10^{10} CFU/mL *(503)*.

B. cepacia is an important respiratory pathogen in individuals with cystic fibrosis. Persistent infection with *B. cepacia* has been associated with worsening pulmonary status and increased mortality when compared with uninfected controls (154,*506–508*). The response to acquisition of *B. cepacia* appears to take one of two forms: about 25% of patients develop fulminant infection characterized by high fever, leukocytosis, and severe progressive respiratory failure, whereas the remaining patients, usually those with mild cystic fibrosis, have persistent colonization without evidence of significant adverse effect (154,*507*). Risk factors associated with acquisition of *B. cepacia* include older age, more advanced pulmonary disease, and exposure to *B. cepacia* from previous hospitalization or a sibling with *B. cepacia* colonization *(506)*.

B. cepacia pneumonia is a serious illness in individuals with chronic granulomatous disease *(509)*. Of note, 6 of 10 cases reported in the literature were not known to have chronic granulomatous disease before the occurrence of *B. cepacia* pneumonia *(509)*. Isolation of this unusual pathogen from patients with community-acquired pneumonia should prompt an evaluation of phagocyte function and screening for cystic fibrosis.

S. maltophilia typically occurs as a late-onset healthcare-associated infection. *S. maltophilia* pneumonia has been associated with previous antibiotic therapy, in particular imipenem and cefepime, tracheostomy, and severity of illness *(510,511)*. *S. maltophilia* has been associated with increased morbidity, but the attributable mortality is uncertain.

The respiratory tract is the most frequent site of *Acinetobacter* infection. In surveys, *Acinetobacter* has ranked from third to the ninth most common cause of VAP accounting for 3.0% to 8.4% of VAPs *(512–514)*. Healthcare-associated pneumonia usually occurs in debilitated ICU patients receiving prolonged mechanical ventilation and broad-spectrum antibiotics (104,*107*,*515–518*). Distinguishing colonization from infection in these patients can be very difficult. Although some investigators have reported very low morbidity associated with the recovery of *Acinetobacter* from ventilated patients *(519)*, others have described severe illness with mortality rates of 36% due to infection (104,*107*,*515*). These latter patients present with fever, purulent sputum, leukocytosis, and multilobar patchy infiltrates on chest radiograph.

Acinetobacter demonstrates a unique seasonal variation in the United States with infection rates twice as high during July to October than during November to June *(520)*. In contrast, rates of *P. aeruginosa* show little seasonal variation. The cause of seasonal variation in *Acinetobacter* infection rates is uncertain and may be important for the design of prevention measures.

Acinetobacter occasionally causes severe community-acquired pneumonia, especially in individuals with

underlying alcoholism and chronic obstructive pulmonary disease*(521–523)*. The illness manifests as an acute, fulminant pneumonia and has a mortality rate of up to 50%. Mortality is strongly associated with inappropriate antibiotic therapy *(521,522)*, which has been linked to misidentification of the bipolar gram-negative rods of *Acinetobacter* as overdecolorized pneumococci.

Other nonfermenters have been associated with respiratory tract colonization but cause little morbidity and little or no mortality *(502,524–527)*.

Urinary Tract Infection

P. aeruginosa adheres well to bladder uroepithelial cells, but is not a common cause of urinary tract infection *(528,529)*. It accounts for only about 10% of healthcare-associated urinary tract infections and ranks fourth in frequency at this site behind *Escherichia coli*, *Enterococcus*, and *Candida (512)*. The pathogenesis of infection, as elucidated from case clusters, primarily involves retrograde introduction of microorganisms into the bladder via urinary drainage catheters or contaminated urologic instruments *(530–532)*. Colonization of the rectum, perineum, or urethra may precede *P. aeruginosa* urinary tract infection *(533,534)*.

P. aeruginosa bacteriuria in catheterized patients often resolves spontaneously within 2 to 3 months *(535)*. Necrotizing infection of the bladder or kidney is extremely rare, and pyelonephritis as a complication of bacteriuria is uncommon *(531)*. Rates of secondary bacteremia in patients with *P. aeruginosa* urinary tract infection were 3.1% in an endemic setting and 4.5% in an epidemic setting *(531,536)*. Urologic procedures have induced *P. aeruginosa* bacteremia, but there is no evidence that the procedure-related risk is greater than for other uropathogens *(381,537,538)*.

P. aeruginosa has been reported to be the most common cause of clustered cases of urinary tract infection *(539)*. Case clusters have been linked to contaminated urologic instruments *(530,532,540)*, urine collection or measuring devices *(531,541–543)*, and cross-transmission due to contamination of the hands of personnel *(544)*. Where infected urine is not well contained, *P. aeruginosa* contamination of the perineum and hands of infected patients and of bed linen has been noted *(544)*.

Efforts to prevent catheter-related urinary tract infection by instilling a disinfectant into the drainage system or by using a silver oxide–coated catheter have not clearly helped against *P. aeruginosa (545,546)*.

Urinary tract infection with nonfermenters other than *P. aeruginosa* is notable for the lack of significant morbidity. All episodes occur in patients who have undergone urologic procedures or bladder catheterization, and most infections are asymptomatic and resolve spontaneously with catheter removal (104,*186,547–549*).

Burn Wound Infections

P. aeruginosa is one of the most common burn wound pathogens, and it has colonized or infected more than one fourth of patients in several series *(550–553)*. An increased extent of burn has been associated with an increased risk of both colonization and burn wound sepsis *(551,554)*. *P. aeruginosa* colonization or infection is almost always hospital-acquired *(242,283,553,554)*. Culture surveys to identify reservoirs of *P. aeruginosa* in burn units have yielded positive cultures from sinks and hydrotherapy equipment *(283,550,553)*. Only hydrotherapy equipment has been compellingly linked to cases. Strains of *P. aeruginosa* acquired during hospitalization have been matched to those in hydrotherapy equipment, and disinfection of the equipment or suspension of its use has been associated with outbreak termination *(283,553)*. Dispersal of *P. aeruginosa*, presumably from colonized or infected patients, has resulted in the contamination of air *(554,555)*, the hands of personnel *(554)*, and surfaces such as bed rails *(550)*, counters *(550)*, food trays *(554)*, and transport equipment *(553)*.

Measures to control *P. aeruginosa* in burn units have included topical treatment of burn wounds, aseptic practices to prevent acquisition, and aggressive systemic antibiotic treatment of infections *(283,552,553)*. The use of selective bowel decontamination regimens to suppress aerobic gram-negative bacilli in the alimentary tract has been proposed *(556)* but may be of limited benefit against microorganisms such as *P. aeruginosa*, which multiply primarily in the burn wound (see also Chapter 25).

Eye Infections

P. aeruginosa is a highly destructive ocular pathogen (31,*557,558*), and it has been reported to account for about 8% of postoperative ocular infections at one center *(559)*. Superficial infection may lead rapidly to corneal or scleral perforation, and endophthalmitis can cause complete loss of vision. Keratitis typically presents as an acute, rapidly progressive corneal ulcer with greenish pus and hypopyon *(560)*. Extension from cornea to sclera may occur and is associated with a poor outcome *(561)*. Postoperative endophthalmitis usually becomes clinically evident within 1 to 2 days but may evolve over 5 to 10 days *(562,563)*.

Several risk factors for *P. aeruginosa* ocular infection have been identified, and most apply to healthcare-associated cases. Keratitis may be a consequence of corneal trauma, corneal surgery, or treatment with multidose eye drops or eyewash solutions that became contaminated during use *(560,562,564,565)*. Scleral irradiation has preceded scleral and corneal infection *(566)*, and neutropenia has been associated with blepharoconjunctivitis *(567)*. Endophthalmitis usually has been a consequence of surgery, and case clusters have been traced to contaminated solutions or implants *(562,563,568)*.

Sporadic cases and clusters of cases of *P. aeruginosa* conjunctivitis have been recognized in patients receiving respiratory care *(569–573)*. Almost all the patients were intubated, had *P. aeruginosa* in their respiratory secretions, and had frequent suctioning to remove respiratory secretions. Strikingly, infection involved primarily the left eye in almost all adult cases *(568,569)*. Hilton et al. *(569)* explained the left eye predominance by showing that *P. aeruginosa* in respiratory secretions was dispersed during suctioning and that nurses usually withdrew suction catheters diagonally across the left side of patients' faces. Cases of healthcare-associated conjunctivitis in newborn infants also have been reported and were traced to contaminated incubators *(574)* (see also Chapter 26). *S. maltophilia* is a rare cause of postoperative endophthalmitis after cataract surgery *(575,576)*. Other nonfermenters are occasionally isolated from conjunctival swabs but are rare causes of infection *(572,577,578)*.

Meningitis

Healthcare-associated meningitis caused by nonfermentative gram-negative bacilli is almost always a complication of neurosurgical procedures. *Pseudomonas* and *Acinetobacter* have been the predominant nonfermenters, accounting for about one fourth to one half of cases of postneurosurgical gram-negative meningitis in adults *(579–582)*. *P. aeruginosa* is also an important cause of meningitis in burn unit patients *(583)* and has caused healthcare-associated meningitis in patients hospitalized for cranial trauma *(584)*.

Investigations of cases of *P. aeruginosa* meningitis several decades ago implicated contaminated medications that had been injected intrathecally *(585,586)* and a contaminated shaving brush used in neurosurgical patients to prepare the site for incision *(587)*. The sources of *P. aeruginosa* causing recent cases have not been reported.

The first reported cases of *Acinetobacter* meningitis were community acquired *(588,589)* and the early genus name *Mima* ("mimic") arose from the frequent misidentification on Gram stain of the bipolar staining rod as *Neisseria meningitides (590)*. *Acinetobacter* meningitis was later reported almost exclusively in association with neurosurgical procedures or cranial trauma *(590,591)*. Occasional cases have occurred in neonates in the absence of invasive procedures *(592)*. Patients with *Acinetobacter* meningitis usually are receiving antibiotic therapy at the onset, and clinical features include fever (95%), mental status changes (50%), neck stiffness (25%), cerebrospinal fluid pleocytosis (100%), and low cerebrospinal fluid glucose (60%) *(591)*. Half of the recent cases have been polymicrobial. The overall mortality rate is about 20%, and survival is associated with prompt appropriate therapy. Sources of *Acinetobacter* causing healthcare-associated meningitis have not been identified. Other nonfermentative gram-negative bacilli have caused sporadic cases of meningitis *(593–598)*.

Surgical Site Infection—Osteomyelitis

Overall, *P. aeruginosa* has been isolated from about 9% of surgical site infections *(599)*. The relative frequency of *P. aeruginosa* as a pathogen is high at some sites such as sternotomy for cardiac surgery *(600–602)*, whereas *P. aeruginosa* accounts for only a few percent of infections following implantation of prosthetic joints *(603,604)*. Because of its virulence, the presence of *P. aeruginosa* in an incisional surgical site at the time of closure has been associated with a risk of subsequent surgical site infection exceeding 30% *(605,606)*. Administration of perioperative antibiotics directed against *P. aeruginosa* appears to diminish the risk *(606)*. Although an uncommon cause of osteomyelitis, *P. aeruginosa* was associated with more than a twofold risk of recurrence compared with infection with *Staphylococcus aureus (607)*.

The source of *P. aeruginosa* causing infection after intra-abdominal operations is generally considered to be the patient *(605,606)*. Exogenous sources in the operating theater have been sought to explain infections following other types of surgery, and positive cultures have been reported from a water bath *(371)*, a scrub sink faucet *(608)*, suction pumps for chest tubes *(608)*, and an arterial pressure monitoring system *(609)*. One cluster of cases of *P. aeruginosa* surgical site infections was attributed to the preparation of the skin incision site with a dilute solution of chlorhexidine contaminated with *P. aeruginosa (187)*, and another cluster, involving orthopedic patients, was traced to contaminated plaster-of-Paris bandages *(610)*.

Acinetobacter is a frequent isolate from skin, and recovery of the microorganism from surgical sites is not surprising. *S. maltophilia* and *B. cepacia* also have been recovered from surgical sites, but typically in mixed culture *(611,612)*. The clinical significance of these microorganisms in surgical site cultures is often uncertain. *Acinetobacter* has been reported as a frequent cause of wound infections complicating combat-related injuries in military personnel; the source of the *Acinetobacter* appears to be the medical facilities rather than the battlefield environment *(*613,*614)*.

EPIDEMIOLOGY

Rates of Healthcare-Associated Infection

The frequency of nonfermentative aerobic gram-negative bacilli as healthcare-associated pathogens has been characterized through the National Nosocomial Infection Surveillance system *(615)*. *P. aeruginosa* and *Acinetobacter* have become increasingly important causes of healthcare-associated pneumonia, surgical site infections, and urinary tract infection (see Table 35-1).

Inanimate Reservoirs

Extensive culture studies have been conducted, mostly during the 1950s and 1960s, to identify hospital sources of nonfermentative gram-negative bacilli. As summarized in Table 35-2, these microorganisms have been found in virtually every moist area of the hospital, many fluids, and an array of equipment and surfaces that were exposed to the hands, secretions, and excretions of patients. Recognition that these microorganisms are ubiquitous has prompted increased attention to aseptic practices, particularly in the use of respiratory equipment *(691)*. Nonetheless, nonfermentative gram-negative bacilli continue to test the adequacy of aseptic practices and to find deficiencies in product manufacturing (*183,186,201,222*,376,*434,664*) and in disinfection of medical devices for reuse *(179,374–380,382,383,568,632,665)*.

The major vehicles by which *P. aeruginosa* is conveyed into hospitals are tap water and food. Tap water is increasingly recognized as a potentially important reservoir for healthcare-associated acquisition of *P. aeruginosa* colonization and infection. One survey found that 14.2% to 50% of *P. aeruginosa* colonization or infection episodes were due to tap water genotypes (715,*716*). The use of point-of-use water filtration has been associated with a significant reduction in positive cultures for *P. aeruginosa* from tap water and a significant reduction in the incidence of infections due to *P. aeruginosa* and other nonfermenting gram-negative bacilli *(616,620,717)*. Vegetables are the most commonly contaminated foods, and rates of positive cultures of salads have ranged from 11% to 44% *(172,696–700)*. The concentration of *P. aeruginosa* in individual vegetables or in salads has ranged up to 10^3 CFU/g *(172,698–700)*.

Studies to ascertain whether environmental isolates of *P. aeruginosa* cause colonization or infection of patients have implicated most of the potential sources listed in Table 35-2. The major exceptions are sinks, drains, and

TABLE 35-1

Percentage and Rank Order of *Pseudomonas aeruginosa* and *Acinetobacter* Species Related to Healthcare-Associated Infection Reported to the National Nosocomial Surveillance System, 1975 and 2003

		Percentage of Isolates (Rank Order)	
Pathogen	***Site***	***1975***	***2003***
Pseudomonas aeruginosa	Pneumonia	9.6 (3)	18.1 (2)
	Bloodstream infection	4.8 (6)	3.4 (6)

suction apparatus. Typing of isolates from serial cultures of patients and sinks has shown that patients typically become culture-positive first and that there are at most a few occasions when the sink or drain might have been the source of patient colonization *(171,642,655,656,659)*.

Animate Reservoirs

Colonization of patients by *P. aeruginosa* constitutes an important reservoir, particularly in specialty care units where patients are exposed to broad-spectrum antibiotics, medical devices, and the hands of healthcare personnel. Culture studies have shown colonization rates of 4% to 58% in hematology–oncology patients *(171,172,718,719)*, 13% to 39% in ICU patients *(643,644,657,720–722)*, 19% to 43% in surgery patients *(639,721)*, and 2% to 51% in special care baby units *(723,724)*. Factors in individual studies that are associated with an increased risk of colonization include prior hospitalization *(639,644)*, age above 65 years *(676)*, endotracheal intubation *(639)* and mechanical ventilation *(635)*, tracheostomy *(722)*, broad-spectrum antibiotic therapy *(643,722)*, previous gastrointestinal surgery *(721)* including ileostomy or colostomy *(639)*, and anemia *(721)*. *P. aeruginosa* is often acquired after admission, and the proportion of patients with positive cultures usually increases by at least 50% during hospitalization *(172,639,643,644,721,723)*. The most common site from which *P. aeruginosa* is recovered is the rectum, and in most studies at least 80% of colonized patients can be detected by cultures of that site *(172,255,643,644)*. The pharynx is usually the second most common culture-positive site *(255,644,719,721)*, although higher carriage rates occasionally have been reported for the perineum or urine *(171,724)*. In a culture study of intestinal contents of 100 cadavers, Stoodley and Thom *(725)* demonstrated that when *P. aeruginosa* was present, it usually could be recovered from both the small intestine and colon and that rates of isolation were about half as high in the jejunum as in lower segments of the gut. The concentration of *P. aeruginosa* has reached 10^6 to 10^7 CFU/g of feces in a patient receiving broad-spectrum, orally administered, nonabsorbable antibiotics for total digestive decontamination *(255)*. In that patient, colonization persisted for at least 5 months.

Hospital personnel infrequently are a reservoir for *P. aeruginosa*. Rates of positive cultures from stool have been <13% *(587,643)*, and the concentration of microorganisms may be too low to be detected by rectal swab *(643)*. Other sites such as nose, throat, or skin may be culture-positive in up to 5% of personnel caring for colonized patients *(554)*. Hand colonization for at least 4 weeks has been reported in a nurse *(644)*.

Acinetobacter is present on the skin in up to one fourth of normal individuals and about one third of hospitalized patients *(726,727)*. Sites that are most frequently culture positive are intertriginous areas such as the toe web and groin. Oropharyngeal or rectal carriage is uncommon, except in patients in ICUs *(728,729)*. The hands of hospital personnel have been sampled for *Acinetobacter*, and the proportion of individuals with at least one positive specimen from serial cultures is about one third *(648,726)*. Persistent colonization of the hands of a respiratory therapist has been reported *(648)*. The frequency of hand colonization by *S. maltophilia* has not been investigated other than in response to outbreaks of infection. During an ICU epidemic, half of the hand cultures from nurses and respiratory therapists were positive *(175)*. *S. maltophilia* rarely is present in stool of outpatients with diarrhea but has been detected in feces of one third of hematologic malignancy patients *(349)*. *B. cepacia* is rarely recovered from sites other than the respiratory tract of patients with cystic fibrosis *(722,730)*. Prior broad-spectrum antibiotic therapy appears to be an important risk factor for colonization or infection by *S. maltophilia* or *Acinetobacter* *(175,404,422,423,731)*.

Transmission

Healthcare-associated transmission of *P. aeruginosa* almost always results either from contact with environmental sources or from patient-to-patient spread via the hands of healthcare personnel. Possible transmission from environmental sources usually has been examined in response to case clusters or unusual clinical events. Even though many

of the early studies did not utilize rigorous epidemiologic methods or *P. aeruginosa* typing systems, plausible circumstantial evidence was provided for transmission from most of the sources listed in Table 35-2. Later studies in which patients and environmental isolates were typed confirmed that contaminated items, such as water *(386,553,716)*, food *(172)*, antiseptics *(199)*, endoscopes *(377,378,380)*, cystoscopes *(381)*, and bronchoscopes (376,*664*), can transmit *P. aeruginosa* to patients. Such transmission occurs infrequently when standard aseptic practices are followed *(171,644)*.

Patient-to-patient transmission of *P. aeruginosa* is documented by prospective studies in which periodic surveillance cultures of patients, personnel, and the environment were performed. Patient-to-patient transmission was considered to occur when a patient acquired a strain of *P. aeruginosa* that matched that of another patient and that was not present in any likely environmental source. Instances of apparent cross-transmission have been noted in increased risk settings, such as ICUs *(492,644,722,732)*, hematology/oncology units *(172,255)*, and pediatric units *(491,659,660)*. Contaminated hands of personnel are the likely vehicle of cross-transmission, and numerous investigations have demonstrated frequent *(476,494,554,644,660,733)* or occasional *(493,734–736)* positive cultures of hands. During routine care and in designed experiments *(491)*, the hands of personnel have become contaminated, especially after contact with heavily colonized patients *(644)*, exudates *(554)*, secretions

(476,644), or excretions *(622,734)*. The frequency of patient-to-patient transmission by personnel probably reflects the inadequacy of staffing, availability of gloves, hand disinfectant solution, and handwashing sinks, as well as attention to hand hygiene and other aseptic practices.

There is compelling evidence that when proper aseptic practices are observed, many apparent acquisitions of *P. aeruginosa* represent the emergence of strains carried in the alimentary tract at concentrations below the threshold of detection. Careful long-term studies in ICUs *(660,737)* and an oncology ward *(172)* showed that "acquisitions" often represent an array of *P. aeruginosa* types that do not match those isolated from environmental or patient reservoirs.

Clusters of cases of colonization or infection with other nonfermenters are usually caused by direct exposure to contaminated fluids or medical devices. Infection is facilitated by breaches in the normal host defenses by endotracheal tubes, intravenous catheters, hemodialyzers, peritoneal dialysis catheters, ventriculostomy tubes, or indwelling urinary catheters. Culture studies and epidemiologic findings sometimes suggest patient-to-patient transmission of *S. maltophilia* via the hands of personnel *(175,516,731)*. *S. maltophilia* is also found in tap water and tap water isolates have been linked to infection *(617)*. Investigations of ICU outbreaks of colonization and infection by *Acinetobacter* have demonstrated multiple likely modes of transmission involving the environment and the hands of personnel. Cultures of surfaces *(109,160,315,326,689,690,728,738–740)*, equipment *(109, 649,658,668,690,729,739)*, hands of personnel *(109,690,739,740)*, and latex gloves worn by personnel *(649,729)* are commonly positive. *Acinetobacter* is notably resistant to desiccation, persisting on dry surfaces for a mean of 27 days *(250)*. This remarkable durability along with intrinsic resistance to antibiotics and disinfectants undoubtedly contributes to persistent outbreaks. Barrier or contact isolation precautions have been at least partly effective in controlling outbreaks *(649,729,738,739)*; in addition, closure of units temporarily for cleaning, disinfection, and/or repainting has been useful in some *(315,690,738)* but not all *(729)* settings. Air samples taken near culture-positive patients have yielded *Acinetobacter (690,738)*, and transmission via droplets is plausible but airborne transmission has not been proven. Conflicting findings about a possible summer peak in the incidence of *Acinetobacter* infections have been reported *(223,312,422,500,516,591,690,741,742)*.

CHAPTER 36

Legionella

Janet E. Stout, Angella M. Goetz, and Victor L. Yu

HISTORY

An explosive outbreak of community-acquired pneumonia occurred in July of 1976. The outbreak was among attendees of the American Legion Convention at a hotel in Philadelphia, PA *(1)*. Six months later, the causative agent was isolated from the lung tissue of Legionnaires' cases by scientists at the Centers for Disease Control and Prevention (CDC), Atlanta, GA *(2)*. The microorganism, an aerobic gram-negative bacterium, was named *Legionella pneumophila*. The pneumonia became known as Legionnaires' disease because the outbreaks occurred in attendees at the American Legion Convention. The first reported epidemic of healthcare-associated *Legionella* pneumonia was identified retrospectively. It occurred in July 1965 at St. Elizabeth's Hospital, a psychiatric institution in Washington, DC *(3)*. In this outbreak, 81 patients were afflicted, with an attack rate of 1.4%. It was not until 1980 that hospital water distribution systems were first implicated as the source for healthcare-associated Legionnaires' disease. Tobin isolated *Legionella* from showerheads in the hospital room of a patient with healthcare-associated Legionnaires' disease *(4)*. *Legionella* was subsequently isolated from potable water distribution systems of numerous hospitals experiencing outbreaks of Legionnaires' disease *(5–9)*.

MICROBIOLOGY

The Legionellaceae family has been characterized as one monophyletic family belonging to the gamma subdivision of the class Proteobacteria *(10)*. Although a single genus and species (*L. pneumophila*) was originally proposed for the family Legionellaceae *(11)*, the Legionellaceae family now contains >50 species and >70 serogroups in the genus *Legionella (12–14)*. Approximately half of these *Legionella* species have been implicated in human disease *(15)*. Among the species, *L. pneumophila* is responsible for 90% of infections (Table 36-1) *(15–17)*. These microorganisms are facultative intracellular gram-negative bacteria found in natural and man-made water systems. They are saprophytic water bacteria that can be intracellular parasites of protozoa (in water) and macrophages and epithelial cells in humans *(18)*. Most cases of legionellosis are caused by *L. pneumophila* serogroups 1, 4, and 6 *(13,17,19)*.

Other species implicated in human infection include *L. micdadei* (the Pittsburgh pneumonia agent), *L. bozemanii*, *L. dumoffii*, *L. tucsonensis*, *L. cincinnatiensis*, *L. feeleii*, *L. longbeachae*, and *L. oakridgensis (15,20)*. *L. longbeachae* is responsible for approximately 30% of Legionnaires' disease in Australia and New Zealand *(15)*. Most patients with nonpneumophila *Legionella* species infections have been severely immunocompromised because of corticosteroid therapy, organ transplantation, or malignancy (*21*,22,*23*,*24*).

Legionella species are small (0.3–0.9 μm in width and ~2 μm in length), faintly staining gram-negative rods with polar flagella (except *L. oakridgensis*) *(25)*. They generally appear as small coccobacilli in infected tissue or secretions, whereas long filamentous forms (up to 20 μm in length) can be seen when they are grown in culture media. Legionellaceae are obligately aerobic slow-growing nonfermentative bacteria. They are distinguished from other saccharolytic bacteria by their requirement for L-cysteine and iron salts for primary isolation on solid media and by their unique cellular fatty acids and ubiquinones. Differences among species have been assessed by phenotypic *(26)* and chemotaxonomic tests. Phenotypic tests include composition of lipopolysaccharides, electrophoretic protein profiles, monoclonal antibodies, fatty acid composition, and cellular carbohydrates. Genotypic tests include random amplified polymorphic DNA profiles, heteroduplex analysis of 5S ribosomal RNA (rRNA) gene sequences, and computer-assisted matching of transfer DNA–intergenic length polymorphism patterns, and sequence-based typing *(27–29)*.

The microorganism can be visualized, with some difficulty, with Gram stains of clinical specimens taken from normally sterile sites (e.g., pleural fluid). Both the Gram and Gimenez stains can be used for clinical specimens, whereas silver impregnation stains, including the Dieterle and Warthin–Starry stains, can be used for paraffin-fixed tissue sections. *L. micdadei* (Pittsburgh pneumonia agent) can stain weakly acid-fast in tissue with Kinyoun and Fite stains and on smears with a modified acid-fast stain in tissue or sputum specimens. These microorganisms are nutritionally fastidious and do not grow on standard bacteriologic media, which explains why the microorganism was so difficult to isolate in the original American Legion outbreak.

TABLE 36-1

Proportion of Legionnaires' Disease Caused by Species and Serogroups of *Legionella*

Species, Serogroup	*All Isolates (%) (n = 2,340)*	*Community-Acquired Infections (%) (n = 1,259)*	*Hospital Infections (%) (n = 890)*
Legionella pneumophila	91.4	90.7	93.6
Serogroup 1	50.5	49.6	52.5
Serogroup unknown	32.1	33.9	28.2
Serogroup 2	1.2	1.4	1.1
Serogroup 3	2.0	1.5	2.9
Serogroup 4	1.1	1.0	1.3
Serogroup 5	1.1	0.8	1.7
Serogroup 6	2.9	1.7	5.2
Serogroups 7–14	0.5	0.8	0.7
L. bozemanii	1.3	1.3	1.2
L. dumoffii	1.5	1.4	1.0
L. gormanii	0.2	0.2	0.2
L. micdadei	2.8	2.8	2.8
L. feeleii	0.2	0.2	0.2
L. longbeachae	2.2	3.3	0.7
L. jordanis	0.3	0.2	0.1

Note: Only isolates identified by culture are included.
(From Benin AL, Benson RF, Besser RE. Trends in Legionnaires' disease, 1980–1998: declining mortality and new patterns of diagnosis. *Clin Infect Dis* 2002;35:1039–1046, with permission.)

PATHOGENESIS

Legionnaires' disease can be acquired by the inhalation of aerosols containing *Legionella* or by aspiration of water or respiratory secretions containing *Legionella (12)*. Other possible modes of transmission include direct inhalation or hematogenous dissemination from other foci of infection *(30)*. Pneumonia is the presenting clinical syndrome in almost all cases of healthcare-associated legionellosis *(31)*. Although rare, extrapulmonary *Legionella* infection has been documented *(30,32–34)*.

Cigarette smokers, patients with chronic pulmonary disease, and alcoholics are at increased risk for Legionnaires' disease. For such individuals, mucociliary clearance is impaired and aspiration is common. As a barrier to entry, mucociliary clearance can be overcome by adherence of the microorganism to respiratory epithelial cells. After aspiration or inhalation, *Legionella* attaches to respiratory epithelial cells. Legionellae possesses pili that are known to mediate adherence to epithelial cells *(15)*. A gene has been identified that demonstrates homology to the type IV pilin genes in other bacteria. *Legionella* has also been detected in oropharyngeal secretions of transplant patients (35), and symbiosis has been shown *in vitro* between oropharyngeal flora and *Legionella (36)*.

Legionella is an intracellular pathogen both in humans and in aquatic environments (*15,37*,38). It has been suggested that the ability of *L. pneumophila* to replicate in protozoa is closely linked to its ability to replicate in human macrophages *(15)*. *Legionella* survives and multiplies as parasites of single-celled protozoa in freshwater and moist soil *(39)*. Virulence may be increased by replication in amoebae. In humans, cell-mediated immunity plays the central role in host defense against *L. pneumophila* as it does against other intracellular pathogens. *Legionella* replicates within mononuclear phagocytes, primarily monocytes, and alveolar macrophages *(40)*. Phagocytosis occurs through a process mediated by complement component C3 and outer membrane proteins such as the macrophage infectivity potentiator (Mip) protein. The uptake of *L. pneumophila* is considered a virulence-directed process that is a consequence of properties of the organism *(15)*. The macrophage readily phagocytoses *Legionella*, a process that is more avid in the presence of specific opsonizing antibody. Once inside the cell, the microorganism evades phagosome–lysosome fusion, converts to a replicative form that is acid tolerant, and multiplies until the cell ruptures (38). Liberated bacteria are phagocytosed by newly recruited cells, and the cycle of ingestion, multiplication, and liberation with cell lysis begins anew.

Although the resident alveolar macrophage normally degrades most microorganisms, *Legionella* is able to subvert this host defense. *L. pneumophila* evades destruction by inhibiting phagosome–lysosome fusion (38). Genes responsible for this survival mechanism have been identified as components of the Dot/Icm secretion system, which is required for intracellular replication and establishing the *Legionella*-containing vacuole *(41)*. Intracellular growth and formation of a replication vacuole requires the products of >26 *L. pneumophila dot/icm* genes *(42)*. This Dot/Icm type IV secretion system is used by *Legionella* to inject effector proteins into host cells to modulate host organelle function *(12,23)*.

Intracellular multiplication of *Legionella* within human monocytes also depends on the availability of iron *(45)*. The lymphokine interferon-γ (IFN-γ) stimulates human

alveolar macrophages and monocytes to resist *Legionella* infection by upregulating reactive oxygen production and downregulating cellular iron content. An analysis of Legionnaires' disease patients showed that they produced less IFN-γ than did non-Legionnaires' disease patients. Impaired IFN-γ response may increase susceptibility to the disease *(43)*. Other cytokines and hemopoietic growth factors, such as interleukin-10 (IL-10) and granulocyte-macrophage colony-stimulating factor, have not been shown to enhance anti-*Legionella* activity *(44)*. Significant rises in the T Helper-1 cytokines IFN-γ and IL-12 were detected in the serum of patients with Legionnaires' disease, supporting the importance of cellular immunity in this disease *(45)*. Neutrophils are less important, and neutropenic patients are not at undue risk for Legionnaires' disease. Nevertheless, *L. pneumophila* is susceptible to oxygen-dependent microbicidal systems *in vitro*. Neutrophils inhibit *Legionella* growth but lack the capacity to kill *L. pneumophila*. Lysis of infected macrophages by lymphokine-activated killer cells or natural killer cells may also be an important cell-mediated immune function for eliminating intracellular *Legionella*. It appears that *Legionella* is resistant to the direct bactericidal functions of neutrophils, but a requirement for neutrophils in the induction of IFN-γ by natural killer cells has been demonstrated *(46)*.

Humoral immunity plays a secondary role in host defense against *Legionella* infection. Patients with Legionnaires' disease have measurable type-specific antibodies (immunoglobulin M and immunoglobulin G) within several weeks of infection. Antibodies do not promote complement-mediated killing nor inhibit intracellular proliferation *(14,47)*. Moreover, immunized animals and patients develop a specific antibody response with subsequent resistance to *Legionella* challenge.

A number of factors have been postulated to contribute to the virulence of *L. pneumophila*: type I and type II secretion systems, a pore-forming toxin, type IV pili, flagella, a *Legionella* toxin, a 24-kd protein called Mip, a zinc metalloprotease, and proteases including enzymes that scavenge reduced-oxygenated metabolites *(15)*.

Strains of *L. pneumophila* differ in virulence. *L. pneumophila* serogroup 1 is known to cause most cases of Legionnaires' disease *(17)*. Although multiple strains of *L. pneumophila* serogroup 1 may colonize water distribution systems, only a few strains are likely to cause disease in patients exposed to the water *(48)*. Monoclonal antibody subtyping of strains of *L. pneumophila* serogroup 1 has shown that a surface epitope recognized by one particular monoclonal antibody (MAB-2/MAb3/1) may be associated with virulence. The immunodominant part of this virulence-associated epitope has been identified as the 8-0-acetyl group of the 0-specific polysaccharide chain of the lipopolysaccharides *(49,50)*. A correlation between virulence-associated MAB-2/MAb3/1 epitope and charge density of the *Legionella* envelope may be the factor that discriminates highly virulent from less virulent strains *(51)*.

Legionella species other than *L. pneumophila* appear to be less virulent and occur almost exclusively among immunocompromised hosts. They also respond more readily to antibiotic therapy *(20,52)*.

EPIDEMIOLOGY

Legionella is now the single most common cause of outbreaks involving drinking water *(53)*. Most legionellosis outbreaks associated with drinking water occurred in healthcare facilities, and nursing homes (54). Heffelfinger et al. *(55)* reported that 25% of 152 hospitals surveyed had reported cases or outbreaks of healthcare-associated Legionnaires' disease from 1989 to 1998. Although legionellosis is a reportable disease in many countries including the United States, the extent of this infection is still uncertain. Underestimates are likely due to cases that are overlooked because of the persistent lack of availability and utilization of the specialized laboratory tests needed to make the diagnosis *(16,56,57)*. The CDC has reported significant increases of legionellosis in the United States by analyzing data submitted to the National Notifiable Disease Surveillance System. There was an increase of 1300 cases in 2002 to over 2000 cases yearly through 2005 (58). The minimum number of *Legionella* cases annually is estimated at 18,000 and approximately 25% are healthcare associated (*16*,59). CDC also reviewed *Legionella* case report data from 2005 to 2007 submitted to the Legionnaires' Disease Supplemental Surveillance System and found that acute care hospitals accounted for 88% of the cases, with long-term care and rehabilitation facilities accounting for 12% of reported cases. The study documented that healthcare-associated Legionnaires' disease continues to have a high case-fatality rate (34%). In a study of reported cases of Legionnaires' disease in western Pennsylvania, Squier et al. also found a high mortality rate for healthcare-associated cases (38–53%), which is significantly higher than the 20% rate identified for community-acquired cases (*16*,59). Consequently, Legionnaires' disease should be considered in the differential diagnosis for all pneumonia cases with prior acute care facility exposure, particularly the elderly, smokers, immunosuppressed patients, and those with chronic lung disease *(60–62)*.

More extensive use of *Legionella* diagnostic testing has revealed that many patients with Legionnaires' do not fall into these typical risk groups. Squier et al. (59) found that 22% of the reported cases did not have any of the typical risk factors. This trend was also identified in a large study in the Netherlands *(63)*. These studies further emphasize the need for clinicians to include *Legionella* in the differential diagnosis of healthcare-associated pneumonia. The variable infection rates among individuals reflect a dependence on multiple variables. These include a contaminated potable water system with *Legionella*, exposure of the host to the contaminated water, susceptibility of the patient exposed, and recognition of the disease by the physician.

Since 1986, legionellosis has also been monitored in Europe. Reports show *Legionella* species to be a common cause of pneumonia, with *L. pneumophila* being the most predominant *(23)*.

Situations labeled as sporadic cases of *Legionella* may represent a chance discovery of the disease occurring at a low endemic period. Likewise, situations labeled as epidemic may represent a cyclical peak at a healthcare facility with endemic but previously undiscovered cases.

Cases surface because of a combination of circumstances: improved diagnostic methods, clinical suspicion of Legionnaires' disease by an individual physician, or

isolation of the microorganism from open lung biopsy or postmortem lung culture *(21)*.

Routine testing for Legionnaires' disease at autopsy identified eight cases of healthcare-associated *Legionella* at a regional transplant center in the southwestern United States *(64)*. The occurrence of three cases in early 1996 led to a retrospective review, which suggested that transmission had occurred for >17 years. An additional 14 cases were identified for a total of 25 culture-confirmed cases of Legionnaires' disease. Thus, situations labeled as sporadic or nonepidemic may merely represent chance discovery of disease occurring at a low endemic level. Likewise, situations labeled as "epidemic" may merely represent a cyclical peak at a hospital with endemic but previously undiscovered disease.

Consistently identified risk factors for Legionnaires' disease include advanced age, males, smoking, alcohol abuse, chronic pulmonary disease, and immunosuppression (malignancy, corticosteroid use). Males are affected at two to three times the rate of women; this may be related to cigarette smoking or underlying medical conditions (e.g., chronic obstructive pulmonary disease). Attributable mortality for Legionnaires' disease is approximately 20%; however, the likelihood of death from *Legionella* infection increases in patients who are younger than 1 year, elderly, or male, with healthcare-associated infection, renal disease, predisposing underlying conditions such as malignancy, or immunosuppression, or delayed administration of appropriate antimicrobial therapy *(23,56,64)*. Mortality can be as high as 40% for healthcare-associated cases *(16)*. When Jespersen et al. *(65)* compared mortality rates between community-acquired and hospital-acquired legionellosis, they found case-fatality rate to be three times higher in the hospital-acquired group.

Healthcare-associated infections due to *Legionella* occur most frequently in immunosuppressed hosts. The patients at highest risk are organ transplant and hematopoetic stem cell transplant recipients *(66)*. During an outbreak in an acute care hospital, 55% (5/9) of all patients undergoing kidney transplantation developed Legionnaires' disease over a 5-month period *(67)*. Healthcare-associated *Legionella* infection has been reported in renal *(67,68)*, heart *(64,69–71)*, and bone marrow transplant recipients *(64,71,72)*. Corticosteroids are an important independent risk factor. Neoplastic disease, diabetes, and renal failure are often cited as risk factors. The broader use of diagnostic testing may result in more patients being identified without these classic risk factors. A retrospective review of over 400 cases of Legionnaires' disease in the Pittsburgh area showed that 25% of reported cases did not have the classic risk factors *(73)*.

There is an association of Legionnaires' disease with surgery. In the past, up to 40% of cases reported in the literature occurred in surgical patients *(74)*. More recently, *Legionella* is mostly related to solid organ transplantation and to a lesser degree to head and neck surgery. Healthcare-associated *Legionella* infection increased with the use of general anesthesia and endotracheal intubation *(64,75,76)*.

Surprisingly, neutropenic or leukemic hosts appear to have an attack rate no higher than that of the general population. The exception is patients with hairy cell leukemia *(77,78)*. Likewise, the risk of *Legionella* infection in the HIV-infected patient appears to be no greater than other high-risk populations, with reports of <1% to 4% *(52)*. However, these patients are prone to extrapulmonary manifestations, bacteremia, and lung abscesses.

Increasing use of diagnostic tests for *Legionella* has led to new risk groups of patients being discovered as susceptible victims for Legionnaires' disease. They include immunocompromised children in pediatric hospitals colonized with *Legionella* and elderly patients residing in long-term care facilities and rehabilitation centers colonized by *Legionella*.

In a CDC survey of reported pediatric legionellosis cases, 72% were healthcare-associated; the source was related to exposure to tap water *(79)*. A review of published reports by Yu and Lee showed that an outbreak involving 11 neonates and another 2 related to "water-birth" delivery were all related to exposed to contaminated water. However, the percentage of tap water site positivity was not reported (80).

Healthcare-associated cases have been reported in immunosuppressed children *(71,81,82)* and children with underlying pulmonary disease (*30*,80,*83*). In three hospitals in which epidemiologic investigations were conducted *(81,83,84)*, a link to the hospital water supply was made.

Pneumonia in long-term care facilities has increased in recent years as the population of this group increases. However, it often is unclear if the cases should be considered community-acquired or healthcare-associated pneumonia. Increased reports of Legionnaires' disease has occurred in assisted-living and long-term care facilities (59). Legionellosis is not a diagnosis typically sought out in this setting. Implementing *Legionella* prevention guidelines in western Pennsylvania raised the index of suspicion, and as a result, the proportion of cases of healthcare-associated Legionnaires' disease diagnosed in long-term care facilities went up from 4% to 65% (59). One investigation in Canada identified *Legionella* in the potable water supply as the source for two outbreaks in nursing homes *(85)*. Aspiration was presumed to be the mode of transmission. In one outbreak, eating pureed food was a significant risk factor for *Legionella*, consistent with aspiration originating from a swallowing disorder *(85)*. In another prospective study, *L. pneumophila* serogroup 1 was isolated from a newly constructed long-term care facility *(86)*. Six cases of Legionnaires' disease were diagnosed over 2 years. DNA subtyping established that the patient isolates were identical to the environmental isolates from the water supply.

In a 10-year report of nursing home–acquired pneumonia by Polverino et al. *(87)*, 150 cases were analyzed. *L. pneumophila* was found in 5% of cases; etiology was reported in only 57 cases. The authors reported inadequate treatment and lack of aspiration assessment.

The CDC and the European Working Group for Legionella Infection have surveyed travel-associated Legionnaires' disease in the United States and Europe. They report an 85% increase from 2005 to 2008. Thus, a careful travel history is important to avoid the assumption that these cases might be related to a healthcare facility *(12)*.

Reservoir

The environmental ecology of *Legionella* is particularly pertinent in that Legionnaires' disease is a pneumonia

that theoretically could be prevented with eradication of the microorganism from its reservoir. The natural habitat for *Legionella* appears to be aquatic bodies including rivers, streams, and thermally polluted waters, although *L. longbeachae* has been isolated from moist soil in Australia *(88)*. Natural aquatic bodies contain only small numbers of *Legionella*. Since *Legionella* tolerates chlorine, the microorganism easily survives the water treatment process and passes into water distribution systems but, again, only in small numbers *(89,90)*.

Subsequent growth and proliferation also occur in man-made habitats, especially water distribution systems, which provide favorable water temperatures (25°C–42°C), physical protection (biofilm), and nutrients *(91)*. The single most important factor appears to be temperature. The microorganism is readily found at the bottom of hot water tanks—a relation that parallels its propensity for colonization in thermally polluted rivers. Interestingly, bacteria populating hot water tanks were more likely to demonstrate a symbiotic relationship with *L. pneumophila* than bacteria populating cold water tanks *(92)*. Bacteria, protozoa, and amoeba also colonize water pipe surfaces, some of which have been shown to promote *Legionella* replication. *Legionella* and other microorganisms attach to surfaces and form biofilms on pipes throughout the water distribution system *(93)*. Water pressure changes that disturb the biofilm may dramatically increase the concentration of *Legionella (94)*.

Healthcare facilities with hot water distribution systems colonized with *L. pneumophila* were significantly more likely to have lower water temperatures (<140°F), have a vertical configuration, be older, and have elevated calcium and magnesium concentrations in the water (*95*). Cold water sources, such as ice machines and fountains, have also been implicated as a source of healthcare-associated infection (*96*). *L. pneumophila* serogroup 8 infection was diagnosed by culture in 13 patients over an 8-month period (*97*). This was determined to be a "pseudo-outbreak" traced to immersing syringes containing saline for bronchoscopy directly into ice water. Molecular typing confirmed that patient isolates were indistinguishable from the strain recovered from the ice machine. Two hospitalized patients acquired their *Legionella* infections as a result of exposure to a contaminated water feature in a radiation oncology suite *(98)*.

The role of *Legionella*-contaminated potable water distribution systems as a source for healthcare-associated Legionnaires' disease has been well established. The British Communicable Disease Surveillance Centre reported that 19 of 20 hospital outbreaks of Legionnaires' disease in the United Kingdom from 1980 to 1992 were attributed to such systems *(99,100)*.

Cooling towers and, to a lesser degree, evaporative condensers were implicated in the earlier outbreaks prior to recognition of potable water as a reservoir. Surprisingly, air conditioners have never been directly implicated as a source of Legionnaires' disease, despite widespread belief that they are. The role of cooling towers in the dissemination of *Legionella* has been challenged *(101)*. Reports of cooling towers as reservoirs for healthcare-associated legionellosis have essentially disappeared. One notable exception was a report published in 1985 of a Rhode Island hospital in which cooling towers were cited as the source *(102)*, which was later linked to the potable water system; this now appears to be a typical scenario of water distribution system contamination in which the original epidemiologic investigation was flawed *(101)*.

Subtyping of *L. pneumophila* with molecular methods has proven invaluable in elucidating environmental sources, permitting application of rational methods for prevention. In fact, application of subtyping provided the first concrete evidence that water distribution systems rather than cooling towers were the actual sources of infection *(103)*. The subtype of *Legionella* isolates taken from patients were identical to the isolates taken from putative environmental reservoirs. Both phenotypic and genotypic methods have been used to demonstrate identity among strains of *L. pneumophila* in epidemiologic investigations. These methods include serotyping, monoclonal antibody subtyping, isoenzyme analysis, protein and carbohydrate profiling, plasmid analysis, restriction endonuclease analysis, restriction fragment length polymorphism of rRNA (ribotyping) or chromosomal DNA, amplified fragment length polymorphism, restriction endonuclease analysis of whole-cell DNA with or without pulsed-field gel electrophoresis (PFGE), DNA fingerprinting using polymerase chain reaction (PCR), and sequence-based typing *(29,90,104,105)*. However, PFGE has been the most widely applied. Maximum discrimination among isolates is achieved by combining both monoclonal antibody subtyping and PFGE (*106,107*,108).

Modes of Transmission

Multiple modes have been identified for transmission of *Legionella* to humans; there is evidence for aerosolization, aspiration, or even instillation into the lung during respiratory tract manipulation. Aspiration of contaminated water or oropharyngeal secretions appears to be the major mode of transmission in the hospital setting *(109)*. Colonization of oropharyngeal flora by *L. pneumophila* is a theoretical possibility *(110–113)*. The evidence for aspiration is impressive. *Legionella* was found to be the most common cause of healthcare-associated pneumonia in a population of oncologic head and neck surgery patients *(114)*; these patients had a propensity for aspiration as a result of their oral surgery and extensive cigarette smoking. Nasogastric tube placement has been shown to be a significant risk factor for healthcare-associated legionellosis in intubated patients; microaspiration of contaminated water was the presumed mode of entry *(109,115,116)*. In the original 1976 outbreak, consumption of water at the implicated hotel was associated with acquisition of disease—an association that has been generally overlooked *(1)*. Contaminated ice and water from an ice machine have been implicated as the source of healthcare-associated infection *(96,117,118)*.

Healthcare personnel frequently use tap water to rinse respiratory apparatus and tubing used for ventilators. If the tap water is contaminated with *L. pneumophila*, the microorganism could possibly be instilled directly into the lung of a patient *(119)*. In numerous studies, the risk of Legionnaires' disease was significantly greater for patients who underwent endotracheal tube placement more often or had a significantly longer duration of intubation than for patients who had other causes of pneumonia *(64,76,120)*. The use of a nasogastric tube, the presence of immunosuppression, and ventilator use were also reported to

be highly correlated with the acquisition of healthcare-associated Legionnaires' disease *(121)*. Use of sterile water for all nasogastric suspensions and for flushing tubes has been recommended to prevent *Legionella* infection. Intermittent positive pressure ventilators have been associated with healthcare-associated legionellosis, or more likely, the tubing attached to these ventilators. The use of such equipment was epidemiologically linked to Legionnaires' disease in 18 hospital patients over a 2-year period; again, it was noted that the equipment was rinsed with tap water between treatments *(109)*. Three cases of *L. pneumophila* pneumonia were acquired from contaminated transesophageal echocardiography probes *(122)*. Again, contaminated tap water had been used to rinse the probes.

Investigators from the CDC presented the first evidence to support the aerosolization theory when reporting the Legionnaires' disease outbreak in Memphis *(123)*. Tracer smoke studies indicated that aerosols from an auxiliary air conditioning tower could have reached an air intake supplying certain patient rooms. However, the attack rate for patients occupying rooms supplied with air from the air intake was not higher than the attack rate for patients occupying rooms in the same wing but receiving air from other sources *(124)*. Cases also occurred in hospital wings having no relationship to the cooling towers. Water was not cultured, since this investigation antedated the discovery that drinking water could be the source for Legionnaires' disease.

Because the first environmental isolation of *L. pneumophila* was from a showerhead *(4)*, it has been widely thought that aerosols from showers may be an important means for dissemination of this microorganism. However, simulation studies show that only small numbers of *Legionella* are aerosolized and only for short distances *(125,126)*. Although a few retrospective studies have suggested showers as a potential source *(127,128)*, an epidemiologic link between showering and acquisition of disease has never been shown in prospective studies; in fact, prospective studies have consistently shown that showers are not a risk factor *(64,109,129–132)*. However, the CDC recommends to restrict severely immunosuppressed patients from taking showers *(133)*.

Aerosolization by respiratory tract devices including the humidifier of oxygen therapy equipment, nebulizers, and room humidifiers has been documented *(119,134)*. Humidifiers are water-filled devices that add water vapor to air, oxygen, or other gases without producing particulate water. Guinea pigs exposed to a room humidifier contaminated with *Legionella* experienced subclinical infection as demonstrated by seroconversion. In a hospital setting, a portable room humidifier filled with *Legionella*-contaminated tap water disseminated the microorganism up to distances of 300 cm. Furthermore, recovery of aerosolized *Legionella* increased with proximity to the humidifier, and seroconversion of exposed animals was directly proportional to the concentration of *Legionella* in humidifier water. Humidifiers have been implicated in transmission of Legionnaires' disease in humans. Five of eight patients with healthcare-associated Legionnaires' disease in an Italian hospital had been exposed to bubble diffuser humidifiers filled with water containing *L. pneumophila (135)*. An immunosuppressed patient at the University of Chicago Hospital acquired Legionnaires' disease after exposure to a room humidifier that had been filled with contaminated tap water for 15 days *(136)*. The statistical association between disease and humidifier exposure was highly significant. Use of a room humidifier was also associated with 18 cases of healthcare-associated Legionnaires' disease in a 2-year period in a limited retrospective study *(137)*. Again, the room humidifiers had been filled with tap water.

A post-laryngectomy patient died from pneumonia following exposure to a room humidifier. *L. pneumophila* serogroups 4 and 5 were isolated from the patient's lung and from the tap water and containers used to fill the humidifier reservoir *(138)*. Distilled water in humidifiers has also been linked to hospital outbreaks of *Legionella* infection; one patient with *L. dumoffii* was exposed to a room humidifier presumably filled with contaminated distilled water *(139)*. Healthcare-associated pneumonia in a neonate was linked to the presence of *Legionella* in the humidifier of the incubator *(140)*. In one French hospital, the use of contaminated tap water to fill the humidifier of oxygen therapy equipment and for aerosol delivery of drugs led to five cases of Legionnaires' disease caused by *L. pneumophila* serogroup 1 *(134)*.

Nebulizers are devices that generate aerosols of uniform particulate size. Ultrasonic nebulizers can produce water particles ranging in size from 0.9 to 10 μm; water droplets of 1 to 2 μm in diameter can reach the alveoli. Medication jet nebulizers have been shown to aerosolize water particles containing *L. pneumophila* when the nebulizer water was seeded with the microorganism *(141)*; these particles were <5 μm in diameter, so it is likely they could bypass the pulmonary defenses and reach the alveoli. Jet nebulizers have been epidemiologically linked to healthcare-associated Legionnaires' disease *(136)*. Inhalation of contaminated tap water aerosols from jet nebulizers was found to be a highly significant risk factor for four patients who acquired Legionnaires' disease.

In addition to filling nebulizers with tap water, rinsing the chambers of hand-held medication nebulizers has been suggested as a source of contamination. In one study of 13 patients with healthcare-associated Legionnaires' disease due to *L. pneumophila* serogroup 3, there was a trend toward more frequent use of nebulizer medications in these patients. It was subsequently established that jet nebulizers were often rinsed with tap water *(141)*. Medication nebulizers have also been implicated in one of the few reports of pediatric healthcare-associated *Legionella* infection *(142)*. Two children with Legionnaires' disease received nebulizer treatments using equipment likely to have been rinsed under tap water.

Aerosolization via excavated soil was suggested as a possible mode of transmission for the outbreaks at the Wadsworth Veterans Administration Medical Center and St. Elizabeth's Hospital; in retrospect, contaminated water distribution systems were probably the actual reservoirs. Finally, person-to-person transmission has not been demonstrated *(143)*.

CLINICAL MANIFESTATIONS

Legionella infection presents as two clinical entities: Pontiac fever and pneumonia (Legionnaires' disease). Pontiac fever is an acute, self-limiting illness. Chills, high fever,

headache, and myalgias are typical. Pneumonia is not seen, and healthcare-associated cases of Pontiac fever have not been reported.

Pneumonia is the predominant clinical syndrome in Legionnaires' disease. The incubation period for Legionnaires' disease usually ranges from 2 to 14 days. One report demonstrated the onset of disease 63 days after discharge from the hospital, and molecular typing linked the hospital water supply as the source. This led to the speculation that oropharyngeal colonization with *Legionella* had occurred *(113)*. Subsequent studies have not been successful in demonstrating oropharyngeal colonization with *Legionella (111,144)*.

Legionnaires' disease encompasses a broad spectrum of illnesses, ranging from mild cough and low-grade fever to stupor, rapidly progressive pneumonia, and multiorgan system failure. Nonspecific symptoms including malaise, myalgias, anorexia, and headache are common in the first 48 hours. Fever is virtually always present, and temperatures in excess of 40°C should lead to the consideration of Legionnaires' disease. In earlier studies, relative bradycardia has been emphasized by some investigators, but this has been found to be a nonspecific finding *(145)*.

Initially, the cough is mild and only slightly productive. The character of the sputum is often nonpurulent. Although the sputum may be streaked with blood, gross hemoptysis is rare. Chest pain, often pleuritic, is common, and when coupled with hemoptysis, can masquerade as pulmonary infarction.

Gastrointestinal symptoms are more prominent in community-acquired pneumonia, but less so in healthcare-associated pneumonia; diarrhea, nausea, vomiting, and abdominal pain are common. The most common neurologic finding in Legionnaires' disease is change in mental status, although a wide variety of findings, including encephalopathy, have been reported *(146,147)*.

There has been a report of *L. pneumophila* cases associated with a widespread macular rash *(148)*.

In the pediatric population, fever, cough, tachypnea, and abnormal pulmonary findings are the most common signs and symptoms.

L. pneumophila microorganisms can disseminate from their pulmonary niche to various extrapulmonary sites, including spleen, liver, kidney, bone marrow, myocardium, and lymph nodes. Dissemination apparently occurs via the hematogenous or lymphatic system. Extrapulmonary healthcare-associated *Legionella* infections occurred in cardiothoracic surgical patients at Stanford University *(32,149)*. Seven patients presented with *Legionella* prosthetic valve endocarditis, three had sternal surgical site infections, and one patient manifested both infections. *L. pneumophila* serogroup 1 and *L. dumoffii* were isolated from clinical samples as well as from the potable water system of the hospital. The origin of the sternal surgical site infections was contaminated tap water used to remove the providone-iodine solution from the operative site.

Other reports have implicated tap water as the source for extrapulmonary *Legionella* infections. In one patient, an open hip wound infection due to *L. pneumophila* was linked to colonized water from a Hubbard tank used for rehabilitation *(150)*. Healthcare-associated extrapulmonary legionellosis involving hemodialysis fistula infections (two cases) *(151)* and a perirectal abscess *(152)* were probably secondary to hematogenous seeding from confirmed *Legionella* pneumonia; however, direct inoculation by contaminated water or equipment could not be excluded. Detection of the microorganism at extrapulmonary sites is problematic. Since selective media must be used to isolate the microorganism, the clinician must think of the possibility of *Legionella* as the cause of the infection. Other bacteria may also be isolated, thereby confounding the diagnosis.

TREATMENT

Originally, patients diagnosed with Legionnaires' disease were found to improve when prescribed erythromycin or tetracycline as compared to those treated with beta-lactam agents or aminoglycosides *(1)*. Presently, the preferred treatment for *Legionella* infection is either fluoroquinolone or azithromycin *(60,153)*. Dosage of quinolones should be maximal. Clarithromycin is an alternative choice for treatment in those countries where azithromycin is not readily available *(153)*. The dosages are usually as follows: levofloxacin 750 IV every 24 hours and then 750 mg p.o. daily for 10 days, moxifloxacin 400 mg IV every 24 hours and then 400 mg p.o. daily for 10 days, *or* azithromycin 500 mg IV and then 500 mg p.o. daily for 7 to 10 days. Combination therapy of quinolone and azithromycin can be considered for patients who are severely ill or have extrapulmonary infections *(153)*. Rifampin may be used in combination with fluoroquinolone or azithromycin in severely ill patients. However, the benefits of combination therapy are unclear *(154,155)*.

LABORATORY DIAGNOSIS

The prompt diagnosis of Legionnaires' disease in the hospital setting can save lives. Not only has early initiation of appropriate therapy been associated with improved outcome, but the diagnosis of a single case of healthcare-associated Legionnaires' disease can prompt the recognition of endemic Legionnaires' disease at the facility *(156)*. For patients with severe pneumonia, the Infectious Diseases Society of America recommends diagnostic tests for *Legionella (157,158)*.

The diagnosis of Legionnaires' disease based on a syndromic approach has been suggested *(31)*; however, most studies have shown that the clinical manifestations of Legionnaires' disease are nonspecific *(145)*. Laboratory abnormalities including abnormal liver function tests, elevated creatinine phosphokinase, hypophosphatemia, hematuria, hemolytic anemia, and thrombocytopenia have been reported. Hyponatremia with a serum sodium of <130 mEq/L occurs significantly more often in Legionnaires' disease than in other pneumonias; it appears to be more common in healthcare-associated Legionnaires' disease than in community-acquired disease. This syndrome probably is caused by salt and water loss rather than inappropriate antidiuretic hormonal secretion (V. L. Yu, unpublished data).

Specialized diagnostic laboratory tests are the key feature for diagnosing Legionnaires' disease because the clinical presentation is nonspecific. Most hospitals, including university and tertiary care hospitals, often do not have the most sensitive tests available, namely, culture on selective media and urinary antigen *(100)*, and up to 40% of hospitals send samples off-site for testing *(159)*. Data from a CDC survey showed that hospitals where *Legionella* diagnostic tests were available on-site were more likely to identify healthcare-associated Legionnaires' disease *(159)*.

Urinary Antigen

The *Legionella* urine antigen test is now the most common method for diagnosing Legionnaires' disease *(16)*. This test has a high sensitivity (90%), high specificity (99%), is relatively low cost, and the results can be available within hours of submission of the test *(160,161)*. The urine antigen test is available as an enzyme immunoassay (EIA) test or an immunochromatographic (ICT) test. The EIA test is available commercially from two US suppliers (Wampole Laboratories, a division of Carter-Wallace Inc., Cranbury, NJ; and Bartels, Issaquah, WA) and includes the Binax *Legionella* Urinary Antigen EIA and the Bartels *Legionella* Urinary Antigen EIA (Intracel, Frederick, MD). The BinaxNOW® *Legionella* urinary antigen test is a rapid ICT membrane assay for qualitative detection of *L. pneumophila* serogroup 1 antigen (Alere, Portland Maine). A swab is dipped in urine and inserted into the test device, and the reagent is added. The reaction is read after 15 minutes as the presence or absence of a visually detectable pink-purple colored line that results from the antigen–antibody reaction, giving the result (Fig. 36-1). The EIA and ICT tests have been shown to have comparable sensitivity and specificity *(162,163)*.

The success of the rapid urine test has prompted more companies to produce similar tests. These include the Legionella V-TesT (Coris Diagnostics, Inc., Calabasas, CA), Uni-Gold Legionella (Trinity Biotech Plc., Wicklow, Ireland), X/pect Legionella (oxoid, Basingstoke, United Kingdom), SAS Legionella test (SA Scientific, Inc., San Antonio, TX), and Accusay Legionella (Launch Diagnostics Ltd, Kent, England). These tests do not perform equally. In our comparative evaluation of seven different urine antigen tests, the Binax NOW gave the highest sensitivity *(164)*.

The fact that test positivity can persist for days, even during administration of antibiotic therapy, makes it useful in those patients who receive empiric anti-*Legionella* therapy *(165)*. A shortcoming of the test is that it can detect only serogroup 1 of *L. pneumophila (166,167)*. Since the other serogroups of *L. pneumophila* and other *Legionella* species are less common in the community *(17)*, this test is still extremely useful for community-acquired legionellosis. Unfortunately for healthcare-associated legionellosis, cases due to serogroups 4 and 6 are common. Culture of the drinking water should alert the infection preventionist (IP) to the usefulness of this test for diagnosis. Early diagnosis and treatment have resulted from the increased use of the rapid urinary antigen test. This, in combination with the increasing empiric use of quinolones for healthcare-associated pneumonia, may explain the decline in Legionnaires' disease-related mortality in the United States. The case-fatality rate for healthcare-associated Legionnaires' disease has decreased from 46% in 1982 to 14% in 1998 *(16)*.

Culture on Selective Media

When Legionnaires' disease is suspected, both a urinary antigen test and a *Legionella* culture of a respiratory specimen should be ordered. The single most important diagnostic test for Legionnaires' disease is isolation of the microorganism by culture. The availability of the clinical isolate from culture can be critical for subsequent

FIGURE 36-1 The NOW immunochromatographic test (ICT) is performed by dipping a swab in urine and inserting it into the test device. Two drops of a reagent are added and the card is closed and allowed to react for 15 minutes. A positive result is the presence of a visually detectable pink-purple colored line (next to the "Sample" line) resulting from the antigen–antibody reaction.

epidemiologic investigations *(168)*. Another reason not to rely exclusively on the urine antigen test is that the urinary antigen test may be negative if the infecting strain is not serogroup 1 or when the infecting strain is serogroup 1 but MAB-2 negative (Dresden Panel MAB-3/1 negative). Among 317 culture-proven cases of Legionnaires' disease, 67 (21%) were healthcare-associated cases. Only 45% of these cases were urine antigen positive, because 22% of the cases were caused by the MAB-2 negative serotype *(167)*.

To achieve a high yield from sputum, multiple media containing antibiotics and dyes are required *(25)*. Buffered charcoal yeast extract agar is the primary medium used for isolation of these microorganisms. The culture media can be made more selective by incorporating antibacterial agents (cefamandole, polymyxin B, vancomycin, aztreonam), antifungal agents (anisomycin), and inhibitors (glycine) into the media to suppress competing microflora. Pretreatment with acid is extremely useful for respiratory tract and environmental specimens, because *Legionella* microorganisms are acid-resistant whereas most other bacteria are not. The addition of dyes to the media enhances the visibility of the colonies because *Legionella* takes up the dye preferentially. The dye-containing media are especially important in detection of the nonpneumophila species. The microorganism grows slowly, taking up to 5 days for visible colonies to develop. Under a dissecting stereomicroscope, the colony surface shows a characteristic ground glass appearance.

Legionella culture is performed only when specifically requested. A physician often orders a *Legionella* urinary antigen test and only a routine microbiology culture. As a result, when the urine antigen test is positive, no sputum is available for *Legionella* culture. We refrigerate all respiratory specimens for 7 days by placing them in bins marked by the days of the week. This practice allows for subsequent retrieval of the specimen for *Legionella* culture if a urine test is positive. The isolate from the patient is now available if an epidemiologic investigation is performed to determine the source of the infection.

Transtracheal aspirate specimens that bypass contaminating oropharyngeal flora can achieve a sensitivity as high as 90% *(25)*. Sputum obtained by bronchoscopy can be useful, but does not provide any higher yield than a good sputum specimen. If sputum is not available, however, bronchoalveolar lavage can yield the microorganism. Bronchial washings, in which the volume of fluid instilled is notably lower than that of lavage, appear to be less sensitive. Transbronchial biopsy can yield the microorganism in tissue by direct fluorescent antibody (DFA) stains and culture and has been successful in identifying *Legionella* when sputum and bronchial washings were unrevealing. Percutaneous needle aspiration of a lung abscess has yielded the microorganism in culture from a patient who had negative sputum and bronchoscopy cultures.

Bacteremia is actually common in severely ill patients *(169)*. The microorganism can be isolated from blood by biphasic buffered charcoal yeast extract agar bottles, a radiometric system (Bactec, Johnston Laboratories, Towson, MD), or the Vacutainer tube (Becton Dickinson, Rutherford, NJ). In one study, 38% of cases of Legionnaires' disease had positive blood cultures when subcultures from Bactec bottles were plated onto buffered charcoal yeast extract agar *(170)*.

Direct Fluorescent Antibody Stain

The reported sensitivity of DFA stains has ranged from 25% to 75% *(180)*. It is highly specific, and the monoclonal antibody test (MONOFLUO, Bio-Rad Laboratories, Redmond, WA) has eliminated the rare occurrence of cross-reactivity with other gram-negative bacilli. Because of low sensitivity compared to culture, we do not perform the DFA on a specimen unless the direct culture is overgrown with competing flora and acid pretreatment of the specimen is required. Polyclonal DFA reagents are available from a number of suppliers for definitive identification of isolates of *Legionella* (Monoclonal Technologies, Atlanta, GA; Meridian Diagnostics, Inc., Cincinnati, OH; Zeus Technologies, Raritan, NJ).

Serology

Antibody tests have become less important with the advent of rapid diagnostic tests. Because the definitive criterion for diagnosis is a fourfold rise in antibody titer, repeat serology is required 4 to 6 weeks after the onset of infection. Sensitivity in the 1976 outbreak was 91% *(171)*, but sensitivity in studies of healthcare-associated pneumonia has been <50% *(172)*. Maximal sensitivity requires detection of both immunoglobulin G and immunoglobulin M antibody. Effective antibiotics and suboptimal timing of specimen collection are possible reasons for the decrease in sensitivity. Diagnosis of Legionnaires' disease by serologic testing has decreased significantly from 1980 to 1998 *(16)*.

Polymerase Chain Reaction

Rapid diagnostic testing is the key to reducing morbidity and mortality *(173)*. DNA amplification by PCR of *Legionella* has been reported from patients with pneumonia using throat swab specimens, bronchoalveolar lavage, urine, and serum *(174–176)*. The primer sequences of the *mip* gene of *L. pneumophila* and the 5S rRNA or 16S rRNA have been utilized in PCR assays. A real-time quantitative PCR assay has been used to detect *L. pneumophila* in respiratory tract secretions *(177)*. Although *Legionella* DNA has been detected in urine and serum samples from patients with legionellosis *(178)*, clinical experience has not shown PCR to be more sensitive than culture. Therefore, the CDC does not recommend the routine use of genetic probes or PCR for detection of *Legionella* in clinical samples *(179)*.

PREVENTION

There is a direct relationship between colonization of hospital water systems with *L. pneumophila* has been documented and the occurrence of healthcare-associated Legionnaires' disease *(180,181)*. *Legionella* species have been shown to colonize between 12% and 85% of hospital water systems *(182,183)*. Prospective studies have demonstrated cases of healthcare-associated Legionnaires' disease in colonized hospitals after environmental and clinical surveillance were initiated *(182)*. Knowledge of this relationship is the first step to prevention. The CDC recommends facilities should use two general strategies to prevent healthcare-associated legionellosis when no cases or sporadic cases have been detected. The first step is to do environmental surveillance for *Legionella* by periodically culturing the potable water system. If any sample cultures

are positive, diagnostic testing is recommended for patients with healthcare-associated pneumonia. In-house laboratory testing is recommended for facilities that have transplantation programs *(184)*. Decontamination of the facility's potable water system should be considered if 30% or more water outlet culture samples are positive. The basis for this approach is that if *Legionella* species is not in the potable water system, healthcare-associated legionellosis will not occur. Physicians should also be informed of water culture positivity so that appropriate diagnostic testing can be done. This proactive approach has been advocated by Pittsburgh investigators and the Allegheny County Health Department in Pittsburgh, PA, for many years *(182)*. This approach recommends proactively culturing the hospital water system as the initial step in making a risk assessment of the facility. Guidelines for *Legionella* prevention from the Allegheny County Health Department and from the state of Maryland specifically recommend routine environmental monitoring of the healthcare facility's water system *(185,186)* (Table 36-2). If any outlets yield *L. pneumophila*, diagnostic tests for *Legionella* are made available in-house. The presence of *L. pneumophila* serogroup 1 in the water supply necessitates the on-site availability of the urinary antigen test. If >30% of outlets are culture-positive for *L. pneumophila*, disinfection of the water system should be considered. This approach has now been adopted as a national guideline for all hospitals of the Veterans Healthcare System—the largest healthcare system in the United States *(186)*. The Texas Department of Health has also issued guidelines that recommend environmental surveillance for *Legionella* only if a risk assessment indicates that the facility has a significant risk of legionellosis transmission *(187)*. For example, a high-risk facility could be a multistory facility with multiple water distribution systems, supplied with water treated with chlorine, stored hot water at 51°C (124°F) and delivered at 43°C (110°F), and housing bone marrow or solid organ transplant recipients or cancer patients undergoing chemotherapy. Proactive approaches mandating routine environmental cultures within hospitals have now been adopted in Denmark, the Netherlands, France, and Taiwan.

The second strategy is the "clinical" approach. In this method, the clinician maintains a high awareness for legionellosis and orders the appropriate diagnostic tests for patients presenting with healthcare-associated pneumonia. If one case of definite or two cases of possible healthcare-associated *Legionella* occurs within 6 months of each other, then an investigation for the source, including the potable water system, should be initiated. However, hematopoietic stem cell transplant and solid organ transplantation recipients are at a high risk for legionellosis, thus culturing of the potable water system should be considered as a prevention strategy in these patient areas *(188,189)*.

The "Guideline for Prevention of Nosocomial Pneumonia" from the CDC's Healthcare Infection Control Practices Advisory Committee (HICPAC) *(190)* was revised and continues to have no recommendation for routine culture of healthcare facilities' potable water systems with the exception of institutions housing transplant units *(179)*. Opposition to routine environmental cultures in the

TABLE 36-2

Guidelines for Control of Legionella in Healthcare Facilities: Veterans Healthcare System, Pennsylvania and Maryland Recommend Routine Environmental Culturing of the Hospital Water System for *Legionella*

State/Organization	*Diagnostic Testing*	*Clinical Surveillance*	*Routine Environment Testing*	*Approach to Prevention*
Veterans Healthcare System Directive 2008-001	Urine antigen testing and culture; all transplants	Active clinical surveillance	Yes: annual	If >30% sites positive, action plan for remediation
Allegheny County Health Department, Pennsylvania 1993/1997	Active: in-house urinary antigen (UA) testing	If environment positive, active clinical surveillance	Yes: annually; transplant hospital: more often	Consider disinfection if >30% sites positive; empiric antimicrobial therapy macrolide or quinolone
Maryland Health Department	Acute care: in-house; transplant hospitals: culture on site	Test pneumonia cases for *Legionella*	Yes: routine culture	If cases identified, disinfection recommended
Texas Department of Health	Acute and long term: UA in-house; transplant hospitals: culture on site	Active case detection after case identified	Routine: no; if high risk of cases: yes	Enhanced clinical surveillance and remediation if cases identified
Centers for Disease Control and Prevention	Routinely test without knowledge of environment colonization	Educate regarding diagnosis per 400+ beds equals UA/culture in-house	No: unless cases identified or transplant unit	Disinfect only if source identified

absence of documented disease is often based on the premise that *Legionella* colonization is ubiquitous, that *Legionella* can colonize water distribution systems without causing disease, and that environmental culturing is expensive *(190–192)*. However, these assertions have been refuted based on numerous studies in both the United States and the United Kingdom *(182,193,194)*.

As part of a comprehensive strategy to prevent Legionnaires' disease in transplant units, HICPAC recommends that facilities with solid organ transplant programs or hematopoietic stem cell transplant recipients should perform periodic culturing for *Legionella* in the transplant unit's potable water supply. This recommendation also appears in the "Guidelines for Prevention of Opportunistic Infections in Bone Marrow Transplant Recipients" *(195)*. If *Legionella* species are detected in the unit's water system, corrective measures (disinfection) should be performed until no *Legionella* is cultured. No such recommendation is made for healthcare facilities treating nontransplant patients or for disinfection of areas serving these patients.

One problem with this approach is that many cases of healthcare-associated Legionnaires' disease occur in nontransplant patients. In Yu's original report of endemic healthcare-associated Legionnaires' disease, none of the patients were transplant recipients and Legionnaires' disease constituted 22.5% (32/142) of the cases of healthcare-associated pneumonia *(196)*. In a Swedish hospital, 31 patients with healthcare-associated Legionnaires' disease were diagnosed over a 14-month period: 8 were from surgical wards, 16 from internal medicine or geriatric wards, 3 each from psychiatric and physiotherapy units, and 1 was from the maintenance department *(197)*.

Environmental Culturing

Routine environmental cultures for *Legionella* are necessary to assess the risk since *Legionella* colonization will vary over time *(198)*. The Allegheny County (Pittsburgh) Health Department recommends once a year culturing of water sites in patient units and wards housing high-risk patients, while the Maryland guidelines recommend flexibility with four times a year culturing if an outbreak has occurred. For those hospitals using systemic disinfection, the World Health Organization (WHO) recommends *Legionella* culture of the drinking water be performed every 3 months to verify efficacy (*199*).

Routine surveillance can be performed by collection of either swab and/or water samples from water outlets throughout the facility. Results will be affected by the type of sample collected and the method of sample collection. For example, swab samples should be collected first and after removal of the faucet aerator to achieve maximum recovery of *Legionella* from the biofilm within the fixture *(200)*. *Legionella* adheres to the biofilm lining pipes and fixtures. When doing a case investigation, two samples—water and swab—should be collected from the same water outlet(s) in the immediate environment of the suspected case *(200)*. Ongoing surveillance for monitoring the efficacy of disinfection efforts should include the previously positive locations for follow-up testing *(200)* (Fig. 36-2).

When collecting swab samples, aerators should be removed. The swab sample should be collected immediately after briefly turning on the hot water faucet or shower. The swab should be inserted into the faucet opening and rotated four times against the inner surface as it moves up into the opening. If a showerhead is cultured, rotate the swab over the entire surface of the showerhead four times. When collecting water samples, turn on the hot water and immediately fill the bottle with at least 120 mL. When culturing the hot water storage tanks, open the drain valve and collect at least 120 mL of the flowing water. Let the water drain for 15to 30 seconds and then collect another 120 mL sample in a second bottle. Label samples appropriately *(200)*. A minimum of 10 outlets plus the hot water storage tank should be cultured for the average 250-bed healthcare facility *(185)*. When taking a culture of the cooling tower, submerge an open bottle just under the surface of the water to obtain at least 120 mL. Swabs are not considered to be appropriate when culturing hot water tanks and cooling towers. If *Legionella* is isolated, specialized laboratory tests should be made available in-house. The urinary antigen is especially recommended as a cost-effective test if the *Legionella* isolated is serogroup 1. Prospective surveillance of healthcare-associated pneumonias should be initiated by the IP *(185,201,202)*. It has been well documented that unless the healthcare laboratory can isolate *Legionella*, healthcare-associated cases can be overlooked *(182)*. It has also been suggested that surveillance for healthcare-associated legionellosis can be targeted to select high-risk patients for cost-effectiveness *(115,201)*; high-risk patients include transplant recipients, immunosuppressed patients, patients with underlying pulmonary disease, and intensive care unit patients. Surveillance could be expanded to all patients with healthcare-associated pneumonia if cases of legionellosis were uncovered in the high-risk group. It is important to point out that if the frequency of contaminated sites is low, disinfection of the water supply is not necessarily required. Antibiotic prophylaxis of transplant patients with macrolides or quinolones has been used to stem outbreaks *(154)*. If the level of contamination increases, the option to disinfect the water supply can be exercised.

Contaminated Respiratory Devices

The use of sterile water for filling and rinsing humidifiers, nebulizers, and other respiratory equipment is recommended. Portable room humidifiers should be prohibited, because they are often filled with tap water and not routinely cleaned or disinfected. Even rinsing respiratory device tubing with tap water may create a secondary reservoir for *Legionella*. Subsequently, reattachment of the device to the patient could directly instill *Legionella*-containing respirable droplets into the respiratory tract. Devices such as medication nebulizers may retain water 12 hours after rinsing *(141)*.

DISINFECTION OF WATER DISTRIBUTION SYSTEMS

Healthcare-associated legionellosis has been effectively controlled by disinfection of the water distribution systems that are colonized by *Legionella*. In 1998, two reviews on disinfection methodologies were published: one for engineers and healthcare facility managers and another for physicians and infection preventionists *(194,203)*. At that

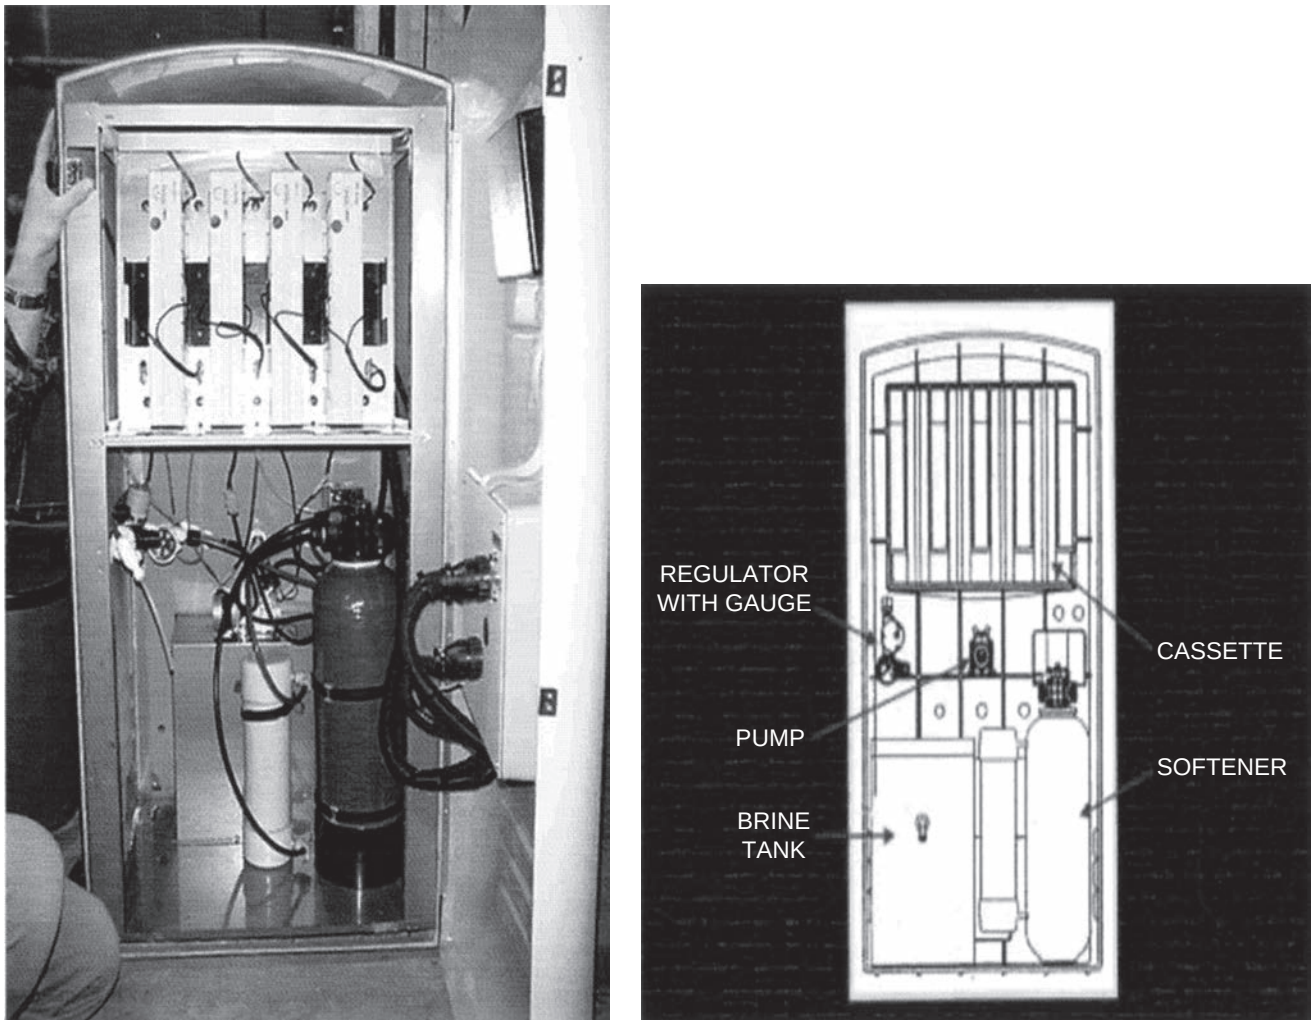

FIGURE 36-2 Chlorine dioxide is a *Legionella* disinfection option that has been used extensively in Europe but has recently been under evaluation in the United States. Chlorine dioxide is generated electrochemically from a sodium chlorite precursor within a self-contained unit. The electrochemical reaction occurs within removable cassettes. The unit generates a solution of concentrated chlorine dioxide (~500 mg/L), which is injected into the water stream to achieve a 0.5 mg/L target concentration. Photograph of generator on left; schematic of generator on right.

time, disadvantages of both hyperchlorination and ultraviolet (UV) light had become manifest and a new technology, copper–silver ionization, was under evaluation. Since then, additional methods have been introduced: use of chlorine dioxide, monochloramine, and point-of-use filters. In the spirit of evidence-based medicine, we have formulated evaluation criteria with the intent of "raising the bar" for manufacturers of disinfection methodologies. These objective criteria for demonstration of efficacy can assist hospitals in making a cost-effective decision.

There are two basic types of disinfection systems: focal and systemic. Focal disinfection is directed at only a portion of the water distribution system, usually the incoming water or individual outlets, but not at the entire water distribution system. Systemic disinfection is directed at the entire water distribution system and the biofilm throughout the system.

Focal modalities include UV light, instantaneous heating systems, and ozone. Focal modalities are not effective if the water distribution system has preexisting *Legionella* colonization, because the *Legionella* in the water distribution system remains unaffected. Focal modalities may work best in a virgin water distribution system (e.g., in a new healthcare facility) *(130)*. For maximal effectiveness, a heat and flush sterilization or shock chlorination prior to activation and intermittently thereafter is advisable. Localized disinfection of faucets or showers by physical cleaning and or chlorination has a short-lived effect and is not effective (204).

Systemic modalities provide a disinfectant residual that is bacteriostatic or bacteriocidal throughout the water distribution system; these modalities include hyperchlorination, copper–silver ionization, and chlorine dioxide (205). Superheat and flush is a systemic modality that cannot be applied continuously; however, maintaining hot water temperatures at 140°F (60°C) minimizes recolonization *(206)*. The duration of the flush must be 30 minutes, not the 5 minutes as recommended by the CDC. Failures have been reported if the shorter flush duration is used *(207)*.

In some hospitals with endemic legionellosis and a high-risk population (especially transplantation patients), multiple disinfection modalities may be needed so that if one modality fails because of human error or mechanical failure, the other modality can serve as a safety net *(208)*. Furthermore, a focal modality (UV light) can be combined with two systemic modalities (superheat and flush, copper–silver) to ensure maximal kill of *Legionella*. Routine continual surveillance with environmental cultures is critical, since mechanical failures and human error are expected with any system. Cultures performed at 2-month intervals are recommended. The endpoints for disinfection should be realistic and clinically relevant. Total sterility is extremely difficult to achieve with any disinfection modality, and zero positivity is not required to prevent healthcare-associated Legionnaires' disease *(209,210)*.

The efficacy of some modalities may vary depending on water use. For example, if superheated water or water containing metallic ions or chlorine cannot reach a site because the faucet is unused, disinfection cannot occur. Although the disinfection modality may remove the larger portion of the biomass of *Legionella*, small pockets of *Legionella* in protected niches may still be present but in insufficient amounts to cause infection. At our institution, *Legionella* infections did not occur until the percentage of colonized sites exceeded 30% *(211)*. The cut point of 30% distal site positivity as an indicator of increased risk of transmission of *Legionella* has not been universally applicable to all healthcare facilities. However, it does demonstrate that the concept of correlating environmental monitoring with predicting increased risk of disease is valid for Legionnaires' disease *(212)*. In a study by the CDC, increased risk was associated with the extent of colonization (percentage of outlets positive) and not the concentration of *Legionella* recovered from a given outlet *(213)*. The precise figure depends not only on the extent of *Legionella* colonization but also on the susceptibility of patient populations to *Legionella* infection. For example, patients on a transplant ward may become infected with *Legionella* with a much smaller inoculum of *Legionella* in the water than would ambulatory patients on a psychiatric ward. This may be the basis for the more stringent recommendations from the CDC for monitoring and disinfection of bone marrow transplant units *(179)*.

Options for Disinfection

It is important to apply a scientific method to the evaluation of disinfection methods. We have proposed that any disinfection method should be subjected to a standardized evaluation with the following steps: (a) demonstrated efficacy *in vitro* against *Legionella* microorganisms, (b) anecdotal experience of efficacy in controlling *Legionella* contamination in individual hospitals, (c) controlled studies of prolonged duration (years, not months) of efficacy in controlling *Legionella* growth and in preventing cases of healthcare-associated Legionnaires' disease in individual facilities, and (d) confirmatory reports from *multiple* healthcare facilities with prolonged duration of follow-up (validation step) *(210)*. Given the current reality of economic constraints, disinfection modalities should also be selected with the long-term goals of sustained efficacy at reasonable costs (Table 36-3). Important factors include the area requiring disinfection (one building or multiple buildings, number of floors), the number of hot water heating systems in place (one vs. multiple), the extent of colonization, and the age of the facility. Older healthcare

TABLE 36-3

Protection of Patients from Healthcare-Associated Legionnaires' Disease: An Evidence-Based Assessment of the New York State Guidelines

Healthcare Facility Function	*Strong Recommendation (Cost-Effective, Practical, Evidence-Based)*	*Weak Recommendation (Costly, Impractical, Not Evidence-Based)*
Infection control	1. Quarterly culturing of the potable water system of transplant units for *Legionella* species [a] 2. Sterile water for rinsing nasogastric tubes and for enteral nutrition for transplant recipients	1. Any *Legionella* spp. detected, decontaminate the water supply, remove aerators, restrict showering[b] (Not all species are pathogenic)
Engineering environmental care and maintenance	1. Complete eradication of *Legionella* is not feasible and regrowth may occur after system disinfection[b] 2. Disinfect dormant water lines in patient care areas prior to being returned to service[c] 3. Store hot water at 140°F (60°C)[b]	1. Routine thermal disinfection (at least semiannually) of the hot water system. Flush each outlet ≥5 min at 160°F (71°C) or ≥2 ppm free chlorine[b] (5-min flush ineffective) 2. Remove, clean, disinfect showerheads and faucet aerators monthly in transplant units[b] 3. Eliminate dead end or capped pipes[c]

facilities generally pose a more formidable task in disinfection than newer facilities because of accumulation of scale and *Legionella* within biofilms, but new healthcare facilities may also colonize rapidly *(214)*. Disinfection efforts that target the hot water system have been effective in controlling *Legionella*. This would suggest that treating the cold water supply may not be necessary. Given the public health implications, any commercial vendor's history of experience and service commitment in *Legionella* disinfection should be reviewed. It would be prudent to obtain assessments from other healthcare facilities that have used the vendor's product.

It should be emphasized that appearance, degree of cleanliness, and regular preventive maintenance of the system have not been shown to minimize *Legionella* contamination (204,*215*). Plumbing modifications including "dead-leg" removal and cleaning or replacing showerheads have been overemphasized. Nevertheless, many engineering guidelines have advocated such unvalidated approaches despite evidence that they are tedious and ineffective (204). The only way to be certain that a system is free of *Legionella* is to obtain samples for environmental cultures.

Finally, a strong infection control program is critical if the approach is to be cost-effective and scientifically valid. We advise that each healthcare facility evaluate the utility of its modality scientifically. Baseline cultures prior to disinfection over an adequate period are critical, so that the efficacy of a new disinfection modality can be adequately evaluated.

Selection of the vendor for installation of a systemic disinfection method is an important decision. Review of our experience in which healthcare-associated Legionnaires' disease recurred after a disinfection system had been installed revealed one consistent finding: the decision for purchase and installation of the disinfection system was made by the engineers within the facilities management team, with minimal input from the Infection Control department. Given the proliferation of numerous companies that now offer such systems, failures have become commonplace with patients contracting Legionnaires' disease despite installation of an expensive disinfection system. As a result, we strongly advocate that the Infection Control Department lead the task force in both selecting the disinfection method and the vendor. Other members of the task force should include hospital engineers and members of the administration. The critical contribution by the infection control preventionist is the insistence for the use of evidence-based data in the selection of the vendor.

Copper–Silver Ionization

Copper and silver are bactericidal *in vitro* against *Legionella* and other waterborne pathogens including *Pseudomonas aeruginosa*, *Stenotrophomonas maltophilia*, *Acinetobacter baumannii*, and mycobacterial species. We recommend copper and silver ion concentrations of 0.20 to 0.80 mg/L copper and 0.01 to 0.08 mg/L silver, respectively, for *Legionella* eradication. Ionization is the only disinfection method that has fulfilled all four evaluation criteria *(210)*. The systems (Tarn-Pure, T.P. Technology, Buckinghamshire, UK; Liquitech, Lombard, IL; Enrich Products, Pittsburgh, PA) use copper–silver electrodes that generate ions when an electrical current is applied. The positively charged ions form electrostatic bonds with negatively hypercharged sites on bacterial cell walls. The distorted cellular permeability coupled with protein denaturation leads to cell lysis and death. Copper–silver ionization provides residual protection throughout the system. Theoretically, microorganisms are killed rather than suppressed, which should minimize the possibility of recolonization. Controlled studies have shown that this modality is highly effective in eradicating *Legionella* (*193*,205,*216*). Two healthcare facilities that switched from thermal eradication (superheat-and-flush) to copper–silver ionization reported that ionization was more effective for reducing the recovery of *Legionella* from their water system *(209,217)*.

Among the first 16 healthcare facilities to use ionization for *Legionella* disinfection, 75% had attempted disinfection with other methods *(210)*. All 16 hospitals were successful in preventing healthcare-associated Legionnaires' disease after installation of ionization systems. Although elevated pH can adversely affect the action of copper *(218)* and there has been speculation of ion resistance *(219,220)*, most facilities reported satisfactory control of *Legionella* within their hot water supply. The systems had been in place from 5 to 11 years. Cost depended on the number of systems installed, but the average cost was $20,000 to $40,000. The Environmental Protection Agency (EPA) sets a maximum containment level (MCL) for copper in drinking water of 1.3 mg/L and for silver 0.1 mg/L (nonenforceable). EPA now requires ionization systems to "register" as a biocide for use in potable water.

Chlorine Dioxide

Chlorine dioxide (ClO_2) is a registered biocide with the US EPA. EPA has set the maximum residual disinfectant level for ClO_2 of 0.8 mg/L, and the MCLs for its by-products chlorite and chlorate are 1.0 mg/L, and chlorate is currently not regulated due to the lack of health data to set an MCL. All chlorine dioxide products used in healthcare facilities must be EPA registered and American National Standards Institute/National Sanitation Foundation certified. Some states require regular monitoring of chlorine dioxide and chlorite. Such testing can be costly and this expense is often overlooked. Potential users should check with their local environmental protection agency for regulatory requirements.

Although this technology has been used to control *Legionella* in European hospital water systems for many years, it has only recently been introduced into the US healthcare market for this application *(221–223)*. New technology now allows for the safe generation of chlorine dioxide on a small scale. Methods for producing chlorine dioxide include controlled mixing of chemical precursors or electrochemical generation. One type of generation unit utilizes an electrical source and membrane technology to directly oxidize sodium chlorite (Halox, Inc., Nalco, Naperville, IL) (Fig. 36-2). These generators typically provide 5 g/h to 2.4 kg/d of chlorine dioxide. Chlorine dioxide can be fed into the water system at various points (cold water supply, hot water supply, reservoir), depending on where disinfection is desired. Preventative maintenance includes replacing various filters and tubing.

Several controlled evaluations of chlorine dioxide have been performed in the United States *(221–223)* and have shown that chlorine dioxide at a concentration of <0.8 mg/L was effective in reducing *Legionella* species

in the healthcare facility's water system. There was a significant reduction in the percentage of positive outlets; however, *Legionella* persisted at a low level in the treated systems and months were required to reach these levels. Difficulties were encountered in maintaining an adequate chlorine dioxide residual in the hot water system; the residual in the hot water was often <0.1 mg/L. This was attributed to a combination of loss of residual with increased distance from the injection point and increased decay of chlorine dioxide at higher water temperatures. Prospective studies of sufficient duration from different institutions are required to validate these results. Cost depends on the number of systems installed, but the average cost was $20,000 to $40,000 plus installation costs.

Point-of-Use Filtration

Point-of-use filters (0.2 μm) (AquaSafe, Pall Medical, East Hills, NY) have been used for prevention of healthcare-associated infections due to *Legionella* and *P. aeruginosa*, particularly in high-risk areas such as intensive care units and transplant units *(224–226)*. In a controlled study, the filter completely eliminated *Legionella* and *Mycobacterium* from the water *(225)*. Some healthcare facilities restrict water use during an outbreak by having patients use bottled water exclusively and restricting all patients from showering. Filters are usually more cost-effective and better tolerated by patients *(227)*. Filters must be changed every 30 days.

Superheat and Flush

If *Legionella* must be eradicated from the water distribution system immediately, the superheat-and-flush method warrants primary consideration. The basic method requires that hot water tank temperatures be elevated to >70°C (158°F), followed by flushing of all faucets and showerheads to kill *L. pneumophila* colonizing these sites (205,*228*).

All hot water tanks are shut down, drained, descaled with high-pressure steam, and then chlorinated to 100 ppm for 12 to 14 hours. The chlorinated water is drained and the tank flushed with water to remove the residual chlorine. The tanks are then placed back on line, and the temperature is elevated to 70°C to 80°C (158°F–176°F) for 72 hours. All distal water sites in patient care wards are flushed once a day for 2 days, whereas those sites located on patient units housing high-risk patients (intensive care units and transplant wards) are flushed once a day for 3 consecutive days. The outlets are flushed for 30 minutes. It is critical that temperatures of the flushed water be monitored to ensure that the temperature exceeds 60°C (140°F) distally. On the fourth day, selected distal sites are recultured; if no *Legionella* microorganisms are recovered, the procedure is considered completed. If *Legionella* is still isolated, the entire heat and flush protocol is repeated. Both maximum temperature and duration of the flush are important for successful decontamination. Healthcare facilities that have used shorter flush times have failed to eradicate *Legionella (207)*. Unfortunately, a minimum flush time of 5 to 10 minutes has been erroneously recommended by HICPAC *(133)*; although the 30-minute flush is tedious, it will be more successful than the 5- to 10-minute flush.

Recolonization can be delayed and minimized by maintaining hot water tank temperatures at 60°C (140°F). At the Pittsburgh Veterans Administration Medical Center, the heat-and-flush method was required only once every 2 to 3 years, making this method a cost-effective one. The costs are low except for personnel time; if overtime is required, the costs can quickly escalate. We used volunteers, when possible, for the flushing process. One healthcare facility reported overtime costs of approximately $20,000 (Table 36-3) (205). Ultimately, we abandoned this method of control in favor of the less labor-intensive copper–silver ionization system *(209)*.

The main disadvantage is that numerous personnel are involved to monitor distal sites, water tank temperatures, and flushing times. Scalding can occur, although such incidents have not been reported in numerous facilities using this method. It should be noted that the Joint Commission has rescinded its earlier standard for a maximum water temperature of 110°F and allows each healthcare facility to establish its own maximum temperature. However, many states have regulations for rehabilitation and long-term care institutions that prohibit temperature in excess of 43°C (110°F) at the tap *(229)*.

Monochloramine

Monochloramine is effective against *Legionella in vitro* and in biofilm-associated *Legionella* in model plumbing systems *(230)*. Two case–control studies suggested that healthcare facilities in municipalities that were supplied with domestic drinking water treated with monochloramine were less likely to report healthcare-associated Legionnaires' disease *(55,231)*. A 2-year prospective environmental study in a California municipality in which monochloramine replaced chlorine for water disinfection, *Legionella* colonization decreased from 60% to 4% with conversion from chlorine to monochloramine in 53 buildings. The median number of colonized sites per building decreased with monochloramine disinfection *(215)*.

The efficacy of on-site monochloramine treatment in individual healthcare facilities has not yet been studied over a prolonged period. A system for delivering monochloramine into building water distribution systems was evaluated at a hospital in Italy. A significant reduction in *Legionella* positivity was seen within 30 days of injecting 1 to 2 mg/L of monochloramine *(232)*.

Monochloramine provides a stable residual that penetrates biofilms and has a wider pH working range than copper–silver ionization and chlorine. Monochloramine can cause anemia in patients undergoing hemodialysis. The on-site generation of monochloramine can be complicated; injecting hypochlorous acid upstream and ammonia downstream in a flow-through pipe could result in coexistence of free chlorine, ammonia, and monochloramine due to incomplete mixing of the reactants.

If a municipality converts from chlorine to monochloramine as the primary treatment method, the healthcare facilities in that municipality become inadvertent beneficiaries if they have a water system colonized with *Legionella (198)*. The downside has been increased populations of other microorganisms (*Mycobacterium* spp.), nitrogen by-products, and increased lead leaching in drinking water. Wide-scale conversion to monochloramine for municipal water supplies appears unlikely today.

Monochloramine appears to be a promising approach in decreasing *Legionella* colonization. Long-term evaluations remain to be reported.

Hyperchlorination

Hyperchlorination has proven disappointing as a long-term solution because of high expense, pipe corrosion (205), introduction of carcinogenic by-products into the drinking water *(233)*, and difficulty in maintaining high concentrations (2–4 ppm) of chlorine to sustain efficacy.

The advantages and disadvantages of sustained and continuous hyperchlorination have been reviewed in detail elsewhere *(194)*. This method widely implemented in the 1980s was found to be the most expensive and most unreliable disinfection approach. Inadequate penetration into piping biofilms, corrosion of the water distribution system leading to pinhole leaks, introduction of carcinogens into the drinking water, and unreliable efficacy led to its abandonment *(234)*. Corrosion can be minimized with the addition of silicate to the water—an additional cost.

Ultraviolet Light

UV light is an attractive option for disinfection since no chemicals are added to the drinking water. UV light kills *Legionella* by disrupting cellular DNA. Its point-of-entry application does not allow distal eradication of *Legionella* within the biofilms of the water distribution system that are distal to the point of entry.

These systems have proven to be effective if disinfection can be localized—for example, to a transplant or an intensive care unit *(154)*. Because UV sterilization provides no residual protection, areas distal to the sterilizer must be disinfected following installation and start-up. One effective approach is to use superheat and flush to disinfect most of the system and then to introduce chemical disinfection (metallic ion or chlorine) as an adjunct. Prefiltration is necessary to prevent the accumulation of scale on the UV lamps. One hospital reported successful control of *Legionella* in the water system after installation of UV units on the main water supply to a newly constructed hospital *(130,235)*. Depending on the size, these units can be installed for approximately $10,000 to $20,000.

GUIDELINES

In the absence of a national consensus policy or a guideline with specific recommendations for control and prevention, different organizations and state health departments have had to devise their own guidelines (Table 36-2) *(236)*. Control and prevention of Legionnaires' disease crosses many disciplines, and as such there are numerous guidance documents and resources for physicians, infection preventionists, engineers, and industrial hygienists. Unfortunately, many recommendations are not evidence-based, including those in the New York State guidelines that emphasize maintenance by engineers and prohibition of showering, leading to adoption of ineffective methods that are tedious, labor intensive, and expensive (Table 36-3) (204). Many of these documents are available via the World Wide Web (Table 36-4). The quality of *Legionella*-related Web sites maintained by private and state institutions, universities, professional organizations, and individuals has been reviewed *(237)*.

CHAPTER 37

Clostridium difficile

Stuart Johnson and Dale N. Gerding

Clostridium difficile was identified as the etiologic agent of antibiotic-associated pseudomembranous colitis (PMC) in 1978 (1,*2*) and is now recognized as the most important identifiable cause of healthcare-associated infectious diarrhea. *C. difficile* may be the only pathogen sufficiently prevalent to warrant testing on a routine basis during the evaluation of healthcare-associated diarrhea *(3,4)*. It is estimated that each case of healthcare-associated *C. difficile* infection (CDI) costs between $10,212 and $13,675 and results in 3.0 to 6.4 excess hospital days *(5)*. Readmission for CDI costs $128,200 per hospital per year *(6)*. A conservative annual cost estimate for CDI in the United States is $3.2 billion *(5)*. Our present understanding of the pathogenesis of *C. difficile* disease and rationale for preventive and interventive measures is supported by (a) observations on antimicrobial use in patients who acquire this pathogen, (b) potential infectious reservoirs, (c) modes of *C. difficile* transmission, and (d) host risk factors.

PATHOGENESIS

The manifestation of enteric disease due to *C. difficile* depends on at least three critical events: disruption of the normal colonic microflora, exposure to a toxigenic *C. difficile* strain, and the presence of one or more host factors. Epidemiologic evidence also supports the order of these events in that, with most cases, exposure to antimicrobials with subsequent compromise of host colonization resistance is followed by *C. difficile* acquisition from exogenous sources (rather than reactivation from an endogenous source).

The normal colonic flora provides a profound resistance to infection with *C. difficile*. It appears that the host is susceptible to infection with this pathogen only after disruption of the colonic flora by antimicrobial therapy or by substances that act as antimicrobial surrogates such as antineoplastic agents *(7)*. The next critical event, exposure to toxigenic *C. difficile*, occurs most often in hospitals and chronic care facilities, which serve as the main reservoirs for this infection. With the recognition that asymptomatic carriage of *C. difficile* is very common among hospitalized patients, it might seem intuitive that these carriers are at high risk of subsequent CDI. However, a meta-analysis of four prospective studies that included 810 patients followed for 1,348 weeks with weekly surveillance cultures indicated that asymptomatic carriers were, conversely, at decreased risk of subsequent CDI (pooled risk difference –2.3% [95% confidence interval 0.3–4.3], *p* .021) *(8,9)*.

In our current hypothesis (Fig. 37-1), a patient is admitted to the hospital and, although exposed intermittently to *C. difficile*, is susceptible to colonization or disease only following antimicrobial therapy. The subsequent clinical outcome is determined shortly after acquisition (within a few days) and, like other enteric and infectious diseases, the majority of patients remain asymptomatic. These asymptomatic carriers are then at decreased risk for CDI when compared with noncolonized patients. Host risk factors comprise the third critical component to the pathogenesis of CDI and are discussed later in this chapter.

C. difficile elaborates two major toxins: toxin B, a potent cytotoxin; and toxin A, a potent enterotoxin that is also cytotoxic *(10)*. Although measurement of cytotoxicity in stool specimens is used to diagnose CDI, the enterotoxic effect of toxin A has been presumed to be critical in the pathogenesis of the disease. The early evidence implicating toxin A includes the observation that disease severity correlates more closely with toxin A production *in vivo (11)* and that toxin A alone, but not toxin B, given intragastrically reproduces the pathology of *C. difficile* cecitis in hamsters *(12)*. However, toxin B acts synergistically with toxin A in this model, and clinical data support virulence for variant strains that produce only toxin B, but not toxin A. Genetic knockout experiments indicate that toxin B, not toxin A, is the toxin essential for causing disease in the hamster model (13). Furthermore, a monoclonal antibody directed at toxin A was ineffective at reducing CDI recurrence, whereas two monoclonal antibodies directed at toxins A and B were effective in reducing CDI recurrence in patients (14,15).

Toxin A is a unique enterotoxin unrelated to cholera toxin or the *Escherichia coli* heat-labile toxin and causes extensive mucosal damage with hemorrhagic fluid response *(16)*. The receptor for toxin A involves a trisaccharide moiety, Gala1–3Galb1–4GlcNAc *(17)*, which is present on antigens within the brush border of human and hamster intestinal epithelium *(18)*. Subsequent toxic cellular events

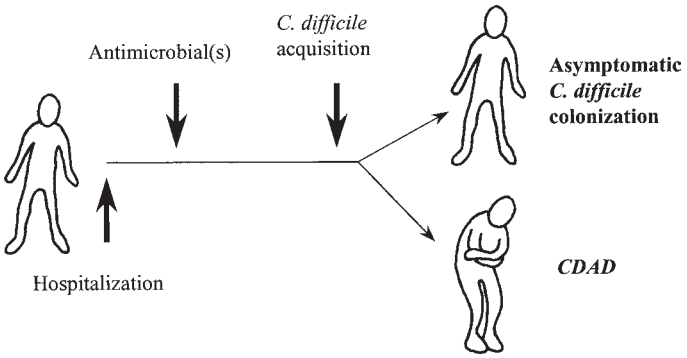

FIGURE 37-1 Hypothesis of the pathogenesis of *C. difficile* infection. Although patients are likely exposed to *C. difficile* throughout their hospitalization, we hypothesize that they are at negligible risk for CDI until exposed to an antimicrobial agent. Following antimicrobial exposure, the patient is now susceptible to infection, and when exposed to *C. difficile*, one of three outcomes ensues: the patient becomes colonized but remains asymptomatic, the patient develops CDI, or potentially the patient does not develop any detectable infection. Once the patient is established as an asymptomatic carrier, data indicate that the patient is at decreased risk for subsequent CDI (*7*). (Reproduced from Johnson S, Gerding DN. *Clostridium difficile*–associated diarrhea. *Clin Infect Dis* 1998;26:1027–1036, with permission.)

involve internalization of toxin A by receptor-mediated endocytosis and disruption of the cellular cytoskeleton. Toxin A (and B) induces glycosylation of small guanosine triphosphate–binding proteins that are important regulators of actin polymerization *(19)*.

Variant strains of *C. difficile* that do not produce toxin A have been recovered from clinical specimens around the world. These toxin A–/B+ strains were initially recovered from asymptomatic children and were not thought to be pathogenic. Recently, a particular toxin A–/B+ variant that has a 1.8-kb deletion in the toxin A gene (referred to as toxinotype VIII, serogroup F, restriction endonuclease analysis [REA] group CF) *(20)* has been recovered from multiple CDI cases, including a fatal case of PMC *(21)*. In addition, two well-documented hospital outbreaks with the A–/B+ variant *(22,23)* suggest that toxin B or some virulence determinant other than toxin A in these strains is sufficient to cause *C. difficile* disease, consistent with the observations in hamsters using toxin A knockout *C. difficile* strains (13).

In addition to toxins A and B, some strains of *C. difficile* (but not toxinotype VIII strains) also produce an adenosine diphosphate–ribosyltransferase (referred to as binary toxin) *(24)*. The role of binary toxin in the pathogenesis of CDI has not yet been determined, but during the first decade of the 21st century, there have been multiple outbreaks of a toxin-variant strain of *C. difficile* that has caused severe CDI in North America, the United Kingdom, and Europe (25,26). It is a toxinotype III strain variously known as type NAP1 by pulse field, type 027 by polymerase chain reaction (PCR) ribotyping, and group BI by REA and is collectively termed BI/NAP1/027 (25). The etiology of the high CDI rates and high severity of illness is not known, but the strains produce large amounts of toxins A and B *in vitro*, produce binary toxin, and have a deletion in the *tcdC* gene responsible for downregulation of toxin production *(27)*.

The other important aspect of *C. difficile* pathogenesis lies within the apparent host resistance of some patients to *C. difficile* disease. Infants in the first year of life frequently carry *C. difficile* in high numbers with high levels of both toxins in their stools *(28)*, yet *C. difficile* disease is rare in this group. Age-dependent expression of the epithelial cell receptor for toxin A may explain this apparent resistance in young infants *(29)*. Additionally, during outbreaks in adult settings, asymptomatic carriage is a more frequent outcome of CDI than is symptomatic infection *(8,30)*. Disease manifestation and severity are not solely strain-specific phenomena *(31)*; although the mechanism of this apparent host resistance in adult asymptomatic fecal excretors is not completely known, host antibody response to toxin A has been one factor implicated (32,33).

CLINICAL DISEASE SPECTRUM

Although the most common clinical manifestation of CDI is diarrhea, the disease spectrum ranges from asymptomatic colonization or fecal excretion to PMC to septic shock with and without toxic megacolon, which may present with signs of an acute abdomen but without diarrhea *(34)*. As with other enteric infections, asymptomatic colonization is two to five times more common than clinical disease associated with *C. difficile (8,30)*. Although colonized patients may carry epidemic strains responsible for illness in other patients, they are not at increased risk of CDI *(9)*, they are not at risk for subclinical protein-losing enteropathy *(35)*, and treatment of these patients with metronidazole or vancomycin is not advised *(36)*. Asymptomatic colonization is also very common in neonates, and it has been difficult to attribute any disease manifestation in neonates to *C. difficile*. However, the pathogenic role of *C. difficile* in children cannot be completely ignored, particularly in children over 1 year of age and especially in children with hypogammaglobulinemia *(37)*.

Diarrhea with or without demonstrable pseudomembranes in the colon is the most common manifestation of *C. difficile* disease. Although *C. difficile* is the most common recognized cause of antibiotic-associated diarrhea, *C. difficile* accounts for only 15% to 25% of these cases *(38)*. CDI may occur during antimicrobial administration or several weeks after discontinuation of the antimicrobial. In a prospective study of clindamycin therapy, one-third of the patients developed diarrhea or colitis several days to 3 weeks after completion of clindamycin treatment *(39)*. This marked variability of time between onset of diarrhea and antimicrobial exposure also supports exogenous acquisition as the major source of CDI. The incubation period for diarrhea after acquisition of *C. difficile* is less than 1 week, with a median onset of 2 days following acquisition *(8,30)*. However, the incidence of CDI in the first 30 days following hospital discharge is very high, suggesting the possibility of either acquisition of the microorganism in the community following discharge or a longer incubation period (40).

The severity and chronicity of diarrhea is also variable. In some cases, symptoms may be mild and respond to simply withdrawing the offending antimicrobial. CDI resolved spontaneously within 48 to 72 hours in 25% of patients in

one series *(41)*. More commonly, the diarrhea becomes chronic and severe if not diagnosed and treated with specific therapy. At presentation, symptoms may consist of only a few loose stools per day or multiple, large-volume, watery stools and signs of dehydration *(38)*. Stools may have mucus or evidence of occult blood but are rarely associated with visible blood *(42)*. Other findings commonly associated with CDI include abdominal pain (22%), ileus (21%), fever (28%), and leukocytosis (50%) *(42)*. CDI should be considered in any hospitalized patient with leukocytosis, particularly those with white blood cell counts >30,000 cells/mm^3, even without the presence of diarrhea *(43)*. Complications of severe disease include dehydration, electrolyte imbalance, hypotension, hypoalbuminemia with anasarca, toxic megacolon, colonic perforation, and sepsis, and in 1% to 7% of cases, death can result (26,*38*). Higher mortality rates have been particularly noted in CDI caused by the epidemic BI/NAP1/027 strain (26,44). A characteristic of CDI is the high rate of clinical recurrence following successful therapy, which may result from either relapse with the same strain or reinfection with a new strain *(45,46)*.

In distinction from antibiotic-associated diarrhea in general, *C. difficile* is responsible for nearly all cases of PMC that have been reported since 1978 *(38)*. The pseudomembranous intestinal lesions associated with *C. difficile* (which are present in only about half the patients who have diarrhea and *C. difficile* toxin in stool) have a characteristic gross and histologic appearance *(47)*. Early in the disease course, small (1–2-mm), raised, yellowish white plaques are noted, which may enlarge and coalesce *(48)*. These lesions, which are composed of fibrin, mucus, necrotic epithelial cells, and leukocytes, are restricted to the colon; therefore, this disease should be referred to as PMC rather than enterocolitis. Although PMC can be visualized by the sigmoidoscope in 90% of patients who have PMC, some patients have disease limited to the right colon, and the presentation may mimic appendicitis or Crohn disease *(49)*.

Fulminant *C. difficile* colitis and toxic megacolon are less common manifestations, but important syndromes to recognize, as they are associated with a high mortality rate and frequently require surgical intervention *(50,51)*. It is ironic that this most severe manifestation of CDI often occurs without diarrhea, and as a result, the diagnosis is frequently missed or delayed *(34)*. Risk factors for severe disease in one study included immunosuppression, prior CDI, and prior surgical procedures *(51)*. A rapidly increasing peripheral white blood cell count with a left shift may be an important clue to impending fulminant disease. A rising white blood cell count during medical treatment that is approaching 50,000/mm^3 or a lactic acidosis approaching 5 mmol/L are indication for colectomy in patients failing medical management *(52)*.

Extraintestinal CDIs are uncommon but include splenic abscess, bacteremia, wound infections, osteomyelitis, pleuritis, peritonitis, and urogenital tract infections *(53)*. As with other enteric infections, CDI has been associated with reactive arthritis *(54)*.

DIAGNOSIS

The diagnosis of CDI depends first on establishing the presence of clinical diarrhea or other gastrointestinal symptoms compatible with *C. difficile* disease such as abdominal pain or, rarely, ileus without diarrhea. Definitions for healthcare-associated CDI have been published and are summarized in Figure 37-2 (55,56). Two major avenues are available to establish the diagnosis in a clinically ill patient: endoscopic procedures to detect the presence of PMC and laboratory studies to document the presence of *C. difficile* or its toxins in the stool. The latter tests include (a) stool culture, antigen tests, and the PCR to detect the microorganism; (b) the cell cytotoxin test for toxin B; and (c) a variety of immunoassay tests for the presence of toxin A or toxins A and B in stool. The best way to establish the diagnosis of CDI remains controversial; however, the availability of commercial PCR tests for the detection of toxigenic *C. difficile* is likely to provide the best combination of sensitivity, specificity, and rapid results reporting for those labs equipped to do PCR (56,*57–60*). Advantages and disadvantages of each of the diagnostic modalities are discussed below. Sensitivity and specificity are summarized in Table 37-1.

Endoscopic Procedures

Endoscopic procedures indirectly indicate *C. difficile* disease by demonstrating PMC. The procedure may be

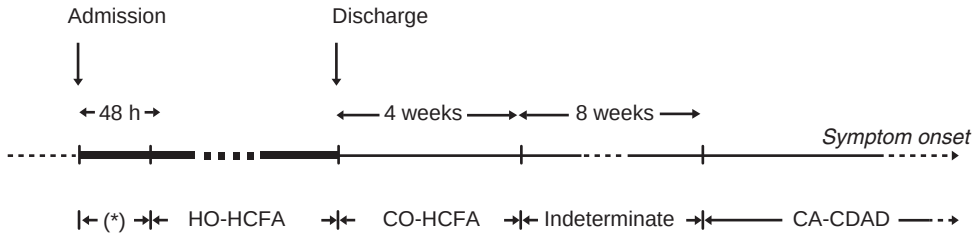

FIGURE 37-2 Time line for definitions of *Clostridium difficile* infection (CDI) exposures. Case patients with symptom onset during the window of hospitalization marked by an *asterisk* (*) would be classified as having community-onset, healthcare facility–associated disease (CO-HCFA), if the patient was discharged from a healthcare facility within the previous 4 weeks; would be classified as having indeterminate disease, if the patient was discharged from a healthcare facility between the previous 4 and 12 weeks; or would be classified as having community-associated CDI (CA-CDI), if the patient was not discharged from a healthcare facility in the previous 12 weeks. HO-HCFA, healthcare facility–onset, healthcare facility–associated CDI. (Adapted from McDonald LC, Coignard B, Dubberke E, et al. Recommendations for surveillance of *Clostridium difficile*-associated disease. *Infect Control Hosp Epidemiol* 2007; 28:140–145.)

TABLE 37-1

Sensitivity and Specificity[a] of Diagnostic Tests for *Clostridium difficile*–Associated Disease

Test	*Sensitivity*	*Specificity*	*Comment*
Pseudomembrane detection			
Flexible sigmoidoscopy	+	+++++	Biopsy may be required
Microorganism detection			
C. difficile culture	+++++	+++	Most sensitive test
C. difficile culture with toxin testing of the isolate	+++++	+++++	Sensitive and specific for diagnosis of *C. difficile* infection
C. difficile GDH immunoassay	++++	+++	Detects GDH
PCR for *C. difficile*	++++	+++++	~90–95% as sensitive as stool culture
Toxin detection			
Cell cytotoxicity	+++	+++++	Highly specific
Immunoassay for toxins A and B	++	++++	Less sensitive than cell cytotoxicity
Immunoassay for toxin A	+	++++	Less sensitive than EIA for toxins A and B

[a]Relative sensitivity and specificity: +++++, highest; +, lowest. PCR, polymerase chain reaction; EIA, enzyme immunoassay; GDH, glutamate dehydrogenase.

performed with a flexible fiberoptic sigmoidoscope or a fiberoptic colonoscope. The latter is the only device that permits visualization of the entire colon, but it is not routinely used for this diagnosis because of the need for extensive colon preparation and the high cost of the procedure. Flexible sigmoidoscopy is the most frequently employed of these procedures and allows visualization of the distal 60 cm of the colon. The diagnosis can be made by direct visualization of the pseudomembranes; biopsy may be required if the lesions are small *(48)*. The major deficiency of endoscopy is that it is highly insensitive. Pseudomembranes were seen in only 51% of patients who had diarrhea, a positive stool cytotoxin assay, and positive stool culture for *C. difficile (42)*. It is probable that PMC is a late manifestation of *C. difficile* disease that is more likely to occur in the proximal colon first, accounting for the low sensitivity of endoscopy for the diagnosis of CDI *(49)*.

Clinically, the major advantage of endoscopy is the rapidity with which a diagnosis can be made. This is particularly important in critically ill patients in whom the diagnosis of a surgical abdominal process is being considered. These patients often have symptoms of ileus or obstruction, which can be caused infrequently by *C. difficile*. Visualization of PMC by endoscopy can avert inappropriate emergency abdominal surgery and permit confident initiation of *C. difficile*–specific treatment. However, the vast majority of *C. difficile*–infected patients are not critically ill, and endoscopy has been almost totally supplanted by laboratory tests for the diagnosis of CDI.

Laboratory Diagnosis

Stool Toxin Tests

Cell Cytotoxin Assay The cell cytotoxin assay has been traditionally considered the most specific of stool diagnostic tests for CDI, albeit not the most sensitive when compared to stool culture *(61–63)*. A wide variety of cell types may be used for testing, but the test requires that laboratories maintain their own cell lines or purchase them in commercially available kits. For the test to be diagnostic, the cytopathic effect of the specimen (primarily due to the effects of toxin B) must be neutralized by specific *C. difficile* or *C. sordellii* antitoxin. Appropriate specimen dilution is critical to achieving test sensitivity and specificity. Sensitivity of the cell cytotoxin assay has ranged from 56% to 100% (depending upon the comparator test) when used to detect *C. difficile* disease in patients with clinically significant diarrhea *(61)*. Low sensitivity is thought to be due to the inactivation of toxins by proteases or other inactivating substances in stool, an occurrence that is more likely if the specimen remains at room temperature for a long period. Despite its relative insensitivity, stool testing for cytotoxin remains one of the gold standards against which *C. difficile* laboratory tests are evaluated. A major drawback of this test is the long (48-hour) turnaround time for results in most laboratories.

Immunoassay for Toxins A and B A variety of immunoassays are available that detect *C. difficile* toxin A, or toxins A and B. Enzyme immunoassays that detect only toxin A have been largely abandoned as they fail to detect clinically significant CDI caused by toxin A–/B+ strains *(21,22)*. These tests have now been widely adopted by clinical laboratories (and are often the only tests offered) because of the rapid turnaround time and decreased workload compared to cytotoxin assays. When compared only to cytotoxin testing, the sensitivity of a battery of immunoassays was 82.8% (range 66.7–91.7%) and the specificity was 95.4% (range 90.8–98.8%) *(64)*. The relative sensitivity of toxin immunoassays compared to culture with confirmation of toxin-producing isolates (also called toxigenic culture) was 75% (range 60–86.4%) and the specificity was 96.1% (range 91.4–99.4%) *(64)*. In an effort to overcome the low sensitivity of toxin immunoassays, clinicians may order multiple stool tests for toxin, but this practice, because of the lack of enzyme immunoassay specificity, leads to more false-positive test results than true positives and this practice should be discouraged by both laboratories and clinicians (56,65). Immunoassays that detect both toxins A

and B are more sensitive than assays that just detect toxin A and they also detect variant A–/B+ strains of *C. difficile* that are not detected by toxin A immunoassays *(66,67)*. The frequency of toxin A–/B+ variant strains has been low (0.2–3%) in most surveys *(67–69)* but may be considerably higher in A–/B+ hospital outbreaks *(22,23)*. Infections due to these A–/B+ variants are important to recognize clinically because of their propensity to cause clinically severe outbreaks worldwide *(21–23)*. Advantages of the toxin immunoassays are the relatively high specificity and rapid turnaround time (if the tests are not batched).

Tests for the Detection of the Microorganism in Stool

Stool Culture Stool culture for *C. difficile* on selective media (cycloserine-cefoxitin-fructose agar [CCFA]) has proven to be the most sensitive tests for CDI *(62,63)*. Special transport of stool specimens is not required for culture; however, CCFA media must be anaerobically reduced prior to inoculation so that residual oxygen in the media does not kill the microorganism when germinating from spores. Addition of taurocholate or lysozyme to CCFA enhances recovery of spores *(70)*. Clinical laboratories must exercise diligent quality control of commercially purchased media, as recovery rates have been shown to vary widely among manufacturers *(71,72)*. Culture is essential if epidemiologic investigation employing microorganism typing (including molecular techniques) is desired. The major criticism of culture as a diagnostic test for CDI is that it lacks specificity when compared with the cytotoxin assay because nontoxigenic *C. difficile* may be isolated and because many patients in hospitals may be asymptomatically colonized with toxigenic *C. difficile* and have diarrhea for reasons unrelated to the microorganism *(61,73)*. When culture and cell cytotoxin assay are both performed for CDI diagnosis, both tests yield positive results in well over half of patients with CDI, but stools are culture-positive and cytotoxin-negative in the remaining patients *(61)*. About 75% of the *C. difficile* isolates recovered from this latter group produce toxins *in vitro*. Patients with culture-positive, cytotoxin-negative stool specimens should be considered CDI cases if the isolated microorganism produces toxin *in vitro* (culture positive for toxigenic *C. difficile*) *(41,74)*.

Antigen Tests The latex agglutination test is a commercially available stool test that was originally thought to detect toxin A but was subsequently shown to detect a different *C. difficile* protein, glutamate dehydrogenase (GDH) *(75)*. The test is rapid, simple to use, and relatively inexpensive, but in its latex agglutination, detection format lacked both sensitivity and specificity and did not distinguish toxigenic from nontoxigenic strains of *C. difficile (62,63)* (Table 37-1). The detection method has been reformulated to use an enzyme-linked immunosorbent test or enzyme immunoassay for GDH, also referred to as "common antigen" *(76,77)*. Because the test is sensitive but not specific due to the lack of distinction between toxigenic and nontoxigenic strains of *C. difficile*, this test must be used in conjunction with a toxin-based assay or toxin gene detection of *C. difficile (77,78)*. Using this "two-step" method of GDH testing followed by cell cytotoxin testing for all positives, the GDH test can be used as a screening test to rule out CDI in the 80% to 90% of patients whose specimens test negative by GDH; however, up to 50% of the patients who test positive by GDH will not have confirmatory toxin found in the stool and will be ultimately reported as negative for *C. difficile* toxin *(77)*.

Polymerase Chain Reaction The use of PCR to detect *C. difficile* in stool is now commercially available and primers for amplification of conserved areas of the toxin B gene are used to detect toxigenic strains of *C. difficile* with a degree of sensitivity between 86% and 94% that of toxigenic culture *(57–60)*. For laboratories that have PCR amplification equipment, the use of PCR for clinical diagnosis will significantly improve sensitivity and specificity of diagnosis of CDI with rapid test results turnaround; however, the cost per test is substantially higher than for other tests. For laboratories that lack PCR capability, the GDH two-step algorithm may be the most effective diagnostic method *(*56*)*.

Diagnostic Summary

Testing of stools for fecal leukocytes *(42)* and examination by Gram stain for gram-positive bacilli *(79)* are of questionable utility as screening tests for CDI because of low sensitivity and low specificity. Of the available laboratory tests, the cell cytotoxin assay is the most specific whereas culture is the most sensitive. For epidemiologic purposes, there is no substitute for stool culture in the diagnosis and epidemiologic management of healthcare-associated CDIs. Because most clinical laboratories have abandoned culture and cytotoxin testing in favor of toxin immunoassays, alternative testing such as PCR or empiric treatment should be considered in patients with negative test results and high pretest probability for CDI (e.g., recent hospitalization and antibiotic exposure). The use of stool PCR for diagnosis in many laboratories is likely to significantly improve CDI diagnostic sensitivity in the future.

EPIDEMIOLOGY

Infection Rates and Epidemic Characteristics

Rates of *C. difficile* diarrhea and colonization vary markedly from one setting to another. The incidence of CDI in acute care hospitals has ranged from 0.3 cases per 1,000 patient admissions *(80)* to 22.5 cases per 1,000 patient admissions or higher (26). An extraordinary incidence of diarrhea (21%) and PMC (10%) was documented at one hospital in patients receiving clindamycin *(39)*, whereas CDI is only infrequently recognized at other hospitals. CDI has also been documented in chronic care facilities and nursing homes at the somewhat lower rate of 0.08 cases per 1,000 resident days *(81)*. Although CDI is rare in newborn infants, up to 60% of neonates are colonized, albeit at markedly different rates on different wards within the same hospital *(28)*. These differences in disease rates may reflect different diagnostic criteria and, particularly in regard to neonates, different clinical settings, but also likely reflect the endemic or epidemic status of *C. difficile* in different institutions, emphasizing the importance of healthcare-associated acquisition over endogenous activation in the pathogenesis of this disease.

C. difficile is only infrequently cultured from stools of healthy adults who have not had recent exposure to

antimicrobial agents *(82,83)*. Rates of *C. difficile* carriage among hospitalized patients, however, can range from 7% to 26% and the rate of acquisition increases linearly with the length of hospital stay *(73)*. Development and application of various typing schemes have demonstrated the importance of healthcare-associated acquisition and have clarified many aspects of *C. difficile* transmission within hospitals (*8*,*30*,*84*,85).

Among the numerous typing schemes that have been employed for *C. difficile*, PCR ribotyping, pulsed-field gel electrophoresis, and REA have been most widely used for epidemiological purposes (85,*86*). Among the newer genotypic methods, multilocus variable-number tandem-repeat analysis (MLVA) is more discriminatory than multilocus sequence typing, and MLVA and REA are best suited for discerning subtle strain differences and tracking outbreak strains geographically (85). We have used the high discrimination of REA to demonstrate the marked genetic diversity of *C. difficile*. Over 200 unique REA types were identified among *C. difficile* isolates from one hospital over a 10-year period *(87,88)*. High CDI incidence periods in this hospital were characterized by large clusters of specific REA types that changed yearly *(88)*. The large cluster outbreak strains at the beginning of the surveillance period had disappeared by the end of this study (1991) and, in retrospect, the current BI/NAP1/027 multicountry epidemic strain was also present in this hospital, but was only seen in isolated cases and the potential significance of this strain was not appreciated at that time *(88)*. In addition to outbreaks of CDI, silent clusters of *C. difficile* acquisitions occur in which few or no patients develop symptoms related to acquisition of that particular strain *(73)*. Even among clinical relapses of CDI in the same patient that occur within the hospital setting, half of the cases involve acquisition of new strains, emphasizing the importance of healthcare-associated transmission *(45,46)*.

Despite a good general understanding of the important aspects of control and treatment of CDI, there was a dramatic epidemiologic change in 2001 with increased rates of hospital-associated disease across the United States, increased reports of hospital outbreaks in North America and Europe, and increases in severe CDI cases. Nowhere was this change more dramatic than in Quebec in 2003 where a multihospital outbreak occurred in which the CDI incidence was 22.5 cases per 1,000 admissions and the CDI-attributable mortality at 30 days was 6.9% (26). It was estimated that 2,000 patients died directly as a result of CDI in Quebec from 2003 to 2004. One particular strain, now referred to as BI/NAP1/027, was responsible for 82% of the cases in these hospitals. The same strain was responsible for outbreaks in US hospitals during the same time period and was characterized by genes for binary toxin in addition to the genes for toxins A and B, polymorphisms in *tcdC* gene, a negative regulator of toxins A and B, as well as high-level fluoroquinolone resistance (25). This strain has been recovered from patients in at least 40 US states, multiple countries in Europe, as well as in Canada, and patients aged 60 to 90 years infected with this strain are twice as likely to die or have severe CDI compared to those infected with other strains (44). The virulence properties of this strain that are responsible for the increased disease severity as well as increased epidemic potential are not clear, but may include increased production of toxins A and B *(27)*, binary toxin production (25), increased sporulation potential *(89)*, and fluoroquinolone resistance (25).

Recent surveys of *C. difficile* isolates from patients with CDI in nonepidemic settings continue to show predominance of BI/NAP1/027 accounting for one-third of all isolates from North American subjects recruited to a large treatment trial conducted between 2005 and 2007 (90). Persistence of this epidemic strain is likely a major contributor to the increased incidence of CDI documented by hospital discharge diagnosis coding of patients in the United States since 2001 *(91)*.

Community-Associated CDI and Nontraditional Risk Populations

In 2005, reports of severe CDI among patients in the community without exposure to healthcare facilities (sometimes without antibiotic exposure) and reports of CDI in peripartum women and children highlighted concern that the epidemiology of CDI was expanding beyond traditional risk populations *(92)*. Community-associated CDI is well-documented, but many cases that are diagnosed in the community are associated with recent hospitalization. Chang et al. found that 78% of the CDI cases that were diagnosed in the clinic or emergency room of a large Veterans Affairs Health System were in-patients who had been recently discharged from the hospital and the antibiotic exposures were during the previous hospitalization (40). Kutty et al. also found many community-onset cases in North Carolina had recent hospitalizations, but they found higher rates of true community-associated CDI *(93)*. However, there is no suggestion of a community epidemic similar to that associated with the USA 300 strain of methicillin-resistant *S. aureus*. Cases of severe CDI among young, peripartum women and older children are well-documented, but other than age, the other traditional risk factors (hospital exposure and/or antibiotic exposure) are usually present.

Antimicrobial Use

Nearly all antibacterial agents given by either oral or parenteral routes have been associated with CDI. Historically, the most commonly implicated agents have been clindamycin, ampicillin, and cephalosporins *(7)*. The unique predisposition of patients treated with clindamycin has been repeatedly documented *(39,42,94,95)*. The mechanism of this unique propensity may be partially explained by the marked activity of clindamycin against anaerobic bacteria and a prolonged effect on the colonic flora. Clindamycin resistance was also a marker for *C. difficile* strains implicated in several CDI epidemics in the early 1990s *(94–96)*, and it was shown that clindamycin use was a specific risk factor for disease due to this highly clindamycin-resistant *C. difficile* strain, REA group J (97). Third-generation cephalosporins have been associated with CDI *(98)*, and studies have demonstrated a lower risk of CDI following treatment with ticarcillin/clavulanate or piperacillin/tazobactam than with ceftazidime or ceftriaxone *(99,100)*. Since 2000, fluoroquinolones have been recognized as a class of antimicrobials with a particularly high risk of CDI. Fluoroquinolones were the most frequently implicated antimicrobial associated with CDI during the multihospital outbreak in Quebec (26) as well as during recent outbreaks in the United States where BI/NAP1/027 was

predominant (101). Resistance to moxifloxacin and gatifloxacin was present in all of the epidemic BI/NAP1/027 isolates from recent US outbreaks, 42% of contemporary nonepidemic strains, and in none of the historic representatives of the BI strain (25). These data suggest that increasing fluoroquinolone use has facilitated dissemination of the once uncommon BI/NAP1/027 strain that has now developed high-level fluoroquinolone resistance.

Antimicrobial agents that are infrequently implicated include tetracycline, erythromycin, chloramphenicol, vancomycin, parenteral aminoglycosides, and metronidazole *(102)*. In addition, CDI can occur during or following antimicrobial therapy at any dosage, and cases have occurred after a few doses given for surgical prophylaxis *(103,104)*. However, prophylactic antimicrobials were not significantly associated with CDI in a prospective case-controlled study *(42)*.

Reservoirs and Modes of Transmission

Environmental Contamination Environmental surfaces contaminated with *C. difficile* spores are a potentially important source of healthcare-associated CDIs. The environment of patients with CDI is more frequently contaminated than the environment of other patients, and the degree of contamination has correlated with *C. difficile* outbreaks *(30,105,106,107)* as well as hands of healthcare workers caring for these patients *(96)*. Floors and bathroom sites tend to be most heavily contaminated *(108)*. In addition, commode chairs, sigmoidoscopes, bed pans, nursery baby baths, patient phones, and electronic thermometers have been found to be contaminated and can serve as reservoirs for healthcare-associated transmission of *C. difficile (109–111)*. Environmental contamination is highest around patients with active CDI, but skin and environmental contamination often persist following resolution of diarrhea (112). Although the environment of patients with CDI is heavily contaminated, the role of the environment in the transmission of *C. difficile* still needs clarification. Other potential modes of transmission, including airborne transmission *(113)* and foodborne transmission *(114)*, are as yet unproven.

Asymptomatic Patient Carriers Whenever patients with healthcare-associated CDI are identified, it can be assumed that higher numbers of asymptomatic *C. difficile* carriers (fecal excretors) are also on the same ward or in the same room *(8,30)*. Although these asymptomatic carriers are not at an increased risk for diarrhea themselves, they are potential reservoirs for infection in other susceptible patients *(8,9)*. Acquisition of *C. difficile* has been documented more frequently and earlier among patients exposed to roommates with positive cultures *(30)*. In one 9-month prospective surveillance study, healthcare-associated patient acquisitions of *C. difficile* were preceded by a documented introduction to that same ward of the identical REA-type strain by a newly admitted patient *(73)*. This sequence of events occurred in 16 (84%) of the 19 instances in which a specific *C. difficile* REA-type strain was isolated from more than one patient. These data suggest that asymptomatic carriers may be an important source of healthcare-associated CDIs.

Personnel Hand Carriage If either the environment or asymptomatic carriers are important sources of infections, *C. difficile* could be transmitted from those sources by direct contact or indirectly by the hands of patient care personnel. Hands are frequently contaminated with *C. difficile (30,106)*, and hand colonization rates as high as 59% after patient contact, which, in some instances, amounted to mere patient assessment and charting, have been documented *(30)*. Vinyl glove use by hospital personnel when handling body substances was also associated with a significant reduction in the incidence of CDI on acute care wards (101). Thus, direct and indirect evidence supports transient hand carriage by patient care personnel as a mode of *C. difficile* transmission.

Host Risk Factors

Before the etiology of PMC was elucidated, this disease was postulated to be an idiosyncratic host reaction to clindamycin. Since the role of *C. difficile* in antibiotic-associated diarrhea and colitis has been clarified, it is clear that CDIs frequently occur as outbreaks associated with unique strains *(8,100)*. However, the clinical manifestations and severity of CDIs are not solely attributable to specific *C. difficile* strains *(31)* but also depend on specific host factors.

Risks of Acquisition Asymptomatic fecal excretion is a more common outcome of infection with *C. difficile* than is diarrhea, and although antimicrobial exposure, the classic risk factor for CDI, has been associated with asymptomatic carriage *(8,42,115)*, this association is not as strong as it is with CDI *(116)*. Risk factors consistently associated with acquisition include advanced age, more severe underlying illnesses, and length of hospital stay *(8,116)*. Acquisition of *C. difficile* is highly correlated with the duration of hospital stay so that, by 4 weeks of hospitalization, 50% of previously uninfected patients may be culture-positive *(73,116)*. Stool softener and antacid use may also be risk factors for asymptomatic carriage *(116)*.

Risks of Illness Increased age, severe underlying illness, and length of hospital stay are the major risks for CDI *(30,42)*. Antimicrobials are highly associated with *C. difficile* disease. Clindamycin, multiple antimicrobials, and antimicrobials given for therapy rather than for prophylaxis have been significantly associated with CDI *(42)*. Failure to develop an anamnestic response to toxin A is a recognized risk factor for CDI (32,33). Shortly after exposure, serum antitoxin A immunoglobulin G levels predict subsequent clinical outcome (32). Asymptomatic carriers have higher levels than those who develop CDI, which may partially explain our previous observation that asymptomatic carriers are at decreased risk for subsequent CDI *(9)*. These antibody responses shortly after exposure also influence the risk of subsequent relapse among those who develop CDI (33).

Another repeated association with *C. difficile* disease has been the manipulation of the gastrointestinal tract by enemas, insertion of nasogastric and gastrostomy tubes, motility altering drugs such as atropine sulfate–diphenoxylate hydrochloride and codeine, and gastrointestinal surgery *(8,109,116)*. A well-controlled prospective cohort study

has demonstrated tube-feeding and, in particular, postpyloric administration as risk factors for acquiring *C. difficile* and developing CDI *(117)*. Insertion of nasogastric and gastrostomy tubes and enema administration may reflect increased contact with hospital personnel and with their potentially contaminated hands, which may be a partial explanation for these risk factors *(81)*.

CDI has also been reported in association with cancer chemotherapy, chronic renal disorders, HIV infection, and inflammatory bowel disease *(109,118)*. *C. difficile* has not been implicated as a cause of inflammatory bowel disease but may be responsible for some of the symptomatic relapses in patients with established inflammatory bowel disease *(119)*. Several recent studies have noted an association of proton pump inhibitor use with CDI, but this association is not consistent and, if validated, is likely much less important than antibiotic exposure (55,*120*). Also, for unknown reasons, women may have a higher rate of *C. difficile* disease than do men *(83)*.

PREVENTION AND CONTROL

No single infection control practice has effectively prevented and controlled healthcare-associated CDI. We postulate that CDI is at least a "three-hit" process that begins with (a) administration of antimicrobial or chemotherapeutic agents, (b) acquisition of the *C. difficile* microorganism, and (c) other factors such as the interaction with the host immune response that result in clinical illness in a minority of the large number of patients who both receive antimicrobials and acquire *C. difficile*. Prevention and control measures have focused largely on (a) interruption of the process of healthcare-associated microorganism acquisition and (b) measures to reduce the likelihood of clinical illness if a patient acquires *C. difficile*. The various interventive measures have been critiqued in terms of established evidence of benefit (Table 37-2). Clinical practice guidelines for prevention and control of CDI have recently been updated by the Society for Healthcare Epidemiology of America (SHEA) and the Infectious Diseases Society of America (IDSA) (56).

Prevention of Acquisition of *C. difficile*

Barrier Precautions Cohorting, patient isolation, hand washing, and glove use are included under barrier techniques. A number of studies indirectly suggest that person-to-person spread of *C. difficile* occurs in the hospital, either from patient to patient or from personnel to patient. Hands of personnel are frequently contaminated with *C. difficile (30,42,121,138)*, and a prospective controlled trial has shown that vinyl glove use by hospital personnel

TABLE 37-2

Infection Control Practices to Prevent Healthcare-Acquired *Clostridium difficile*–Associated Disease

Practice	*Efficacy*	*Reference*
Barrier precautions		
Glove use when handling body substances	Proven	*121*
Hand washing before treating each patient	Probable	*122*
Isolation precautions and cohorting	Probable	*80*, *123–125*
Environmental cleaning and disinfection		
Rectal thermometers		
Substitution of disposables	Proven	*111*
Switch to tympanic thermometers	Proven	*126*
Gastrointestinal endoscopes	Accepted	*127*, *128*
Hypochlorite disinfection of patient rooms	Probable	*108*, *129–131*
Identification and management of asymptomatic carriers		
Vancomycin treatment of asymptomatic carriers	Possible	*36*, *132*
Metronidazole treatment of asymptomatic carriers	Ineffective	*36*, *124*
Isolation or cohorting of asymptomatic carriers	Untested	
Measures to reduce the risk of symptomatic disease		
Antimicrobial use restriction		
Clindamycin	Proven	*94*, *95*, *125*
Cefotaxime (switch to piperacillin/tazobactam)	Probable	*100*
Gatifloxacin	Possible	*133*
Moxifloxacin	Ineffective	*134*
All fluoroquinolones	Possible	*135*
Prophylaxis agents for patients receiving antimicrobials		
Saccharomyces boulardii	Possible	*136*
Actimel (yogurt drink)	Possible	*137*
Orally administered antibodies	Untested	
Colonization with nontoxigenic *C. difficile*	Untested	
Toxoid vaccination	Untested	

when contacting patient body substances was effective in interrupting transmission *(121)*. CDI rates declined from 7.7/1,000 patient discharges to 1.5/1,000 ($p = .015$) after glove use was instituted, whereas control wards in the same institution showed no significant change in rates. Hand washing following patient or body substance contact should also be an effective way to interrupt transmission via the hands of personnel, although the efficacy of soap in removing *C. difficile* from hands was questioned in one study, whereas chlorhexidine appeared effective *(30)*. Both agents were equally effective in removing seeded *C. difficile* from the hands of volunteers *(122)*. The widespread introduction of waterless alcohol-based hand hygiene products (that are not sporicidal) has raised concern about the effect on healthcare-associated transmission of *C. difficile*. Although introduction of alcohol hand gels have not been associated with increased healthcare-associated CDI rates *(139)*, these agents are not effective in removal of *C. difficile* spores from hands (140,141), and in the setting of an outbreak, consideration should be given to institution of hand washing with soap after care of patients with CDI.

The difficulty in implementing isolation techniques (private rooms, enteric isolation, cohorting) in the control of *C. difficile* transmission is that they cannot be employed rapidly (unless patients are isolated before infection is identified). Assessment of efficacy is difficult, because isolation methods frequently are not employed alone as control measures *(123–125)*. Whereas hand washing and glove use can be employed in the care of all patients, isolation techniques are directed at those patients who have been identified as infected. These patients are almost always symptomatic with diarrhea and have been diagnosed with CDI prior to being isolated. Aggressive patient identification and rapid isolation were employed by Struelens et al. *(80)* and were associated with a reduction in the rate of *C. difficile* cases from 1.5/1,000 to 0.3/1,000 admissions. However, patients were treated early with vancomycin and the environment was disinfected with formaldehyde and glutaraldehyde, making the contribution of isolation impossible to discern. Current SHEA/IDSA recommendations include placement of patients with CDI in private rooms with Contact Precautions or cohorting patients with a dedicated commode if private rooms are not available (56), although this was a C-III level recommendation.

Environmental Cleaning and Disinfection Numerous environmental sites and devices have been shown to be contaminated with *C. difficile (105,106)*. The rate of room contamination is proportional to the status of the patient in the room: highest for patients with CDI, intermediate for patients with asymptomatic *C. difficile* colonization, and lowest for patients without the microorganism *(30)*. Spread of *C. difficile* has been linked to contaminated environmental devices including commodes, electronic rectal thermometer handles, and baby baths *(28,142,143)*. Replacement of contaminated electronic thermometers with disposable thermometers *(111)* and subsequent replacement of all disposable thermometers (rectal and oral) with tympanic thermometers *(126)* showed a reduced incidence of CDIs. Flexible sigmoidoscopes and colonoscopes are frequently contaminated by *C. difficile* microorganisms following endoscopy in patients with CDI *(127)*. The potential for spread of *C. difficile* by contaminated endoscopes is real but has not been documented. The presently recommended regimen of endoscopic cleaning and disinfection with 2% glutaraldehyde immersion for as short a time as 10 minutes is sporicidal for *C. difficile (127,128)* and should adequately prevent transmission via endoscopes, provided the procedures are reliably followed.

Contamination of the patient's environment can be reduced significantly by employing a sporicidal disinfectant such as unbuffered hypochlorite solution (500 ppm available chloride), phosphate buffered hypochlorite (1,600 ppm chloride), or a combination of 0.04% formaldehyde and 0.03% glutaraldehyde (*108,125*). Three additional studies have documented reduced CDI rates on wards where hypochlorite environmental disinfection was introduced, but the results have not been uniformly effective and effectiveness of this intervention may be confounded by additional factors *(129–131)*. Wilcox et al. used a chlorine-containing agent (1,000 ppm available chlorine) in a cross-over study and showed a correlation with reduced CDI incidence on one of two wards *(130)*. Mayfield et al. used a hypochlorite-based solution (5,000 ppm available chlorine) and showed an effect of decreased CDI rates on one of three wards *(129)*. The ward with decreased rates was also the ward with the highest baseline rate of CDI. Newer technologies using vaporized hydrogen peroxide *(144)* and ultraviolet-C radiation *(145)* delivered by mobile devices in vacated patient rooms show promise for environmental decontamination, but additional issues of cost and practicality need further study.

Identification and Treatment of Asymptomatic C. difficile Carriers Asymptomatic patient carriers of *C. difficile* are a potential source of spread of the microorganism to other susceptible patients via contamination of the environment or the hands of personnel *(73,132)*. Although there is a decreased risk of CDI in the carriers themselves, they may be a source of transmission to other patients *(8)*. Identification of asymptomatic carriers requires extensive stool and/or rectal swab culturing, which is labor intensive for both infection control and laboratory personnel. The appropriate action following carrier identification is unknown *(73)*. No one has attempted a study of carrier isolation or cohorting. Intervention studies that involved treatment of asymptomatic colonized patients with metronidazole or vancomycin were ineffective *(124)*, inconclusive *(146)*, or the potential effect was confounded by other simultaneous interventions *(132)*. A randomized study that attempted to eradicate colonization found that whereas vancomycin was temporarily effective, treated patients were more likely to be colonized at the end of follow-up than were placebo-treated control patients *(36)*. Metronidazole treatment results were no different that placebo. Thus, whether to and how to address the asymptomatic colonized patient remains unresolved.

Reducing Risk of Clinical Illness

Antimicrobial Restriction Prior exposure to antimicrobials is virtually universal in patients who develop symptomatic *C. difficile* disease. Risk of CDI is increased for specific antimicrobials such as ampicillin, amoxicillin, clindamycin, cephalosporins, and fluoroquinolones (26,*42,147*). Risk is

higher if multiple antibiotics are administered, if the number of doses or days of therapy is higher, and if antimicrobials are administered to treat an infection rather than for prophylaxis (*42*,*94*,*116*,*125*). These observations suggest the opportunity to reduce *C. difficile* disease risk by reducing exposure and duration of antimicrobial therapy. There are three examples of a restricted clindamycin use policy that have reduced CDI rates *(94*,*95*,*125)*. In one instance, this intervention stopped an extended outbreak within a month of implementation *(94)*. Subsequent investigation showed that this outbreak was due to a highly clindamycin-resistant epidemic strain and that clindamycin use was a risk factor (97). The most convincing intervention strategy for cephalosporin restriction was a prospective, ward-based, crossover study replacing empiric cefotaxime therapy with piperacillin/tazobactam *(100)*. Piperacillin/tazobactam use was associated with a lower incidence of colonization and CDI; rates increased when cefotaxime was reintroduced. More environmental contamination was also documented during cefotaxime use.

Considering the strong association of fluoroquinolone use and recent outbreaks of the BI/NAP1/027 strain, the effect of fluoroquinolone restriction has been studied by several investigators *(133–135*,*148)*. Two studies have looked at the effect of "with-in-class" formulary switches of fluoroquinolone agents after documenting increased CDI rates when switching from levofloxacin to a newer fluoroquinolone. The first study noted a decrease in CDI rates when they switched back to levofloxacin from gatifloxacin in their long-term care facility *(133)*, whereas the second study did not see a decrease when they switched back to levofloxacin from moxifloxacin at their community hospital *(134)*. There is one study in which all fluoroquinolones were temporarily restricted and where decreased CDI rates were seen, but this study was somewhat confounded by a change in the environmental services contractor shortly after implementation of the antibiotic intervention *(135)*. Finally, reduction in the overall antimicrobial use was effective in controlling an outbreak in a Montreal hospital due to BI/NAP1/027 *(148)*.

Prophylactic Measures for Patients Receiving Antimicrobials Although as yet unproven, the hypothesis that patients receiving antimicrobials can be treated effectively with a prophylactic agent that will prevent CDI is an attractive one. Probiotics, orally administered antibodies, and active vaccination have been proposed as preventive agents *(136*,*137*,*149–151)*. *Saccharomyces boulardii* has been used in humans and was found to reduce antibiotic-associated diarrhea significantly ($p = .038$) when given during and for 2 weeks after antibiotic administration. CDI was also reduced, but this was not statistically significant ($p = .07$) *(136)*. A subsequent study failed to show efficacy of *S. boulardii* in elderly hospitalized patients receiving antibiotics *(150)*. There is one report of a randomized study in which a yoghurt drink was given to patients taking antibiotics and a decreased rate of both antibiotic-associated diarrhea and CDI was noted in the group taking yoghurt *(137)*. This study has been criticized because of several methodological issues including exclusion of patients with "high-risk" antibiotics and further study is needed to confirm these findings.

Whey protein in immunized cow's milk containing high levels of secretory IgA has been used in a trial of CDI recurrence prevention, but the results are inconclusive and the study was open label and uncontrolled *(149)*. Lactobacilli in yogurt and acidophilus milk have been used to reduce diarrheal side effects of antibiotics and to treat relapsing CDI, but efficacy remains questionable. A novel approach that has been highly successful in the hamster model and is undergoing phase I studies in humans involves colonization with nontoxigenic strains of *C. difficile* to prevent CDI *(151)*. A toxoid vaccine is currently undergoing phase II studies in prevention of CDI recurrences, but results are not yet available. No data are available as yet for whey protein, lactobacilli, nontoxigenic *C. difficile*, and vaccination use in the prevention of CDI.

PART B. Mycobacterial Infections

CHAPTER 38

Mycobacterium tuberculosis

William R. Jarvis

Tuberculosis (TB) is a major global health problem. Worldwide, an estimated 8 million new cases occur each year and 2 million deaths are attributed to this disease annually *(1)*. TB case rates in the United States have been decreasing since the most recent peak in cases in 1992, but an increasing number of TB outbreaks in institutional settings, including hospitals, have been noted. Of greatest concern are outbreaks due to microorganisms resistant to multiple anti-TB drugs *(2)*.

THE ETIOLOGIC AGENT

Tuberculosis is caused by bacteria of the *Mycobacterium tuberculosis* complex, which includes *M. tuberculosis*, *M. bovis*, *M. bovis* [bacille Calmette Guérin (BCG)], *M. africanum*, and *M. microti*. *M. tuberculosis* is by far the most frequent and most important pathogen in this complex. It grows slowly and usually is identified by its rough, nonpigmented, corded colonies on oleic acid albumin agar; a positive niacin test; generally weak catalase activity, which is lost completely by heating to 68°C; and a positive nitrate reduction test. *M. bovis* is indistinguishable from *M. tuberculosis* except by culture followed by *in vitro* tests, restriction fragment length polymorphism (RFLP), or phage typing *(3,4)*.

MODE OF TRANSMISSION

M. tuberculosis is carried in airborne droplet nuclei, which are produced when persons with pulmonary or laryngeal TB cough, sneeze, speak, or sing. The nuclei also can be produced by irrigation or manipulation of tuberculous lesions (e.g., wounds) or processing of tissue or secretions in the hospital or laboratory. Droplet nuclei are so small (1–5 μm) and light that ambient air currents can keep them airborne for long periods of time and carry them substantial distances. Persons who breathe air contaminated with infectious *M. tuberculosis* droplet nuclei may inhale microorganisms into the alveoli of the lungs and become infected. The risk of infection is correlated with the concentration of infectious droplet nuclei in the air and the duration of exposure to the contaminated air. Airborne transmission of *M. bovis* also can occur.

PATHOGENESIS OF TUBERCULOSIS

Once tubercle bacilli become implanted in a respiratory bronchiole or alveolus, they are engulfed by macrophages, but they can remain viable and even multiply within the cells. Then, tubercle bacilli are spread via the lymphatic channels to regional lymph nodes and via the bloodstream to more distant sites. A specific cell-mediated immune response, which usually develops several weeks after infection, may limit further multiplication of the bacilli; the lesions heal, although the tubercle bacilli may remain viable. This results in a condition known as latent *M. tuberculosis* infection (LTBI), in which the person is asymptomatic and noncontagious. Bacilli deposited in some sites, for example, upper lung zones, kidneys, bones, or brain, may find an environment favorable for growth before specific immunity develops and limits multiplication. Hypersensitivity to *M. tuberculosis* components, as demonstrated by the development of a positive reaction to the tuberculin skin test (TST), develops 2 to 10 weeks after the initial infection.

At any point after this first infection, tubercle bacilli that have spread through the body may begin to replicate and produce active disease. In approximately 5% of all *M. tuberculosis*-infected persons, disease occurs within 1 year of infection. In another 5%, containment of the infection fails at a later time and *M. tuberculosis* active disease results. The most common site for this reactivation of *M. tuberculosis* infection is the upper lung zone, but foci anywhere in the body can be the sites of disease. The ability of the host to contain the infection is reduced by certain diseases, especially human immunodeficiency virus (HIV) infection, silicosis, or diabetes mellitus, and by treatment

with corticosteroids or other immunosuppressive drugs. In these circumstances, the likelihood of TB developing can be >10% per year *(5)*. For persons with LTBI, the risk of progressing to active TB is greatly reduced in persons with drug-susceptible strains by LTBI preventive therapy (e.g., isoniazid or rifampin).

CLINICAL FEATURES

Early symptoms of TB include fatigue, anorexia, weight loss, or low-grade fever. However, a few patients may present with an acute febrile illness. Erythema nodosum may occur with the acute onset of TB.

Pulmonary TB is the most common form of the disease and the most important from the perspective of hospital infection control. In pulmonary TB, there is insidious onset of cough, which usually progresses slowly over weeks to months to become more frequent and associated with the production of mucoid or mucopurulent sputum. Hemoptysis also may occur. Some patients present with the acute onset of productive cough, fever, chills, myalgia, and sweating similar to the signs and symptoms of influenza, acute bronchitis, or pneumonia. Hoarseness or a sore throat may suggest tuberculous laryngitis. Laryngeal involvement usually is associated with extensive pulmonary involvement, a large number of microorganisms in the sputum, and a very high degree of contagiousness. Physical findings of pulmonary TB may include crackles or signs of lung consolidation.

The infectiousness of a TB patient correlates with the number of microorganisms expelled into the air; this correlates with the site of disease (i.e., pulmonary, laryngeal, tracheal, or endobronchial TB being the most infectious), the presence of cough (or performance of cough-inducing procedures), the presence of acid-fast bacilli (AFB) on sputum smears, the presence of cavitation on chest radiograph, the duration of adequate chemotherapy, and the ability or willingness of the patient to cover his/her mouth when coughing.

Other clinical manifestations of the disease include tuberculous pleuritis, hematogenous dissemination (miliary TB), genitourinary tract TB, TB of the lymph nodes, skeletal TB, tuberculous meningitis, tuberculous peritonitis, or tuberculous pericarditis.

In addition to these sites, there are many other potential body sites where TB may occur less commonly. TB in most of these extrapulmonary sites, without pulmonary or laryngeal involvement, usually is not contagious. However, irrigation or other manipulation of tuberculous lesions can produce infectious droplet nuclei and result in transmission of *M. tuberculosis*, as can laboratory processing of specimens that contain *M. tuberculosis*. Standard textbooks can be consulted for information on disease at these sites.

DIAGNOSIS

Radiography

In patients who have signs or symptoms suggesting pulmonary or pleural TB, standard anterior–posterior and lateral radiographs of the chest should be obtained. Special imaging techniques, for example, computed tomography or magnetic resonance imaging, may be of value in defining nodules, cavities, cysts, calcifications, contours of large bronchi, or vascular details in lung parenchyma.

The radiographic manifestation of initial infection in the lung, whether in a child or an adult, usually is parenchymal infiltration accompanied by ipsilateral lymph node enlargement. The parenchymal lesion may be detected at any stage of development and in any portion of the lung, or it may be too small to be seen on the radiograph.

In adults with progression from LTBI to active TB disease, the common presentation is lesions in the apical and the posterior segments of the upper lobes or in the superior segments of the lower lobes. However, lesions may appear in any segment. Cavitation is common except in immunocompromised patients. Other findings include atelectasis or fibrotic scarring with retraction of the hilus and deviation of the trachea. Rarely, patients with pulmonary TB may present with normal chest radiographs, particularly patients with HIV infection or other conditions associated with severe cell-mediated immunosuppression.

Hematogenous TB is characterized by diffuse, finely nodular, uniformly distributed lesions on the chest radiograph. The word *miliary* is applied to this appearance because the nodules are about the size of millet seeds (~2 mm in diameter). Unilateral or, rarely, bilateral pleural effusion usually is the only radiographic abnormality evident with pleural TB.

Laboratory Procedures

The identification of *M. tuberculosis* microorganisms is of great importance for diagnosing TB. Therefore, careful attention should be given to the collection and handling of specimens. Specimens should be transported to the laboratory and processed as soon as possible after collection.

Because TB may occur in almost any body site, a variety of specimens may be appropriate to collect, including sputum (natural or induced), bronchial washings or biopsy material, gastric aspirates, urine, cerebrospinal fluid, pleural fluid, pus, endometrial scrapings, bone marrow biopsy, or other biopsy or resected tissue. All of these materials should be stained and examined by microscopy for the presence of AFB and should be cultured for mycobacteria.

The detection of AFB in stained smears is the easiest and quickest procedure that can be performed, and it provides preliminary support for the diagnosis. Also, the smear is of importance in assessing the patient's degree of infectiousness. The use of fluorescence microscopy allows the smears to be read much more rapidly than does standard microscopy. If necessary for confirmation, smears stained for fluorescence microscopy can be overstained and examined by standard light microscopy under an oil immersion lens.

All specimens from patients suspected of having *M. tuberculosis* disease should be inoculated (after appropriate digestion and decontamination, if required) onto appropriate culture media, such as Lowenstein-Jensen or Middlebrook 7H10. Nucleic acid amplification (NAA) testing should be performed on at least one respiratory specimen from each patient with signs and symptoms of pulmonary TB for whom a diagnosis of TB is being considered but has not yet been established, and for whom the test result would alter case management or TB control activities.

Genotyping, or DNA fingerprinting, of *M. tuberculosis* is used to determine the clonality of bacterial cultures. Because this technology is useful for studying the molecular epidemiology of *M. tuberculosis* and investigating outbreaks, the Centers for Disease Control and Prevention (CDC) established a National TB Genotyping and Surveillance Network in the 1990s. This diagnostic technique in conjunction with traditional epidemiologic methods has enhanced TB surveillance and control programs *(6)* and has been instrumental in the identification of several pseudo-outbreaks of active TB caused by laboratory cross-contamination of sputum samples from patients without clinical signs of TB *(7–10)*.

Drug-Susceptibility Testing

The initial isolate from all patients with positive cultures for *M. tuberculosis* should be tested for susceptibility to anti-TB drugs. Drug-susceptibility tests for *M. tuberculosis* are important for choosing the most effective treatment regimen. The laboratory should report to the clinician the amount of growth on drug-containing medium as compared with growth on drug-free control medium. By counting the colonies on the drug-containing medium and on the control medium, the proportion of resistant cells in the total population can be calculated and expressed as a percentage. Generally, when ≥1% of a bacillary population become resistant to the critical concentration of a drug, then that agent is not, or soon will not be, useful for continued therapy, because the resistant population will soon predominate. If broth culture is used, results are reported as resistant or susceptible, and no colony percentage is reported.

Newer Diagnostic Techniques

Radiometric Technology Compared with standard culture methods using solid media, radiometric culture methods, which employ a ^{14}C-labeled substrate medium that is almost specific for mycobacteria, provide much more rapid detection of growth and rapid drug-susceptibility testing. These automated broth culture systems using Middlebrook 7H12 media with added material for detection of mycobacteria can detect growth in 1 to 3 weeks, compared to 3 to 8 weeks for solid media. However, at least one container of solid culture media should be used in conjunction with broth culture systems *(11)*. Combining radiometric culture with techniques for rapid species identification (e.g., genetic probes, high-performance liquid chromatography, or monoclonal antibodies) can further shorten the time required for species identification.

Genetic Probes Genetic probes offer tremendous promise for providing rapid identification. One such probe, an NAA test (Gen-Probe, San Diego, CA), has been approved by the U.S. Food and Drug Administration (FDA) for detection of *M. tuberculosis* in AFB smear-positive or smear-negative respiratory specimens in patients suspected of having TB. Another NAA test (Amplicor, Roche Diagnostic Systems, Branchburg, NJ) is approved by the FDA only for use on AFB smear-positive respiratory specimens. Interpret NAA test results in correlation with the AFB smear results (12). If the NAA result is positive and the AFB smear result is positive, presume the patient has TB and begin anti-TB treatment while awaiting culture results. The positive predictive value of FDA-approved NAA tests for TB is >95% in AFB smear-positive cases. If the NAA result is positive and the AFB smear result is negative, use clinical judgment whether to begin anti-TB treatment while awaiting culture results and determine if additional diagnostic testing is needed. Consider testing an additional specimen using NAA to confirm the NAA result. A patient can be presumed to have TB, pending culture results, if two or more specimens are NAA positive. If the NAA result is negative and the AFB smear result is positive, a test for inhibitors should be performed and an additional specimen should be tested with NAA. Sputum specimens (3–7%) might contain inhibitors that prevent or reduce amplification and cause false-negative NAA results. If inhibitors are detected, the NAA test is of no diagnostic help for this specimen. Use clinical judgment to determine whether to begin anti-TB treatment while awaiting results of culture and additional diagnostic testing. If inhibitors are not detected, use clinical judgment to determine whether to begin anti-TB treatment while awaiting culture results and determine if additional diagnostic testing is needed. A patient can be presumed to have an infection with nontuberculous mycobacteria if a second specimen is smear positive and NAA negative and has no inhibitors detected. If the NAA result is negative and the AFB smear result is negative, use clinical judgment to determine whether to begin anti-TB treatment while awaiting results of culture and additional diagnostic tests. Currently available NAA tests are not sufficiently sensitive (detecting 50–80% of AFB smear-negative, culture-positive pulmonary TB cases) to exclude the diagnosis of TB in AFB smear-negative patients suspected to have TB. Probes specific for the genus *Mycobacterium*, the *M. tuberculosis* complex, and the two species *M. avium* and *M. intracellulare* are available.

Diagnosis of Latent Tuberculosis Infection

Tuberculin Skin Test The TST is the standard method available for identifying persons infected with *M. tuberculosis (11,13)*. Currently available TSTs remain substantially <100% sensitive and specific for detection of infection with *M. tuberculosis*. Some causes of false-negative reactions are shown in Table 38-1. False-positive reactions can be due to prior infection with other mycobacteria, BCG vaccination, or problems with the antigen. Anecdotal reports also have raised concern that different commercially available reagents produce different degrees of induration *(14)*; however, a large-scale study of the two reagents available in the United States revealed comparable specificity in people at low risk for *M. tuberculosis* infection *(15)*.

The intradermal administration of 0.1 mL purified protein derivative (PPD) tuberculin into the skin of the volar surface of the forearm (Mantoux technique) is the preferred method of performing the TST. Tests should be read by a trained health professional between 48 and 72 hours after injection. The basis of reading is the presence or the absence of induration, which should be measured transversely to the long axis of the forearm and recorded in millimeters.

The positive predictive value of the TST varies widely in relation to the prevalence of true *M. tuberculosis* infection in any given population; furthermore, as already noted, the

TABLE 38-1

Factors Causing Decreased Ability to Respond to Tuberculin Skin Tests

Factors related to the person being tested
Infections
Viral (measles, mumps, chicken pox, HIV)
Bacterial (typhoid fever, brucellosis, typhus, leprosy, pertussis, overwhelming tuberculosis, tuberculous pleurisy)
Fungal (South American blastomycosis)
Live virus vaccination (measles, mumps, polio, varicella)
Metabolic derangements (chronic renal failure)
Low protein states (severe protein depletion, afibrinogenemia)
Diseases affecting lymphoid organs (Hodgkin's disease, lymphoma, chronic leukemia, sarcoidosis)
Drugs (corticosteroids and many other immunosuppressive agents)
Age (newborns, elderly patients)
Stress (surgery, burns, mental illness, graft-versus-host reactions)
Factors related to the tuberculin used
Improper storage (exposure to light and heat)
Improper dilutions
Chemical denaturation
Contamination
Adsorption (partially controlled by adding Tween 80)
Factors related to the method of administration
Injection of too little antigen
Subcutaneous injection
Delayed administration after drawing into syringe
Injection too close to other skin tests
Factors related to reading the test and recording results
Inexperienced reader
Conscious or unconscious bias
Error in recording

(From American Thoracic Society/CDC. Diagnostic standards and classification of tuberculosis in adults and children. *Am J Respir Crit Care Med* 2000;161:1376–1395, with permission.)

risk of progression to disease from LTBI varies according to the characteristics of the infected person *(11,13)*. Thus, to increase the likelihood that a positive test represents true infection with *M. tuberculosis* and to improve the benefit-to-risk ratio of preventive therapy, the cut point used for defining a positive TST is varied in different populations. A reaction ≥5 mm is considered positive in persons with HIV infection or severe immunosuppression, persons with close contacts of infectious TB cases, or persons with abnormal chest radiographs consistent with TB.

A reaction ≥10 mm is classified as positive in persons who do not meet the above criteria but who have other risk factors for TB. These would include (a) recent (≤5 years) immigrants from countries with a high prevalence of TB; (b) intravenous drug users; (c) residents and employees of high-risk congregate settings (e.g., correctional institutions, nursing homes, healthcare facilities, homeless shelters, or mental institutions); (d) persons with medical conditions that have been reported to increase the risk of TB (e.g., silicosis, gastrectomy, jejunoileal bypass, being ≥10% below ideal body weight, chronic renal failure, diabetes mellitus), some hematologic disorders (i.e., leukemias, lymphomas, or carcinomas of the head, neck, or lung); (e) mycobacteriology laboratory personnel; (f) children <4 years of age or infants, children, and adolescents exposed to adults in high-risk categories; and (g) other high-risk populations identified locally as having a relatively high incidence of TB.

A reaction of ≥15 mm is classified as positive in persons with no risk factors for TB.

The TST can be valuable for identifying persons newly infected with *M. tuberculosis* when repeated periodically in surveillance of tuberculin-negative persons likely to be exposed to TB (e.g., healthcare workers) *(13)*. However, there are special considerations in identifying newly infected persons.

First, there are unavoidable errors in even the most carefully performed tests. For this reason, small increases in reaction size may not be meaningful. For persons whose previous reaction was negative, an increase in reaction size of ≥10 mm in diameter within 2 years should be considered a TST conversion. Healthcare workers with some degree of TST induration as a result of nontuberculous mycobacterial infection or previous BCG vaccination have converted, if induration increases by ≥10 mm over previous tests. For healthcare workers at low risk of exposure with a history of a negative TST, an increase of 15 mm within a 2-year period may be more appropriate for defining a recent conversion. Converters should be considered newly infected with *M. tuberculosis* and strongly considered for preventive therapy *(11,16)*.

A second problem in identifying newly infected persons is the so-called booster phenomenon *(17)*. Repeated testing of uninfected persons does not sensitize them to tuberculin. However, delayed hypersensitivity to tuberculin, once it has been established by infection with any species of mycobacteria or by BCG vaccination, may gradually wane over the years, resulting in a TST reaction that is negative. The stimulus of this test may recall the immune reaction, which results in an increase in the size of the reaction to a subsequent test, sometimes causing an apparent conversion that is then interpreted as indicating new infection. The booster effect can be seen on a second test done as soon as a week after the initial stimulating test and the booster effect can persist for a year and perhaps longer.

When tuberculin skin testing of adults is to be repeated periodically, the initial use of a two-step testing procedure can reduce the likelihood of interpreting a boosted reaction as representing recent infection *(18)*. In two-step testing, an initial TST is performed. If the reaction to the first test is negative, a second test should be given 1 to 3 weeks later. If the reaction to the second of the initial two tests reaches the appropriate cut point for a positive result in the patient, this probably represents a boosted reaction. On the basis of this second test result, the person should be classified as being previously infected and managed accordingly. If the second test result remains below the appropriate cut point, the person is classified as being uninfected. A positive reaction to a third test (with an appropriate increase) in such a person, within the next

2 years, is likely to represent the occurrence of new infection with *M. tuberculosis* in the interval.

Whole-Blood Interferon-γ Release Assays In 2005, a new *in vitro* test, QuantiFERON-TB Gold (QFT-G, Cellestis Limited, Carnegie, Victoria, Australia), received final approval from the FDA as an aid in diagnosing *M. tuberculosis* infection, including both LTBI and TB disease. This enzyme-linked immunosorbent assay test detects the release of interferon-gamma (IFN-γ) in fresh heparinized whole blood from sensitized persons when it is incubated with mixtures of synthetic peptides simulating two proteins present in *M. tuberculosis*: early secretory antigenic target-6 (ESAT-6) and culture filtrate protein-10 (CFP-10). ESAT-6 and CFP-10 are secreted by all *M. tuberculosis* and pathogenic *M. bovis* strains. Because these proteins are absent from all BCG vaccine strains and from commonly encountered nontuberculous mycobacteria except *M. kansasii*, *M. szulgai*, and *M. marinum*, QFT-G is expected to be more specific for *M. tuberculosis* than tests that use tuberculin PPD as the antigen. QFT-G represents one type of interferon-γ release assay (IGRA). Tests such as QFT-G measure the IFN-γ released by sensitized white blood cells after whole blood is incubated with antigen. Tests such as ELISpot enumerate cells releasing IFN-γ after mononuclear cells recovered from whole blood are incubated with similar antigens. Two IGRAs have been approved by FDA for use in the United States: the original QuantiFERON-TB test (QFT) and the recently approved QFT-G. The two tests use different antigens to stimulate IFN-γ release, different methods of measurement, and different approaches to test interpretation. QFT was approved as an aid for diagnosing LTBI, whereas QFT-G is approved as an aid for diagnosing both LTBI and TB disease. QFT is no longer commercially available.

Each of the three tests (TST, QFT, and QFT-G) relies on a different immune response and differs in its relative measures of sensitivity and specificity. The TST assesses *in vivo* delayed type hypersensitivity (Type IV), whereas QFT and QFT-G measure *in vitro* release of IFN-γ. The TST and the QFT measure response to PPD, a polyvalent antigenic mixture, whereas QFT-G measures response to a mixture of synthetic peptides simulating two specific antigenic proteins that are present in PPD. The IGRA is less likely to be concordant with the TST in persons with a history of BCG vaccination and in persons with immune reactivity to nontuberculous mycobacteria *(19)*. The advantages of the IGRA test are that it requires only one patient visit, does not boost immune response like the TST, and is less subject to reader bias and error. Its disadvantages are that it requires phlebotomy, processing within 12 hours, and 16 to 24 hours of incubation.

QFT-G can be used in all circumstances in which the TST is used, including contact investigations, evaluation of recent immigrants who have had BCG vaccination, and TB screening of healthcare workers and others undergoing serial evaluation for *M. tuberculosis* infection. QFT-G usually can be used in place of (and not in addition to) the TST. A positive QFT-G result should prompt the same public health and medical interventions as a positive TST result. No reason exists to follow a positive QFT-G result with a TST. Persons who have a positive QFT-G result, regardless of symptoms or signs, should be evaluated for TB disease before LTBI is diagnosed. At a minimum, a chest radiograph should be examined for abnormalities consistent with TB disease. Additional medical evaluation would depend on clinical judgment on the basis of findings from history (including exposure to infectious TB), physical examination, and chest radiography. HIV counseling, testing, and referral is recommended, because HIV infection increases the suspicion for TB and the urgency of treating LTBI. After TB has been excluded, treatment of LTBI should be considered.

The majority of healthy adults who have negative QFT-G results are unlikely to have *M. tuberculosis* infection and do not require further evaluation. However, for persons with recent contact with persons who have infectious TB, negative QFT-G results should be confirmed with a repeat test performed 8 to 10 weeks after the end of exposure, as is recommended for a negative TST result. The CDC guidelines for use and interpretation of the interferon-γ test are listed in Table 38-2 (20).

GENERAL EPIDEMIOLOGY OF TUBERCULOSIS IN THE UNITED STATES

In the United States, TB affects certain segments of the population disproportionately because the factors that affect the likelihood of exposure to and infection with *M. tuberculosis* and the likelihood of progression from LTBI to disease are not homogeneously distributed throughout the population.

For 2008, 12,898 episodes of TB were reported to the CDC, reflecting a rate of 4.2 cases per 100,000 population *(21)*. This represents the 16th consecutive year that TB cases declined and the lowest rate recorded since national reporting began in 1953. However, the rate of decline has slowed; an average of 7.3% decline from 1993–2000 to 3.8% during 2000–2008. In 2008, the largest declines occurred in persons ≥65 years and older (from 17.7 per 100,000 in 1993 to 6.4 in 2008), in adults aged 45 to 64 years (from 12.4 to 5.0), in adults aged 25 to 44 years (from 11.5 to 5.1), and in children <15 years of age (from 2.9 to 1.3), each group having decreased more than 50% *(22)*. The rate declined by 32% in those 15 to 24 years of age (from 5.0 to 3.4). Six percent were children <15 years of age, 11% were age 15 to 24, 33% were age 25 to 44, 30% were age 45 to 64, and 19% were ≥65 years old.

The overall national trend reflects the impact of changes within population subgroups. Of the 12,824 incident cases of known origin, 5,283 (41.2%) were U.S. born and 7,541 (58.8%) were foreign born. From 1993 to 2008, there was a 72.6% decline in TB cases among U.S.-born persons of all age groups to a rate of 2.0 per 100,000 population. Among foreign-born persons in the United States, both the number and the rate of TB declined, 3.9% compared to 2007 and 69.7% compared to 1993; the 2008 rate was 20.2 per 100,000 population—a 2.6% decline from 2007 and a 40.6% decline since 1993. In 2008, four countries accounted for approximately half (50.1%) of foreign-born TB cases: Mexico (1,742), the Philippines (855), India (598), and Vietnam (580). U.S.-born non-Hispanic Blacks comprised the largest number of TB cases among US born (42.2%; 2,227/5,283).

TABLE 38-2

Interpretation of QFT-G[a] Results, from IFN-γ[b] Concentrations in Test Samples

ESAT-6–Nil[c] or CPF-10–Nil[d] or Both	*Nil*	*Mitogen–Nil[e]*	*QFT-G Result*	*Interpretation*
≥0.35 IU/mL[f] and >50% above nil	Any	Any	Positive	*Mycobacterium tuberculosis* infection likely
<0.35 IU/ml	≤0.7	≥0.5	Negative	*M. tuberculosis* infection unlikely but cannot be excluded especially when illness is consistent with TB[g] disease and likelihood of progression to TB disease is increased
<0.35 IU/mL	Any	<0.5	Indeterminate	QFT-G results cannot be interpreted as a result of low mitogen response
≤50% above nil	>0.7	any	Indeterminate	QFT-G results cannot be interpreted as a result of high background response

The geographic distribution of TB in the U.S. also is not homogeneous. In 2008, four states (California, Florida, New York, and Texas) reported approximately half (49.2%) of all TB cases and each reported >500 cases each. However, by 2008, 35 states had met the Advisory Council for TB Elimination interim goal of ≤3.5 cases/100,000 population. Cases of TB remained concentrated in urban areas: in 2001, 39% of TB cases were reported from 64 major cities *(23)*.

A total of 125 cases of multidrug-resistant TB (MDR-TB) were reported in 2007, the most recent year with complete drug-susceptibility testing data. Of those with drug-susceptibility results in 2006 and 2007, 97.4 (10,477/10,762) were susceptible to isoniazid and 97.8% (10,190/10,421) to rifampin. The percentage of TB cases that were MDR-TB for 2007 (1.2%; 125/10,190) was similar to that of 2006 (1.2%; 124/10,477). The percentage of MDR-TB cases among persons without a previous history of TB has remained stable at approximately 1.0% since 1997. In 2007, the percentage of MDR-TB cases among persons with a previous history of TB was 3.6%. In 2007, MDR-TB continued to disproportionately affect foreign-born persons, who accounted for 81.6% of MDR-TB cases. Foreign-born persons had a higher percentage of MDR-TB, both among those with (5.2%) and without (1.5%) a previous history of TB. Cases of extensively drug-resistant TB (XDR-TB) have been reported every year in the United States except 2003 since drug-susceptibility reporting began in 1993. Four XDR-TB cases were reported in 2006 and two in 2007. Provisional data indicated that four XDR-TB cases were reported in 2008.

Data on the HIV status of persons with TB reported to the national TB surveillance system at the CDC are limited. Reporting of HIV status has improved slowly since 1993, the year such information was first included on TB case reports submitted to the CDC. In 2001, 3,254/5,630 (58%) TB case reports for persons aged 25 to 44 years included information about HIV status *(22)*. In 2001, 26 states reported HIV test results for at least 75% of cases in persons in this age group. Of these 26 states, the percentage of TB cases in persons aged 25 to 44 years who were coinfected with HIV ranged from 0% (New Hampshire, South Dakota, and Wyoming) to >39% (District of Columbia and Florida). To help estimate the proportion of reported TB cases coinfected with HIV, state health departments have compared TB and acquired immunodeficiency syndrome (AIDS) registries. During 1993 to 1994, 14% of all TB cases (27% of cases in persons aged 25–44 years) had a match in the AIDS registry *(24)*. In 2008, among 7,625 persons with TB with a known HIV test result, 802 (10.5%) were infected with HIV. California, Michigan, and Vermont data were not available for this calculation. In 2007, excluding California and Vermont, among 8,289 persons with TB and an HIV test, 884 (10.7%) were infected with HIV *(21)*.

From 1953, when national reporting of incident TB cases was first fully implemented in the U.S., through 1984, the number of cases reported to the CDC decreased from 84,304 to 22,255. This average annual decline of 5% to 6% was interrupted only by a transient increase in 1980, which was attributed to cases arising from a large influx of refugees from Southeast Asia *(25)*. Between 1984 and 1992, there was a dramatic reversal of the long-standing decline in the number of TB cases.

From 1985 through 1992, reported cases increased 20.1%, from 22,201 to 26,673. Based on an extrapolation of the trend in cases observed from 1980 through 1984, approximately 52,000 excess cases of TB were reported to the CDC from 1985 through 1992 *(26)*.

Increases in the number of cases in the late 1980s were mainly due to the HIV/AIDS epidemic and the emergence of MDR-TB. Other contributing factors include (a) an increase in the number of cases occurring in persons who immigrate to the United States from areas of the world that have a high prevalence of TB; and (b) an increase in active transmission of *M. tuberculosis* caused largely by adverse social conditions and an inadequate healthcare infrastructure *(26)*.

The decline in the overall number of reported TB cases and in the level of MDR-TB since 1992 has been attributed to stronger TB controls that emphasize prompt identification of persons with TB, initiation of appropriate therapy, and ensuring completion of therapy. The declining TB trend among US-born persons reflects the reduction of community transmission of *M. tuberculosis*, particularly in areas with a high incidence of HIV *(27)*. In comparison, the relatively stable number of reported cases of TB among foreign-born persons indicates that most cases of active TB disease among foreign-born persons residing in the United States results from infection with *M. tuberculosis* in the person's country of birth (28). The CDC, in collaboration with state and local health departments, continues to focus on its comprehensive plan to reduce active TB disease among foreign-born persons residing in the United States. This plan includes strategies to (a) improve case finding and completion of therapy, (b) conduct contact investigations, (c) screen those at high risk for infection, and (d) ensure completion of preventive therapy in eligible candidates *(29)*.

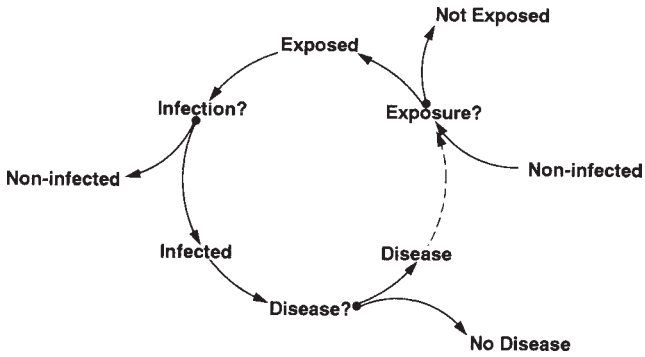

FIGURE 38-1 Schematic illustration of the steps involved in the acquisition of tuberculous infection and the development of active tuberculosis.

EPIDEMIOLOGY OF HEALTHCARE-ASSOCIATED TUBERCULOSIS IN THE UNITED STATES

Factors Influencing the Epidemiology of Healthcare-Associated Tuberculosis

The factors that influence the epidemiology of healthcare-associated TB are the joint probabilities that exposure to *M. tuberculosis* will occur, exposure will result in infection, and infection will lead to active TB (Fig. 38-1). In a healthcare facility, the likelihood of exposure to *M. tuberculosis* may be affected by factors such as the prevalence of infectious TB in the population served by the facility; the degree of crowding in the facility; the effectiveness of the facility's TB infection control program in rapidly identifying, isolating, and treating persons with infectious TB; and the effectiveness of engineering controls, such as directional airflow and booths for cough-inducing procedures, in preventing the spread of contaminated air throughout the facility.

Factors that may affect the likelihood that exposure to *M. tuberculosis* will result in infection are largely related to the effectiveness of the facility's infection control program. These factors include the effectiveness of the program in identifying and successfully treating persons with infectious TB, thereby rendering them noninfectious; the effectiveness of engineering controls, such as ventilation and ultraviolet germicidal irradiation (UVGI), in reducing the concentration of infectious droplet nuclei in the air; and the effectiveness of the respiratory protection program in preventing the inhalation of infectious droplet nuclei. Additionally, although supporting data are lacking, it is possible that medical conditions that cause severe suppression of cell-mediated immunity may increase susceptibility to infection with *M. tuberculosis*; thus, the prevalence of such conditions, either in patients or healthcare workers, may affect the likelihood that exposure of these persons will result in infection.

Factors that are likely to influence the risk that infection with *M. tuberculosis* will result in progression to active TB probably include the prevalence in the facility's patient and healthcare worker population of medical conditions that increase the likelihood of progression from LTBI to active disease (e.g., HIV infection). In addition, the infection control program's effectiveness in identifying persons who have been exposed and infected and providing them with appropriate preventive therapy is likely to influence the likelihood of progression to active disease. Events or conditions that alter any of these probabilities (the probability of exposure, infection, or progression to active TB) may result in changes in the epidemiology of TB in a healthcare facility.

Several types of information may be considered in describing the epidemiology of healthcare-associated TB. These include surveillance for active TB in healthcare workers, surveillance for LTBI (i.e., TST conversions or IGRA-positive) in healthcare workers, and reports of episodes of healthcare-associated *M. tuberculosis* transmission (such as reports of outbreaks).

Surveillance for Active Tuberculosis in Healthcare Workers

There are very few national data on the recent or current risk of active TB in healthcare workers. Information on the occupation of persons with TB was not collected in the national TB surveillance system until 1993, at which time limited variables on occupation were added to the data collection forms. However, without appropriate denominators, it is not possible to calculate incidence rates or relative risks for healthcare workers. In 2001, 50 of the reporting areas in the United States reported information

on occupation for at least 75% of TB cases. There were 414 reported TB cases among healthcare workers in 2001, a slight decline when compared to the 427 cases reported in 2000 *(22,30)*. The percentage of cases occurring among healthcare workers in 2001 ranged from 0% in the District of Columbia, Idaho, Indiana, Nevada, North Dakota, South Dakota, Utah, Vermont, West Virginia, and Wyoming to 6.6% in Massachusetts and 15.8% in New Hampshire.

In a questionnaire survey of medical school–affiliated physicians in California, Barrett-Connor *(31)* found that 3.5% had been treated for active TB. Seventy-five percent of cases of active disease began when the physicians were within 10 years of beginning medical school; 62% of cases of active disease followed infection acquired after beginning medical school. In the cohort of those who graduated between 1966 and 1975, disease rates after beginning medical school were 0% (0/54) among those who were TST positive at entry; 1.0% (7/669) among those who were TST negative at entry; and 10.0% (7/69) among those who became TST positive after entry.

A questionnaire survey of 1938 to 1981 graduates of the University of Illinois Medical School found that, for most years, the incidence of TB in the cohort of graduates was higher than that in the general population *(32)*. More than two thirds of all cases of TB occurred during medical school or within 6 years of graduation.

Finally, a review of the recorded occupations of persons with TB reported to the North Carolina TB control program found that TB case rates in hospital personnel in 1983 and 1984 were similar to or lower than rates in the general population *(33)*. However, these data were not adjusted for age or race, nor was a definition of the term *hospital employee* provided.

In summary, data concerning the recent or current risk of active TB in healthcare workers in the United States are very limited. Two questionnaire surveys suggest an increased risk among physicians, whereas a third study suggests that the risk for hospital employees in general is similar to that for the general population. The data from Barrett-Connor's survey suggest a protective effect of a previous positive TST. The incidence of TB is a relatively insensitive measure of the actual risk posed to healthcare workers by occupational exposure to *M. tuberculosis*. A more sensitive measure of this risk is the rate of TST conversions or IGRA positives among healthcare workers.

Surveillance for TST Conversions in Healthcare Workers

The annual rate of TST conversions in healthcare workers is the best potential indicator of the risk of becoming infected with *M. tuberculosis* through occupational exposure in the healthcare setting. However, there is no systematic national surveillance for such conversions in U.S. healthcare workers. In 1995, the CDC, in collaboration with selected state and local health departments, began a prospective TST surveillance project to estimate the incidence of occupational transmission of *M. tuberculosis* to healthcare workers. Participating sites (Florida, Massachusetts, Mississippi, New Jersey, New York City, San Francisco, and San Diego) were required to implement TST programs consistent with current CDC guidelines and to pilot test a CDC-developed microcomputer software system, staffTrakTB, to assist with collection, tracking, management, and analysis of data *(34a,34b)*. The project areas enrolled 26 facilities: eight hospitals, five health departments, two long-term-care facilities, three correctional facilities, and eight other facilities (including a state laboratory). From 1995 to 1997, a total of 29,004 healthcare workers were enrolled in the project; 9,088 (31.3%) were included in the analysis. TST conversions (i.e., ≥10 mm increase in reaction size on follow-up TST) were documented in 1.1% (104 of 9,088) of healthcare workers *(35)*. Conversion rates varied by project area, ranging from 0% in Florida to 4.2% in New York City, and by facility (correctional, 2.1%; health departments, 1.3%; hospitals, 1.0%; or nursing homes, 0.8%). TST conversion rates also varied by occupation of the healthcare worker (outreach worker, 4.2%; scientist, 2.7%; technician, 2.2%; nurse, 1.2%; housekeeper, 1.2%; clerical worker, 1.0%; administrator, 0.8%; attending physician, 0.6%; and social worker, 0.3%). TST conversion rates among nurses were highest in New York City (4.2%) and San Francisco (2.2%) and lowest in Mississippi (0.1%) and Florida (0%), probably reflecting an elevated risk of *M. tuberculosis* transmission in areas with high TB incidence such as New York City and San Francisco. Healthcare workers who were outreach workers, nonwhite, non–U.S.-born, or BCG-vaccinated were at a significantly higher risk of conversion. These data suggest that foreign-born status and certain occupations may be associated with an elevated risk of *M. tuberculosis* transmission, possibly reflecting more exposure to infectious individuals in the healthcare worker's household or community, and in certain healthcare settings.

There are several reports in the literature of the risk of TST conversion among U.S. healthcare workers (Table 38-3) (*18*,*31*,*33–50*,51,*52–59*). These reports suggest that, since 1980, the risk of TST conversion among hospital employees in general has been ≤1%.

One prospective study followed workers at an urban hospital in a high TB-incidence area where TST screening was required of all eligible employees every 6 months *(59)*. This study found an overall TST conversion rate of 0.38% per year. TST conversion was not associated with the degree of patient contact, but was associated with BCG vaccination, low annual salary, and increasing age. The researchers concluded that, in a hospital with an effective TB infection control program, TST conversion rates were low and that the most important risk factors for TST conversion among workers were not occupational.

At least two other studies have found a higher risk for TST conversion with increasing age of the workers *(40,43)*. A third study that examined age as a risk factor for TST conversion found an association with increasing age when two-step TST was not used to establish the employees' baseline skin test status; however, when two-step TST was used to eliminate apparent conversions caused by the booster phenomenon, there was no longer any correlation between age and the risk of conversion *(18)*. This finding suggests that the higher rate of apparent conversion sometimes observed in older workers may actually be the result of an increased level of boosting in older persons.

Race has been found to correlate with risk of TST conversion in two studies. One of these reported a higher risk among non-whites compared with whites, and a higher risk among employees in the lowest socioeconomic quintile *(40)*.

TABLE 38-3

Tuberculin Skin Test Conversion Rates in Healthcare Workers United States, 1960–1998

First Author (Reference)	*Institution Location*	*Time Period*	*Population*	*Annual Conversion Rate (%)*[a]
Levine (36)	Kings County Hospital Brooklyn, New York	1960–1967	Student nurses	1.05
Weiss (37)	Philadelphia General Hospital, Philadelphia, Pennsylvania	1962–1971	Student nurses	4.20
Atuk (38)	University of Virginia Hospital, Charlottesville, Virginia	1968–1969	Hospital employees	1.92
Gregg (39)	State Park Health Center, South Carolina	1969–1973	Hospital employees	4.08
Berman (40)	Sinai Hospital of Baltimore, Baltimore, Maryland	1971–1976	Hospital employees	1.41
Craven (41)	University of Virginia Hospital, Charlottesville, Virginia	1972–1973	Hospital employees	0.52
Vogeler (42)	LDS Hospital, Salt Lake City, Utah	1972–1975	Hospital employees	0.16
Ruben (43)	Montefiore Hospital, Pittsburgh, Pennsylvania	1973–1975	Hospital employees	3.07
Ktsanes (44)	Charity Hospital New Orleans, Louisiana	1972–1981	Hospital employees	1.04
Barrett-Connor (31)	Multiple institutions, California	1974–1975	Medical school–affiliated physicians	0.4–1.8
Weinstein (45)	Mount Sinai School of Medicine, New York City	1974–1982	Medical students	0.13
Chan (46)	Jackson Memorial Hospital, Miami, Florida	1978–1981	House staff	3.96
Bass (18)	University of South Alabama, Medical Center Mobile, Alabama	1979	Hospital employees	2.9
Thompson (47)	10 hospitals, 9 states[b]	1979	Hospital employees	2.9
Kantor (43)	Veterans Administration Medical Center Chicago, Illinois	1979–1986	Hospital employees	0.94
Price (33)	167 hospitals, North Carolina	1980–1984	Hospital employees	1.14
Aitken (49)	114 hospitals, Washington	1982–1984	Hospital employees	0.87
Malasky (50)	Multiple Institutions Multiple US cities	1984–1986	Pulmonary fellows	5.65
Raad (51)	Shands Hospital, Gainesville, Florida	1984–1987	Hospital employees	0.13
Raad (51)	Florida State Psychiatric Hospital, Chattahoochee, Florida	1985–1987	Hospital employees	0.42
Ramirez (52)	Humana Hospital, University of Louisville, Louisville, Kentucky	1986–1991	Hospital employees	0.68
Ikeda (53)	Health Science Center State, University of New York, Syracuse, New York	1989–1990	Hospital employees	0.84
Ramaswamy (54)	Bronx, New York	1990–1993	Hospital employees	1.40
Zahnow (55)	Multiple institutions providing HIV-related healthcare	1992–1993	House staff	3.00
Christie (56)	Children's Hospital Medical Center, Cincinnati, Ohio	1986–1994	Hospital employees	0.03–0.28
Panlilio (57)	5 hospitals, New York City, Boston, Massachusetts	1994–1995	Hospital employees	1.61
Manangan (58)	Multiple institutions multiple cities	1996	Hospital employees	0.27[a]
Larsen (59)	Grady Memorial Hospital, Atlanta, Georgia	1994–1998	Hospital employees	0.38

[a]In some cases, the annual conversion rate has been recalculated from data provided in the article referenced.
[b]The nine states are Pennsylvania, Colorado, Maryland, Texas, New Mexico, Ohio, Montana, New Hampshire, and Georgia.

The other found a higher risk of TST conversion among black employees than among non-blacks; however, among blacks, the risk was higher among nurses than among persons in other job categories *(44)*. In the one study that examined gender as a potential risk factor, no association was found between gender and the risk of TST conversion *(40)*. A survey that included multiple institutions throughout North Carolina found that the risk of conversion varied according to geographic region within the state *(33)*.

Few reported studies have examined the relationship between job category and risk of TST conversions. One study found a higher risk of conversion among persons

in laundry, housekeeping, and engineering and maintenance departments than among persons in other departments *(40)*. A second study found a higher conversion rate among nurses than among persons in other job categories *(44)*. A third study found higher conversion rates among admissions clerks, phlebotomists, and nurse technicians than among respiratory therapists, environmental services workers, or registered nurses *(52)*. A survey of self-reported TST conversions among medical fellows at multiple institutions found a higher reported rate of conversion among pulmonary fellows than among infectious diseases fellows *(50)*. Finally, a survey of self-reported TST conversions among medical school–affiliated physicians in California found that physicians in the major clinical specialties reported comparable infection rates before and during medical school, but that rates after medical school were highest in medicine, pediatrics, and surgery; intermediate in obstetrics and gynecology and orthopedics; and lowest in radiology and psychiatry *(31)*. In this survey, the cumulative percentage of TST-positive physicians was at least twice the estimated age-specific infection rate for the general U.S. population.

Several studies have found higher conversion rates among workers with a higher likelihood of exposure to patients with TB than among those with a relatively lower likelihood of such exposure *(38,39,41,42,57,58)*. In contrast, in a hospital in Pennsylvania, the reported conversion rates for groups with high or low degrees of exposure to patients with TB were not significantly different *(43)*. Similarly, in a multi-institution survey in Washington, reported conversion rates were not significantly different in hospitals that had admitted no patients with TB compared with hospitals that had admitted patients with AFB smear-negative TB or hospitals that had admitted patients with AFB smear-positive TB *(49)*. In this study, however, postexposure conversions were excluded from analysis, and there was no analysis by risk of exposure within the hospitals that did admit TB patients. A study from Florida reported a higher conversion rate among employees in a psychiatric hospital, in which there was presumably a low risk of exposure, than in a general hospital in which the risk of exposure was presumably higher (51). Again, this study did not examine the risk of TST conversion according to the likelihood of exposure within each hospital. Finally, a prospective study to assess the prevalence of TST positivity among healthcare workers providing service to HIV-infected persons found no association between the amount or the type of contact with HIV-infected individuals and the risk of TB infection *(55)*. Therefore, according to this study, caring for HIV-infected patients was not related to an increased rate of TB infections among healthcare workers in these settings.

These studies, in addition to being few in number, have substantial limitations. With the exception of one study *(59a)*, most are retrospective; the populations being studied often are not well defined; participation rates are not consistently reported but are variable and often quite low; the methods of applying and reading the tests are variable and often rely on employees' self-reporting of results; two-step TST to establish a baseline is rarely used; the definitions of positive skin tests or of TST conversions are not always specified and are variable; the classification of job categories and the definitions of exposure are inconsistent; there are essentially no data on background risk in the community or on the performance of serial TST in the general population from which to make estimates of attributable risk; the analyses often are insufficiently detailed to allow an estimation of relative risks for different job categories; and problems with the specificity and positive predictive value of the TST rarely are addressed adequately. Furthermore, the antigens used often are not described and appear to vary between, and possibly within, studies. It has been noted that a change in products can result in an increase in the conversion rate or pseudo-outbreak *(14)*. For these reasons, interpretation of the data is difficult, and comparison of data from different studies is problematic. In spite of all these limitations, it is interesting that the overall risk among hospital employees in general seems to be fairly consistent.

In summary, available data suggest that the risk of TST conversion among hospital employees in general is ≤1%. The data, although conflicting, also suggest that there may be substantial variation in risk according to the type of hospital, geographic location, occupational category, and a priori likelihood of exposure. Interpretation of the data is made difficult by methodologic limitations, by the lack of specificity and positive predictive value of the TST, by the difficulty of differentiating occupational risk from exposure in the community, and by an inadequate understanding of serial TSTs reflected in some studies. In international settings or domestic settings with large numbers of healthcare workers who have received BCG, the use of IGRAs may be more useful than TST for monitoring potential occupational exposures to *M. tuberculosis (59b)*.

Healthcare-Associated Outbreaks of Tuberculosis

A healthcare-associated outbreak of TB may be defined as transmission of *M. tuberculosis* in a healthcare setting, resulting in the acquisition of LTBI or the development of TB among exposed persons. There is no systematic national surveillance for healthcare-associated TB outbreaks; therefore, data on such outbreaks are limited to reports in the literature. Since 1960, at least 41 healthcare-associated outbreaks occurring in the United States have been reported in the literature (Table 38-4) (*48*,*53–55*,*60–64*,65,*66,67*,68,*69*,70,*71*,72,73,*74*,75,76,*77–96b*).

The reported outbreaks have occurred in a wide variety of geographic areas. Most have occurred in general medical-surgical hospitals; one occurred in a health department clinic, one in an outpatient methadone treatment program, one in an outpatient hemodialysis unit, one in a pediatric office, one at a children's hospital, one in two nursing homes and a community hospital, and one involved both a general hospital and a hospice. Outbreak settings within the hospitals have included emergency departments, inpatient medical wards, adult or neonatal intensive care units, a surgical suite, radiology suites, inpatient HIV wards and an outpatient HIV clinic, an inpatient renal transplant unit, an inpatient prison ward, an autopsy suite, a nursery, a maternity ward, and bronchoscopy rooms.

The earlier reports of outbreaks in this series primarily focused on transmission of *M. tuberculosis* from patients to healthcare workers, with an occasional secondary case

identified in another patient. The apparent infrequency of transmission to other patients in these outbreaks may be artifactual because of the difficulty often encountered in obtaining follow-up information on exposed patients and the natural history of TB. Because the interval from infection to disease is highly variable (ranging from weeks to decades), the occurrence of active TB is not likely to be attributed to a hospitalization in the more remote past. Thus, in the absence of temporal clustering of TB cases or the appearance of strains of *M. tuberculosis* with distinctive drug resistance or DNA fingerprint patterns, transmission to patients in a hospital may go unrecognized *(2)*. In contrast to the earlier reports, many of the more recently reported outbreaks have occurred in settings where many of the persons exposed were severely immunocompromised patients. These outbreaks have involved rapid propagation of active TB among relatively large numbers of patients.

A variety of factors have been identified as possibly contributing to the reported healthcare-associated TB outbreaks. In many cases, these factors represent empiric observations, and the actual contribution of any given factor cannot be calculated. In some instances, the analysis presented has allowed an estimate of the relative contribution of a specific factor. In general, potential contributing factors can be categorized into those that increase the likelihood of exposure to *M. tuberculosis*, those that increase the likelihood of infection occurring among persons who are exposed, and those that increase the likelihood of active disease in persons who become infected.

Factors That Affect the Likelihood of Exposure A major factor increasing the likelihood of exposure to *M. tuberculosis* has been failure to promptly identify and isolate a potential source of transmission, usually a patient with undiagnosed and untreated, or inadequately treated, TB (Table 38-4). In at least three outbreaks, healthcare workers also have been implicated as sources of transmission (70,*88,94*); in one, transmission only occurred from healthcare worker to healthcare worker in a setting where routine employee screening did not take place *(94)*. Failure to identify persons with infectious TB (including parents or visitors for pediatric patients) has resulted in these persons not being isolated and appropriately treated, thus increasing the number of persons exposed.

In most instances, transmission has occurred from patients with pulmonary TB. However, in two outbreaks, transmission occurred as a result of irrigation or manipulation of an undiagnosed *M. tuberculosis* abscess or skin ulcer *(64,71)*. The presence of drug-resistant microorganisms that are inadequately treated also may lead to prolonged infectiousness and an increased likelihood of exposure.

In some outbreaks, there often have been multiple sources, resulting in a web of possible transmissions, rather than a clearly defined single chain of transmission. In at least three recent outbreaks, DNA fingerprinting using RFLP has demonstrated the presence of more than one chain of transmission involving different strains of *M. tuberculosis*, when epidemiologic evidence seemed to suggest a single chain of transmission (68,72,*92*).

Inadequate ventilation also has increased the likelihood of exposure to *M. tuberculosis*. In some instances, the presence of positive air pressure in isolation rooms has allowed potentially contaminated air to escape from the isolation rooms into other areas of the facility. In most situations, the presence of other potentially contributing factors has made it difficult to assess the effect of positive air pressure alone; however, in one outbreak in which other aspects of the infection control program were adequately implemented, the role of positive air pressure was clearly demonstrated *(53)*. In other instances, recirculation of potentially contaminated air from sputum induction or isolation rooms into other areas of the facility has been implicated as a factor in transmission (*61,63,66*,72).

Lapses in isolation practices have increased the likelihood of exposure in several outbreaks. Such lapses have included not keeping isolation room doors closed, thereby allowing efflux of potentially contaminated air from the room into adjacent areas; not keeping patients with infectious TB confined to their rooms; not enforcing the use of masks by patients with infectious TB when they are out of their rooms; and not maintaining isolation for a period long enough to ensure that the patient is no longer infectious. Additionally, inadequate cleaning, disinfection, or leak testing of bronchoscopes after performing bronchoscopy in pulmonary TB patients led to transmission of infection and active TB disease *(86,94)* (see also Chapter 62).

Factors That Affect the Likelihood of Infection In general, factors that are likely to produce a relatively high concentration of infectious droplet nuclei in the air also are likely to increase the likelihood that an exposed person will inhale tubercle bacilli and become infected. Thus, patients identified as outbreak sources often have had chest radiographs showing extensive cavitary disease and sputum smears that were positive for AFB—factors suggesting a high bacterial burden. However, in outbreaks among immunocompromised persons, extensive cavitary disease has been relatively infrequent (67,68,72,73,75,*77,87,95,96*). Furthermore, in rare instances, high rates of transmission from persons with sputum smears that were negative for AFB have been documented *(48,62)*.

Inadequate ventilation rates and recirculation of potentially contaminated air within closed environments can lead to increased concentrations of infectious droplet nuclei in the air and have been implicated in several outbreaks (*48,61–63,66*,68,70,72,*74*,76,*77*). Patients in rooms in close proximity to a room housing a patient with infectious TB have been shown to be at increased risk when the isolation room is not under appropriate negative pressure (*64*,73,76).

Performing procedures that stimulate cough or generate aerosols in persons with TB also may lead to an increased concentration of infectious droplet nuclei in the air. A number of such procedures have been reported in association with outbreaks. These procedures have included endotracheal intubation and suctioning (*61–63*,68,*90*); bronchoscopy (*62*,68,*93*); surgical drainage and irrigation of a *M. tuberculosis* abscess, and surgical debridement of an *M. tuberculosis* skin ulcer *(64,71)*; administration of aerosolized pentamidine (*66*,72); and autopsy *(48)*. Finally, lack of or inappropriate use of respiratory protection also has been reported in some outbreaks (*63*,68,76,*77,90,93,94*).

Whether or not underlying HIV infection causes increased susceptibility to infection with *M. tuberculosis* is not yet

TABLE 38-4

Reported Healthcare-Associated Outbreaks of Tuberculosis (TB), United States, 1960–1999

Type of Facility, First Author (Reference)	*Setting*	*Patients (Including Source)*		*Healthcare Workers (Including Source)*		*Contributing Factors*
		Infection	*Active Disease*	*Infection*	*Active Disease*

[a]Includes source(s) of outbreak.
[b]See also Table 37-5.
[c]For multidrug-resistant outbreaks, the number of cases in patients and the number of healthcare workers listed in this table include only those identified in the initial investigation.
[d]Although the initial report of this outbreak notes several "skin test conversions" in healthcare workers, the criteria used to define a skin test conversion in that report did not meet the general accepted definition.
[e]All exposed neonates presumptively treated with isoniazid for 6 months.

clearly established. In an MDR-TB outbreak in the New York state prison system, HIV infection was not found to be associated with an increased risk of becoming infected with *M. tuberculosis*; however, the small numbers included in this analysis limited the power of the analysis to detect such a risk *(97)*. In two studies, patients with HIV hospitalized for active TB caused by drug-susceptible microorganisms developed secondary infection with a hospital-acquired MDR-TB *(98,99)*.

Factors That Affect the Likelihood of Active Tuberculosis Although, hypothetically, the virulence of the infecting microorganism may increase the likelihood of progression from LTBI to active TB, this issue remains unresolved *(100)*. Profound suppression of cell-mediated immunity in the infected host is the only factor that has been definitively identified in the outbreaks as increasing the likelihood of active TB. In most cases, immunosuppression has resulted from coinfection with HIV (Table 38-4). In one outbreak, the cause was pharmacologic immunosuppression in renal transplant recipients (68). In each of these cases, immunosuppression has increased both the risk of developing active disease and the rate at which it developed, leading to rapid and widespread propagation of the outbreak.

In summary, at least 41 healthcare-associated outbreaks of TB in the U.S. have been reported in the literature since 1960. Because there is no systematic national surveillance of such outbreaks, it is unknown how many other outbreaks may have occurred but have not been reported, nor is it known whether those that have been reported are representative of all outbreaks. A multiplicity of factors potentially contributing to the reported outbreaks has been identified. Although it is difficult to estimate the quantitative contribution of each of these factors to the outbreaks, it is clear that failure to identify and appropriately isolate and treat persons with infectious TB is one of the most important factors.

Healthcare-Associated Outbreaks of Multidrug-Resistant Tuberculosis In the 1990s, several large, healthcare-associated outbreaks of MDR-TB were reported (Tables 38-4 and 38-5) (2). Outbreaks of MDR-TB are not a new phenomenon, having been reported in at least three communities, a residential substance-abuse treatment center, and a homeless shelter since 1976 (*82,85,94–96,101–105*). However, in contrast to these earlier outbreaks, which were relatively small and propagated slowly, the healthcare-associated outbreaks of the early to mid-1990s involved large numbers of patients in institutional settings and propagated rapidly.

From 1990 through 1992, the CDC collaborated with officials from state and local health departments, hospitals, and prisons to investigate eight outbreaks of MDR-TB in hospitals and in the New York state prison system (*53*,72,73,*74*,75,76,*77–97*,*106–110*). In addition to the initial investigations, follow-up investigations were conducted in some of the hospitals to evaluate the effectiveness of infection control interventions that were initiated after the outbreaks were detected (111,*112*,113,114). The total number of cases identified in each of the outbreaks has ranged from approximately 8 to 70, with the total for all the outbreaks combined >300 cases.

All of these outbreaks involved the transmission of MDR *M. tuberculosis* from person to person, including from patient to patient, patient to healthcare worker, and healthcare worker to healthcare worker. In each instance, the epidemiologic evidence of healthcare-associated transmission was compelling. For patients, factors associated with an increased risk of MDR-TB have included previous hospitalization in the associated outbreak hospital, previous hospitalization on the same ward as a patient with infectious MDR-TB, physical proximity to a patient with infectious MDR-TB during a previous hospitalization, or previous exposure to patients with infectious MDR-TB in an outpatient clinic. For healthcare workers, exposure to patients with MDR-TB has been associated with a higher risk of TST conversion than has exposure to patients with drug-susceptible TB (72). This is probably explained by prolonged infectiousness of patients with inadequately treated MDR-TB rather than by increased infectiousness of such patients. In all of the outbreaks, the epidemiologic evidence of healthcare-associated transmission was corroborated by laboratory evidence in the form of DNA fingerprinting using RFLP.

Nearly all patients in these outbreaks have had *M. tuberculosis* isolates resistant to both isoniazid and rifampin, the two most effective anti-TB drugs available. Most isolates also have been resistant to other drugs. In four hospitals and the New York state prison system, the outbreak strain was resistant to seven anti-TB drugs. Mortality among patients with MDR-TB in these outbreaks was extraordinarily high (43–93%) and has been associated with rapid progression from diagnosis of TB to death (range of median intervals: 4–16 weeks). The high mortality rates observed in these outbreaks are probably explained by the severe degree of immunosuppression in many of the patients combined with ineffective treatment for unrecognized drug-resistant disease.

In all but two of these outbreaks, >85% of cases have occurred in persons infected with HIV. This high proportion of HIV infection can be explained in two ways. First, the outbreaks have occurred predominantly in settings, for example, HIV wards and clinics, in which most of the persons exposed to and infected with *M. tuberculosis* have been HIV infected. Second, once infected with *M. tuberculosis*, HIV-infected persons are highly likely to develop active TB, especially when they are profoundly immunosuppressed, as often was true of the persons exposed in these outbreaks.

Healthcare workers at hospitals experiencing outbreaks of MDR-TB also have been affected. In some instances, it has been difficult to document infection of healthcare workers, because results of baseline TSTs were not available. However, in several of the facilities, it was possible to document TST conversions in healthcare workers in association with exposure to patients with MDR-TB (Table 38-4) (*53*,72,75,*77,95,96,109*). At least 23 healthcare workers at these facilities developed active MDR-TB; at least 11 of these workers died with MDR-TB.

The factors contributing to the MDR-TB outbreaks are essentially the same as already described for other outbreaks, including delayed diagnosis and isolation of patients with TB. Of particular importance has been delayed recognition of drug resistance leading to delays

[a]Includes cases identified during initial investigation and cases identified during subsequent follow-up.
[b]All cases resistant to drugs listed outside of parentheses; some cases resistant to drugs listed in parentheses.
[c]INH, isoniezid; RIF, rifampin; EMB, ethambutol; ETA, ethionamide; SM, streptomycin; CYC, cyloserine; KM, Kanamycin; RBT, rifabutin; PZA, pyrazinamide.
[d]HIV, human immunodeficiency virus.
[e]Includes only cases for which outcome information has been ascertained.
[f]HIV infection was part of the case definition in this outbreak.
[g]Includes 24 cases also counted with Hospital C.

in initiating effective therapy that, in turn, resulted in even more prolonged periods of infectiousness. In several instances, the delays that occurred in identifying persons with TB and recognizing drug resistance were exacerbated by delays in performing and reporting the results of laboratory tests.

Also of particular importance is the observation that each of the MDR-TB outbreaks occurred in a setting where many HIV-infected and often profoundly immunosuppressed patients were exposed. In one outbreak, 21/346 (6.1%) patients with AIDS hospitalized on the same ward as ≥1 patients with infectious MDR-TB were subsequently diagnosed with active MDR-TB, demonstrating the very high disease attack rate that can occur in such a setting (73). In several of the outbreaks, the interval from exposure to onset of active TB (i.e., incubation period) was estimated (72,73,76,*77,97*). Although different methodologies used in these calculations make summary and comparison difficult, all documented remarkably short incubation periods, possibly as short as 3 to 4 weeks. As a result of the short incubation period, as many as three complete generations of transmission and onset of clinical TB were observed in one outbreak in a 12-month period (CDC, unpublished data). Thus, the amplifying and accelerating effect that HIV has on the pathogenesis of TB has contributed substantially to the propagation of these outbreaks.

Healthcare-associated MDR-TB outbreaks also have been reported from countries other than the U.S. *(99,115–122)*. Clinically and epidemiologically, these outbreaks are similar to those reported in the United States. Many episodes occurred in HIV-infected patients with short onset of active TB after exposure, and high mortality rates *(99,115–122)*.

In summary, MDR-TB outbreaks in hospitals and correctional facilities illustrate the tremendous rapidity and extent of spread that can occur when persons who have undiagnosed or untreated (or inadequately treated) TB, caused by drug-resistant microorganisms, are brought together with highly vulnerable, immunosuppressed persons in an enclosed and relatively densely populated environment in the absence of adequate infection control precautions.

Special Settings

Pediatric Settings Healthcare-associated transmission of *M. tuberculosis* in the pediatric setting usually has involved exposure of hospitalized infants or children to hospital employees or adult visitors with active TB *(88,96b,123–129)*. Transmission from infants and young children is generally regarded as unlikely because an infant's microorganism load is low, cavitary disease is usually absent (indeed, many cases of TB in children involve primary disease with minimal pulmonary involvement), and infants have a reduced ability to expectorate *(130–132)*. However, TST conversion occurred in two healthcare workers who cared for an infant on a ventilator with widely disseminated congenital TB diagnosed at autopsy *(89)*. In another case, possible transmission to healthcare workers from a 5-year-old child with cavitary TB was reported *(133)*. In a third case, TST conversions occurred in 3.7% (5/134) of hospital employees identified as contacts of a 7-year-old child with cystic fibrosis who was hospitalized for 2 months with undiagnosed, disseminated pulmonary TB *(38)*. In a fourth case, TST conversion occurred in one healthcare worker not using respiratory protection who intubated a neonate with congenital TB *(90)*. Thus, although transmission of *M. tuberculosis* from infants and young children probably is uncommon, there are circumstances in which it may occur. In addition, parents have been associated with potential transmission of *M. tuberculosis* to patients and healthcare workers *(96b)*.

Nursing Homes and Chronic Care Facilities Transmission of *M. tuberculosis* in nursing homes and chronic care facilities has been well documented. Several outbreaks of TB in such facilities have been reported *(91,134–139)*. These outbreaks have involved transmission both to residents of the facilities and to staff. In each case, the source of the outbreak was a resident with pulmonary TB in whom the diagnosis was delayed by 2 to 12 months or was only made postmortem. In some instances, the outbreaks were discovered as a result of a routine TST screening program for staff or residents *(134,137,139)*; in other instances, the outbreaks were discovered in the course of conducting a contact investigation *(135,136,138)* (see also Chapter 98).

Dental Settings An outbreak of TB in dental patients following tooth extractions has been reported *(140)*. The source of the outbreak was a dentist with undiagnosed pulmonary TB. Of 15 secondary cases, 13 involved tuberculous lesions in the mouth with involvement of regional lymph nodes, one involved both the mouth and the lungs, and one involved a pleural effusion with associated erythema nodosum. The investigators postulated that the tooth sockets became infected at the time of extraction, presumably by mycobacteria on the dentist's fingers. In another outbreak, transmission occurred from one dental worker to another in an HIV patient dental clinic without evidence of transmission to dental patients *(94)*. The source of the index worker's infection was not determined. Both workers were HIV positive and the clinic had no routine screening program for employees. There are no reported episodes of *M. tuberculosis* transmission from a patient with TB to dental workers as a result of performing dental procedures.

One prospective study has been conducted on the TST conversion rates of dental healthcare workers in Texas counties along the Mexican border with a high prevalence rate of TB in the population. Although the study size was small (n = 240), the authors reported a 1.7% conversion rate after 12 months *(141a)*. Dental personnel should be familiar with specific recommendations for reducing risk of *M. tuberculosis* in dental settings (141b).

International Settings Tuberculosis is increasing in the developing world *(142)*. Since TB infection control programs in most low-income countries are nonexistent or ineffective, there is concern about the risk of *M. tuberculosis* transmission to healthcare workers in those settings. There are several reports suggesting that healthcare workers caring for infectious TB patients in low-income countries are at increased risk of *M. tuberculosis* infection and disease. During 1993 to 1994, a study of the incidence of TB disease in nurses working at a hospital in Malawi showed that 12/310 (4%) nurses had been diagnosed and treated

for TB *(143)*. The number of nurses acquiring TB while working on the medical and the TB wards was significantly higher (13%) than among nurses working in other areas of the hospital (3%). Rates of TB among the nurses working on medical or TB wards were five times higher than rates among nurses working in other hospital areas *(143)*.

In 1996, a TST cross-sectional evaluation of 512 healthcare workers working in a hospital in Abidjan, Ivory Coast, was conducted to assess the risk of TST positivity and to identify risk factors for occupational *M. tuberculosis* acquisition *(144)*. Seventy-nine percent of the healthcare workers had positive TST at the 10-mm cutoff. The duration of employment in areas where TB patients were admitted and the level of patient care influenced levels of positive TST reactions. Healthcare workers working ≥1 year in areas where TB patients were admitted and those involved in patient care (physicians, nurses, and midwives) had a significantly higher rate of TST positivity than those working in the same areas for <1 year or those who did not have patient contact. Five healthcare workers had radiographic abnormalities suggestive of TB. Two of those, both working in areas with high TB prevalence, were diagnosed with active TB.

In 1996, a similar TST survey was conducted among 911 healthcare workers in a hospital in Chiang Rai, Thailand *(145)*. Sixty-nine percent of healthcare workers had an initial positive TST at the 10-mm cutoff. Risk factors for TST positivity included working in the hospital 1 year and having contact with patients. Eleven healthcare workers had an abnormal chest radiograph compatible with TB; of these, seven (64%) were determined to have active TB.

The increased risk of active TB among healthcare workers is not limited to nations with high rates of HIV. For example, the rate of active TB among healthcare workers in Estonia was 1.5–3 times that of the general population from 1994 through 1998 *(146)*. Reported rates were 30–90 times higher among workers in a regional chest hospital. MDR-TB accounted for 38% of disease among healthcare workers, but was 10% to 14% of TB in the general population. A lack of infection control strategies for protecting workers from infectious patients was cited as the cause of the high rates of active disease.

An increased risk of healthcare-associated acquisition of *M. tuberculosis* infection also was shown among Brazilian healthcare workers *(147)*. In 1997, 542 healthcare workers in a large urban hospital in Belo Horizonte, Brazil, completed an exposure questionnaire and received a two-step TST. Of those, 48% had TST reactions ≥10 mm. Having a positive TST was associated with working in areas of the hospital where TB patients were admitted and with prolonged employment duration. A study in Rio de Janeiro, performed during 1994 to 1997, evaluated the risk of TST conversion among 351 healthcare workers in a large urban hospital (A. L. Kritski, personal communication). TST conversion was defined as an increase of ≥10 mm for BCG-negative healthcare workers and an increase of ≥15 mm for healthcare workers who had a previous history of BCG vaccination. TST conversion rates among healthcare workers were significantly higher than in the general population (8% vs. 1%). Also, TST conversion rates were significantly higher among medical, technical, and nursing personnel (14%, 13%, and 11%, respectively) compared to administrative and maintenance personnel (1%). An additional study in Rio de Janeiro evaluated the risk of TST conversion after 1 year among 414 junior and senior medical students with negative two-step TST in 1998. The 1-year TST conversion rate was 3.9%, and the degree of patient contact in the teaching hospital was independently associated with TST conversion (148a). Another longitudinal study of TST conversions after an initial two-step TST conducted at four Brazilian hospitals also documented increased risk of TST conversion of 10.7 per 1,000 person months and documented an increased healthcare worker TST conversion rate at hospitals without TB control measures (148b).

In 1997, teams from the CDC composed of industrial engineers and medical epidemiologists visited several healthcare facilities in five developing countries (Malawi, Brazil, Thailand, Ivory Coast, and Latvia) to develop simple, cost-effective, and feasible TB control interventions to be implemented in these settings. During these visits, a number of factors contributing to the spread of healthcare-associated *M. tuberculosis* were identified. The main factors contributing to the healthcare-associated spread of *M. tuberculosis* in low-income countries are delays in diagnosis, usually due to the lack of suspicion of TB by healthcare providers, slow laboratory turnaround of sputum AFB smears, and atypical clinical manifestations in HIV-infected patients. Inadequate isolation of infectious TB patients, underestimation of risk due to BCG coverage leading to a false sense of security, and the lack of personal protection during high-risk procedures (i.e., bronchoscopy, sputum induction, or autopsies) are additional factors contributing to the spread of healthcare-associated *M. tuberculosis* in low-income countries. TB control guidelines for hospitals in resource-limited countries have been published by the World Health Organization *(149)*.

Other Modes of Transmission

Although healthcare-associated transmission of *M. tuberculosis* nearly always occurs via the airborne route, there are occasional reports of transmission by other routes. Primary cutaneous inoculation TB has been reported in medical students, autopsy students, or laboratory workers as a result of accidental self-inoculation during postmortem examinations *(150,151)* and during injection of laboratory animals with *M. tuberculosis (152,153)*. A case of primary cutaneous inoculation TB was reported in a nurse who was lacerated with a needle that had been inserted in the port of a central line catheter of a patient who had disseminated TB with positive blood cultures for *M. tuberculosis (154)*.

Transmission of *M. tuberculosis* to patients via bronchoscopes that have been used on patients with TB have been reported *(93,155a,)*. In one case, the bronchoscope had been inadequately disinfected with a detergent soap solution, wiped with alcohol, and soaked for 30 minutes in a solution of povidone-iodine, ethanol, and sterile water *(155)* (see also Chapter 62). In another, an undetected leak in the distal end of a bronchoscope or a sheath used on a patient with cavitary TB created a reservoir for bacteria and apparently inoculated nine subsequent patients, two of whom developed active disease with the same strain as the index patient *(93)*. In another, a hole in the bronchoscope sheath led to inadequate disinfection and infection

in at least two patients *(93)*. In another outbreak, specimen contamination occurred after an inadequately disinfected bronchoscope (use on a patient with AFB smear positive TB) was used on two subsequent patients; no evidence of infection was documented *(155b)*.

Finally, transmission of *M. tuberculosis* via organ transplantation has been reported (*156a,156b*,156c). TB is a known infectious disease complication associated with organ transplantation; it occurs in an estimated 0.35% to 6.5% of organ recipients in the United States and Europe post-transplantation (156c). In one incident, active TB developed in two patients, each of whom received a kidney from the same cadaver donor, whose cerebrospinal fluid cultures grew *M. tuberculosis (156a)*. In another incident, active TB in a double lung transplant in the United States was traced to the donor from Guatemala; a previously undetected pulmonary opacity was identified in the transplanted lung and the genotype of the isolate was distinct from U.S., but similar to TB isolates from Guatemala *(156b)*. In 2007, a deceased donor of tissue was identified 3 weeks postmortem to have had TB (156c). Disseminated TB developed in two-third recipients of the tissue, one of whom died; genotypes of the donor and the recipient isolates were identical.

PREVENTION AND CONTROL OF HEALTHCARE-ASSOCIATED TRANSMISSION OF M. TUBERCULOSIS

Because *M. tuberculosis* is transmitted by the airborne route, its control is complex and requires multiple interventions. Therefore, prevention of healthcare-associated transmission of *M. tuberculosis* requires the complete implementation of an appropriately designed TB infection control program that ensures the early identification, isolation, and treatment of persons who have active TB (157). In each of the healthcare-associated TB outbreaks previously described, the CDC guidelines for preventing the transmission of *M. tuberculosis* were incompletely implemented *(79,82,84,86,97,101–103,112,124–126)*. Follow-up studies at several of these hospitals have documented termination of patient-to-patient and/or patient-to-healthcare worker *M. tuberculosis* transmission after implementation of the recommended guidelines (111,*112*,113,114).

The TB infection control program should be based on the hierarchy of control measures recommended to prevent healthcare-associated *M. tuberculosis* transmission. This hierarchy includes (a) administrative procedures to reduce the risk of exposure to persons with infectious TB, (b) engineering controls to reduce the concentration of infectious droplet nuclei and prevent their spread, and (c) a respiratory protection program to protect healthcare workers and other persons in settings where administrative and engineering controls alone may not provide adequate protection (e.g., airborne infection isolation [AII] rooms).

Specific measures to reduce the risk of healthcare-associated *M. tuberculosis* transmission (Table 38-6) include (a) clearly assigning to specific persons the responsibility for the TB infection control program; (b) conducting a risk assessment and developing a written program based on this assessment; (c) developing protocols to facilitate the early identification of persons who may have infectious TB, and promptly initiating and maintaining isolation for such persons; (d) using ventilation and other engineering controls to reduce the potential for airborne exposure to *M. tuberculosis*; (e) maintaining an appropriate healthcare worker respiratory protection program; (f) educating and training healthcare workers about TB; (g) maintaining a program for routine periodic counseling and screening of healthcare workers for LTBI and TB; (h) evaluating possible episodes of *M. tuberculosis* transmission in the facility; (i) coordinating activities with the appropriate public health department; and (j) periodically evaluating the effectiveness of the control program and modifying it, if necessary.

Administrative Controls

To ensure the appropriate design, implementation, and evaluation of the TB infection control program, one person should be assigned supervisory responsibility. This person should have expertise in infection control and occupational health and should work with a multidisciplinary team, including persons with experience in infection control, infectious diseases, pulmonary medicine, microbiology, occupational health, engineering, administration, and employee representation.

The first step in the development of the TB control program is to assess the risk of *M. tuberculosis* transmission in each area of the healthcare facility and in certain occupational groups (Table 38-7 and Fig. 38-2). The risk assessment should be based on the incidence of TB in the community, the number and location of TB patients in the facility, the likelihood of healthcare worker exposure to a patient with infectious TB, the incidence of healthcare worker TST conversions in each area and job category, and the evaluation of possible person-to-person transmission of *M. tuberculosis*. Based on the results of the risk assessment, a written TB infection control plan with explicit policies and procedures should be developed. Systematic, periodic reassessment of these data will allow estimation of the number of TB isolation rooms needed, facilitate identification of healthcare-associated *M. tuberculosis* transmission and outbreaks, allow estimation of the risk of occupational *M. tuberculosis* exposure, and suggest ways in which the infection control program can be made more effective and efficient.

Information on the incidence of TB in the community can be obtained from the public health department. To determine the hospital areas where TB exposures are most likely to occur, microbiology and infection control records should be reviewed to identify all TB patients seen in the facility and the locations in which they were evaluated or treated. These data should be examined to identify the degree of risk in various locations within the hospital. Examination of these data, including evaluation of drug-susceptibility test results, also may lead to recognition of possible healthcare-associated transmission from patient to patient and to recognition of the need to enhance the initial treatment regimen that is used empirically until drug-susceptibility results are available. These data should be collected prospectively and analyzed periodically to identify changes in the distribution of infectious TB patients by location,

TABLE 38-6

Characteristics of an Effective Tuberculosis (TB) Infection Control Program[a]

I. Assignment of responsibility
  A. Assign responsibility for the TB infection control program to qualified person(s).
  B. Ensure that persons with expertise in infection control, occupational health, and engineering are identified and included.
II. Risk assessment, TB infection control plan, and periodic reassessment
  A. Initial risk assessments
    1. Obtain information concerning TB in the community.
    2. Evaluate data concerning TB patients in the facility.
    3. Evaluate data concerning purified protein derivative (PPD) tuberculin skin test conversions among healthcare workers (HCWs) in the facility.
    4. Rule out evidence of person-to-person transmission.
  B. Written TB infection control program
    1. Select initial risk protocol(s).
    2. Develop written TB infection control protocols.
  C. Repeat risk assessment at appropriate intervals.
    1. Review current community and facility surveillance data and PPD-tuberculin skin test results.
    2. Review records of TB patients.
    3. Observe HCW infection-control practices.
    4. Evaluate maintenance of engineering controls.
III. Identification, evaluation, and treatment of patients who have TB
  A. Screen patients for signs and symptoms of active TB.
    1. On initial encounter in emergency department or ambulatory care setting.
    2. Before or at the time of admission.
  B. Perform radiologic and bacteriologic evaluation of patients who have signs and symptoms suggestive of TB.
  C. Promptly initiate treatment.
IV. Managing outpatients who have possible infectious TB
  A. Promptly initiate TB precautions.
  B. Place patients in separate waiting areas or TB isolation rooms.
  C. Give patients a surgical mask, a box of tissues, and instructions regarding the use of these items.
V. Managing inpatients who have possible infectious TB
  A. Promptly isolate patients who have suspected or known infectious TB.
  B. Monitor the response to treatment.
  C. Follow appropriate criteria for discontinuing isolation.
VI. Engineering recommendations
  A. Design local exhaust and general ventilation in collaboration with persons who have expertise in ventilation engineering.
  B. Use a single-pass air system or air recirculation after high-efficiency particulate air (HEPA) filtration in areas where infectious TB patients receive care.
  C. Use additional measures, if needed, in areas where TB patients may receive care.
  D. Design TB isolation rooms in healthcare facilities to achieve >6 air changes per hour (ACH) for existing facilities and >12 ACH for new or renovated facilities.
  E. Regularly monitor and maintain engineering controls.
  F. TB isolation rooms that are being used should be monitored daily to ensure they maintain negative pressure relative to the hallway and all surrounding areas.
  G. Exhaust TB isolation room air to outside or, if absolutely unavoidable, recirculate after HEPA filtration.
VII. Respiratory protection
  A. Respiratory protective devices should meet recommended performance criteria.
  B. Respiratory protection should be used by persons entering rooms in which patients with known or suspected infectious TB are being isolated, by HCWs when performing cough-inducing or aerosol-generating procedures on such patients, and by persons in other settings where administrative and engineering controls are not likely to protect them from inhaling infectious airborne droplet nuclei.
  C. A respiratory protection program is required at all facilities in which respiratory protection is used.
VIII. Cough-inducing procedures
  A. Do not perform such procedures on TB patients unless absolutely necessary.
  B. Perform such procedures in areas that have local exhaust ventilation devices (e.g., booths or special enclosures) or, if this is not feasible, in a room that meets the ventilation requirements for TB isolation.
  C. After completion of procedures, TB patients should remain in the booth or the special enclosure until their coughing subsides.

(*Continued*)

TABLE 38-6

Characteristics of an Effective Tuberculosis (TB) Infection Control Program[a] (*Continued*)

IX. HCW TB training and education
- A. All HCWs should receive periodic TB education appropriate for their work responsibilities and duties.
- B. Training should include the epidemiology of TB in the facility.
- C. TB education should emphasize concepts of the pathogenesis of and occupational risk for TB.
- D. Training should describe work practices that reduce the likelihood of transmitting *M. tuberculosis*.

X. HCW counseling and screening
- A. Counsel all HCWs regarding TB and TB infection.
- B. Counsel all HCWs about the increased risk to immunocompromised persons for developing active TB.
- C. Perform PPD skin tests on HCWs at the beginning of their employment, and repeat PPD tests at periodic intervals.
- D. Evaluate symptomatic HCWs for active TB.

XI. Evaluate HCW PPD test conversions and possible healthcare-associated transmission of *M. tuberculosis*.

XII. Coordinate efforts with public health department(s).

[a]A program such as this is appropriate for healthcare facilities in which there is a high risk for transmission of *Mycobacterium tuberculosis*. (From Centers for Disease Control and Prevention. Guidelines for preventing the transmission of *Mycobacterium tuberculosis* in healthcare facilities, 2005. *MMWR Recomm Rep* 2005;54:(RR-17):1–147.)

possible clusters of patient infection, and changes in *M. tuberculosis* antimicrobial resistance patterns by location.

To determine the risk of acquiring *M. tuberculosis* infection or active disease from occupational exposure and to assess the effectiveness of the infection control program, employee health records should be maintained to identify all healthcare workers who have developed active TB or those who have had TST conversions (or IGRA evidence of LTBI or disease) and to facilitate analysis of this information. At the time of hire, all healthcare workers should be screened for a history of TB or receipt of BCG and should receive either a TST using the two-step Mantoux method (if analysis of the data indicates a very low level of boosting, for example, <1%, two-step testing may not be needed) or be tested using a single IGRA.

If the TST is used, it should be applied and read by trained personnel responsible for maintaining healthcare worker TST records, not by the healthcare workers who are being tested. Individual results should be recorded in the employee's health record and a retrievable aggregate database. Persons with positive TSTs or TST conversions should be evaluated for preventive therapy. All TST-negative healthcare workers (paid and unpaid) with the potential for exposure to infectious TB patients or *M. tuberculosis*–contaminated air should be included in the facility's ongoing TST program. The frequency of repeat testing (TST or IGRA) should be based on the risk in each area or occupational group (157). Initial and then periodic review of these data will allow identification of areas where healthcare workers are at increased risk for *M. tuberculosis* infection or disease and permit classification of these areas by degree of risk. This permits focusing of infection control and educational efforts to areas where they are most needed.

Healthcare worker *M. tuberculosis* infection conversion rates (i.e., the number of healthcare workers who have converted to positive divided by the number of healthcare workers tested) should be calculated during the initial risk assessment and then periodically during reassessments for healthcare workers in each area of the hospital and for healthcare workers in job categories that involve work in multiple areas of the facility (e.g., respiratory therapists). Overall hospital conversion rates may dilute high rates in specific units or occupational categories and fail to detect problem areas; therefore, ward- or unit-specific rates should be calculated (113). If a cluster of *M. tuberculosis* infection conversions is identified (i.e., two or more TST conversions or positive IGRAs occurring within a 3-month period among healthcare workers in a specific area or occupational group, with epidemiologic evidence suggesting occupational [healthcare-associated] transmission), additional control measures should be immediately implemented and further evaluation conducted to identify factors that may be leading to transmission (Fig. 38-3).

The most important element of the TB control program is early identification, treatment, and triage of patients with suspected or confirmed infectious TB. To prevent healthcare-associated *M. tuberculosis* transmission, it is essential that all potentially infectious TB patients be rapidly identified on first contact with the healthcare facility. This requires that physicians, nurses, and other triage personnel who perform initial patient evaluations understand the signs and symptoms of TB, the populations at greatest risk of TB, and the appropriate approach to the evaluation and initial management of patients with TB. In addition, written protocols to facilitate the early identification of persons who have infectious TB should be developed. These protocols may vary in different facilities, depending on the incidence of TB in the area and the characteristics of the TB patients treated in the facility.

Previously, most healthcare-associated *M. tuberculosis* transmission was associated with exposure to an unknown or unsuspected TB patient *(158)*. Often, these patients were either unsuspected or unknown, were not receiving anti-TB therapy, or were receiving inadequate therapy. Clinicians should be alert to the possibility of concomitant infection with other pathogens. In particular, HIV-infected patients may be coinfected with *M. tuberculosis* and *Pneumocystis carinii* or *M. avium (67,159)*. For these reasons, HIV-infected patients with signs and symptoms of TB and AFB-positive sputum smears should be

TABLE 38-7

Elements of a Risk Assessment of Tuberculosis in Healthcare Facilities

1. Review the community TB profile (from public health department data).
2. Review the number of TB patients who were treated in each area of the facility (both inpatient and outpatient). (This information can be obtained by analyzing laboratory surveillance data and by reviewing discharge diagnoses or medical and infection control records.)
3. Review the drug-susceptibility patterns of TB isolates of patients who were treated at the facility.
4. Analyze purified protein derivative (PPD) tuberculin skin test results of healthcare workers (HCWs), by area or by occupational group for HCWs not assigned to a specific area (e.g., respiratory therapists).
5. To evaluate infection control parameters, review medical records of a sample of TB patients seen at the facility:

Calculate intervals from:

- Admission until TB suspected
- Admission until TB evaluation performed
- Admission until acid-fast bacilli (AFB) specimens ordered
- AFB specimens ordered until AFB specimens collected
- AFB specimens collected until AFB smears performed and reported
- AFB specimens collected until cultures performed and reported
- AFB specimens collected until species identification conducted and reported
- AFB specimens collected until drug-susceptibility tests performed and reported
- Admission until TB isolation initiated
- Admission until TB treatment initiated
- Duration of TB isolation

Obtain the following additional information:

- Were appropriate criteria used for discontinuing isolation?
- Did the patient have a history of prior admission to the facility?
- Was the TB treatment regimen adequate?
- Were follow-up sputum specimens collected properly?
- Was appropriate discharge planning conducted?

6. Perform an observational review of TB infection control practices.
7. Review the most recent environmental evaluation and maintenance procedures.

(From Centers for Disease Control and Prevention. Centers for Disease Control. Guidelines for preventing the transmission of *Mycobacterium tuberculosis* in healthcare facilities, 2005. *MMWR Recomm Rep* 2005;54(RR-17):1–147.)

assumed to have TB until proven otherwise. In MDR-TB outbreak settings, early identification, treatment, and triage of infectious TB patients significantly reduced or terminated patient-to-patient and patient-to-healthcare worker transmission (111,*112*,113).

Patients suspected of having TB should be immediately triaged to an appropriate isolation room. In the outpatient setting (e.g., emergency room or clinic), such patients should not be placed in common waiting rooms or in areas where air is recirculated to other patient areas without high-efficiency particulate air (HEPA) filtration. They should either be masked (surgical masks) or instructed to cover their mouth and nose with tissues when coughing or sneezing while they are waiting or being evaluated. Ambulatory care settings in which patients with TB are frequently examined or treated should have a room that is equipped for TB isolation.

Inpatients should be placed in AII rooms and promptly evaluated for TB by appropriate history, physical examination, TST or IGRA, and appropriate laboratory (smears and cultures) and radiologic tests. Healthcare facilities in which TB patients are evaluated should have the capability to provide AFB sputum smear results to clinicians within 24 hours. To reduce the time from specimen collection until smear, culture, and antimicrobial-susceptibility results are available, more rapid methods such as fluorescence staining of smears and use of radiometric culture and susceptibility testing and genetic probes are recommended *(160,161)*.

Prompt treatment with appropriate antimicrobial agents significantly reduces the period of infectiousness. Because of the relatively high proportion of adult patients with TB caused by microorganisms that are resistant to isoniazid, four drugs are necessary in the initial phase for the 6-month regimen to be maximally effective *(162)*.

Patients in TB isolation should remain in their rooms with the door closed, unless a medically essential procedure is necessary and cannot be performed in the room. Persons entering AII rooms should wear appropriate respiratory protective devices (see below). Patients with suspected or confirmed TB should remain in isolation until the diagnosis of TB has been ruled out or until they are no longer infectious (i.e., they have clinical improvement *and* negative AFB sputum smears on three separate days). Patients with MDR-TB are at risk of relapse and thus should be considered for isolation during their entire hospitalization. When infectious TB patients are kept in appropriate isolation rooms, the risk of healthcare-associated *M. tuberculosis* transmission from patient to patient is significantly reduced (111,*112*,113,114,*115–123*). When TB patients are to be discharged, continuation of therapy should be ensured by coordinating with the public health department and local healthcare providers prior to the time of discharge. The patient's treatment strategy should always emphasize directly observed therapy.

The last element of administrative controls is providing healthcare workers with education and training about TB. All healthcare workers should be educated about the epidemiology and the pathogenesis of TB, the risk of occupational *M. tuberculosis* transmission, the infection control measures needed to reduce *M. tuberculosis* transmission, the increased risk of disease in immunocompromised healthcare workers, the importance of adhering to infection control recommendations, the importance of the healthcare worker *M. tuberculosis* infection detection (TST/IGRA) program, and the importance of prompt evaluation of healthcare workers with symptoms consistent with TB.

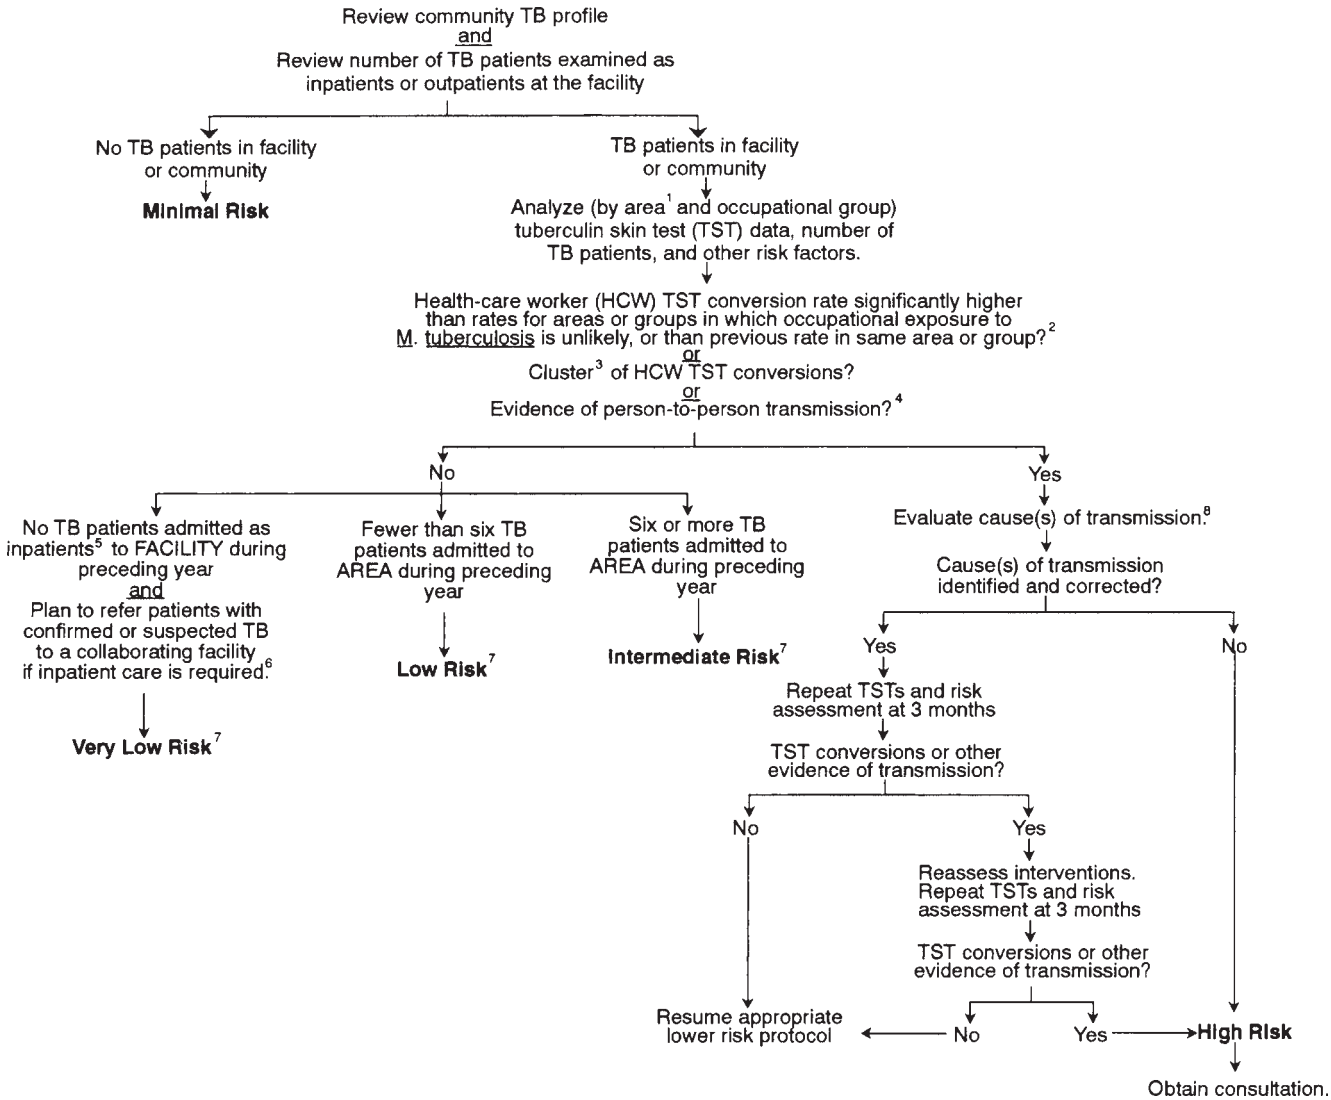

FIGURE 38-2 Example of an algorithm for conducting a tuberculosis risk assessment in a healthcare facility.

Environmental Controls

The most important environmental control measures include engineering controls via ventilation and the use of UVGI. There are a variety of methods that can be used to reduce the concentration of airborne droplet nuclei and achieve appropriate directional airflow (i.e., negative pressure) (Table 38-8). Ventilation controls can be divided into local exhaust, general exhaust, and air cleaning.

Local Exhaust Ventilation Local exhaust captures infectious droplet nuclei at the source and removes them before dispersion into the air. This is the safest and most efficient type of control, since it prevents infectious *M. tuberculosis* particles from ever getting into the air circulation system. This method is primarily used during medical procedures, such as sputum induction, bronchoscopy, or aerosolized pentamidine administration. Local exhaust hoods can be of the enclosing type, where the hood totally or partially encloses the source, or the exterior type, where the source is near but not inside the hood. The enclosing type of hood, booth, or tent is preferable *(163)*. Booths or other enclosing-type devices should have sufficient air flow capacity to remove nearly 100% of airborne particles between patient uses. The time required to remove airborne particles depends on the number of air changes per hour, the rate at which air enters the device, the location of the air inlet and outlet, and the rate of air exhaust. To minimize the possible escape of infectious *M. tuberculosis* droplet nuclei, the exhaust fan should be located on the discharge side of the filter at the booth discharge. For exterior devices, the patient should face directly into the opening and the air flow should be sufficient (200 ft/min) across the patient's breathing zone to prevent crosscurrents near the patient's face.

Air from booths, tents, and hoods may be discharged into the room in which the device is located or it may be exhausted to the outside. If the air is discharged into the

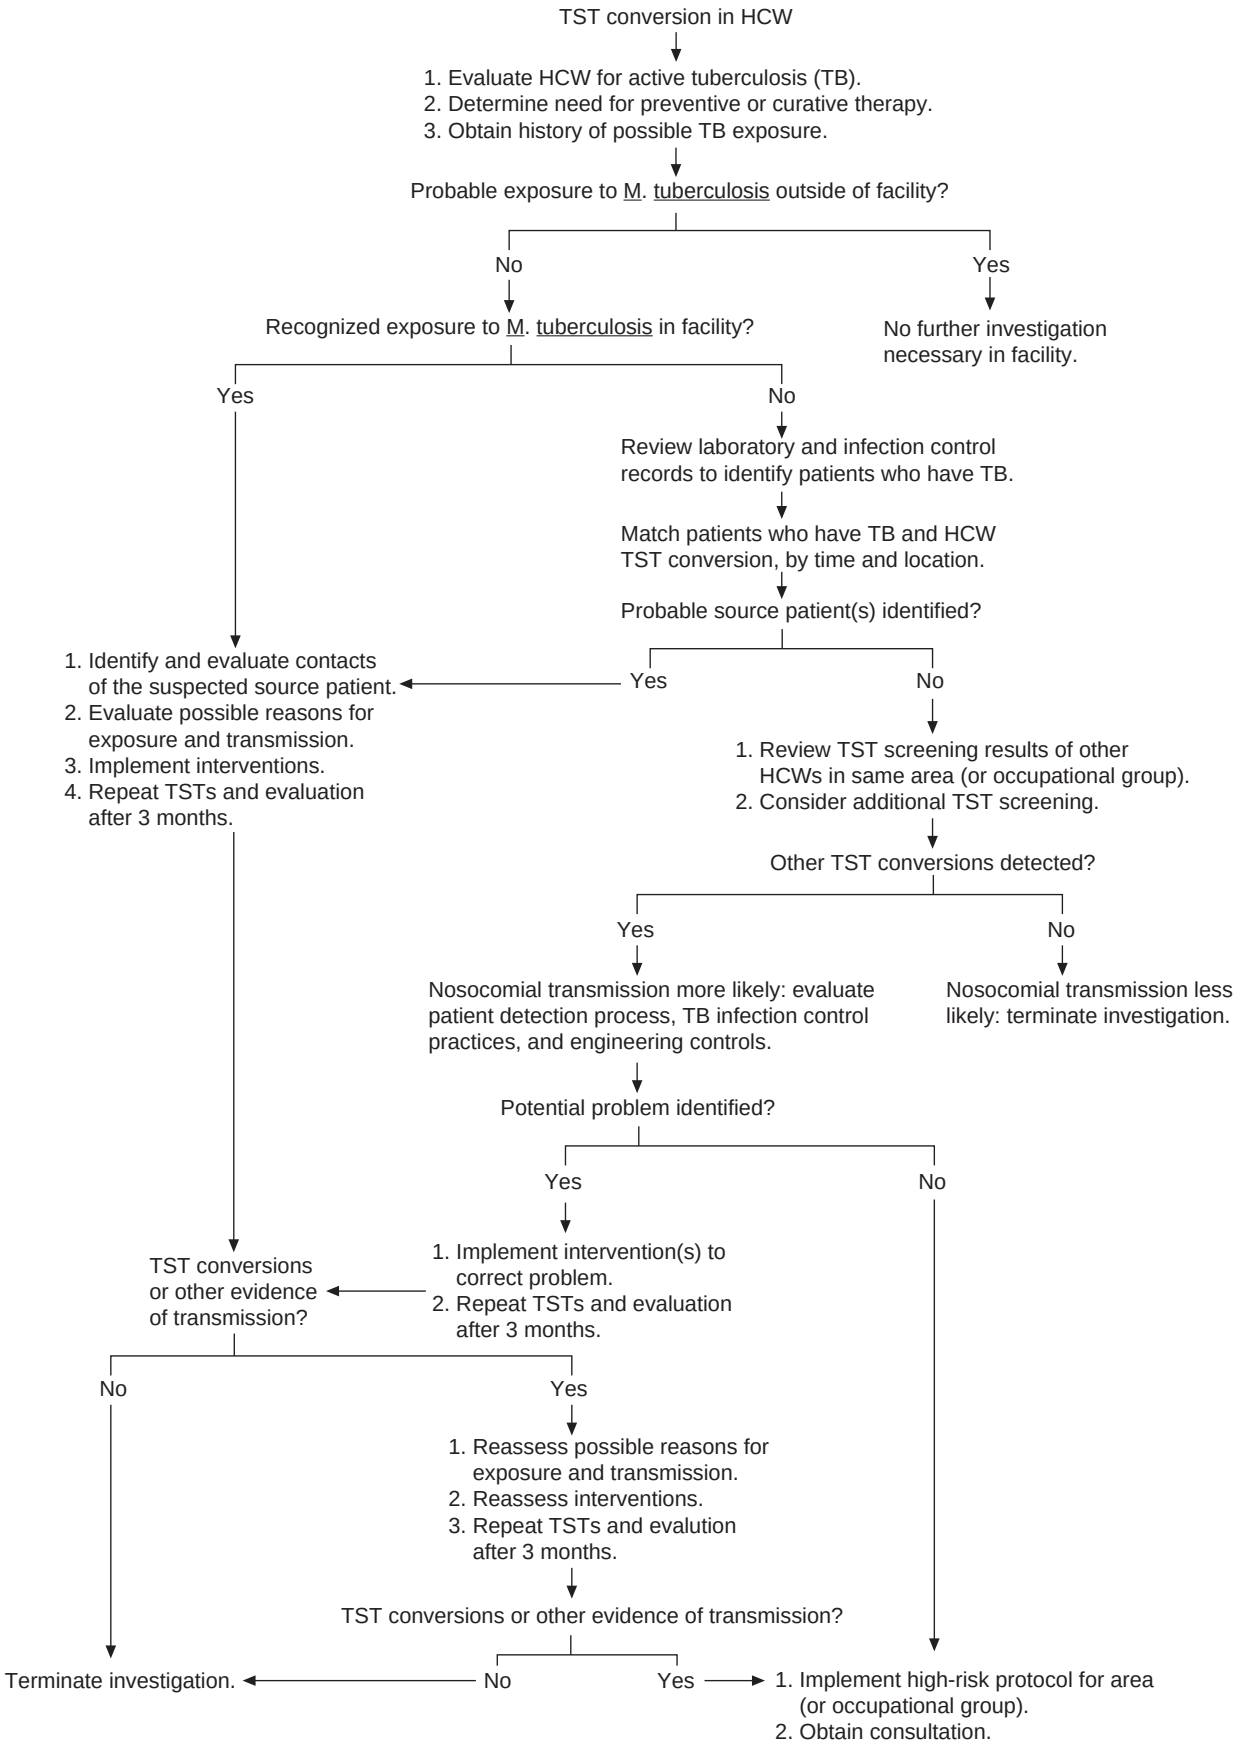

FIGURE 38-3 Example of an algorithm for investigating tuberculin skin test (TST) conversions in healthcare workers (HCWs).

room, a HEPA filter should be incorporated at the discharge duct or vent of the device. The exhaust fan should be located on the discharge side of the HEPA filter to ensure that the air pressure in the filter housing and booth is negative with respect to adjacent areas. If the device does not incorporate a HEPA filter, the air from the device should be exhausted directly to the outside.

General Exhaust Ventilation General ventilation reduces airborne contaminants by dilution and removal and can be achieved by either single-pass or recirculating systems. In single-pass systems, the supply air is either outside air or air from a central system that supplies a number of areas. After air passes through the room or the area, 100% of that air is exhausted directly to the outside. This type of ventilation system is preferred in areas where infectious airborne contaminants exist, since it prevents contaminated air from being recirculated to other areas of the facility. In recirculating systems, a small portion of the exhaust air is discharged to the outside and is replaced with fresh air, which mixes with the portion of exhaust air that was not discharged to the outside. The resulting mixture, which can contain a large proportion of contaminated air, then is recirculated to the areas serviced by the system. If the air mixture is recirculated into the general ventilation, airborne contaminants could be carried from contaminated to uncontaminated areas. Alternatively, the air mixture could be recirculated only within a specific room or area in which case other areas of the facility will not be affected.

Recommended general ventilation rates for healthcare facilities are based on comfort and odor control rather than infection control considerations. For facilities built or renovated before 2001, the American Society of Heating, Refrigerating, and Air Conditioning Engineers (ASHRAE) and the American Institute of Architects (AIA) recommend six air changes per hour for isolation and treatment rooms *(164,165)* to reduce the concentration of droplet nuclei. Where feasible, this airflow should be increased to 12 air changes per hour by adjusting or modifying the ventilation system or by using auxiliary means (e.g., recirculation of air through fixed HEPA filtration units or portable air cleaners or use of UVGI). Since 2001, the AIA has recommended 12 air changes per hour for renovated or newly constructed isolation and treatment rooms (166), a recommendation now endorsed by the CDC and the Healthcare Infection Control Practices Advisory Committee (HICPAC) *(167)*.

The number of air changes per hour is equal to the ratio of the volume of air entering the room per hour to the room volume and is equal to the exhaust flow divided by the room volume multiplied by 60. Because air mixing within a room usually is not perfect, this calculated ventilation rate should be multiplied by a mixing factor to estimate the effective ventilation rate (157). Although ventilation rates higher than six air changes per hour probably improve dilution and removal of airborne particles, few if any studies have been done assessing the efficacy of this or any other level of air flow in reducing transmission of *M. tuberculosis*. Airflow patterns should be from more clean to less clean areas. For example, in emergency departments or AII rooms, air should flow inward to prevent spread of airborne infectious droplet nuclei.

AII isolation rooms should be designed to have negative pressure with respect to the hallway or adjacent rooms. The airflow direction in AII rooms should be checked with smoke tubes on a periodic basis, preferably each day that an infectious TB patient is in the room. An anteroom outside the AII room is not essential, but may serve as an extra measure of protection to prevent the escape of droplet nuclei during opening and closing of the isolation room door.

Air from AII rooms and treatment rooms used for patients with TB should be exhausted directly to the outside of the building and away from air-intake vents, persons, and animals in accordance with applicable laws and regulations. If recirculation of air from such rooms into the general ventilation system is unavoidable, the air should be passed through a HEPA filter before recirculation.

TABLE 38-8

Hierarchy of Ventilation Methods for Tuberculosis Isolation Rooms and Treatment Rooms

Reducing concentration of airborne tubercle bacilli[a]
Facility heating, ventilation, and air-conditioning system
Fixed room-air high-efficiency particulate air (HEPA) recirculation system
Wall- or ceiling-mounted room-air HEPA recirculation system
Portable room-air HEPA recirculation unit[b]
Achieving directional airflow using negative pressure[c]
Facility HVAC system
Bleed air[d] from fixed room-air HEPA recirculation system
Bleed air from wall- or ceiling-mounted room-air HEPA recirculation system
Bleed air from portable room-air HEPA recirculation unit
Exhaust air from room through window-mounted fan[e]

[a]Ventilation methods are used to reduce the concentration of airborne tubercle bacilli. If the facility HVAC system cannot achieve the recommended ventilation rate, auxiliary room-air recirculation cleaning methods may be used. These methods are listed in order from the most desirable to the least desirable. Ultraviolet germicidal irradiation may be used as a supplement to any of the ventilation methods for air cleaning.

[b]The effectiveness of portable room-air HEPA recirculation units can vary depending on the room's configuration, the furniture and persons in the room, the placement of the unit, the supply and exhaust grilles, and the achievable ventilation rates and air mixing. Units should be designed and operated to ensure that persons in the room cannot interfere with or otherwise compromise the function of the unit. Fixed recirculating systems are preferred over portable units in TB isolation rooms of facilities in which services are provided regularly to TB patients.

[c]Directional airflow using negative pressure can be achieved with the facility HVAC system and/or the auxiliary air recirculation cleaning systems. These methods are listed in order from the most desirable to the least desirable.

[d]To remove the amount of return air necessary to achieve negative pressure.

[e]This method simply achieves negative pressure and should be used only as a temporary measure.

(From Centers for Disease Control and Prevention. Centers for Disease Control. Guidelines for preventing the transmission of *Mycobacterium tuberculosis* in healthcare facilities, 2005. *MMWR Recomm Rep* 2005;54(RR-17):1–147.)

Air Cleaning: High-Efficiency Particulate Air Filtration High-efficiency particulate air filtration can be used as a method of air cleaning to supplement other ventilation measures. HEPA filters can be used in a number of ways to reduce the concentration of infectious droplet nuclei in the air. These methods include placement of HEPA filters (a) in exhaust ducts to remove droplet nuclei from air being discharged from a room or a booth to the outside or into the general ventilation system; (b) in fixed room-air cleaners, which may be built into a room or may be mounted on the wall or ceiling; and (c) in portable room-air cleaners. With wall- or ceiling-mounted or portable HEPA filter units, the effectiveness of the unit is dependent on all the air in the room circulating through the HEPA filter, which can be difficult to achieve. The effectiveness also is dependent on the room configuration, unit placement, and location of furniture and people. Thus, the effectiveness of the unit may vary considerably in rooms with different configurations or in the same room if moved from one location to another within the room. Portable HEPA filtration units have been evaluated for their ability to remove aerosolized particles in the size range of *M. tuberculosis (168)*. Although this study indicates that portable filtration units reduce levels of airborne particles similar in size to infectious droplet nuclei, studies are needed to confirm that these units reduce *M. tuberculosis* exposure risk. If HEPA filtration units are used, they must be installed, maintained, and monitored properly.

Ultraviolet Germicidal Irradiation UVGI is effective in killing *M. tuberculosis* under experimental conditions *(169–172)*. UVGI is another method of air cleaning that can be used to supplement other TB control measures. UVGI can be installed in the ventilation duct, as was the case in the experiments of Riley et al. *(169–172)*, or can be placed in the upper part of the room. Duct UVGI, in which UV lamps are placed inside the ducts that remove air from the room, has two advantages: high levels of UV irradiation may be produced; and since the UVGI is inside the duct, the risk of human exposure is reduced or eliminated. Duct UVGI is dependent on adequate air flow from the room into the duct. Duct UVGI may be particularly useful in AII rooms and other patient areas, such as waiting rooms and emergency departments. Most of the experimental data on UVGI are derived from studies using duct irradiation.

In upper room air irradiation, UVGI lamps are suspended from the ceilings or mounted on walls. The lamp must be shielded so that radiation is directed upward rather than down toward patients or healthcare workers. The UVGI disinfects the upper air; thus, adequate air mixing in the room is essential. Contact time is very important; thus, increased ventilation rates actually may decrease the efficacy of UVGI. The effectiveness of upper room UVGI depends on the room configuration, lamp placement, air flow pattern and mixing, intensity of the UVGI, relative humidity, and contact time.

Appropriate installation, regular maintenance, and monitoring are essential if UVGI is used. Short-term exposure to UV irradiation can cause keratoconjunctivitis or erythema of the skin (173). UVC radiation is classified by the International Agency for Research on Cancer as "probably carcinogenic to humans" *(174)*. Recommended exposure limits for occupational exposure to UV radiation have been published (173). If UVGI is used, workers should be educated about how UVGI works and its limitations, the potentially hazardous effects of overexposure, the potential for photosensitivity, and the principles of maintenance of UVGI fixtures.

Respiratory Protection

The precise level of effectiveness of respiratory protective devices in protecting healthcare workers against inhaling *M. tuberculosis* is unknown. Numerous studies have been conducted on the efficacy of respiratory protection for other hazardous airborne materials, but not *M. tuberculosis*. Information concerning the transmission of *M. tuberculosis* is incomplete; for example, neither the smallest infectious dose of *M. tuberculosis* nor the highest level of exposure to *M. tuberculosis* at which transmission will not occur has been defined. The size distribution of droplet nuclei and the number or concentration of viable *M. tuberculosis* particles generated by infectious TB patients have not been adequately defined. Nevertheless, personal respiratory protection should be used by (a) persons entering rooms where patients with known or suspected TB are being isolated, (b) persons present when cough-inducing or aerosol-generating procedures are performed on such patients, and (c) persons in other settings where administrative and engineering controls are not likely to protect them from inhaling infectious airborne droplet nuclei. These other settings should be identified on the basis of the facility's risk assessment. Respiratory protective devices used in these settings should have characteristics that are suitable for the microorganism they are protecting against and the settings in which they are used.

In 1990, the CDC first recommended that particulate respirators be used by healthcare workers for protection against inhalation of *M. tuberculosis (175)*. In 1994, the CDC's TB guidelines enhanced its recommendations to include specific performance criteria (157). In 1995, the National Institute for Occupational Safety and Health (NIOSH) developed a new set of regulations, 42 CFR 84, for testing and certifying nonpowered, air-purifying, particulate-filter respirators *(176)*. The new regulation provides for nine classes of filters (three levels of filter efficiency, each with three categories of resistance to filter efficiency degradation). The three levels of filter efficiency are 95%, 99%, and 99.97% (referred to as 95, 99, 100). The three categories of resistance to filter efficiency degradation are as follows: not resistant to oil, resistant to oil, and oil proof (labeled as N, R, and P). For example, a filter labeled N95 would mean an N-series respirator (not resistant to oil) that is at least 95% efficient. All nine classes of nonpowered, air-purifying, particulate-filter respirators certified under 42 CFR 84 meet or exceed the CDC filtration efficiency performance criteria set forth in the 1994 CDC Guidelines. Current Occupational Safety and Health Administration (OSHA) policy permits the use of any 42 CFR 84 particulate filter for protection against TB *(177)*.

To understand the complex nature of arriving at an appropriate respirator recommendation for healthcare workers to prevent occupational acquisition of TB, it is important to understand the relationship between OSHA and NIOSH. OSHA requires that any respiratory protective device used to protect workers *must be* NIOSH-certified.

NIOSH certifies respirator filtration in two ways. N100, R100, and P100 particulate-filter respirators are challenged with the most penetrating aerosol size (~0.3 μm) particles; 99.97% of particles must be collected in a filter (i.e., the instantaneous penetration must be <0.03%). N99, R99, and P99 are challenged with the same-size aerosol, with 99% of the particles collected (<1% penetration). N95, R95, and P95 are challenged with the same-size aerosol, with 95% of the particles collected (<5% penetration). No certification test uses a biologic particle or a particle size similar to that of *M. tuberculosis*, nor is there evidence to indicate that a biologic particle acts any differently than a nonbiologic particle.

Based on all of the above considerations, the CDC recommends that respiratory protective devices used in healthcare settings for protection against inhaling *M. tuberculosis* should meet the following standard criteria: (a) the ability to filter particles 1 μm in size in the unloaded state with a filter efficiency of 95% at flow rates of up to 50 L/min; (b) the ability to be qualitatively or quantitatively fit-tested in a reliable way to obtain a face-seal leakage of ≤10%; (c) the ability to fit different facial sizes and characteristics of healthcare workers, which can usually be met by making the respirators available in at least three sizes; and (d) the ability to be checked for face-piece fit by healthcare workers each time they put on their respirator. The facility's risk assessment may identify a limited number of selected settings (e.g., bronchoscopy performed on patients suspected of having TB) where the estimated risk for transmission of *M. tuberculosis* may be such that a level of protection exceeding the standard criteria is appropriate. The N95 respirators meet the above criteria.

Follow-up data from several of the MDR-TB outbreak hospitals show that use of submicron surgical masks or dust-mist respirators that meet the CDC filtration criteria, when used with a fully implemented CDC TB control program, prevents patient-to-healthcare worker *M. tuberculosis* transmission (111,*112*,113). Furthermore, *in vitro* studies of particulate respirators show that some dust-mist or dust-fume-mist respirators filter >95% of particles with a mean size of 0.8 μm, smaller than the estimated size of droplet nuclei that contain *M. tuberculosis*.

Factors used to determine the efficacy of respirators include face seal and filter efficacy. Face-seal leakage may compromise the ability of particulate respirators to protect the healthcare worker from airborne droplet nuclei. Face-seal leakage may result from incorrect face-piece size or shape, defective face-piece or sealing lip, beard growth, moisture (i.e., perspiration, facial oils), failure to use the head straps properly, improper maintenance, or damage. Filter leakage through the respirator is dependent on filter filtration characteristics, size of the aerosol, velocity through the filter, filter loading, and electrostatic charge. All healthcare workers with potential exposure to infectious TB patients should be fit tested and trained in the proper use and maintenance of respirators and should fit check the respirator before each use in accordance with the OSHA regulations, which require that a respiratory protection program be in place whenever a respirator is used to prevent exposure of the healthcare worker, regardless of class of respirator. The OSHA-mandated program includes written standard operating procedures, selection of respirators based on the hazard, respirator use instruction and training, cleaning and disinfection of the respirators, storage of the respirators, inspection of the respirators, surveillance of work area conditions, evaluation of the respirator protection program, medical evaluation of the user's ability to wear a respirator, and the use of NIOSH-certified respirators.

BCG Vaccination

Because of the risk of occupational acquisition of TB, some have advocated the BCG vaccination of healthcare workers. Over the years, there has been considerable debate about the efficacy of BCG. A large number of studies of BCG vaccination of infants have been conducted. These studies provide widely disparate results, with vaccine efficacy ranging from 0% to 100% *(178)*. Differences in vaccine efficacy may be due to different BCG products used, different populations studied (e.g., rural vs. urban, high risk vs. low risk, geography), differences in the prevalence of TB and nontuberculous mycobacteria, or the intensity of follow-up. These studies suggest that when BCG is efficacious, it does not prevent infection but rather prevents disseminated disease or mortality, especially in infants and young children. Few data exist assessing the efficacy of BCG given for the first time in adulthood. This would be the situation with healthcare workers in most U.S. hospitals, since BCG is not given in infancy in the United States.

Potential advantages of using BCG are that it is inexpensive and that, even with 50% efficacy, it might reduce the risk of TB disease in some healthcare workers. The disadvantages are that, once given, it will hinder the interpretation of the TST (but perhaps not the IGRA) as a measure of *M. tuberculosis* infection, thus halting the use of preventive therapy, an intervention with a known and predictable effectiveness. TST studies among healthcare workers in the Ivory Coast, Thailand, and Brazil showed that having a BCG scar was associated with a positive TST when considering the 10-mm cutoff *(144,145,147)*. No association between having a BCG scar and a positive TST was seen when using the 15-mm cutoff. Furthermore, BCG is unlikely to be protective (and may even be harmful) in the highest risk healthcare worker group, those who are infected with HIV or are otherwise severely immunocompromised.

Transmission of *M. tuberculosis* in healthcare facilities poses a risk not only to healthcare workers, but also to patients, volunteers, and visitors. Therefore, BCG vaccination of healthcare workers cannot substitute for a comprehensive TB infection control program. In the United States, BCG vaccination of healthcare workers may be considered on an individual basis in high-risk settings where (a) a high proportion of *M. tuberculosis* isolates are resistant to both isoniazid and rifampin, (b) there is a strong likelihood of transmission and infection with such drug-resistant microorganisms, and (c) comprehensive TB infection control precautions have been implemented but have proved inadequate. BCG vaccination is not recommended for HIV-infected persons. BCG vaccination is not recommended for healthcare workers in settings in which there is a relatively high risk of *M. tuberculosis* transmission but most isolates are susceptible to isoniazid or rifampin, nor is it recommended in settings in which there is a low risk of transmission *(179)*.

Special Considerations in Pediatric Hospitals

It is a widely held belief that pediatric TB patients usually are not infectious. Unfortunately, this is the result of

historical belief rather than extensive published scientific data. Several factors are given for assuming that pediatric patients are less infectious. First, pediatric patients usually present with primary disease, whereas adults usually present with disease resulting from progression of LTBI. For this reason, it is believed that the bacterial burden is less in pediatric TB patients. Second, pediatric TB patients, particularly those <10 years of age, usually do not produce sputum with coughing. Most pediatric TB patients are diagnosed as a result of contact investigation of an adult, and <50% of pediatric patients with active disease have a positive culture. In contrast, adults often have cavitary, endobronchial, or laryngeal TB and cough and have AFB-positive sputum smears.

Despite these facts, there is no documentation that pediatric patients always are noninfectious, and markers to identify infectious pediatric TB patients have not been developed. In contact investigations, an adult with TB is usually present, and any secondarily infected patients are thought to have acquired the infection from the adult rather than the pediatric patient. Although one study reports TST conversion rates between 0.03% and 0.40% from 1986 to 1994 among workers in a pediatric hospital in Ohio with mandatory annual TST screening *(56)*, most children's hospitals have not maintained active healthcare worker TST programs (particularly including house staff or attending physicians), so that documentation of TST negativity after pediatric TB patient exposures is lacking. An observational study of adherence to TB control guidelines was conducted during 1996 to 1997 in two pediatric hospitals *(178)*. Investigators noted that despite frequent lapses in respiratory protection and isolation, neither institution had documented any healthcare worker TST conversions in the previous 2 years. These studies suggest that the risk to workers in pediatric hospitals is low, but no separate guidelines for pediatric hospitals exist. The TB infection control program in a pediatric hospital should be designed with consideration of the epidemiology of TB in its catchment area and with awareness that teenage patients with active TB may be as infectious as adults.

Because pediatric patients with suspected or confirmed TB may transmit *M. tuberculosis*, such patients should be evaluated for potential infectiousness using the same criteria as adults (i.e., on the basis of symptoms, radiologic findings, sputum AFB smears, treatment status, and performance of cough-inducing or aerosol-generating procedures). Children who may be infectious should be placed in AII until the diagnosis of TB is ruled out or they are determined to be noninfectious. Pediatric patients who may be infectious include those with laryngeal or extensive pulmonary involvement (especially with pulmonary cavitation), pronounced cough, or AFB-positive sputum smears, or those for whom cough-inducing procedures are being performed. Because the source of infection for a child with TB often is a member of the child's family, parents and other visitors of all pediatric TB patients should themselves be evaluated for TB as soon as possible *(96b)*.

Regulation of Tuberculosis Infection Control

The OSHA has been concerned about the safety of healthcare workers from the threat of occupationally acquired TB infection. In 1997, OSHA published a draft standard for the protection of healthcare workers from TB in hospitals, but to date no standard has been adopted *(179)*. Concern expressed from the medical community over the necessity and cost of such regulation and potential compromise of patient care has halted implementation of these proposed regulations indefinitely. Even without regulation, hospitals have improved their application of TB infection control guidelines (114,*180*), although institutions still exhibit problems with the inclusion of attending physicians and house officers in mandatory employee TB screening programs, consistent use of appropriate respiratory protection by healthcare workers, or testing of engineering controls in isolation rooms (114,*178,180,181*). Despite these lapses, these studies did not find evidence of ongoing transmission of *M. tuberculosis* to healthcare workers. In hospitals that apply the CDC guidelines, the risk of exposure to *M. tuberculosis* in the workplace can be minimized effectively in both low- and high-transmission areas *(56,59)*. In light of hospitals' continued improvement in the application of CDC guidelines, OSHA will continue to regulate TB infection control under its general duty clause for employee protection from hazards in the workplace, rather than under separate and specific TB infection control regulations.

The OSHA general duty clause states in section 5(a) *(1)* of the Occupational Safety and Health Act of 1970 that the employer "shall furnish.. a place of employment which is free from recognized hazards that are causing or are likely to cause death or serious harm to his employees." Every hospital that may treat a patient with active TB should maintain a TB protection program addressing five abatement methods outlined by OSHA's 1993 enforcement policy *(183)*: (a) a protocol for early identification of patients with active TB, (b) a program of medical surveillance of employees, (c) evaluation and management of employees with a positive TST or active TB, (d) isolation of persons with suspected or confirmed TB, and (e) appropriate training of employees. The implementation of these methods may be tailored to the specific needs of the institution; OSHA expects institutions to follow the CDC guidelines in selecting these methods (157). In the states and territories where OSHA has direct jurisdiction, citations for failure to protect healthcare workers may be issued only where exposure of workers to *M. tuberculosis* occurs and where every known feasible and useful method to correct the hazard has not been implemented. Hospitals are in compliance with OSHA as long as the methods they select for TB control ensure that no exposure occurs *(184,185)*.

CHAPTER 39

Nontuberculous Mycobacteria

Barbara A. Brown-Elliott and Richard J. Wallace, Jr

Although the existence of nontuberculous mycobacteria (NTM) was recognized over a century ago, the microorganisms were originally thought to be contaminants or harmless colonizers. Increases in numbers of severely immunosuppressed patients, extensive utilization of invasive procedures, and more sensitive diagnostic tests have contributed to an increase in the isolation of the NTM from clinical samples (*1–6*,7). As a consequence, over the past four decades, the recognition and relative importance of NTM as a cause of human disease have increased dramatically. NTM are ubiquitous in nature, having been isolated from a variety of environmental sources, including dust, water, soil, domestic and wild animals, milk, and food *(5,8–18)*. More than 130 species are currently recognized. While many of these species are nonpathogenic, an increasing number, including *Mycobacterium avium* complex (MAC), *M. kansasii*, *M. chelonae*, *M. fortuitum*, *M. mageritense*, *M. xenopi*, *M. lentiflavum*, *M. marinum*, *M. simiae*, *M. haemophilum*, and *M. genavense*, have been associated with disease in normal and immunosuppressed hosts *(1,2,4,19–30)*. A select number of these species have also been linked to healthcare-associated disease, including the *M. fortuitum* group, the *M. chelonae/abscessus* group (including *M. immunogenum*, *M. chelonae*, and *M. abscessus* [recently reclassified as *M. abscessus* subsp. *abscessus* and *M. abscessus* subsp. *bolletii (31)*, and collectively referred to hereafter as *M. abscessus* group]), *M. neoaurum, M. bacteremicum, M. kansasii,* MAC, and *M. xenopi*.

MICROBIOLOGY

The slowly growing NTM, including those species usually associated with healthcare-associated diseases, grow well on the same types of media used for cultivation of *M. tuberculosis* complex (MTBC). Optimal incubation temperatures vary from 28°C (for species typically associated with cutaneous infections such as *M. marinum, M. haemophilum*, and *M. chelonae*) to 35°C to 37°C for most of the slowly growing NTM.

M. xenopi grows optimally at 42°C to 43°C but, with prolonged incubation, will grow at 37°C. Most species produce visible colonies on solid agar within 7 to 14 days. More than 60 species of rapidly growing mycobacteria (RGM) are recognized, with this number increasing rapidly with the primary use and availability of 16S ribosomal RNA (rRNA) gene sequencing for identification. The RGM are susceptible to the NaOH decontamination process performed on sputum to facilitate isolation of MTBC. They are nonfastidious microorganisms that produce mature, visible colonies on solid agar in 3 to 7 days. The microorganisms grow well at 30°C to 37°C on standard bacterial media, including 5% sheep's blood and chocolate agar, and on media specifically formulated for mycobacterial species. Isolation of *M. chelonae* is optimal at an incubation temperature of 28°C to 32°C.

IDENTIFICATION

The reemergence of tuberculosis including multidrug-resistant strains (MDR and XDR) as well as the heightened awareness of NTM as human pathogens has fueled an intense effort to develop rapid and accurate methods of identifying mycobacteria at the species level. Traditional identification schemes for slowly growing species utilize growth rates, pigment production, and biochemicals such as niacin production, urease, and catalase. Biochemical tests traditionally used in identifying the pathogenic RGM include the rapid (3-day) arylsulfatase reaction, iron uptake, nitrate reduction, and the ability to utilize mannitol, inositol, and/or citrate as carbon sources *(32)*. Although these biochemical methods (utilized throughout the 1980s) have been replaced by molecular methods and high-performance liquid chromatography (HPLC), some laboratories report the NTM only to a group or complex level.

The decade of the 1990s saw identification of NTM by HPLC *(33,34)*, while the last 10 years have seen a revolution of molecular-based tests, including commercial DNA probes, polymerase chain reaction (PCR) amplification followed by PCR restriction-enzyme analysis (PRA), 16S rRNA *rpoB*, *hsp65*, and other gene sequencing *(35–40)*. HPLC methods for separation of mycolic acids have allowed the identification of some slowly growing mycobacterial species and some RGM groups or complexes, with a greater specificity and speed than traditional biochemical methods *(33,34)*. Nonradioactive commercial probes are available (Accu-Probe, Gen-Probe) and are routinely utilized for identifying isolates of MTBC, MAC, *M. kansasii,* and *M. gordonae*. These probes offer excellent sensitivity and specificity, and because they can be used directly on broth

cultures (usually the first medium to show growth), they have significantly reduced the time for final reporting of results *(41,42)*. Currently, no commercial probes are available for identification of the RGM. Newest among the modern identification methods are adaptations of PCR technology for detection and identification of mycobacteria in clinical samples *(43)*. Two different nucleic acid amplification techniques for assaying directly from sputum are now commercially available (Amplicor, Roche; and MTD test, Gen-Probe) and are approved for detection of *M. tuberculosis*. Currently, no systems are commercially available for direct detection of NTM from clinical specimens or for species identification of pure cultures, although several novel approaches have been published. One approach utilizes PCR to amplify the gene encoding the 16S rRNA. The amplified fragment is then analyzed by species-specific probes or partial nucleotide sequencing *(39)* for speciation. A second approach capitalizes on species-specific restriction fragment length polymorphisms (RFLPs) in a PCR-amplified segment of the 65 kDa heat shock protein gene *(44–46)*.

TYPING SYSTEMS

Typing systems for RGM have utilized a number of phenotypic and genotypic methods, including detailed species identification, heavy metal and antimicrobial susceptibility patterns, plasmid profiles, multilocus enzyme electrophoresis (MEE), pulsed-field gel electrophoresis (PFGE), and, more recently, random amplified polymorphic DNA (RAPD) PCR (*47*,48,49,*50–52*). PFGE has proven to be a highly useful tool for strain typing of RGM. This method utilizes restriction endonucleases with rare recognition sites such as *Xba*I, *Dra*I, and *Asn*I to generate a small series of large genomic restriction fragments (LRFs), the pattern of which is strain specific. Wallace et al. (48) described the use of PFGE to type *M. chelonae* and the *M. abscessus* group with three reference strains, 28 sporadic isolates, and 62 healthcare-associated isolates from 10 healthcare-associated outbreaks. LRF patterns satisfactory for comparison were achieved in 54% of the *M. abscessus* group and 90% of *M. chelonae* isolates by using the restriction endonucleases *Dra*I, *Asn*I, *Xba*I, and *Spe*I. The sporadic isolates were all highly variable. Isolates from 5 of 10 outbreaks that gave satisfactory LRF patterns were identical. Strains that had been repetitively isolated from patients over periods of time ranging from 2 to 11 years demonstrated that LRF patterns were highly stable. Previous studies with *M. fortuitum* with this technique showed similar results, except that satisfactory LRF patterns were obtained with all strains studied (49,*53*). Environmental water isolates were identical (clonal) to some outbreak strains, indicating that water was the likely source of these past outbreaks. No human carrier or environmental nonwater sources have been identified as an outbreak source by this technique. PFGE is currently the most definitive epidemiologic tool available for comparing suspected outbreak strains of most isolates and species of RGM.

More recently, methods have been introduced for DNA stabilization, which prevent the DNA denaturation seen with PFGE with select strains of bacterial species. Application of one of these methods, the use of hydroxyurea in the running buffer, allows for quality PFGE patterns with the approximate 50% of the *M. abscessus* strains that produced broken DNA *(50)*.

Another nucleic acid amplification technique, RAPD-PCR or arbitrary primer -PCR, has also been applied to the investigation of outbreaks of the *M. abscessus* group *(50–52)*. This technique offers the advantage of being simpler and unaffected by spontaneous lysis of the DNA sample during preparation for PFGE, as occurred previously with 50% of isolates of *M. abscessus* (48). Its major disadvantage is that fewer patterns are produced with each primer; hence, at least three primers that produce quality patterns are needed—a finding that likely reflects the closely related character of these strains *(50,52)*.

PFGE has also been used to study clustering or pseudo-outbreaks of slowly growing mycobacteria, including MTBC, *M. xenopi (53,54)*, *M. kansasii (55,56)*, *M. simiae*, *(57–59),* and MAC *(60–62)*. Other fingerprint techniques used for slowly growing species include MEE with *M. fortuitum (47)*, the *M. abscessus* group *(63)*, *M. simiae (64)*, and the use of hybridization with repetitive insertional elements for *M. xenopi (53)*, *M. kansasii (55)*, and *M. avium (60)*. Previously, serotyping of MAC was used for strain typing *(62)* but currently has been replaced by molecular strain typing.

Recently, a commercial system from DiversiLab system (BioMerieux, Durham, NC), using repetitive elements interspersed throughout the genome, was introduced for strain typing of microorganisms including mycobacteria. The method was reported to be more rapid, required less sample size, and provided equivalent or better than standard RFLP for some species of mycobacteria *(65)*.

Another method that has been evaluated recently with isolates of *M. fortuitum* and the *M. abscessus/chelonae* group is the enterobacterial repetitive intergenic consensus (ERIC) PCR. In an outbreak of the *M. abscessus* subsp. *bolletii* in Brazil recently, the ERIC PCR showed higher discrimination than PFGE for the *M. abscessus* group but less discriminatory power among isolates of *M. fortuitum (66–68)*.

Finally, multigene sequencing has recently been used to characterize isolates of *Mycobacterium* in hemodialysis water and may provide a reliable method of DNA strain typing *(69)*.

EPIDEMIOLOGY

NTM are not reportable by law in most states, and thus, precise estimates of their incidence and prevalence are not available. Most NTM species, with the exception of MAC, are found in specific geographic areas. Overall, MAC is the most common NTM species recovered in the United States, followed by *M. kansasii* and the *M. abscessus* group *(1)*. Although less frequently recovered in the United States, *M. xenopi* is the second most commonly isolated NTM species in England and Canada *(70)*. In some areas of northern Europe, *M. malmoense* is second only to MAC (7). Although this species is rare in the United States, *M. simiae* is second to MAC in some cities in the southwestern United States *(57,58,71,72)*. Tap water and biofilms in the pipes appear to be the major reservoirs for *M. kansasii, M. xenopi*, and *M. simiae*, and a reservoir for *M. avium* and *M. intracellulare* (73).

In contrast to surveys done in the late 1970s and early 1980s *(1,70,74)*, more recent studies show that there

are now more laboratory isolates of NTM in developed countries, especially MAC, than isolates of *M. tuberculosis*. The epidemiology of disease due to NTM has changed because of the improvement in laboratory recovery and identification of these species and the increased awareness of the clinician of these species as potential pathogens. The emergence of better antiretroviral therapies for human immunodeficiency virus (HIV) infection (acquired immunodeficiency syndrome [AIDS]) has resulted in a dramatic decline in the incidence of NTM disease in patients with far advanced disease. Among AIDS patients, MAC had been a common mycobacterial cause of opportunistic infection and a frequent cause of disseminated disease.

The RGM are the most commonly described and the most significant NTM for healthcare-associated epidemiology (75). Of the human diseases attributable to this group of microorganisms, over 90% are due to *M. fortuitum*, the *M. abscessus* group, and *M. chelonae* (*2*,*13*,*21*,75). These species readily survive nutritional deprivation and extremes of temperature. For example, most pathogenic species have been shown to grow and survive in distilled water, and they have been identified from soil, dust, domestic animals, and marine life (*3*,*5*,73,*76*,*77*). Multiple water sources have been identified, including tap water, municipal water, and aquariums (*2*,*3*,*5*,*10*). Mycobacteria have also been found in high numbers in biofilms on water-delivery devices, such as dental hand pieces *(78)*. Similar biofilms may exist within bronchoscope channels, endoscope washers, ice machines, and water tanks, explaining the tendency of these devices to become colonized with mycobacteria. Biofilms are important not only because they enable bacteria to adhere and persist on artificial surfaces but also because they provide protection from the action of disinfectants *(79–82)*.

PATHOGENESIS AND CLINICAL MANIFESTATIONS

The pathology of NTM infection can be identical to that of *M. tuberculosis*. Chronic inflammation, acute suppuration, nonnecrotic epithelioid tubercles, and caseation are all seen on histopathology. The coexistence of granulomatous and acute inflammation (so-called dimorphic inflammatory response) is not seen with tuberculosis but is commonly seen in cervical lymph nodes *(83)* and cutaneous disease *(2,21,84)* due to the NTM. Animal models to study the pathology of NTM have been difficult to develop, even when the animals are immunosuppressed *(85,86)*.

Isolation of NTM in the laboratory may represent an environmental or laboratory contaminant, transient patient colonization, or true disease. In the absence of known environmental contamination, isolation of any NTM from a normally sterile site should be considered significant. Contamination of a skin wound with these microorganisms is rare, and even a single positive culture from this site generally indicates disease. Similarly, recovery of these microorganisms from cultures of lymph node specimens or blood is sufficient for establishing the diagnosis of nontuberculous lymphadenitis or disseminated disease, respectively.

In contrast, isolation of NTM from pulmonary specimens can be particularly difficult to evaluate. The American Thoracic Society last published criteria for the diagnosis of NTM pulmonary disease in 2007 (7). According to these criteria, a definitive diagnosis requires compatible clinical symptoms along with characteristic radiographic abnormalities, which are not attributable to any other cause. Multiple cultures of respiratory specimens are required to demonstrate persistent culture positivity. The microorganism must be grown from two acid-fast bacilli (AFB) specimens of sputum or from at least one specimen obtained from a normally sterile site such as a bronchial wash or bronchopulmonary tissue. The clinical syndromes most commonly associated with NTM infections and the microorganisms usually responsible are summarized in Table 39-1. The major risk factor for pulmonary NTM disease appears to be underlying bronchiectasis.

TABLE 39-1

Clinical Presentations of Nontuberculous Mycobacterial Species

Clinical Syndrome	*Common Causes*	*Less Common Causes*
Bronchopulmonary infection	*M. avium* complex *M. kansasii* *M. abscessus* group	*M. xenopi* *M. fortuitum* group *M. chelonae* *M. malmoense* *M. immunogenum* *M. szulgai* *M. simiae* *M. asiaticum*
Lymphadenitis	*M. avium* complex	*M. malmoense* *M. abscessus* group *M. fortuitum* group

Skin and soft tissue infection	*M. marinum* *M. fortuitum* group *M. chelonae* *M. abscessus* group *M. ulcerans*	*M. haemophilum* *M. smegmatis* group *(M. goodii, M. wolinskyi)* *M. mageritense*

Note: *M. abscessus* group includes isolates now reclassified as *M. abscessus* subsp. *abscessus* and *M. abscessus* subsp. *bolletii*.

DESCRIPTION OF COMMUNITY-ACQUIRED INFECTIONS

Rapidly Growing Mycobacteria

Cutaneous Disease RGM most commonly cause post-traumatic and postsurgical skin and soft tissue infections but can also cause lymphadenitis, keratitis, suppurative arthritis, osteomyelitis, endocarditis, peritonitis, bacteremia, and disseminated disease (*21*,*51*,*87–90*,91,*92–98*). In a review of 125 cases of infection due to RGM (*2*), 60% presented with cutaneous manifestations, half of which were due to penetrating trauma. The usual pathogens in this setting are *M. fortuitum*, the *M. abscessus* group, and the former *M. fortuitum* third biovariant complex *(2,99)*. (The major species within the *M. fortuitum* third biovariant complex include *M. porcinum*, *M. houstonense*, *M. senegalense*, and less commonly, *M. boenickei*, *M. brisbanense*, and *M. neworleansense*.) Patients with the *M. fortuitum* group and the *M. abscessus* group are generally healthy, and drug-induced immune suppression is not considered a risk factor in contrast to those patients with *M. chelonae* in which corticosteroid usage is a major risk factor.

Infections are typically chronic and may heal spontaneously or after surgical debridement. Even without medical intervention, the lesions usually remain well localized. Infections typically present as cellulitis with acute and chronic inflammation, which may form ulcers or sinus tracts with serous, watery drainage *(2,51,84,100,101)*.

Disseminated Disease Disseminated disease due to RGM is typically related to immunosuppression, particularly corticosteroid therapy (91,*92*,*93*). Dissemination primarily occurs in patients with *M. chelonae* and, to a lesser degree, with *M. abscessus*. These patients typically have no history of trauma but present with multiple draining skin lesions. Infections with *M. chelonae* and the *M. abscessus* group have been described in solid organ transplant patients, including renal, heart, and lung transplant patients as well as patients with rheumatoid arthritis or other autoimmune disorders on long-term, low-dose corticosteroids *(2,21,93,102)*. In one series of renal transplant patients, 10 patients with *M. chelonae* infections (including both *M. chelonae* and the *M. abscessus* group) were identified over a 6-year period from four hospitals *(103)*.

Pulmonary Disease Chronic pulmonary disease may occur with RGM, especially in older women with bronchiectasis. The *M. abscessus* group accounts for >80% of these cases. Pulmonary infection is usually chronic, insidious, and slowly progressive. Lung infection may also be associated with MAC, and similarities between patients with MAC and those with the *M. abscessus* group suggest a common pathogenicity or host susceptibility defect (7). Patients may have minimal symptoms of cough or fatigue for many years, and subtle changes on high-resolution computed tomography scanning or subtle deterioration in pulmonary function may be the only markers of disease progression. Clinically, these patients are older and typically present with bilateral nodular interstitial disease associated with cylindrical bronchiectasis *(2,21,*75,*104)*. Their presentation appears identical to that in women with MAC lung disease.

Patients with cystic fibrosis may also be involved with increasing frequency, and *M. abscessus* appears to be more frequent than MAC in this setting. Primary risk factors for susceptibility to NTM lung infection include bronchiectasis and chronic recurrent airway and parenchymal infections with other microorganisms (7).

Other RGM including *M. chelonae*, the *M. smegmatis* group, and *M. fortuitum* infrequently may be associated with pulmonary disease in such underlying disorders as achalasia or lipoid pneumonia (7).

Hypersensitivity pneumonitis has been observed among factory workers working with metalworking fluids contaminated with a newly described species, *M. immunogenum (105)*, and among users of poorly maintained indoor hot tubs in association with MAC *(106,107)*.

Bone and Joint Infection

Osteomyelitis may follow open bone fractures, puncture wounds, and hematogenous dissemination. The most frequent pathogens in this setting are members of the *M. fortuitum* group, although two newly described species in the *M. smegmatis* group—*M. goodii* and *M. wolinskyi*—may also be involved (7,*108*).

Slowly Growing Nontuberculous Mycobacteria

Among the slowly growing NTM, *M. malmoense*, *M. kansasii*, MAC, *M. xenopi*, and *M. simiae* can all occasionally cause community-acquired pulmonary or extrapulmonary disease in HIV-negative patients (*4*,7). MAC, *M. kansasii*, *M. haemophilum,* and *M. genavense* are the usual causes of infections including disseminated disease in HIV-infected persons. However, the slowly growing species are less frequent causes of healthcare-associated disease than the RGM (*4*,7). Detailed descriptions of the clinical disease associated with these microorganisms are reported elsewhere (*4*,7,*13*).

Previous studies in different sections of one hospital in Madrid, Spain, have shown identical strains of MAC in clinical samples—21/23 (91%) of urine isolates and 5/19 (26%) of respiratory isolates by PFGE and other typing methods such as hybridization with IS1245 *(109)*. The investigation hypothesized that contamination of clinical samples with an environmental strain was the most likely cause since none of the patients with this strain had disease *(109)*. A similar study in California examined potable water as a possible source of MAC infection in both AIDS and non-AIDS patients. The investigation revealed that the MAC isolates from potable water in three homes, two commercial buildings, one reservoir, and eight hospitals had varying degrees of genetic relatedness to 19 clinical isolates from 17 patients. Hospitals had the highest incidence (93%) of MAC isolates. Aronson et al. stated that the large number of isolates found in hospital water with a close genetic relationship to patient isolates suggested the possibility of a healthcare-associated spread of MAC to immunocompromised patients, especially AIDS patients, although a prospective epidemiologic study was not performed *(110)*.

DESCRIPTION OF HEALTHCARE-ASSOCIATED INFECTIONS

Healthcare-associated mycobacterial infections (almost exclusively due to RGM) have been recognized for more than 25 years and remain relatively common. They have been most often recognized primarily as causes of surgical site infections and postinjection abscesses; however, they have also been reported to cause catheter-related infections, dialysis-related infections, bronchoscope and endoscope contamination, and most recently, infections resulting from cosmetic procedures including plastic surgery, liposuction, and a healthcare-related practice involving subcutaneous injections of minute quantities of various drugs called mesotherapy (*47*,48,111,*112*,113,*114*,*115*). For outbreaks and sporadic reports of infections due to RGM, there is a strong geographic relationship to the Gulf Coast and southeastern states in the United States. Figure 39-1 demonstrates the focal geography of some of the early outbreaks reported in the United States. Recently, several outbreaks of NTM have occurred in South and Central America (*66*,*116*,117,*118–121*).

Surgical Site Infections

Outbreaks of mycobacterial surgical site infections were first recognized in 1975 to 1976 with the report of four such outbreaks *(122–124)*. These reports were followed in the 1980s by at least 14 additional outbreaks *(125–130)*. Outbreaks have been described involving cardiothoracic surgery, plastic surgery, augmentation mammaplasty, and arthroplasty *(122–130)*. A summary of the major healthcare-associated outbreaks due to RGM is given in Table 39-2. Following recognition of epidemic surgical site infections, it became apparent that most surgical site infections due to RGM are sporadic *(21,47,125,131–143)*. Such infections with RGM have been described following vascular surgery, oophorectomy, neurosurgery, corneal surgery, the insertion of middle ear tubes, biopsy procedures, and plastic surgery, including procedures such as face-lifts and liposuction *(94*,*96*,*136*,*137*,*140*,*143–150*). It is unclear whether there is a predisposition for certain types of surgery; however, more than 60% of surgical site infections due to RGM reported in the 1980s were reported after cardiac surgery *(122,126,129,134)* or augmentation mammaplasty *(125,137,145)*. In the past 10 years, however, these latter surgeries have been replaced in incidence by cosmetic surgical procedures (111,*116*,117,*118*,*120*,151).

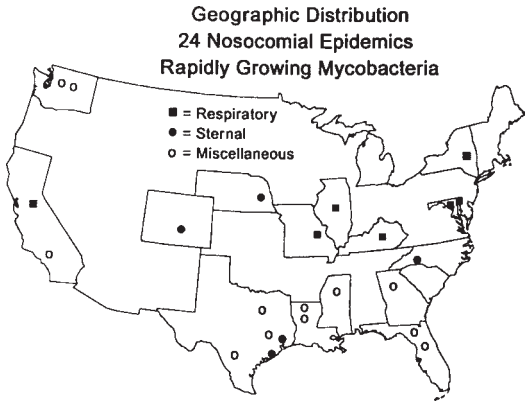

FIGURE 39-1 The geographic focality of healthcare-associated outbreaks due to rapidly growing mycobacteria.

Cardiothoracic Surgery

A review of RGM isolates associated with cardiac surgery was published in 1989 *(47)*. This study evaluated isolates from eight cardiac surgery outbreaks, as well as 45 sporadic isolates. Disease isolates were recovered from sternal wounds, donor vein graft sites, blood, and artificial valves. The isolates included *M. fortuitum*, the *M. abscessus* group, and the *M. smegmatis* group *(47)*. Several years later, the development of DNA fingerprinting for *M. fortuitum* and the *M. abscessus* group permitted better evaluation of these outbreaks (48,49,*50–52*). The first reported cardiac surgery–associated outbreak occurred in 1976 in North Carolina. Nineteen cases of disease due to *M. abscessus* occurred over a 10-week period, but no source was identified. Five (26%) patients died of their disease. In a second similar outbreak in Colorado, 10 of 75 cardiac surgery patients developed infections with *M. fortuitum*. *M. fortuitum* was recovered from a settling plate in the operating room *(122)*, but subsequent molecular studies using PFGE showed that the environmental strain differed from the disease strain *(53a)*.

The best clue to the potential reservoir for these outbreaks was provided in a later outbreak from Texas involving both *M. fortuitum* and the *M. abscessus* group. An isolate of *M. fortuitum* with a DNA fingerprint identical to that of the outbreak strain was isolated from the tap water in the operating room, ice water used to cool the cardioplegia solution, ice machines, and municipal water coming into the hospital. An identical strain was recovered from patients with several types of noncardiac surgical site infections. In this same outbreak, RAPD-PCR showed *M. abscessus* isolated from hospital ice water used to cool the cardioplegia solution and a pair of surgical scissors was identical to some disease isolates *(47,52,53a,126)*. This investigation was the first major study to identify water (in this case as ice used for surgical purposes) as the major reservoir for the microorganism. Another unreported outbreak in Texas also helped to clarify the role of water as a reservoir for RGM. In this outbreak, PFGE demonstrated the clonality of tap water and case isolates (Fig. 39-2). Several cases of perivalvular infection occurred following contamination of commercial porcine valves with *M. chelonae* *(152,153)*.

Outbreaks of sternal wound disease have not been limited to the United States. An outbreak of sternal infections due to *M. abscessus* following cardiac surgery in Budapest was described in 1976, but the source was not identified *(124)*. An outbreak of sternal surgical site infections caused by *M. fortuitum* and *M. peregrinum* occurred in Hong Kong among patients who had undergone cardiothoracic surgery at a single hospital during 1987 to 1989 *(130)*. Investigators used rRNA gene RFLP to determine that, in most cases, the microorganism belonged to one of two groups. The source of contamination could not be identified and was presumed to be environmental in origin. No additional outbreaks have been reported since 1989, presumably because of avoidance of contaminated tap water and ice in the operating room.

TABLE 39-2

Outbreaks Due to Rapidly Growing Mycobacteria

Source of Infection	*Year of Outbreak*	*Location*	*Microorganism*
Types of Surgery			
Cardiac surgery	1977	Hungary	*M. abscessus* group
	1987–1989	Hong Kong	*M. fortuitum* and *M. peregrinum*
	1987	Texas	*M. abscessus* group
	1976	N. Carolina	*M. abscessus* group
	1976	Colorado	*M. fortuitum*
	1976	Multistate	*M. abscessus* group
	1981	Nebraska	*M. fortuitum*
	1981	Texas	*M. fortuitum* and *M. abscessus* group
Laparoscopic surgery	1986	Mississippi	*M. abscessus* group
	2002–2004	Brazil	*M. fortuitum* group
Arthroscopic surgery	2005–2007	Brazil	*M. abscessus* subsp. *bolletii* (formerly *M. massiliense, M. bolletii*)
Prosthetic endocarditis	1999–2008	Brazil	*M. chelonae*
Herniotomy/orchiopexy	1998	India	*M. abscessus* group
Plastic surgery	2002–2003	Bangalore, India	*M. chelonae*
Augmentation mammaplasty	1985	Florida	*M. abscessus* group
	2002–2004	Brazil	*M. fortuitum group*
Vascular (vein stripping)	1974	Spain	*M. abscessus* group
Nasal surgery	1987–1988	Mexico	*M. abscessus* group?[a]
Liposuction /liposculpture	1996–1997	California	*M. chelonae*
	1996–1998	Venezuela	*M. fortuitum/M. abscessus* group
Abdominoplasty	2003–2004	Dominican Republic	*M. abscessus* group
Ocular surgery (LASIK)	1991	Taiwan	*M. fortuitum* and *M. chelonae*
	1998–2000	Brazil	*M. chelonae*
	2003	Brazil	*M. immunogenum*
Injection abscesses	1961	Belgium	*M. fortuitum?*[a]
	1962	Congo	*M. fortuitum?*[a]
	1963	Texas	*M. fortuitum?*[a]
	1966–1968	England	*M. chelonae*
	1969	Netherlands	*M. chelonae*
	1977	Texas	*M. abscessus* group
	1989	Georgia	*M. chelonae*
	1993	Colombia, SA	*M. abscessus* group
	1995–1996	Multistate	*M. abscessus* group
	1997–1998	China	*M. abscessus* group
	1999	Texas	*M. abscessus* group
	2005	Korea	*M. abscessus* subsp. *bolletii* (formerly *M. massiliense, M. bolletii)*
Injection abscesses (mesotherapy)	2000	Brazil	*M. chelonae*
	2006–2007	Argentina	*M. immunogenum*
	2006–2007	France	*M. chelonae, M. frederiksbergense*
	2004–2009	Brazil	*M. abscessus* subsp. *bolletii*
EMG needles	1985	Washington	*M. fortuitum*
Podiatry jet injector	1988	Florida	*M. abscessus* group
Dialysis-related	1982	Louisiana	*M. abscessus* group
	1987	California	*M. abscessus* group
	1987	Washington	*M. mucogenicum*[b]
Bronchoscopy/endoscopy	1981	Illinois	*M. chelonae*?[a]
	1989	Missouri	*M. immunogenum*
	1989	England	*M. immunogenum*
	1989	Switzerland	*M. immunogenum*

TABLE 39-2

Outbreaks Due to Rapidly Growing Mycobacteria (*Continued*)

Source of Infection	*Year of Outbreak*	*Location*	*Microorganism*
	1991	Missouri	*M. immunogenum*
	1991–1992	England	*M. fortuitum* and *M. chelonae*
	1992	Maryland	*M. immunogenum*
	1992	Ireland	*M. chelonae*
	1992	Australia	*M. chelonae*
	1992	Kentucky	*M. immunogenum*
	1992	Taiwan	*M. chelonae*
	1993	Florida	*M. chelonae*
	1999	Scotland	*M. chelonae*
Catheter-associated bacteremia	2006	Texas	*M. mucogenicum, M. porcinum*
Respiratory	1985	New York	*M. peregrinum*
	1988–1989	California	*M. fortuitum*
	1989–1990	Washington, DC	*M. fortuitum*
Other			
Bone marrow biopsy	1987	Texas	*M. fortuitum*
Middle ear irrigation	1988	Louisiana	*M. abscessus* group
Acupuncture	2001	Korea	*M. abscessus* group
Tattoos	2007–2008	Minnesota	*M. chelonae*
	2005	France	*M. chelonae*
Furunculosis (nail salons)	2000	California	*M. fortuitum*
	2002–2003	Georgia	*M. mageritense*
Cutaneous (wading pool) "hand and foot disease"	2003	Alberta, Canada	*M. abscessus* group

Note: *M. abscessus* group designation includes the new taxonomic reclassification of *M. abscessus* subsp. *abscessus* (formerly *M. abscessus*) and *M. abscessus* subsp. *bolletii* (formerly *M. massiliense* and *M. bolletii*) unless specifically stated as *M. abscessus* subsp. *bolletii*. (Outbreaks occurred prior to reclassification.)
[a]Species of the microorganism by current taxonomy has not been confirmed.
[b]Formerly known as *M. chelonae-like organism* or MCLO.
SA, South America; EMG, electromyography.

In addition to these outbreaks, numerous sporadic infections due to RGM have been reported following cardiac surgery *(2,134,139,154–157)*, including a case of subacute bacterial endocarditis for which a source was never documented. When 89 isolates from cardiac surgical site infections were analyzed, 45 were sporadic; these were more likely to be due to *M. fortuitum* or the *M. smegmatis* group. Eighty percent were from southern coastal states (48). Sporadic cases of disease continue to be seen.

Cardiac surgery patients with surgical site infections due to RGM have presented with failure of surgical site healing or breakdown of healed surgical sites with drainage of serous fluid. Endocarditis patients presented with fever and cutaneous and embolic phenomena, along with positive blood cultures 4 to 12 weeks after surgery *(2,158)*. In the outbreak related to contaminated porcine valves, patients presented with pericardial effusions and aortic abscesses.

Plastic Surgery/Augmentation Mammaplasty

Infections due to RGM following plastic surgery for breast augmentation have been well described *(125,127,135, 137,142,145)* and, along with cardiac surgery infections, were the most common surgical site infections due to these microorganisms. However, with the exception of one outbreak, the pathogenesis of these infections has yet to be defined *(125,127,159)*. The one outbreak in which a well-defined source was identified included infections following both augmentation mammaplasty and blepharoplasty *(127)*. During April to October 1985, an outbreak of *M. abscessus* was identified affecting eight patients. *M. abscessus* was recovered from the gentian violet in the office and the stock solution in the pharmacy, which had been using distilled water to reconstitute the gentian violet crystals instead of 10% alcohol, thus allowing *M. abscessus* to replicate. Previous studies have shown that isolates of the *M. abscessus* group grow well in potable and distilled water *(8,76,126)*. No source has been identified for any of the cases of sporadic mammaplasty wound infections, although the tendency for more than one case to occur in a plastic surgeon's practice makes environmental sources highly likely *(125,142,159)*. Almost 90% of sporadic cases of surgical wound infections following augmentation mammaplasty have been reported from three states—Texas, North Carolina, and Florida *(125,142)*. Sporadic surgical wound infections after other types of breast surgery

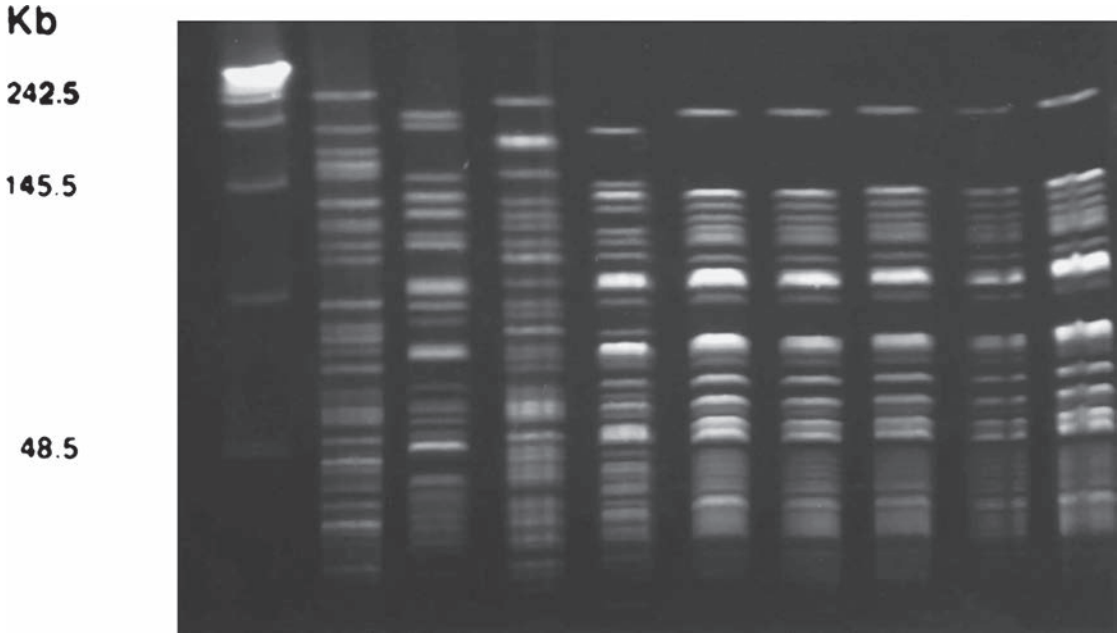

FIGURE 39-2 Pulsed field gel electrophoresis of *M. abscessus* from a surgical site outbreak in Texas using xba.1. Lanes 1–5 are genomic DNA and control strains. Lanes 6 and 10 are isolates obtained from tap water, and lanes 7–9 are case isolates from infected patients.

as well as spontaneous breast infections have also been reported *(142)*.

Outbreaks and/or sporadic wound infections have been described after other types of plastic surgery procedures, including face-lifts *(141)*, blepharoplasty *(136)*, and liposuction (111). In a liposuction-associated outbreak reported in 2001 involving an outpatient clinic, tap water was used for flushing and rinsing suction tubing, and inadequate sterilization procedures were in place. *M. chelonae* isolates recovered from patient wounds and the tap water system were clonal when studied by PFGE (111).

Although reports of NTM outbreaks following cardiac surgery or augmentation mammaplasty have declined in the United States recently, a cluster of cases of postaugmentation mammaplasty surgical site infections occurred between 2002 and 2004 in southern Brazil. RGM were isolated from samples from 12 patients. Eleven isolates of *M. fortuitum* and one of *M. porcinum* were identified by molecular studies *(66)*. A total of 492 patients in 12 hospitals were evaluated. Fourteen cases were confirmed. Fourteen were possible and one was a probable case using clinical criteria. Molecular strain typing revealed that the outbreak was caused by polyclonal strains at different institutions, and in one hospital, a unique genotype was responsible for the majority of cases *(160)*.

Outbreaks of NTM infections also have recently been associated with laparoscopic and cosmetic procedures in Brazil, the Dominican Republic, and Venezuela (*116*,117,*118*,*121*,151).

Miscellaneous Surgery

Although outbreaks of surgical site infections were first reported after cardiac surgery and augmentation mammaplasty, outbreaks have been described after general surgical procedures as well. In one outbreak, a cluster of the *M. abscessus* group in surgical site infections occurred in a Mississippi hospital in 1985 in women who had undergone laparoscopy. In this outbreak, four cases confirmed by culture and 12 probable cases were identified. An isolate of *M. abscessus* with the same antimicrobial susceptibility profile as the patient isolates was identified from the mineral oil used to lubricate the laparoscope and from multiple specimens of tap water throughout the hospital. The outbreak stopped when a sterile aqueous-based solution was substituted for mineral oil as a lubricant and when laparoscopes received high level disinfection without exposure to tap water (CDC investigation no. 91-01).

Similar outbreaks of laparoscopic port sites have also occurred in 2002 to 2003 in Bangalore, India. The presence of biofilms on the surgical instruments and improper rinsing was hypothesized but not confirmed as the source of the outbreak *(161)*.

One of the largest recent postsurgical outbreaks has involved the recently reclassified species, *M. abscessus* subsp. *bolletii* (formerly identified as two separate species, *M. massiliense* and *M. bolletii*), in 63 hospitals in the state of Rio de Janeiro, Brazil, between August 2006 and July 2007. One hundred and ninety-seven cases were confirmed from 38 hospitals. A total of 148 isolates were recovered from 146 patients. DNA strain typing by PFGE revealed a single clone with the same PFGE pattern that was previously observed in other regions of Brazil (*116*,117).

Previous reports of outbreaks associated with *M. abscessus* subsp. *bolletii* (formerly *M. massiliense*) in Brazil described post–video-assisted surgical infections that began in 2004 (151,*162*) in the northern and central regions of Brazil. No infections following video-assisted medical procedures had been reported prior to 2004 in Brazil although video-assisted technology was available since 1990 *(116)*.

The first outbreak related to this series occurred in 2004 to 2005 in the northern region of Brazil. Fifty-eight

of the 67 isolates studied were from patients who had undergone laparoscopic surgeries (151). A second cluster occurred between 2005 and 2007 in the central region of Brazil and involved laparoscopic and arthroscopic surgeries on 18 patients from seven private hospitals. Again, in both of these outbreaks, the confirmed cases belonged to a single clone *(162)*.

A postsurgical outbreak of herniotomy and orchiopexy in 45 patients in a pediatric unit in New Delhi, India, was associated with the *M. abscessus* group. The outbreak ceased when the source of the outbreak—a leaking vacuum pump and faulty pressure gauge in the autoclave used to sterilize the gauge and boiled tap water—was repaired *(163)*.

Postsurgical wound infections with NTM usually manifest several weeks to months following the surgical procedure *(162)*. Clinical evidence of disseminated infection is uncommon in patients who are immunocompetent.

Postinjection Abscesses

The first description of *M. fortuitum* as a pathogen in 1936 involved an abscess that resulted from a vitamin injection *(164)*. Since that time, a number of sporadic cases as well as outbreaks of localized cutaneous abscesses have been reported involving injections with needles *(51,84,165–174)*. Unlike other healthcare-associated infections, outbreaks of postinjection abscesses are most often due to *M. chelonae*, although outbreaks involving *M. fortuitum* and *M. abscessus* have also been reported. Some outbreaks, especially those before the 1980s, relate to reused or inadequate sterilization of needles *(165,172)*. Other outbreaks appear to relate to contaminated biologics, especially the use of multidose vials or materials. An outbreak among student nurses occurred when a single liter bottle of saline was used repetitively to practice injection techniques *(166)*. An outbreak of *M. abscessus* (identified then as *M. chelonae* subspecies *abscessus*) was identified from a podiatry practice in which jet injectors were placed in distilled water for rinsing between patients. *M. abscessus* was identified in the container of distilled water. A similar outbreak of *M. fortuitum* infections occurred in patients who had undergone electromyography. This office was using reusable needle electrodes that were disinfected with 2% glutaraldehyde and then rinsed with tap water. The outbreak stopped when the needles were routinely autoclaved between patients. Tap water was considered the likely source of infection, but no environmental cultures were positive *(173)*.

An outbreak of *M. abscessus* following penicillin injections in 86 patients in a factory hospital was recently reported in the People's Republic of China from 1997 to 1998. During the investigation of the outbreak, seven lids from bottles of penicillin from the same lot number that was used and stored in the outpatient department of the hospital along with 1 out of 25 soil samples from the floor were revealed to be similar to 50 clinical strains using sodium dodecyl sulfate -polyacrylamide gel electrophoresis of whole cell proteins and plasmids *(175)*. An additional epidemic of *M. abscessus* subsp. *bolletii* (formerly *M. massiliense*) associated with intramuscular injection of an antimicrobial was reported in 2005 in South Korea *(176)*. This procedure, known as mesotherapy, was originally indicated for cases of medical trauma but has gained universal popularity for various cosmetic and noncosmetic reasons including fat reduction, body contouring, reduction of rheumatism pain, or treatment of psychoneurological disorders (113). Most of the recent NTM outbreaks have been associated with aesthetic fat reduction.

Outbreaks of mesotherapy-associated subcutaneous infections derived from the inappropriate cleaning of the automatic repetitive device used for the injections have also been described in France from 2006 to 2007. Cultures grew *M. chelonae* and *M. frederiksbergense*. PFGE patterns of *M. chelonae* from 11 patients who had undergone mesotherapy and that obtained from tap water in the examination room were identical (113).

Even though these infections have been described for more than four decades, they continue to occur. From 1995 to 1996, an outbreak of abscesses occurred in 87 patients throughout the United States (177). All had received intramuscular injections of a preparation alleged to be adrenal cortex extract provided by a single physician as part of a weight-loss regimen. The extract, which had not been approved by the U.S. Food and Drug Administration (FDA), was found to be contaminated with *M. abscessus*. The largest single outbreak of postinjection abscesses due to RGM occurred in Colombia, South America *(51,84,170)*. Of 2,000 patients treated by a single physician from November 1992 to April 1993, 350 developed skin abscesses due to the *M. abscessus* group. Five representative isolates from the epidemic were identical by RAPD-PCR *(51)*. The outbreak was associated with local injections of lidocaine administered by the physician, and the microorganism was recovered from one of the reusable multidose vials *(170)*. The most recent reported outbreak of postinjection abscesses occurred in 1999 and involved the use of contaminated benzalkonium chloride used for skin disinfection. Clinical and environmental isolates of the *M. abscessus* group were indistinguishable by RAPD-PCR (178).

Single sporadic cases of postinjection abscesses likely occur in the same way as epidemic disease *(174)*. Focal abscesses, especially of the arm or hip, should therefore be investigated for any relationship to injections, and if a relationship is identified, infection control policies and procedures should be reviewed to prevent recurrences and outbreaks.

Dialysis Related

Hemodialysis The risk of infection due to RGM in patients undergoing hemodialysis was first reported in 1982, when 27 cases of NTM infection were identified in a group of patients from two Louisiana hemodialysis centers. *M. abscessus* was identified in 24 patients, and *M. mucogenicum* was cultured from one patient sample. The attack rate in one dialysis unit was 19%. Bacteremia occurred in 18 patients, and four had localized infections. There were 13 deaths, for an overall mortality rate of 48%. NTM were identified throughout the water system in two dialysis centers. *M. abscessus* (later shown by PFGE to be identical to disease isolates) (48) was identified in the water of the reverse osmosis room, the reverse osmosis tank, and the formaldehyde used to reprocess dialyzers, and from the blood compartment side of 5 of 31 dialyzers. The outbreak stopped when the reuse of dialyzers was discontinued *(179)*.

A number of important lessons were learned from this outbreak. Tap water is not sterile and allows the growth of RGM. These microorganisms are relatively resistant

to chlorine and glutaraldehyde, and decontamination of dialyzers and dialysis machines may be difficult. Protocols for disinfection and reprocessing of dialyzers must therefore be rigorously followed. Finally, cultures of dialysis patients should be held for a minimum of 14 days to facilitate identification of fastidious or unusual water microorganisms *(179,180)*.

From 1987 to 1988, another outbreak of *M. abscessus* disease occurred; this one involved a hemodialysis unit in California. Infection occurred in five patients; four of five had arteriovenous graft infections and two died. *M. abscessus* was subsequently identified from municipal water and the hose of the water spray device used for reprocessing the high-flux but not the regular dialyzers. High-flux dialysis had been instituted in this center in 1986, and in 1987, renalin (hydrogen peroxide/peracetic acid–based disinfectant) was substituted for 4% formaldehyde to reprocess dialyzers. A number of infection control issues were identified that may have contributed to the outbreak *(180–183)*. These types of infections may increase with widespread use of high-flux dialysis, reprocessed dialyzers, and increasing use of renalin. The effectiveness of dialyzer disinfection is critical to providing patients with safe dialysis *(180,183)*.

No major outbreak of mycobacterial infection involving hemodialysis has been reported since 1987, although a recently described species, *M. llatzerense*, has been identified from a pure-water distribution unit and hemodialysis water in a single hospital in Spain *(184)*.

Peritoneal Dialysis Peritonitis is a common complication of chronic ambulatory peritoneal dialysis (CAPD). After beginning peritoneal dialysis, 60% of patients develop peritonitis in the first year and 80% develop peritonitis within 2 years. Most episodes are due to staphylococci (40–70%) and aerobic gram-negative bacilli (15–30%). Culture-negative peritonitis represents 8% to 27% of reported episodes of CAPD-related peritonitis. Mycobacteria account for <3% of cases but may be more common and simply underrecognized. Hakim et al. *(185)* reviewed 31 cases of peritonitis in CAPD patients due to NTM. Most of the cases reported in the literature have been due to RGM (86%), mostly *M. fortuitum*, although other mycobacteria have also been implicated *(95,186–190)*. In one outbreak involving 17 cases due to RGM *(191)*, most patients presented with fever, abdominal pain, and cloudy dialysis fluid. Catheter dysfunction, vomiting, diarrhea, and weight loss were also described. However, the illness may be more insidious in onset, signaled only by increases in cell counts in the dialysis fluid, particularly with polymorphonuclear leukocytes. Diagnosis is usually made by culture, since AFB smears are generally negative. The unexpected staining and growth characteristics of the RGM may result in misidentification as diphtheroids or debris due to fragmentation and beading on the Gram stain. When gram-positive rods resembling corynebacteria are isolated from peritoneal fluid, a smear stained for AFB should be examined *(191–195)*. Peritoneal biopsies may be helpful in some cases, particularly if they show mixed acute and chronic granulomatous inflammation with pyogenic abscesses or sinus tracts *(2)*. Management consists of catheter removal along with multidrug chemotherapy, based on *in vitro* susceptibility (7,*95*,*196*). Catheter removal improves the success rate *(197)*. Treatment in the past has consisted of aminoglycosides, although the fluoroquinolones, clarithromycin, and imipenem have also shown potential utility *(95,191,197,198)*.

Catheter-Related Infections

Catheter-related infections are currently the most frequently encountered healthcare-associated infection due to RGM. They are well-described complications of central intravenous catheters, arteriovenous catheters, peritoneal dialysis catheters, and even lacrimal duct catheters. Exit-site infections, tunnel infections, and bacteremias have all been reported *(2,94,199–206)*. One of the largest single series of infections was reported by Raad et al. *(201)*, who described intravenous catheter-related infections due to rapid growers in 15 cancer patients over 12 years duration at M. D. Anderson Hospital (Texas). These authors also reviewed the literature through 1991 and described an additional 14 cases. Among the M. D. Anderson cases, 60% had cancer as an underlying disease. There were 11 bacteremias and four catheter-site infections with nine due to *M. fortuitum* and six due to the *M. chelonae/abscessus* group (the authors did not discriminate between *M. chelonae* and *M. abscessus*). All the patients who had their catheter removed recovered. Treatment failed in seven bacteremic patients who had their central line left in place. After catheter removal, six of the seven infections subsequently responded. Foreign bodies and devices appear to play a significant role in facilitating and perpetuating such infections *(131,142,153,202,203,205)*. An unusual syndrome of cholestatic hepatitis associated with fever, right upper quadrant pain, and marked elevation of alkaline phosphatase has been observed in some patients with central venous catheter sepsis due to mycobacteria. The patients have granulomas with positive cultures on liver biopsies. The syndrome presumably results from seeding of the liver at the time of bacteremia *(207)*. An additional syndrome is the development of multiple pulmonary nodules, which presumably relates to seeding of the lung from the central catheter.

Recently, an outbreak of a newly described RGM species, *M. phocaicum,* and *M. mucogenicum* was reported in five patients with central venous catheters in an oncology unit in a Texas hospital (208). This was the first report of clinical isolates of *M. phocaicum* in a hospital in the United States. Rare reports of catheter sepsis have falsely incriminated slowly growing mycobacteria *(209–212)* due to undetected mycobacteria (RGM), failure to use appropriate culture media, and/or too short an incubation time. The most common species associated with central line infections is *M. fortuitum*. Other associated species include the *M. abscessus* group, *M. chelonae*, *M. mucogenicum*, and two pigmented species—*M. neoaurum* and the newly described *M. bacteremicum (206)*.

Infectious Keratitis Following LASIK

Laser in situ keratomileusis (LASIK) has recently been involved in outbreaks of NTM including *M. chelonae*, *M. szulgai*, and *M. immunogenum (119,213–215)*. Importantly, NTM keratitis is characterized by an indolent course and poor response to antimicrobial therapy *(119)*. One major outbreak occurred in a Texas medical center and

was traced to ice used to cool the interface lavage syringe from an ice machine contaminated with *M. szulgai (213)*. Freitas et al. summarized three published cases of NTM clusters of infectious keratitis following LASIK including the publication by Holmes et al. The other two clusters involved *M. chelonae* but no source of the outbreaks was identified *(119,216)*.

Infections Related to Foreign Bodies/ Prosthetic Devices

Healthcare-associated infections due to RGM have been described after the insertion of a variety of prosthetic devices other than catheters and silicone breast implants, including prosthetic hips, prosthetic knees, pacemakers, defibrillators, and myringotomy tubes. Although most cases have been sporadic, disease outbreaks have been reported. Seventeen cases of otitis media due to *M. abscessus* (identified then as *M. chelonae*, subsp. *abscessus*) identified in Louisiana in 1987 were related to an outbreak in an ear, nose, and throat (ENT) practice *(217)*. All of the patients involved in the outbreak had myringotomy tubes and developed chronic otorrhea. The most important risk factors for infection were presence of a perforation or myringotomy tube, suctioning of the ears, and an increasing number of ear examinations. Pathology showed abundant granulation tissue and multiple granulomas with positive AFB smears. In outbreak cases, the suction catheters used to wash out patients' ears had been rinsed with tap water. Instruments were not disinfected or sterilized properly. Ear specula were never sterilized. *M. abscessus* was identified in the water supply *(217)*. However, the epidemic isolate seen in 13 of 14 cases had high-level aminoglycoside resistance (including amikacin), subsequently shown to result from an acquired point mutation in the 16S rRNA gene *(218)* that occurs only with prior aminoglycoside therapy *(94,218–220)*. This finding suggests that the epidemic strain originated from an infected patient rather than the tap water in the physician's office and spread because of improper sterilization of instruments between patients.

Subsequently, 21 sporadic cases of chronic otitis media due to RGM were reported. All the patients with available histories had prior myringotomy tubes, and more than 90% of cases were due to the *M. abscessus* group *(94)*. In a survey of infection control practices in ENT offices, 70% of ENT physicians were using tap water on their instruments, and 52% used tap water to rinse suction catheter tips between patients. Eighty-six percent reported performing high-level disinfection on their instruments between patients, but only 67% used adequate time to actually achieve high-level disinfection (30 minutes in a 2% glutaraldehyde solution, boiling for 5 minutes, and autoclaving for 20 minutes) *(217)*. Epidemic disease potentially could occur with high-level tap water colonization or spread from an already infected patient. In addition to these infections due to RGM, foreign body–associated healthcare-associated infections with other NTM have been reported sporadically *(209,210)*. These have included meningitis in a baby with a ventriculoperitoneal shunt *(211)*, peritonitis in patients undergoing peritoneal dialysis *(189,190,212)*, and endocarditis in a patient with a prosthetic aortic valve *(221)*.

A recent study identified the occurrence of *M. chelonae* valve endocarditis from a cardiac bioprosthesis in a Brazilian hospital. Investigators showed that the microorganisms were present in the prosthesis received from the manufacturer. Five of the 15 AFB-positive paraffin-embedded samples generated 100% similarity by DNA sequencing of the 16-23S internal transcribed sequence region (*222*). A previous probable manufacturer with mycobacterial contamination was reported in 1978 *(223)*. Other cases of cardiac NTM infection have been pacemaker related *(224)*.

Miscellaneous

Additional outbreaks of NTM infections have been associated with receiving acupuncture treatments and tattoos *(225,226)*.

Forty patients who received acupuncture in a single Korean medicine clinic had genetically identical isolates of *M. abscessus*. The source of the outbreak was not determined, although the majority of the patients with infections received deep insertions on the back and knee joint area. Investigators hypothesize that the *M. abscessus* may have been introduced via contaminated towels or hot pack covers to the site, but this was never proven *(225)*.

Reports of 20 men with skin infections with *M. chelonae* in France may be the first NTM outbreak associated with tattoos *(226)*. Subsequent NTM outbreaks in France and, most recently, the United States have occurred *(227,228)*. Interestingly, the infections have involved the gray parts of the tattoo. The gray wash is traditionally prepared by diluting black pigment with tap water, which may have been the source of the outbreaks *(226,227)*. The true incidence of tattoo-associated NTM infections is unknown *(226)*.

A large outbreak of lower extremity furunculosis was caused by *M. fortuitum* in more than 100 patrons of a northern California nail salon as a result of exposure to improperly cleaned whirlpool footbaths (229). The microorganism was cultured from contaminated footbaths and from the inlet suction screens containing hair and other debris. Shaving the legs with a razor prior to the footbath and pedicure was a major risk factor, although some patients who did not shave were also infected (229,*230–232*).

A survey of 18 nail salons (30 foot spas) from five California counties recovered 10 species of NTM from whirlpool footbaths including *M. fortuitum, M. mucogenicum, M. smegmatis* group, *M. mageritense, M. neoaurum*-like RGM, a nonidentified pigmented RGM, MAC, *M. simiae*, *M. gordonae*, and *M. lentiflavum. M. fortuitum* was most commonly recovered and found in 47% of the 30 foot spas cultured. The RGM were the more frequently encountered NTM and were found in 23 (76%) of the foot spas. Investigators hypothesized that the NTM were likely introduced via the municipal water supply where they colonized parts of the spas and plumbing to the spas *(230)*.

One limitation of the survey was the inability to quantify the risk for infection despite the recovery of the NTM. The investigators stated that the findings in the 18 nail salons may not be representative of other nail salons, although the presence of potentially pathogenic NTM is of public health concern *(230)*.

Another smaller outbreak of two patients occurred in a nail salon in Georgia. PCR restriction enzyme analysis using a 439-bp segment of the 65 kDa heat shock protein gene and

HPLC identified the isolates as *M. mageritense*. Subsequent cultures from three of the seven foot spas yielded *M. mageritense*, and PFGE patterns for the patient and environmental isolates appeared to be closely related (233).

An outbreak of cutaneous infections involving the hands and feet in "*M. abscessus* hand-and-foot disease" of 41 children and one adult is the first documented *M. abscessus* outbreak associated with wading pool exposure. The rubber mat in the implicated pool was the suspected reservoir, and installation of a smooth nonabsorbent surface was recommended to prevent future outbreaks *(234)*.

PSEUDOINFECTIONS AND PSEUDO-OUTBREAKS

Generally, an increase in frequency of NTM isolates recovered from patients without disease should alert healthcare personnel to the possibility of a pseudo-outbreak. Often, the recovered species is subsequently isolated from one or more environmental sources. Unless pseudo-outbreaks are recognized, patients may receive unnecessary therapy.

Equipment Related

Bronchoscopes Since the early 1980s, mycobacteria have been the major pathogens transmitted via the bronchoscope, resulting in both pseudoinfections and true infections. Mycobacterial contamination of bronchoscopes and other endoscopes has previously been reported most commonly with *M. abscessus* and *M. chelonae*. A subsequent study has shown, however, that the isolates of *M. chelonae/abscessus* recovered in this setting were actually a related species called *M. immunogenum* (235). Contamination has also occurred with *M. xenopi* and MAC (236,*237–240*,241,*242–248*) and has been linked to suction valves, suction channels, and biopsy forceps. Further contamination has been linked to automated endoscope washers, use of tap water to rinse endoscopes after manual disinfection, and failure to disinfect endoscopes adequately between patients (*58*,236,*238*,241,*245*,*256*). Bronchoscopes and other endoscopes as well as automated washers are difficult to disinfect, in part due to the propensity for formation of biofilms, which are resistant to chemical disinfectants (249). Colonization of some automated endoscope disinfection machines with NTM has been associated with contamination of bronchoscopic and other endoscopic equipment due to problems with product design that facilitated the formation of biofilms in the automated washers (236,*237*,241,*244*,*246*). One such outbreak occurred in St. Louis, Missouri, from December 1989 to September 1990, when 14 patients were identified with *M. abscessus* (later identified as *M. immunogenum*) in their bronchoscopic washings in a hospital using an automated disinfection machine to reprocess bronchoscopes. All specimens were smear negative and no patients developed disease. The patient isolates had the same DNA fingerprint pattern by PFGE (236). This same isolate (with the same fingerprint pattern) was identified from the rinse water in the endoscope-disinfecting machine. The PFGE patterns from this outbreak are shown in Figure 39-3. To determine the mechanism of bronchoscope contamination, experiments were performed to evaluate the mycobactericidal activity of the glutaraldehyde solution being used to disinfect the bronchoscopes. The microorganisms were susceptible to glutaraldehyde. However, a 2% concentration of glutaraldehyde <14 days old was required to kill *M. chelonae* (236).

Outbreaks of endoscope contamination have been described with the Olympus EW 10 and EW 20 and the Keymed auto disinfector II. In 1990, because of these reports,

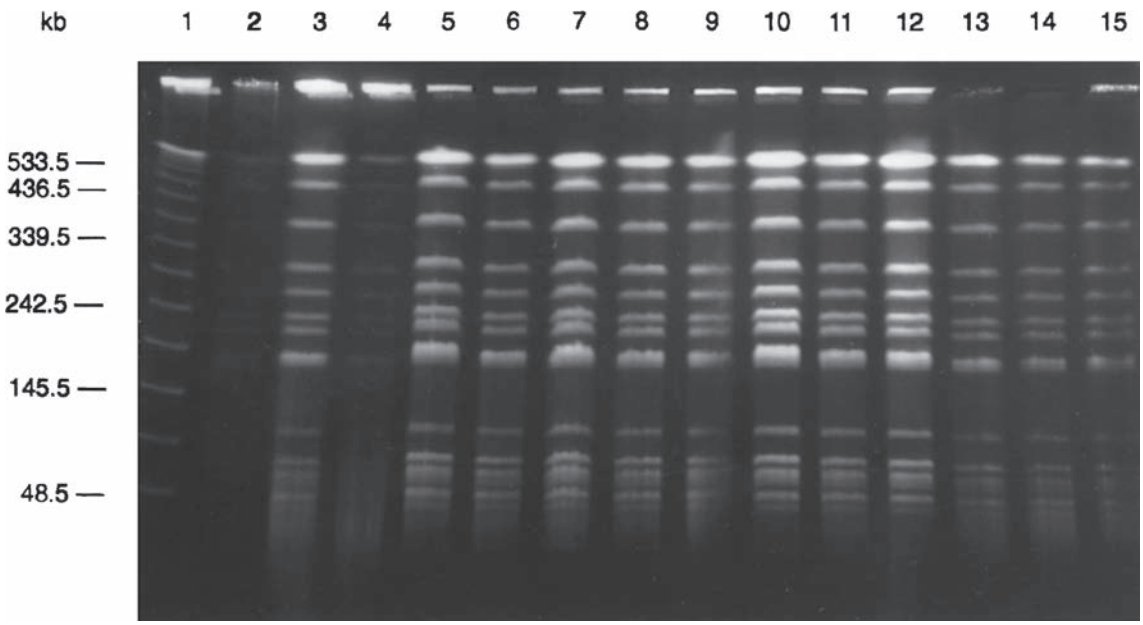

FIGURE 39-3 Pulsed field gel electrophoresis of *M. immunogenum* (originally identified as *M. abscessus)* associated with bronchoscope contamination from St. Louis, Missouri. Lane 1 is genomic DNA, lane 6 is an isolate from the rinse water, and lane 7 is the isolate identified from the endoscope washing machine. All other lanes are patient isolates of *M. immunogenum* obtained from bronchoalveolar lavage.

the FDA issued a class II recall prohibiting further sale of the Olympus EW 10 and EW 20 washers in the United States. The manufacturer was also required to modify the machines in use in US hospitals to try to eliminate the problem. A product alert was also issued, recommending that all users institute a terminal rinse of endoscopes or bronchoscopes with 70% alcohol after disinfection in one of these automated washers.

However, pseudoinfection and contamination of endoscopes have been reported from automated washers that have undergone modifications (241). Maloney et al. (241) reported 15 patients with *M. abscessus* (later identified as *M. immunogenum*) (235) pseudoinfection due to bronchoscopes contaminated by an automated endoscope washer. *M. immunogenum* positive cultures were more likely to have been obtained from bronchoscopes than from gastroscopes ($p = .002$) and from bronchoscopes that had been processed by an automated washer rather than manual disinfection ($p = .001$). *M. immunogenum* was cultured from the inlet water, a flexible bronchoscope, and the automated washer. Environmental and case isolates had identical large restriction fragment patterns of genomic DNA separated by PFGE (241).

Several similar outbreaks have been reported from outside the United States *(243–247)*. In another pseudo-outbreak from England, bronchoscopes became contaminated with RGM when the endoscopes were rinsed with tap water after they had undergone manual high-level disinfection with glutaraldehyde. *M. chelonae* (details were not provided as to whether the causative agent was *M. immunogenum*) was identified from the detergent dispensers and the water in the room used to reprocess the bronchoscopes. The contamination was impossible to eradicate until the bronchoscopes were sterilized with ethylene oxide and the use of tap water for rinsing was discontinued *(243)*.

Although this issue has been reported numerous times, the problem is probably still underrecognized. RGM survive well in adverse conditions and are resistant to antibiotics and disinfectants. Since they are present in tap water, the use of tap water has been associated with contamination of instruments and specimens. *M. fortuitum* and *M. abscessus* can also multiply to levels of 10^4 to 10^6 in commercially distilled water and retain viability with only a slight decline in 1 year *(76)*. Tap water should not be used to rinse bronchoscopes or critical or semicritical instruments. If tap water must be used, it should be followed by a 70% alcohol rinse (236,241,*243*,*246*,*251*). (For additional information on cleaning and disinfection of endoscopes, see Chapter 62.)

Ice Machines Hospital ice contaminated with NTM has been associated with several healthcare-associated outbreaks due to RGM. These outbreaks have included cardiac surgery infections *(126)* and a pseudo-outbreak involving bone marrow aspirates *(252)*. Another pseudo-outbreak involving 14 respiratory and one stool specimen from 10 patients admitted to the same tertiary care medical center *(253)* was related to contaminated ice. It has not always been determined whether the machine was contaminated or the contaminated ice reflected contamination of the hospital water supply. In one outbreak, a single ice machine was at fault. This outbreak occurred in 1987 when 30 patients in a New York hospital became colonized with *M. peregrinum* (identified at the time as *M. fortuitum* biovariant *peregrinum*). *M. peregrinum* was identified in a single ice machine and in the ice produced by the machine. Contamination of sputum samples in these patients was associated with consumption of tap water, melted ice, and ice chips, as well as showering and bathing immediately before obtaining the sputum samples *(128)*. Pseudoinfections due to contamination of bone marrow specimens were reported from a Texas hospital where *M. fortuitum* was cultured from bone marrow aspirates in four patients. Only syringes chilled with ice from contaminated ice machines were involved. Both the ice and the ice machine were found to be contaminated *(252)*.

From June 1980 to 1981, the Delaware State Laboratory noticed an increased number of positive cultures for *M. gordonae*. Extensive hospital cultures of water, ice, and ice water from contaminated ice machines was found to be the source of this pseudoepidemic. The number of isolates sharply decreased following cleaning of the ice machines *(254)*.

Outbreaks and Pseudo-Outbreaks Directly Related to Contaminated Hospital Water Supplies

The prior sections discussed contaminated equipment, but these pseudo-outbreaks were almost certainly associated with the hospital and/or municipal water supply being contaminated with the same microorganism that contaminated the equipment. Direct contamination of culture specimens or colonization or transient contamination of the respiratory tract with NTM has been a major healthcare-associated problem related to contaminated hospital water systems. Healthcare-associated respiratory tract infections due to these microorganisms have been rare and have been limited to occasional single cases. This, presumably, reflects the fact that, despite frequent exposure from the environment, the lungs are relatively resistant to infection.

M. gordonae, MAC, *M. scrofulaceum*, *M. fortuitum*, the *M. abscessus* group, *M. chelonae*, *M. mucogenicum*, *M. immunogenum*, *M. terrae* complex, *M. kansasii*, *M. simiae*, *M. xenopi*, and a newly described species, *M. paraffinicum* have all been identified from hospital water systems (*49*,*54*,*61*,250,*253*,*255–259*). Some of these microorganisms have been associated with hospital outbreaks/pseudo-outbreaks and, thus, are of significance for the healthcare epidemiologist and infection preventionist (IP).

M. xenopi has been associated with four healthcare-associated outbreaks/pseudo-outbreaks in the United States. The first of these occurred in a Los Angeles hospital in 1983; *M. xenopi* was identified in 43 specimens from 34 patients. Fewer than five colonies were recovered from cultures in 70% of these cases. None of the patients had a clinical picture compatible with mycobacterial disease, except a 76-year-old woman whose isolate was obtained from a lung biopsy that showed caseating granulomas with AFB, from which *M. xenopi* was identified on culture. Cultures yielded *M. xenopi* throughout the hospital water system. Case control studies suggested that patients acquired *M. xenopi* from exposure to hospital water in various ways, including showering (CDC investigation 84-78-1).

A second outbreak/pseudo-outbreak occurred in a Connecticut hospital where 608 patients over a 7-year

period had positive respiratory cultures for *M. xenopi* due to heavy contamination of the hospital water supply. The water was maintained at 110°F, and *M. xenopi* grows in water at temperatures as high as 115°F. By 1981, 19 patients had developed healthcare-associated pulmonary disease *(260,261)* (CDC investigation 92-01).

The third outbreak/pseudo-outbreak occurred over a 3-year period from 1988 to 1991 in a Michigan hospital *(54)*. Seventeen isolates of *M. xenopi* were identified, of which 13 were bronchoscopy specimens. *M. xenopi* was isolated from warm tap water samples taken from various parts of the hospital, including the bronchoscopy unit. Tap water had been used to rinse the bronchoscopes following disinfection.

A fourth outbreak was identified in 1993 when CDC investigated a hospital that had recovered 13 of the 20 isolates of *M. xenopi* isolated in Indiana (250). All the specimens were smear negative and yielded rare or few colonies on culture. Only one isolate was identified from each of 13 patients. None of the patients met American Thoracic Society criteria for pulmonary disease; however, 38% of the patients were treated with antituberculous therapy for a mean of 3 months. The investigation found frequent use of tap water throughout the hospital, including use of tap water to rinse bronchoscopes and bedpans as well as use of tap water gargles before sputum induction. *M. xenopi* was isolated from 17 of 19 (89%) water samples in patient care areas, and heavy growth of *M. xenopi* was observed on cultures from the hospital water mixing tank. This pseudo-outbreak was terminated by improving culture techniques and by eliminating the use of tap water to rinse bronchoscopes (250).

Although *M. xenopi* has been found in hot water taps in hospitals (250,*255*), it has generally not been identified in city water. The microorganism can replicate between 43°C and 45°C; thus, small numbers of microorganisms may enter hospital water tanks and multiply, resulting in colonization of the water systems. The pseudo-outbreak in the Indiana hospital was thought to have occurred after the hospital decreased its baseline water temperature in the tanks from 54°C to 49°C. Overgrowth or contamination may be eradicated from hospital water systems by mechanically cleaning the holding tanks, increasing the water temperature to 82°C for 1 hour, flushing the system, and then increasing the baseline hot water temperature to 54°C. Routine surveillance cultures may be indicated in certain areas to detect overgrowth (*54*,250,*255*,256,*261*). In another similar outbreak, *M. terrae* was identified from 163 patients in a hospital that had recently renovated one wing *(257)*. The source of contamination was the new water system. No *M. terrae* was cultured from patients after the water system was flushed and hyperchlorinated.

M. simiae has been a problem in several hospitals in the southwestern United States *(57–59)*. A New Mexico hospital reported an outbreak of *M. simiae* involving 56 patients over a 3-year period. *M. simiae* was identified from sputum, stool, and gastric biopsy specimens. None of the patients had clinical disease due to *M. simiae*. Although environmental cultures have been negative to date, MEE was performed on 23 isolates and demonstrated three electrophoretic types. Eighteen (78%) were type 1, four were type 2, and there was a single isolate of a third type, implying a likely common environmental source *(64)*. (For more information on pseudo-outbreaks, see Chapter 9). A similar cluster of 33 isolates, identified over 12 months, was reported from a single clinical laboratory in Tucson, Arizona. It was the third most common NTM to be recovered during this time period. Isolates studied by PFGE were either the same or highly related (clonal), suggesting a common source *(57)*. It is unclear whether these represented hospital pseudo-outbreaks or if most samples were contaminated from another source.

Recently, two pseudo-outbreaks involving *M. simiae* have been reported from Texas, with identical strains recovered from the hospital water systems. El Sahly et al. reported recovery of 65 isolates of *M. simiae* from 62 patients in a single hospital in Houston *(58)*. This represented 90% of *M. simiae* isolates recovered in the city. *M. simiae* was recovered from multiple sites in the hospital water system, with identical or highly related genomic DNA restriction patterns by PFGE. Conger et al. *(59)* reported recovery of seven patient isolates over a 5-month period from a single hospital in San Antonio, with identical DNA patterns by PFGE that also matched the pattern of microorganisms from the hospital water supply. The latter two pseudo-outbreaks represent the first recovery of *M. simiae* from the environment.

Another pseudo-outbreak involving an unusual species of slowly growing NTM occurred from 1999 to 2000 in the Veterans Affairs Medical Center (VAMC) in Houston, Texas. During that period, 37 strains of *M. szulgai* were isolated from patients at the VAMC. The previous base rate for the past 10 years had been <1 isolation of this species annually. The phenotypic properties and genetic relatedness of these strains (31 of which were nonpigmented) suggested a common source for this strain of *M. szulgai*. A single clinical strain isolated in 1996 was the only pigmented strain and the only strain associated with disease. Investigation found no common reagents, specimen-processing patient locations, or procedures linking the pseudoepidemic strains. However, a pigmented strain by gene sequence and DNA strain typing was identical to a strain recovered from a hospital water storage tank. The conclusion was that this latter strain was transiently inoculated into the patients, and although no disease was associated with this cluster, the pseudo-outbreak caused unnecessary expense and concern because most of the patients were immunocompromised and were candidates for opportunistic infections *(262)*.

Contaminated Biologics

There have been numerous reports of pseudoinfections with NTM due to contaminated biologics. In one hospital, pseudoinfection of the urinary tract with *M. avium-intracellulare* was related to contamination of urine specimens by contaminated phenol red *(62)*. In another report, a cluster of *M. gordonae* was identified in bronchoscopy specimens due to a contaminated dye used in the topical anesthetic *(263)*. Multiple pseudo-outbreaks due to RGM and slowly growing species have been linked to the BACTEC blood culture system. In one report, pseudoinfection with *M. gordonae* was traced to the BACTEC antimicrobial solution and enrichment broth added by the user to the BACTEC vials *(264,265)*. Pseudoinfection with *M. gordonae* has also been described in association with the BACTEC TB system and a contaminated antimicrobial additive. In this pseudo-outbreak, *M. gordonae* was recovered from 46 specimens

submitted for culture for mycobacteria over 8 weeks in a single northeastern laboratory. Two lots of BACTEC PANTA Plus shipped to 173 laboratories were found to be contaminated with *M. gordonae*. The contamination was due to failure to sterilize the water used in processing. This was the first report of mycobacterial pseudoinfection due to a commercially distributed product. Twenty other laboratories also reported contamination *(263)*. In a more recent report, 23 blood cultures from HIV-positive patients grew *M. abscessus*, which was ultimately traced to a multidose supplement vial used with the BBL Septi-check AFB culturing system *(63)*. Additionally, a series of 18 out of 21 samples of MGIT liquid medium tubes (Becton Dickinson, Sparks, NJ) in a hospital laboratory in Spain were positive for *M. gordonae*. The source of the epidemic strain was not confirmed, although RAPD analysis showed the profiles of the outbreak strains were identical but different from nonoutbreak isolates *(266)*.

Laboratory Cross-Contamination

A number of pseudo-outbreaks have resulted from laboratory cross-contamination involving the BACTEC system or related to specimen contamination at the time of digestion or processing. In one case, *M. chelonae* was identified due to contamination of the BACTEC system during automated reading *(264)*. Similar pseudo-outbreaks, attributed to inadequate heating of the needle probe of the BACTEC system, have been reported more recently *(267,268)*. Given the large numbers of specimens processed in many laboratories and the close proximity of the specimens, it is not surprising that cross-contamination occurs. In another case, a 6-year long laboratory pseudo-outbreak of *M. abscessus* used DNA strain typing to identify a strain of *M. abscessus* from an in-house distilled water source (269). As molecular typing techniques become more widely available, more precise confirmation will be possible. Laboratories should be aware of this potential problem and take steps to limit the possibility of cross-contamination.

Other Pseudo-Outbreaks with a Nonspecific Source of Contamination

Pseudo-outbreaks of mycobacteria may be difficult to recognize due to the extended time required to culture some species of NTM. A 2006 report from a clinical laboratory revealed a slowly growing NTM species, *M. terrae,* was cultured from 12 patients at two hospitals over a 6-day interval. However, the isolates were originally misidentified as *M. fortuitum*. Subsequent investigation by PFGE at the Centers for Disease Control and Prevention (CDC) determined that the isolates were an identical strain of *M. terrae* from 22 samples of 20 patients, thus confirming the pseudo-outbreak. Since the outbreak, the number of cultures of *M. terrae* has returned to baseline without any specific intervention *(259)*.

PREVENTION AND CONTROL OF DISEASE DUE TO NONTUBERCULOUS MYCOBACTERIA

Surveillance plays an important role in early recognition and identification of outbreaks and pseudo-outbreaks due to NTM. Surveillance should identify and facilitate investigation of any increase in isolation of NTM above thresholds. In addition, given the strong association with healthcare-associated disease, IPs should evaluate every patient with an NTM infection, particularly NTM isolated from surgical patients, dialysis patients, bronchoscopy specimens, or sterile sites. Active surveillance should facilitate early identification of healthcare-associated infections or pseudoinfections and, thereby, limit the extent of the problem. In addition, personnel in areas in which immunosuppressed, high-risk patients are hospitalized or where diagnostic or therapeutic procedures that require high-level disinfection of instruments are performed should receive intensive education about healthcare-associated pathogens and the relationship between NTM and tap water.

Education regarding the appropriate disinfection procedures for critical and semicritical instruments may help prevent healthcare-associated infections and pseudoinfections. Special attention must be given to meticulous cleaning and disinfection of items that are particularly difficult to disinfect, including bronchoscopes and other endoscopes. Personnel should be reminded that tap water should not be used to rinse instruments or for preparing specimens for culture, including tap water rinses for sputum expectoration. Use of ethylene oxide to sterilize endoscopes or other instruments between patients can eliminate contamination due to NTM, but processing with ethylene oxide is expensive and requires extended periods of time for sterilization and aeration following sterilization. Glutaraldehyde disinfection using an automated system has been shown to be effective, provided appropriate safeguards are taken to guard against contamination *(270)*. Some strains of NTM with increased resistance to glutaraldehydes have been noted *(116)*.

Some problems with instrument disinfection have been associated with slowly progressive dilution of glutaraldehyde during multiple uses, and RGM have been demonstrated to survive in 2% glutaraldehyde (236,*271*). Personnel using glutaraldehyde must be aware of the necessity for monitoring its concentration, the duration of its activity after activation, and the immersion time required for high-level disinfection *(251,272)*. Other than glutaraldehyde, mycobactericidal disinfectants include peracetic acid, iodophors, ethyl and isopropyl alcohol, chlorine compounds (minimum/1,000 ppm free chlorine), formaldehyde, and hydrogen peroxide *(273)* (see also Chapter 80).

Active surveillance, periodic review of cleaning and disinfection procedures for equipment, and the use of sterile water to rinse critical and semicritical items after disinfection are strongly recommended as infection control measures to prevent both true outbreaks and pseudo-outbreaks due to NTM *(274)*. A recent study has shown that disinfecting bronchoscopes with 70% alcohol prior to the use of automated washers, increasing the glutaraldehyde concentration to 3%, and recirculating used disinfectant were effective in the elimination of established contamination. The use of in-line filters may help reduce water contamination. Ice should be considered potentially contaminated, and its use should be limited in operating rooms. Dialysis units should be aware that water may be a source of NTM. Dialysis units need to be meticulous when they disinfect and reuse dialyzers, and they must perform careful

surveillance for infections. Tap water cultures are routinely performed as a quality assurance measure in many dialysis units; these data should be evaluated to determine whether excessive contamination or colonization is developing. Elimination of colonization above established thresholds before any patients develop infections should be the goal of performing such cultures. In addition, renalin may be a less effective disinfectant than formaldehyde or glutaraldehyde, and so, its use must be monitored closely. Dialysis centers that reuse dialyzers or perform high-flux dialysis should be particularly meticulous in their disinfection practices and their surveillance.

If increases in the isolation of NTM are detected, a chart review should be performed to determine whether patients are infected and to obtain demographic information, medical history, information on inpatient or outpatient procedures, and other possible risk factors. A case definition should be developed and microbiology and pathology records reviewed to find additional cases. The laboratory should be notified to save all isolates so that case and environmental isolates may be typed. Investigations should focus on the key issues described above, including the relationship of NTM to tap and distilled water, ice, ice machines, and improperly or inadequately sterilized instruments. Policies and procedures for obtaining and processing specimens and for disinfecting equipment should be reviewed. Frequently, direct observation of the process is often more enlightening than reviewing the written procedure. The written policy and procedure may be technically correct, but direct observation of the performance of the procedure may provide evidence to suggest the route of contamination. Selected environmental cultures may be useful to identify the source of the contamination. Patients who have been exposed to contaminated bronchoscopes or other critical or semicritical instruments should be followed closely for the development of disease.

Increasing recognition of the role of NTM in healthcare-associated pseudoinfections and infections should facilitate early identification of clusters and outbreaks. Prevention and control of these infections relies on active surveillance and rigorous attention to aseptic technique, appropriate disinfection and sterilization of instruments, and awareness that water is frequently contaminated with NTM. Recent improvements in culture, species identification, and application of molecular typing methods will also facilitate more prompt identification of the source of the problem so that prevention and control measures can be instituted.

PART C. Fungal Infections

CHAPTER 40

Candida

Michael M. McNeil and Tom M. Chiller

Medical and surgical advances in the areas of chemotherapeutics, cancer therapy, biological therapy, and organ transplantation have markedly altered the hospitalized patient population. Widespread use of these advances has considerably lessened the morbidity and mortality associated with a wide spectrum of severe life-threatening medical and surgical conditions and enabled the survival of a greater number of hospitalized patients who are severely ill. Frequently, these patients are in medical and surgical intensive care units (ICUs) that care for neonatal, pediatric, and adult patients. These patients are at increased risk for infections with opportunistic fungal infections caused by *Candida* species. Increasingly, healthcare-associated *Candida* species infections have been recognized to cause serious morbidity and mortality, in particular in immunocompromised hospitalized patients, and they have caused several well-documented healthcare-associated infection (HAI) outbreaks.

This chapter reviews current knowledge of the epidemiology of healthcare-associated *Candida* species infections, placing special emphasis on recent changes in the epidemiology associated with *Candida* species among hospitalized adult and pediatric patients, pathogenesis of these infections, newer laboratory methods for their diagnosis, risk factors for the development of healthcare-associated *Candida* infections, application of molecular typing techniques for *Candida* microorganisms, and current strategies and control measures for preventing both superficial and invasive infections.

ETIOLOGY

Among the many different *Candida* species described in the literature, relatively few are common human pathogens and isolated from clinical specimens. In humans, *Candida albicans* has been recognized as the most common *Candida* species causing both colonization and infection. In general, the spectrums of disease caused by *C. albicans* and by non–*C. albicans* species have been similar. However, notable differences exist between *C. albicans* and pathogenic non–*C. albicans* species with respect to some important healthcare-associated epidemiologic associations, their prevalence in surveillance cultures, virulence potential, and innate resistance to antifungal drugs.

The only major natural reservoirs for *Candida* species microorganisms are humans and animals. Although there have been reports of healthcare-associated *Candida* species outbreaks in which the microorganism was isolated from hospital environmental sources, these are usually not implicated as causes of *Candida* species outbreaks. *C. albicans* is the most common *Candida* species to be implicated in healthcare-associated fungal infections. Other medically important *Candida* species include *C. glabrata*, *C. tropicalis*, *C. parapsilosis*, *C. krusei*, *C. lusitaniae*, *C. guillermondii*, and *C. dubliniensis*. Since the 1980s, there has been a marked increase in bloodstream infections (BSIs) due to non–*C. albicans Candida* species, especially *C. glabrata* in the United States and *C. parapsilosis* and *C. tropicalis* in Europe, Canada, and Latin America coincident with the widespread implementation of azole drug prophylaxis and therapy. Because of the emergence of pathogenic non–*C. albicans* species that have variable resistance to antifungal drugs and their widely variable interinstitutional occurrence, the accurate identification of bloodstream and other invasive *Candida* isolates to species level has become an infection control priority. In addition, surveillance of antifungal susceptibility patterns for *Candida* species may be important as a component in an institution's infection control program for these healthcare-associated fungal infections.

Candida albicans

C. albicans is generally the most frequently identified *Candida* species in the clinical laboratory and is one of the major pathogenic *Candida* species of humans. *C. albicans* is a part of the normal microbial flora of the human respiratory, enteric, and female genital tracts. Acquisition in most persons probably results soon after birth, presumably from the maternal vaginal flora; thereafter, carriage of this species in normal healthy persons, particularly in the gastrointestinal tract, is extremely common. Superficial *C. albicans* infections often affect the oropharynx (oral

thrush), esophagus, skin, nails, and vagina. Oral thrush especially occurs in neonates. However, adult patients may also be affected, especially denture wearers, diabetics, women taking oral contraceptives, pregnant women in the third trimester, patients taking inhaled or systemic steroids, and HIV-infected patients. These superficial infections are usually self-limited except in rare, often immunocompromised, individuals who may develop chronic mucosal involvement.

Importantly, *C. albicans* may exploit any deficiency in the host's cell-mediated immune defenses. This is evidenced by the development of unusually severe, chronic, and intractable *Candida* infection of cutaneous and mucosal sites in HIV-infected patients and patients who develop chronic mucocutaneous candidiasis. The most common AIDS-related *Candida* species infections are chronic or recurrent oral candidiasis, candidal esophagitis, and vulvovaginitis. Patients with chronic mucocutaneous candidiasis have a rare genetic condition that results from a specific alteration in cell-mediated immunity to *Candida*. Despite chronic and occasionally dramatic clinical involvement of mucosal and superficial sites with *Candida* species, candidemia and invasive candidiasis is a relatively rare complication in these patients and in HIV-infected patients; in the latter, it has usually been associated with the presence of other risk factors such as intravenous catheters.

Severely immunocompromised, usually granulocytopenic patients and patients on multiple immunosuppressive agents, are the major populations at high risk for the development of invasive *C. albicans* infection, and infection in these patients may involve multiple deep organ systems. Invasive infections caused by *C. albicans* may include fungemia, meningitis, brain abscess, ocular infection, pneumonia, endocarditis, peritonitis, enteritis, pyelonephritis, cystitis, arthritis, and osteomyelitis. Important additional factors that may affect the normal host defenses and predispose patients to invasive candidiasis include prematurity, surgery (especially gastrointestinal), parenteral drug abuse, the administration of broad-spectrum antimicrobial agents and total parenteral nutrition, and the use of indwelling central venous catheters (CVCs).

Candida glabrata

C. glabrata is also a common commensal in healthy individuals. It has been shown to become more common with increasing age. Over the last two decades, *C. glabrata* has been documented as an important emerging healthcare-associated pathogen. Compared to other *Candida* species, especially *C. albicans*, *C. glabrata* isolates tend to be associated with acquired *in vitro* resistance particularly to fluconazole. Thus, the selection of *C. glabrata* has been documented in patients treated with fluconazole for prolonged periods including AIDS patients with oropharyngeal/esophageal candidiasis, women with complicated vaginitis, and compromised hospitalized patients with fungemia. Cancer centers in particular have reported a shift away from *C. albicans* toward *C. glabrata* as a cause of fungemia. This is presumed to be related to increased utilization of fluconazole for prophylaxis in these high-risk patient populations *(1)*. Among cancer patients, *C. glabrata* fungemia has emerged most prominently in those with hematologic malignancies and hematopoietic stem cell transplants (HSCTs), compared with those with solid tumors. *C. glabrata* fungemia is seen more often in older adults (who also appear to have increased risk of death from the infection) and is uncommonly found in neonates and young children. Management of patients infected with *C. glabrata* and *C. krusei*, a species associated with inherent reduced susceptibility to azole drugs, is difficult.

Candida parapsilosis

C. parapsilosis is a component of the normal human skin flora and has been found particularly in cultures of the healthy subungual space. Rarely, this species causes onychomycosis. *C. parapsilosis* has also rarely been found colonizing the human gastrointestinal tract and female genital mucosal surfaces and may be an infrequent cause of vulvovaginitis or oral candidiasis. Additional specific sites of isolation of *C. parapsilosis* may include the oropharynx of healthy neonates and asymptomatic diabetics and the feces of malnourished patients. *C. parapsilosis* is most often isolated from the bloodstream, in particular from hospitalized patients. It is also known to be common among neonatal and infant patients. However, studies reporting the prevalence of *C. parapsilosis* BSIs have shown that this varies among institutions; in a review of reported series of *C. parapsilosis* fungemia from large hospitals, Weems *(2)* found that the prevalence of this infection ranged between 3% and 27%.

In contrast with fungemia caused by *C. albicans* and *C. tropicalis*, *C. parapsilosis* may more often be an important hospital environmental contaminant and gain access to the bloodstream from environmental sources. Although most *Candida* species have demonstrated the ability to form biofilms, this has become recognized as one of the characteristics of infections with this pathogen *(3,4)*. Healthcare-associated *C. parapsilosis* infections have been associated with both implanted prosthetic devices and invasive procedures. Several reports of healthcare-associated outbreaks of *C. parapsilosis* fungemia and endophthalmitis have implicated contaminated hyperalimentation solutions, intravascular pressure-monitoring devices, and ophthalmic irrigating solutions, respectively (Table 40-1) (*5–13)*. Transmission on healthcare workers' hands has recently been confirmed by molecular subtyping in an outbreak of prosthetic valve endocarditis *(14)* and candidemia in a neonatal intensive care unit (NICU) *(15)*.

Extravascular involvement caused by *C. parapsilosis* is relatively uncommon. Endophthalmitis is the most important ocular infection and usually arises following cataract extraction and intraocular lens implantation procedures. Rarely, this infection also occurs in patients as a complication of primary fungemia. *C. parapsilosis* may also cause arthritis and has a predilection for involvement of the large joints. In such patients, development of the infection often is preceded by prior joint surgery (e.g., placement of a joint prosthesis, intra-articular injection, or arthrocentesis). Peritonitis caused by *C. parapsilosis* has been reported among patients undergoing long-term ambulatory peritoneal dialysis or patients who have undergone abdominal surgery for intestinal perforation or other procedures involving peritoneal lavage. These patients may have a history of intraperitoneal and systemic antimicrobial therapy for bacterial peritonitis.

TABLE 40-1

Healthcare-Associated *Candida* species Outbreaks Investigated by the Centers for Disease Control and Prevention 1981–2009

Year (Reference)	*Fungi*	*Infection*	*No. of Patients*	*Unit/Service*	*Source*	*Control Measures*
1981 *(5)*	*C. parapsilosis*	Fungemia	5	Medical and Surgical	Contaminated PN	Discontinue use of pharmacy PN pump
1983 *(6)*	*C. parapsilosis*	Fungemia	8	NICU	Contaminated PN	General infection control
1984 *(7)*	*C. parapsilosis*	Endophthalmitis	13	Ophthalmic Surgery	Contaminated solution[a]	Discontinue product
1985 *(8)*	*C. parapsilosis*	Fungemia	12	ICU	Contaminated PN	General infection control
1988 *(9)*	*Candida* spp.	Fungemia	24	Hematology–oncology	Endogenous	General infection control
1989 *(10)*	*C. albicans*	Sternal wound infection	15	Cardiac surgery	OR scrub nurse carrier	Removal from or of implicated personnel
1990 *(11)*	*C. albicans*	Fungemia and endophthalmitis	4	Ophthalmic surgery and general surgery	Contaminated IV anesthetic agent[b]	Discontinue use of product, general infection control
1991 *(12)*	*C. parapsilosis*	Fungemia	5	NICU	Contaminated liquid glycerin[c]	Discontinue product and general infection control
1997 (CDC)	*C. parapsilosis*	Fungemia	5	NICU	Unknown	General infection control
1998 (CDC)	*C. parapsilosis and C. albicans*	Fungemia	4	NICU	Possibly personnel hand carriage	General infection control
1999 (CDC)	*C. parapsilosis*	Fungemia	5	Outpatients on home hyper-alimentation	General Infection Control	General infection control
2002 (CDC) *(13)*	*C. parapsilosis*	Fungemia	22	ICU	Personnel hand carriage	General infection control
2002 (CDC)	*C. parapsilosis*	Fungemia	9	ICU	Possibly personnel hand carriage	General infection control
2002 (CDC)	*C. parapsilosis*	Fungemia	8	NICU	Possibly personnel hand carriage	General infection control

[a]Intrinsic contamination.
[b]Extrinsic contamination.
[c]Unpublished data.
NICU, neonatal intensive care unit; ICU, intensive care unit; PN, parenteral nutrition fluid; OR operating room.

Recent reports of high MIC to therapeutic ratio in *C. parapsilosis* to echinocandins have been suggested as a cause of the recent increases in this pathogen as a cause of C*andida* infections *(16)*.

Candida tropicalis

C. tropicalis has been identified much less commonly than *C. albicans* or *C. glabrata* as a commensal fungal microorganism and has been an infrequent isolate from cultures of the urine, oropharynx, and stools of hospitalized patients. *C. tropicalis* is an important opportunistic *Candida* species that has been implicated in invasive candidiasis, in particular in acute leukemia patients. No specific risk factors for invasive *C. tropicalis* infections have been identified that differ from those for invasive *C. albicans*. However, a clinical triad of fever, rash, and myalgias has been suggested as characteristic of the clinical presentation of *C. tropicalis* infection *(17)*.

Other *Candida* Species (*C. krusei, C. lusitaniae, C. guillermondii, C. dubliniensis*)

C. krusei has been identified as a colonizing yeast in the gastrointestinal, respiratory, and urinary tracts of severely granulocytopenic patients, particularly patients with underlying hematologic malignancies, and has been associated with invasive opportunistic infections in these patients. Local gastrointestinal mucosal deterioration secondary to cytotoxic chemotherapy or radiation has been suggested as a risk factor for *C. krusei* fungemia *(18)*. In granulocytopenic patients, *C. krusei* fungemia is associated

with a high mortality. A shift to non–*C. albicans* species, predominantly *C. krusei* and *C. glabrata*, has been well documented in bone marrow transplant patients exposed to fluconazole prophylaxis.

C. lusitaniae is an unusual *Candida* species that has been recognized as a healthcare-associated pathogen. In the laboratory, *C. lusitaniae* may be misidentified as *C. parapsilosis* (both are germ tube negative and form blastoconidia and pseudohyphae on corn meal agar) *(19)*. Rarely, *C. lusitaniae* colonizes the gastrointestinal, respiratory, and urinary tracts of hospitalized patients. In addition, *C. lusitaniae* has caused invasive infections similar to *C. albicans* infections in immunocompromised patients. There have also been reports that clinical *C. lusitaniae* isolates may possess natural and sometimes acquired resistance to amphotericin B, a finding that may complicate the outcome of infected patients.

C. guillermondii is a rare, potentially pathogenic yeast that may colonize skin and has been described to cause invasive candidiasis in intravenous drug abusers (endocarditis), postsurgical patients, and severely immunocompromised patients. A pseudo-outbreak in a NICU has also been reported *(20)*.

C. dubliniensis is a species that shares many phenotypic characteristics with *C. albicans*, including the ability to form germ tubes and chlamydospores. Isolates have been recovered mainly from HIV-infected patients' oropharyngeal cultures, most often patients with recurrent oropharyngeal candidiasis following antifungal treatment. This species has been associated with invasive disease *(21)*. Although preliminary studies indicate that most strains of *C. dubliniensis* are susceptible to antifungal agents, fluconazole resistant strains have been detected. It has been suggested that *C. dubliniensis* may develop azole resistance faster than other *Candida* species *(22)*. The clinical importance and role of drug resistance in its epidemiology have yet to be determined *(22)*.

PATHOGENESIS

Candida species have been identified as saprophytes in the human respiratory tract, gastrointestinal tract, and vagina. Therefore, in the clinical laboratory, isolation of these microorganisms from specimens from these sites and the skin may be considered a normal finding. In addition, epidemiologic evidence suggests that in severely immunocompromised hospitalized patients, commensal yeast microorganisms are the major source of subsequent invasive infections. The pathogenesis of *Candida* species infections is multifactorial. Invasion by these colonizing *Candida* strains may be facilitated when there is disruption of local barriers, interference with the cellular host defenses, or both.

C. albicans appears to possess a number of virulence determinants, including proteases, adhesins, surface integrins, and switching, that may aid colonization at multiple sites and enable tissue invasion. Biofilm formation is a potential virulence factor that has been studied *in vitro* on catheter materials *(23)*. It provides a protective niche from antifungal treatment for these microorganisms and thus may be the source of persistent infection *(4)*. Relative to noninvasive *Candida* strains and species, invasive ones appear to be superior at forming biofilms, and unique biofilm morphology of *C. albicans* has been demonstrated compared to *C. parapsilosis*.

The intact skin is an effective barrier to invasion by *Candida* species. However, local disruption resulting from wounds (including intravascular catheters, burns, and ulceration) may permit skin penetration by these yeast microorganisms. Excessive moisture, as occurs in the perineum (in diapered infants), and hands and intertriginous regions (in workers whose hands are frequently immersed in water), may be another important local factor in determining sites of cutaneous or mucosal involvement.

Similarly, the intact gastrointestinal mucosa serves as a mechanical barrier preventing bloodstream invasion by *Candida* species. The passage of some *Candida* species microorganisms across the gastrointestinal tract wall may occur normally. However, disruption of this barrier, as occurs in patients with severe burns or those receiving cytotoxic chemotherapeutic drugs, may lead to *Candida* colonization and invasive infection.

Another locally protective mechanism in the gastrointestinal tract is the normal bacterial gut flora, which competes with colonizing *Candida* species microorganisms and prevents their overgrowth and subsequent bloodstream invasion. Antimicrobial agents that eliminate the gastrointestinal tract bacterial microflora and permit selective overgrowth of yeasts may be another cause of invasive disease in hospitalized patients.

The spectrum of host defenses against tissue invasion by *Candida* species include cell-mediated immunity that comprises cytokine release by lymphocytes and activation of natural killer cells and lymphocytes by interleukins. An increasing body of evidence also supports a role for specific antibody in protection against invasive *Candida* infection, which may have implications for potential vaccine development *(24)*. Clinical observations indicate that mucocutaneous *Candida* infections are commonly associated with defective cell-mediated immune responses. Innate immunity is the dominant protective mechanism against disseminated candidiasis. Recognition of *C. albicans* by Toll-like receptors (TLRs) (mainly TLR2 and TLR4), on phagocytic cells activates intracellular signaling pathways that trigger production of proinflammatory cytokines that are critical for innate host defense and orchestrate the adaptive response *(25)*. T helper (Th) cell reactivity plays a central role in regulating immune responses to *C. albicans*. Fungal infectivity is controlled by this proinflammatory (Th1) host response and optimized further through activation of Th2 and regulatory (Treg) cells. Recently, a new subset of Th cells, Th17, has been shown to play an important role in antifungal immunity *(25)*. A mutation in the beta-glucan receptor dectin-1 important for development of Th-17 cells and related stimulation of cytokine production has also been found in women with recurrent vulvovaginal candidiasis or onychomycosis *(26)*. Quantitative and qualitative abnormalities of neutrophils and monocytes are associated with invasive candidiasis.

The results of pathogenicity studies have suggested that *C. parapsilosis* and *C. krusei* isolates may be less virulent than those of other *Candida* species (*C. albicans* or *C. tropicalis*) *(2,4,27,28)*. Other potentially important findings are the enhanced growth of *C. parapsilosis* isolates in solutions with high glucose concentration and an apparent selective growth advantage of the yeast in hyperalimentation solutions.

TYPES OF HEALTHCARE-ASSOCIATED INFECTIONS CAUSED BY *CANDIDA* SPECIES

Invasive Infections

Of the HAIs caused by *Candida* species, BSI has been reported most frequently. As previously mentioned, *C. parapsilosis* candidemia has commonly been associated with the use of contaminated intravascular catheters or pressure-monitoring devices. An outbreak of *C. albicans* candidemias in postsurgical patients was also traced to use of a contaminated intravenously administered anesthetic agent *(11)*. Clusters of healthcare-associated *C. albicans* and *C. tropicalis* sternal surgical site infections have also been reported *(10,29)*.

Mucocutaneous Infections

Outbreaks of *Candida* species infections affecting mucocutaneous sites have rarely been described. However, one outbreak of oral thrush has been reported in the NICU of a hospital in the United Kingdom *(30)*. The source of these infections was traced to a bowl contaminated with *C. albicans*, *C. glabrata*, and *C. tropicalis* that was used for soaking rubber teats from infants' feeding bottles. In addition, investigation of an outbreak of superficial groin candidiasis in a team of college athletes identified use of a communal ointment container *(31)*.

CLINICAL MANIFESTATIONS

In severely immunocompromised patients, *Candida* infections usually have no specific symptoms and signs, and the only indication of underlying fungal infection may be fever that is unresponsive to antibacterial therapy. Nonetheless, clinical suspicion for the infection should be high in the management of predisposed severely ill patients. For patients predisposed to the infection, a careful search should be instituted for evidence of candidemia. For infected patients, establishing the diagnosis rapidly avoids an excessive and potentially life-threatening delay in instituting specific antifungal treatment.

The clinical presentation associated with candidemia may be variable. Some patients may have an acute onset of sepsis accompanied by high fever, chills, tachycardia, tachypnea, and hypotension with rapid progression to septic shock; alternatively, a chronic low-grade febrile illness may develop without any specific clinical findings. Development of septic shock in nonimmunocompromised patients with candidemia is rare, more often occurs in patients who have demonstrable renal failure, and is associated with a very high mortality *(32)*. Importantly, patients with candidemia may progress to develop disseminated disease with eventual widespread involvement of multiple organs.

Cutaneous lesions may develop in patients with candidemia, especially those with acute leukemia. Although these lesions may be extremely variable in number and appearance, they are usually described as firm, erythematous, raised nodules. A definitive diagnosis is provided only by histopathologic examination of a skin biopsy specimen that demonstrates the presence of *Candida* species microorganisms in the dermis. Distinctive skin lesions also occur in premature neonates with congenital cutaneous candidiasis. This rare disorder results from prenatally acquired *Candida* species infection and is often associated with the presence of an intrauterine foreign body. The spectrum of involvement in these neonates ranges from diffuse skin eruption (macules, papules, and/or pustules that may evolve into vesicles and bullae) in the absence of systemic infection, which usually affects infants weighing more than 1,000 g, to widespread desquamating and/or erosive dermatitis predominately, which affects infants who weigh under 1,000 g and is associated with frequent development of invasive candidiasis and high mortality *(33)*. In addition, candidemic patients frequently have evidence of muscle tenderness, particularly of the lower extremities. This may be the only clinical indication that the patient has an associated *Candida* myositis, and the diagnosis requires a muscle biopsy that shows histopathologic evidence of invasion of muscle tissue by *Candida* species.

Ocular candidiasis is common in patients with other clinical evidence of candidemia or invasive candidiasis. Ocular infection with *Candida* species is usually unilateral and often is asymptomatic. Patients with *Candida* species infection and ocular involvement demonstrate visual impairment, which may range from scotomata to complete blindness. Two prospective studies reported 9% and 26% candidemic patients, respectively, developed ocular candidiasis and emphasized the funduscopic finding of chorioretinitis (a focal white chorioretinal lesion with or without overlying vitreal haze) and less frequently the classic white fluffy mass with extension from the retina to the vitreous or a vitreal abscess (endophthalmitis) *(34,35)*. It has been proposed that the less common occurrence of endophthalmitis in candidemic patients may result from more of these patients receiving prophylactic antifungal therapy. In a postmortem study by Edwards et al. *(36)*, 22 of 26 patients (85%) had tissue candidiasis if hematogenous ocular candidiasis was present. Between 10% and 15% of surgical patients who were prospectively studied and received parenteral nutrition were found to demonstrate these same lesions *(37)*. The diagnosis of *Candida* endophthalmitis usually relies on characteristic intraocular findings in a patient with risk factors for invasive candidiasis along with positive blood or vitreous fluid cultures *(34)*. Krishna et al. *(35)* have recommended ophthalmologic follow-up for development of ocular candidiasis be done in patients for at least 2 weeks after an initial negative eye examination. The treatment of choice for this infection is usually systemic and intraocular amphotericin B therapy with or without flucytosine in conjunction with appropriate surgical management for advancing lesions or lesions threatening the macular (38); however, fluconazole is considered an acceptable alternative for less severe endophthalmitis (38). Among newer antifungal agents, voriconazole shows most promise, achieves high local and therapeutic concentrations in the vitreous against most *Candida* spp., when administered orally, and alternatively may be given as an intravitreal injection for sight-threatening macular involvement and vitritis. This agent may be useful for fluconazole-resistant, voriconazole-susceptible *Candida* strains *(39)*. However, serum levels should be monitored because of high variability among patients *(39)*. Posaconazole and the three echinocandins do not achieve adequate therapeutic levels in the vitreous *(40)*. Removal of a lens implant, if present in the infected eye, is considered critical for the resolution of the infection *(41)*. The outlook regarding the patient's vision is usually guarded.

Dissemination of *Candida* infection to the central nervous system (CNS) as a result of hematogenous spread has been increasingly recognized and may often be accompanied by invasive *Candida* species infection at other sites. Characteristic involvement of the CNS by candidiasis may include meningitis, diffuse cerebritis with microabscesses, mycotic aneurysms, fungus ball formation, and parenchymal hemorrhage. In infected patients, the diagnostic usefulness of cerebrospinal fluid (CSF) examination may vary; involvement of specific anatomic CNS sites determines whether fungal microorganisms are in the CSF and the nature of the cellular content. Meningitis caused by *Candida* species has been most frequently reported to affect newborns *(42)*. Intravenous amphotericin B with or without flucytosine is usually effective and intrathecal amphotericin B may be added to this regimen in some patients. Fluconazole is not recommended as primary therapy unless treatment with amphotericin B is contraindicated (38). Although the length of primary therapy has not been defined, several weeks of therapy are recommended before transition to treatment with an azole and only after the patient has demonstrated clinical and CSF improvement (38). Voriconazole may be appropriate therapy for *C. glabrata* or *C. krusei* meningitis after initial treatment with amphotericin B and flucytosine. Echinocandins are not recommended for CNS candidiasis. Removal of an infected ventricular device is recommended with systemic or systemic and intraventricular injection of amphotericin B into the device before its removal (38).

Chronic disseminated candidiasis (also called "hepatosplenic candidiasis") is a form of localized invasive candidiasis that, as the name implies, most commonly involves the liver and/or spleen. As with other forms of invasive candidiasis, blood cultures are frequently negative in these patients, and the diagnosis may not be made until postmortem examination. The most common histopathologic findings are hepatic granulomas and microabscesses. This form of the disease predominantly affects severely granulocytopenic patients, in particular patients receiving chemotherapy with cytosine arabinoside for underlying acute myeloblastic leukemia. The disease usually coincides with recovery of the patient's granulocyte count following a course of ablative chemotherapy. In these patients, gastrointestinal tract ulceration complicates receipt of this and other chemotherapeutic agents and allows gut-colonizing *Candida* species to gain direct access to the portal venous system. It has been suggested that this diagnosis should be suspected in any immunocompromised patient with unexplained fever with or without elevation of serum alkaline phosphatase or bilirubin. Magnetic resonance imaging is a technique that has also been shown to have high diagnostic accuracy for the acute, subacute-treated, and chronic-healed lesions of hepatosplenic fungal disease *(43)*. Optimal antifungal therapy for the infection is considered to be amphotericin B for the acutely ill patient or when there is refractory disease (38). Fluconazole is recommended in clinically stable patients or step-down therapy following initial therapy with amphotericin B. Recently, however, the disease incidence has decreased dramatically at large leukemia and bone marrow transplant centers where fluconazole prophylaxis has been extensively used.

Endocarditis caused by *Candida* species often has been associated with disseminated infection in patients with malignancies. It can originate from intravenous catheters and affect high-risk infants, patients receiving parenteral nutrition, parenteral drug abusers, and cardiac surgical patients, particularly as a complication of prosthetic heart valve implantation *(44)*. This infection may be an uncommon cause of persistent candidemia. However, only 50% of patients diagnosed postmortem with *Candida* endocarditis have positive premortem blood cultures for *Candida* species. Natural heart valves appear to be rarely affected; the infection usually is associated with implanted prosthetic heart valves. In their review of the Cleveland Clinic experience, Nasser et al. *(45)* found that patients with prosthetic heart valves who develop healthcare-associated candidemia are at significant risk of having or developing *Candida* prosthetic valve endocarditis even months or years later. These investigators also suggested that late-onset candidemia and lack of an identifiable portal of entry should heighten concern about *Candida* prosthetic valve endocarditis in such patients. Of 10 of their 11 patients with *Candida* prosthetic valve endocarditis treated with amphotericin B and valve replacement, 2 patients had a total of three documented relapses. Endocarditis may also occur as a secondary complication of an indwelling transvenous pacemaker, and surgical removal of the infected device and prolonged systemic antifungal therapy are required *(46)*.

Suppurative peripheral thrombophlebitis caused by *Candida* species has been reported to be a distinct clinical entity that may uncommonly cause persistent candidemia. Walsh et al. *(47)* reported seven patients with this infection over a 15-month period. Factors implicated by these authors as important in the occurrence of these infections were catheter insertion techniques and suboptimal care of the catheter insertion site. Therapy usually comprises removal of the catheter, surgical intervention, and a short course of systemic antifungal therapy (38). Rarely, *Candida* species may infect arteriovenous dialysis fistulas, and effective treatment in these patients includes removal of the fistula and systemic antifungal therapy *(48)*.

Peritonitis caused by *Candida* species has been reported as a complication in patients receiving long-term ambulatory peritoneal dialysis. Also, *Candida* species peritonitis may occur secondary to a perforated ulcer or postoperative anastomotic leakage following colonic surgery (as part of a polymicrobial infection) and may be complicated by the formation of intraperitoneal abscesses or subsequent candidemia. In patients with *Candida* species peritonitis, both an early diagnosis of the infection and prompt institution of specific systemic antifungal therapy are essential. In addition, appropriate surgical intervention in these patients to repair an underlying bowel perforation or to drain peritoneal abscesses may also be required.

Invasive renal candidiasis is most frequently the result of hematogenous dissemination and complicates candidemia or disseminated candidiasis. The kidney is the most commonly involved organ in invasive candidiasis (90%) *(49)*. Rarely, usually only when there is coexistent obstruction, renal parenchymal infection and pyelonephritis are the result of retrograde renal tract infection.

DIAGNOSIS

Diagnosis of mucocutaneous *Candida* species infections usually depends on examination and identification

of typical morphologic forms in a potassium hydroxide–stained smear preparation. Detection of budding yeasts and pseudohyphae is characteristic of *Candida* species. This same morphologic appearance on direct microscopic examination of other clinical specimens may also be important for the rapid presumptive diagnosis of invasive *Candida* species infection. The yield from direct microscopic examination of these specimens may be significantly improved by use of calcofluor white stain and subsequent examination by fluorescence microscopy. Use of commercial agar with chromogenic substrates may aid in rapid presumptive identification of *C. albicans*, *C. tropicalis*, and *C. krusei* in cultures; some reports have suggested modifications to this medium to allow for differentiation of *C. glabrata* and the incorporation of fluconazole to not only identify the *Candida* species present but to also identify antifungal drug resistant isolates during initial isolation *(50)*. A molecular-based method, the *C. albicans* peptide nucleic acid fluorescence *in situ* hybridization (PNA FISH AdvanDx) test uses a fluorescein-labeled probe that is added to smears made directly from blood culture bottles that test positive and in which yeasts were observed by Gram staining, which are then examined under fluorescence microscopy. The test is unaffected by the type of blood culture system or broth formulation (e.g., lytic or other medium) used, it may provide a time savings in the laboratory of 24 to 48 hours compared with conventional laboratory identification methods, and single-center and multicenter studies have demonstrated its sensitivity (99–100%) and specificity (100%) in direct identification of *C. albicans* from blood cultures (51). FDA has approved several commercially available PNA-FISH kits (AdvanDx) for identification of yeasts (*C. albicans*, *C. parapsilosis*, *C. tropicalis*, *and C. dublinensis*) in a single assay directly from blood cultures. The test can rapidly (1.5 hours) indicate whether *C. albicans* is present or not and can thus help indicate whether a non–*C. albicans* yeast is present. With this test, laboratories can report whether a positive blood culture with yeast contains *C. albicans* within a few hours after the culture becomes positive *(52,53)*.

In patients with invasive candidiasis, the diagnosis can be difficult to establish because of the suboptimal sensitivity of blood cultures. Frequently, a high index of clinical suspicion, the use of blood cultures and diagnostic imaging techniques (computed tomography and magnetic resonance imaging), and invasive biopsy procedures are required. The combination of histopathologic demonstration of morphologically compatible yeasts and hyphal forms if present (*C. glabrata* does not form pseudohyphae/hypha) together with a positive culture is considered to be the gold standard for diagnosing invasive *Candida* species infection.

The sensitivity of routine blood culture methods has improved but is still not ideal (50–70%) (54); in granulocytopenic patients, this may be further exaggerated (<20%) (51). Advances reported to improve the recovery of *Candida* species from the bloodstream of infected patients include the lysis centrifugation system (Isolator, Wampole Laboratories, United States). and automated, continuous-monitoring, broth-based systems. Automated broth-based systems, for example, Bactec (Becton Dickinson) and BacT/Alert (bioMerieux), have equal sensitivity for detecting *Candida* species to the more labor-intensive lysis-centrifugation method (51). However, despite these advances in blood culture technology, recovery of *Candida* species from blood still does not identify many patients with invasive infections. In patients with postmortem-confirmed candidiasis, Berenguer et al. *(55)* found a direct relationship between the number of visceral organs involved and the frequency with which lysis centrifugation blood cultures detected *Candida* species. Using this modern method, only 28% patients with single visceral organ involvement (excluding gastrointestinal tract) and only 58% of patients with involvement of two or more visceral organs were fungemic.

False-positive *Candida* species blood cultures (positive culture in the absence of candidemia or invasive infection in the patient) may occur; this most often occurs when blood for culture is drawn via an intravascular catheter that itself has become colonized with *Candida* species. Another important mechanism of contamination of blood culture specimens is inoculation with extrinsic yeasts from sources such as the skin of the patient or personnel. This can occur because of improper techniques of specimen collection and handling or laboratory manipulation.

A single positive blood culture growing *Candida* species should be considered a clinical infection unless evidence suggests otherwise. From an infection control standpoint, *Candida* species is considered a recognized pathogen and fulfills the Centers for Disease Control and Prevention (CDC) National Healthcare Safety Networks (NHSNs) surveillance definition of a central line–associated bloodstream infection (CLABSI) if the patient has a central line in place, the infection is not incubating or present on admission, and there is no infection at another site *(56)*. Further clinical evaluation of the patient is indicated to confirm whether it represents invasive infection, colonization of the central line it was drawn out of, or contamination of the blood culture during the culturing process. The finding of a single blood culture positive for *Candida* species, even when possibly caused by an indwelling intravascular line, should prompt empiric treatment and further clinical evaluation of the patient for evidence of invasive infection *(57)*.

Intravascular catheters may not only serve as the portal of entry for *Candida* species and be an important primary source of candidemia but also provide a secondary site of attachment for *Candida* species that invade the bloodstream from other sites, most frequently the gastrointestinal tract. A semiquantitative method developed principally for detecting catheter-associated bacteremia also is applicable to the evaluation of catheter-associated candidemia. Following removal from the patient, the distal (5-cm) intravascular segment of the catheter is rolled four times across the surface of a sheep's blood agar plate and immediately afterward is placed into a tube of broth medium for additional culturing. Growth of 15 or more colony-forming units (CFU) on the solid medium has been used to identify bacteria as the cause of catheter-associated bacteremia *(58)*. However, it has been suggested that the recovery of *Candida* species in any amount from either the solid or liquid media cultures of a vascular catheter tip should prompt a thorough clinical reevaluation of the patient for invasive candidiasis *(58)*.

Candida species in urine is an abnormal finding in clean-voided specimens or specimens obtained by suprapubic aspiration from normal individuals. However, the incidence of candiduria is high in ICU patients and often coexists with candidal colonization at other anatomical sites *(59)*. The

most commonly identified risk factor for the development of candiduria is an indwelling Foley catheter. Additional important factors that may coexist with an indwelling urinary catheter in seriously ill patients include diabetes mellitus, administration of antimicrobial agents, urinary tract instrumentation, and prior bacteriuria.

The presence of candiduria in an ICU patient may indicate extrinsic contamination of the urine specimen, innocuous lower urinary tract colonization from an indwelling Foley catheter, or, most importantly, invasive upper or lower urinary tract infection. Quantitative urine yeast colony counts are an unreliable method both for distinguishing active infection due to *Candida* species from colonization and for localizing the source of candiduria; although a level of $<10^4$ CFU/mL argues against renal candidiasis *(60)*, levels above 10^5 CFU/mL may be associated with a colonized indwelling Foley catheter. Microscopic examination of a Gram-stained urine specimen may not be helpful; however, the presence of hyaline renal tubular casts containing *Candida* species, particularly with pseudohyphae, may correlate with renal infection.

In patients following neurosurgery, the clinical significance of a single CSF sample culture positive for *Candida* species when obtained via an indwelling device (shunt) is difficult to assess, and a definitive diagnosis may require repeated cultures of CSF samples obtained by lumbar puncture *(61)*.

Conventional serologic techniques for detecting serum anti-*Candida* antibodies have not been useful for diagnosing invasive candidiasis, because most normal individuals have circulating antibodies to this microorganism and, in immunocompromised patients, antibody production is variable.

Several prototype antigen/metabolite tests (secreted aspartyl proteinases, D-arabinitol [Roche Diagnostic Systems], and Platelia Candida Ag test [Bio-Rad]) have been described and appear promising as methods for the diagnosis of invasive candidiasis, and these have been recently reviewed (54). Detection of β-1,3-glucan (BG) found in the cell wall of common pathogenic yeasts and other fungal pathogens is detected by two commercial kits, the Glucatell (Associates of Cape Cod) and the Fungitec-G (Seikagaku Corp.). The qualitative detection of BG in the serum of patients does not identify the infecting fungus, but these tests may be used as a rapid screening assay (results within 2 hours) permitting earlier initiation of antifungal therapy in patients with symptoms of or medical conditions predisposing to invasive fungal infections. A single positive test result provides generally good sensitivity and specificity *(62)*; however, repeat testing improves the specificity (repeat positive tests) and negative predictive value (repeat negative tests) *(62,63)*. Of note, BG is ubiquitous in the environment and false-positive results may be caused by hemodialysis using certain cellulose membranes, exposure to certain types of gauze, and recent receipt of albumin or immunoglobulin *(64)*. New approaches to shorten the time required to identify *Candida* species from blood (currently more than 24 hours using automated blood culture systems) include a rapid immunomagnetic separation system for *Candida* species from blood that will recover yeast directly from the specimen so they can be inoculated onto growth media *(65)* and real-time polymerase chain reaction (PCR) methods. Although real-time PCR has the ability to detect candidemia much earlier than conventional blood culture, it does not always detect all cases of invasive infection with all species *(66–68)*. Bennett has recently reviewed use of this technique that is likely to be used alongside blood culture protocols while it is developed further *(69)*.

EPIDEMIOLOGY

Descriptive Epidemiology

Candida species commonly cause healthcare-associated BSIs among patients in ICUs. Data from the CDC's National Nosocomial Infections Surveillance (NNIS) system during 1990 to 1999 have shown that risk-adjusted HAI rates decreased for all three body sites (i.e., respiratory tract, urinary tract, and bloodstream) monitored in ICUs *(70)*. In particular, rates for healthcare-associated BSIs decreased markedly in medical (nonsurgical) ICUs (44%), coronary ICUs (43%), pediatric ICUs (32%), and surgical ICUs (31%) *(70)*. However, coincident with this significant decrease in the incidence of *C. albicans* BSIs was a significant increase in the incidence of *C. glabrata* BSIs *(71)*. It has been postulated that these trends likely occurred in association with a national increase in fluconazole use, which received U.S. Food and Drug Administration (FDA) approval in 1990.

A review of NNIS system data from NICUs during 1995 through 2004 found a significant decrease in the incidence of candidemia among very low birthweight (<1,000 g) infants (3.51 per 1,000 patient days in 1995–1999 to 2.68 per 1,000 patient days in 2000–2004) but a stable rate among heavier birthweight infants (72). This decrease was also found for both the number of candidemias per 100 patients (attack rate) and the risk-adjusted CVC-associated BSI rate. In order of frequency, the *Candida* species causing primary BSIs in this high-risk population was *C. albicans*, *C. parapsilosis*, *C. tropicalis*, *C. lusitaniae*, *C. glabrata*, and *C. krusei*. In addition, no increase in infections by *Candida* species that tend to demonstrate resistance to fluconazole (*C. glabrata* or *C. krusei*) was observed.

In 2005, CDC's NHSN, which replaced the NNIS system and adds surveillance of selected HAI data at locations other than ICUs in hospitals and other types of healthcare facilities, began collecting data. The first NHSN report from January 2006 to October 2007 identified *Candida* species as the fourth commonest pathogen group associated with HAIs overall and the second commonest species causing catheter-associated urinary tract infection, third commonest species causing CLABSI, seventh commonest species causing ventilator-associated pneumonia, and eighth commonest species causing surgical site infection (73). *C. albicans* was the predominant species identified in each of these categories with the exception of CLABSI where the proportion identified as *C. albicans* was not different from that of other *Candida* species/not otherwise specified.

Hospital Discharge Data National surveillance of healthcare-associated BSIs conducted prospectively in 49 hospitals in the United States by the SCOPE group (Surveillance and Control of Pathogens of Epidemiologic Importance) between 1995 and 1998 found *Candida* was the fourth leading cause of healthcare-associated BSIs,

accounting for 7.6% of all infections *(74)*. Of 934 episodes of candidemia, 46.8% were due to the non–*C. albicans* species identified as *C. glabrata* (42.3%), *C. tropicalis* (26.1%), *C. parapsilosis* (21.1%), *C. krusei* (3%), and other *Candida* species (2%) *(74)*. The proportion of non–*C. albicans* species isolates varied with geographic region and ranged from 30.2% in the Southwest to 54.5% in the Northeast *(74)*. A suggested important factor responsible for this increased trend in fungemias caused by non–*C. albicans* species is widespread use of fluconazole for prophylaxis and therapy. A follow-up report from this group on 22,631 episodes of BSIs during 1995 through 2001 observed that despite *Candida* species accounting for 9% and 8% of isolates recovered from all neutropenic and nonneutropenic patients with BSIs, respectively, *Candida* species was notably isolated latest during the patient's hospital stay (mean, 18 days) and monomicrobial *Candida* species BSIs were associated with the worst outcome (crude mortality rate, 45%), and this did not differ according to the patient's neutropenic status *(75)*.

The National Epidemiology of Mycoses Survey (NEMIS) prospectively identified *Candida* species isolated from blood and other normally sterile sites during 1993 to 1995 from patients hospitalized in surgical and NICUs of six academic medical centers located in Oregon, Iowa, California, Texas, Georgia, and New York *(76,77)*. The incidence reported for healthcare-associated BSIs due to *Candida* species was 0.99/1,000 patient days for surgical ICU patients and 0.64/1,000 patient days for NICU patients. Of the patients surveyed (4,276 surgical ICU patients and 2,847 babies), 30% to 50% developed incidental stool colonization, 23% of surgical ICU patients developed incidental urine colonization, and one-third of surgical ICU healthcare workers' hands were positive for *Candida* species. In addition to a marked interinstitutional variation in rates of BSIs due to *Candida* species, there was variation found in antifungal susceptibility to fluconazole *(77)*. Analysis of patient isolates using a DNA subtyping method enabled investigators to identify 13 clusters of suggested cross-infection occurring in five of the study centers. Nine (69%) of these clusters involved non–*C. albicans* species. The conclusions from this analysis were that the possible mechanisms of *Candida* species transmission that occurred were from patient to patient (*C. albicans*, *C. glabrata*, *C. tropicalis*, and *C. parapsilosis*) and from healthcare worker to patient (*C. albicans*, *C. parapsilosis*, and *C. krusei*) *(76)*. A comprehensive molecular subtyping study of *C. albicans* isolates from patients with BSIs and surgical ICU and NICU healthcare workers from four hospitals participating in the NEMIS study demonstrated that for the majority of patients (90%), isolates collected from commensal sites before and after collection of a BSI isolate were highly similar or identical to the BSI isolate *(78)*. The study also suggested that multiple endemic strains rather than a single, dominant endemic strain were more often responsible for healthcare-associated BSIs in surgical ICUs and NICUs and that cross-contamination occurs between patients and healthcare workers and between healthcare workers in the same ICU and in different ICUs *(78)*.

The SENTRY Antifungal Surveillance Program has been operational since 1997 and prospectively collects healthcare-associated bloodstream isolates from 72 participating hospitals in the United States, Canada, Latin America, and Europe *(79)*. Eighty percent of BSIs reported to this system were healthcare-associated (vs. community-acquired) and 50% occurred in patients in an ICU. In addition, this system has noted differences in species distribution, with US medical centers having higher rates of BSIs due to *Candida* species, such as *C. glabrata* and *C. krusei*, which are less susceptible to the triazoles compared with Canada and South America *(79)*. Data from this system have also demonstrated differences in antifungal resistance among isolates from pediatric and adult patients, which likely reflect differences in the distributions of infecting *Candida* species between these age groups (i.e., predominance of *C. albicans* and *C. parapsilosis* in age groups ≤1 year and 2–15 years of age and fewer *C. albicans* and significantly more *C. glabrata* infections in persons ≥65 years) *(80)*. A further report from this system has shown variation in antifungal susceptibility to fluconazole among *C. glabrata* bloodstream isolates according to geographic location and age group (i.e., lowest in Pacific [44%] and East South Central [47%] regions and highest in West South Central region [82%], and isolates from pediatric patients were virtually all susceptible to fluconazole, whereas the highest frequency of resistance was observed in isolates from patients 16–64 years of age) *(81)*. The SENTRY system in 2008 to 2009 has also reported that *C. glabrata* bloodstream isolates may show lower susceptibility rates to both azoles and echinocandins with the highest rates of resistance detected in 20- to 59-year-old patients *(82)*.

Reports of surveillance for candidemia conducted in other countries have increased understanding of the epidemiology of the condition. In a study of French hospitals in 1995, Richet et al. *(83)* reported an overall incidence rate of 0.29 per 1,000 admissions, ranging from 0.71 per 1,000 admissions in cancer referral centers to 0.17 per 1,000 admissions in general hospitals. In this study, *C. albicans* (53%) was the predominant species isolated, a CVC (26%) was the most common portal of entry, and 50% of the candidemic patients had a neoplasm. Bougnoux et al. *(84)* conducted a 1-year prospective observational study in 24 adult ICUs in France and identified mean incidence of 6.7 and 27.4/1,000 admissions for healthcare-associated candidemia and candiduria, respectively. Using multilocus sequence typing (MLST), these investigators found 8% of the candiduric patients developed candidemia with the same species, both types of infections were acquired late (i.e., 19 and 17 days after their ICU admission) and with high crude mortality (62% and 31%, respectively). Prospective candidemia surveillance conducted in 1992 to 1994 in 14 Canadian medical centers found a 4:1 adult to child ratio, more frequent occurrence of *C. parapsilosis* (second only to *C. albicans* and associated with lower mortality), and age >60 and stay in an ICU as the two most significant risk factors for overall mortality *(85)*. Five-year population surveillance in the Calgary Health Region during 1999 through 2004 found the annual incidence for invasive *Candida* species infections was 2.9 per 100,000. The highest risk was in patients with comorbidities and those at the extremes of age and 30% isolates showed reduced susceptibility to fluconazole *(86)*. In a retrospective review of *Candida* species BSIs in nine Australian tertiary referral hospitals during 1995 to 1998, Slavin's group *(87)* reported a rate for

candidemia of 0.1 to 0.27 per 1,000 discharges and demonstrated a decreasing trend in the proportion of *C. albicans* to non–*C. albicans* species. In a follow-up study, these investigators reported that hospitalizations with a diagnosis of disseminated, invasive, and noninvasive candidiasis added 31, 17, and 12 days to patients' length of stay, and costs of AU $33,274, AU $12,954, and AU $7,694 with the associated mortality being 26%, 9%, and 8%, respectively *(88)*. A retrospective analysis of candidemia episodes in an ICU in the United Kingdom found the attributable mortality for candidemia varied between 21.5% and 34.7% and infected patients spent on average more than 5.6 days in ICU than matched control patients and generated mean additional costs of at least £8,252 per patient, £16,595 in adults only *(89)*. By comparison, the estimated costs attributable to an episode of invasive candidiasis in the United States have been estimated to be US $28,000 to US $48,000 for pediatric and adult patients *(90,91)*. In a review of candidemia from Finland, Poikonen et al. *(92)* found the annual incidence increased from 1.7 per 100,000 population in 1995 to 2.2 per 100,000 in 1999; however, the proportion of non–*C. albicans* species cases (30%) did not increase during the study period. In addition, the highest annual incidence (24.4/100,000 population) occurred in 1999 in infants <1 year of age, which was primarily caused by *C. albicans*. A 1-year (November 2001–October 2002) surveillance program in Japan identified a similar species distribution of *Candida* bloodstream isolates and fluconazole resistance rate to those reported in North America and Europe *(93)*. A study of all Icelandic *Candida* spp. bloodstream isolates from 1991 to 2000 (n = 219 isolates) detected an increased incidence from 3.7 per 100,000 during 1991–1994 to 5.8 per 100,000 during 2003–2006 *(94)*. Using PCR fingerprinting, these authors found that between 19% and 40% of their isolates were from small unrecognized healthcare-associated clusters (average of only 2 patients), which significantly affected patients in adult and NICUs.

The Transplant-Associated Infection Surveillance Network (TRANSNET) is a consortium of 23 US transplant centers established in 2001 to perform prospective surveillance for invasive fungal infections among organ transplant recipients. Data from this network through 2006 for HSCT recipients found that invasive candidiasis represented only a minority (28%) of invasive fungal infections in this group, which compares to higher rates among this patient population during the 1980s and 1990s (95). Non–*albicans Candida* species accounted for almost 70% of these infections. Widespread use of azole prophylaxis likely influenced the decreased incidence and shift in epidemiology in the HSCT setting although other factors may be important. These are very similar findings to those described from another multicenter observational registry of United States and Canadian medical centers included in the Prospective Antifungal Therapy Alliance (PATH Alliance), which also monitors trends in the epidemiology, diagnosis, treatment, and outcomes of solid organ transplant recipients *(96)*.

Data from the TRANSNET through 2006 for solid organ transplant recipients, identified invasive candidiasis as the most common invasive fungal infection in each organ transplant type, except among lung transplant recipients, the median time to onset of candidiasis was 103 days, and the associated overall mortality was high (66% 12-month survival) *(97)*. The overall mortality was similar to that seen in recent treatment trials of candidemia and other forms of invasive candidiasis. The network has also found the distribution of *Candida* species to be similar to that reported in recent national surveys among hospitalized patients (*C. albicans* and *C. glabrata* were the predominant species). These are very similar findings to those described from the PATH Alliance *(98)*.

Population-Based Data National incidence rates for invasive candidiasis estimated using data from the National Hospital Discharge Survey (NHDS), which samples nonfederal short-stay hospitals, found an annual incidence of 22 to 24 infections per 100,000 population per year (19–20 per 10,000 hospital discharges) from 1996 through 2002, with an increase to 29 infections per 100,000 (24 per 10,000 discharges) in 2003 (51). This extrapolated to a national burden of approximately 63,000 infections in the United States per year. This estimate was similar to a high but stable population-based surveillance estimate for the Baltimore MD metropolitan area (24 per 100,000) during 1998 to 2000 *(99)*. However, it contrasts with the NNIS system data, which found a decline in frequency of healthcare-associated candidemia in ICUs in the United States between 1989 and 1999 *(71)*. Of note, Hajjeh et al. *(99)* found that during 1998 through 2000, only 36% of *Candida* BSIs occurred in the ICU, whereas 28% had onset outside the hospital; however, infection beginning outside the hospital may be a reflection of changing healthcare practices with more immunocompromised patients receiving care as outpatients.

Multiple-cause-of-death data obtained from NCHS found that age-adjusted crude (all-cause) mortality of patients with invasive candidiasis increased steadily from 1980 to peak in 1989 followed by a gradual decline through 1996 *(100)*. Pfaller and Diekema updated this analysis using the same data source and found the rate remained steady at approximately 0.4 deaths per 100,000 population per year from 1997 through 2003 (51). These data suggest the incidence and mortality associated with invasive candidiasis are not declining.

Rees et al. *(101)* reported the results of population-based active laboratory surveillance conducted for invasive mycotic infections during 1992 and 1993 in three California counties in the San Francisco Bay Area; they found the cumulative incidence for these infections was 17.8 per 100,000 per year and *Candida* (7.3 per 100,000 per year) was the most common infection. The case–fatality ratio was 33.9%. The *Candida* species they identified in order of frequency were *C. albicans* (50.9%), *C. parapsilosis* (22.2%), *C. glabrata* (11.7%), and *C. tropicalis* (7.9%). Species-specific case–fatality ratios were *C. tropicalis* (44.1%), *C. albicans* (38.1%), *C. glabrata* (34.7%), and *C. parapsilosis* (16.8%). Major underlying conditions among all patients with invasive candidal infections were nonhematologic malignancies (18.2%), HIV infection (15.3%), diabetes mellitus (13.6%), and chronic lung disease (13.6%) *(101)*. Recent abdominal or cardiac surgery had been performed on 17.9% of patients with invasive candidiasis and was particularly associated with *C. tropicalis* and *C. glabrata* infections. *C. parapsilosis* was the most frequently isolated invasive fungal pathogen in children under 10 years of age (cumulative incidence: 3.3 per 100,000 per year) followed

by *C. albicans* (29.6 per million per year), and for both of these species the race-specific cumulative incidence rates among blacks were more than double those of other racial groups. The majority of infections with *C. parapsilosis* and *C. albicans* in children <10 years occurred in those <1 year. No cases of invasive *C. glabrata* infection occurred in patients under 20 years of age *(101)*. Kao et al. *(102)* also reported results of prospective, active population-based surveillance for candidemia in Atlanta and San Francisco during 1992 to 1993. The average annual incidence of candidemia at both sites was 8 per 100,000 population; the highest incidence (75 per 100,000) occurred among infants ≤1 year old. In 20% of patients, candidemia developed prior to or on the day of admission. Underlying medical conditions included cancer (26%), abdominal surgery (14%), diabetes mellitus (13%), and HIV infection (10%). In 47% of cases, non–*C. albicans* species were isolated, most commonly *C. parapsilosis*, *C. glabrata*, and *C. tropicalis*. Antifungal susceptibility testing of 394 isolates revealed minimal levels of azole resistance among *C. albicans*, *C. tropicalis*, and *C. parapsilosis*.

Most recently, the CDC has conducted active, population-based laboratory surveillance from 2008 to 2010 in two locations in the United States: Baltimore City and County, Maryland (population: 1.4 million) and Metropolitan Atlanta, Georgia (population: 3.8 million). After 1 year of surveillance, an increase in incidence rates was found over prior surveillance (14/100,000 in Atlanta and 31/100,000 in Baltimore) *(103)*. Prevalent underlying medical conditions included surgery in the 3 months prior to candidemia (55%), diabetes (30%), cancer (24%), or liver-related diagnoses (22%). The case-fatality rate was 30% in Atlanta and 26% in Baltimore. In Atlanta, the species-specific incidence of candidemia rose dramatically from previous rates in 1992 to 1993 for both *C. glabrata* (4.5 vs. 1.0/100,000) and *C. parapsilosis* (3.2 vs. 1.8/100,000). In Baltimore, the incidence of candidemia due to *C. parapsilosis* doubled from previous rates from 1998 to 2000 (5.5 vs. 2.5/100,000). These preliminary data suggest that the incidence of candidemia is increasing and that the increase is being driven by increases mainly in *C. glabrata* and *C. parapsilosis*. Ongoing surveillance in sentinel sites around the United Statesis essential to help monitor and understand changes in epidemiology.

Reservoirs and Sources of Infection

Candida species may enter the blood via several routes; the major routes are intubation, intravenous catheterization, and intestinal translocation. The last route becomes important when the burden of yeast microorganisms exceeds a certain but as yet undetermined threshold in humans. A prospective study involving biweekly quantitative stool cultures from very low birth weight (≤1,500 g) infants during the first 6 weeks of life revealed a threshold (8×10^6 *Candida* species CFU/g of stool) beyond which 50% of the patients developed gastrointestinal symptoms *(104)*. More than half of these same patients also developed invasive infection within the following weeks. These results may be of particular importance, because they provide a basis for developing and evaluating effective interventions for the prevention of candidemia originating from the gut in these high-risk pediatric patients.

In most hospitalized *Candida*-infected patients, the likely source of the infecting strains is *Candida* species from the patient's own endogenous fungal flora of the gastrointestinal tract and skin. Clinical studies using newer molecular typing techniques have confirmed that patients' endogenous colonizing *Candida* species strain(s) may be the cause of invasive disease *(105–107)*. Long-term indwelling intravascular catheters, in particular CVCs, provide another portal of entry for endogenous pathogenic *Candida* species. Finally, despite the isolation of *Candida* species from a variety of hospital environmental sources, including air, food, fomites, and environmental surfaces, these have not been implicated as sources for healthcare-associated *Candida* species infections.

Modes of Transmission of Infection

Healthcare-associated transmission of *Candida* species may result from either extrinsic or intrinsic contamination of solutions or devices. Carriage of *Candida* species on the hands of hospital personnel may cause extrinsic contamination of central lines and devices, parenteral hyperalimentation fluids, and other intravenous solutions and medications. Outbreaks of healthcare-associated *Candida* species infections have been reported often in special care units and attributed to cross-infection (Table 40-1). Outbreaks of healthcare-associated *C. parapsilosis* fungemia, in particular, have been traced to contaminated intravascular lines and pressure-monitoring devices and/or parenteral hyperalimentation fluids (Table 40-1). Extrinsic contamination of a new intravenous anesthetic agent without a preservative was also responsible for an outbreak of postsurgical *C. albicans* fungemia and endophthalmitis *(11)*. In a multistate outbreak of *C. parapsilosis* endophthalmitis, the vehicle identified was an intrinsically contaminated ophthalmic irrigating solution *(7)*. Antifungal susceptibilities of outbreak isolates found them to have a uniform pattern that differed from those of control isolates *(108)*. In the outbreak of candidemia in an NICU reported by Sherertz et al. *(109)*, infants' BSIs were traced to the administration of *Candida* species–contaminated retrograde medication syringe fluid. Pertowski et al. *(10)* investigated an outbreak of sternal wound infections in patients following cardiac surgery and found that exposure to a particular scrub nurse in the operating room with a history of recurrent vulvovaginal candidiasis was significantly associated with case-patients. Molecular subtyping of case patients' isolates was performed and these results suggested a common source; however, no isolates from the scrub nurse were available. Following reassignment of the scrub nurse outside the operating room, the outbreak ceased. Also, a distinctly unusual source, a multidose bottle of liquid glycerin used for per-rectal administration, was identified by Welbel et al. *(12)* in an outbreak of *C. parapsilosis* BSIs in neonates.

More specific evidence regarding healthcare-associated *Candida* species transmission has been provided by several investigators who have used new molecular typing methods to study isolates from infected patients, hospital personnel, and the hospital environment. In an outbreak of *C. tropicalis* sternal surgical site infections in patients undergoing cardiac surgery, a staff member carrier was identified who had contact with all the case-patients and

who was colonized (nares and hand) by a *C. tropicalis* strain with a DNA type identical to that of the case-patient isolates and different from those of control *C. tropicalis* isolates *(29)*. In another report, three of four infants infected over a 3-month period from an unspecified source in a NICU acquired the same strain of *C. albicans (110)*. In a third report, 5 of 98 bone marrow transplantation unit (BMTU) patients studied prospectively acquired *C. parapsilosis* exogenously during their admission; although isolates of a single DNA type were isolated from four patients, the hands of three hospital staff members, and two environmental surfaces in the BMTU, no common source could be identified, and a total of three different DNA types were demonstrated for the outbreak isolates *(111)*. In a prospective study of 98 patients admitted to a university hospital's medical ICU and BMTUs, prolonged stay in the unit and prior antimicrobial use were each identified as significant risk factors for healthcare-associated *C. glabrata* colonization *(112)*. Molecular subtyping analysis of *C. glabrata* isolates obtained from patients, healthcare workers' hands, and the environment further suggested that exogenous healthcare-associated acquisition of these isolates may have occurred from sources in the hospital environment, and indirect contact may have been important in their transmission *(112)*. Kuhn et al. *(113)* evaluated isolates from a *C. parapsilosis* community hospital outbreak and using DNA fingerprinting confirmed they belonged to one clone compared with clinical isolates from patients with sporadic infections in a separate tertiary hospital. These same investigators found that biofilm expression by the outbreak clone was significantly greater than that of the sporadic clinical isolates. Application of these newer methods of molecular typing to the study of *Candida* species infection should enhance our understanding of the epidemiology of this important healthcare-associated pathogen.

Risk Factors for Infection

Factors that have increased the number of severely immunocompromised hospitalized patients who are at highest risk for healthcare-associated fungal infections include modern pharmacologic treatments for hematologic and other malignancies, including intensive ablative and immunosuppressive chemotherapeutic regimens, broad-spectrum antimicrobial agents, parenteral hyperalimentation, and prolonged treatment of patients in adult and NICUs, frequently with invasive devices such as CVCs. Other important factors contributing to the number of highly immunocompromised hospitalized patients include the AIDS epidemic and an increase in the number of patients with solid organ (kidney, heart, liver) or HSCTs.

Few well-controlled studies have properly assessed predisposing factors for the development of healthcare-associated invasive candidiasis. Karabinis et al. *(114)* studied candidemia in cancer patients and, in a multivariable analysis of a matched case–control study, found that positive surveillance cultures for *Candida* species, central venous catheterization, and neutropenia were significant independent risk factors for infection in these patients. In a matched case–control study by Wey et al. *(115)*, the stepwise logistic regression analysis identified four independent variables that together predicted the acquisition of healthcare-associated candidemia: the number of antibiotics received before infection, prior hemodialysis, prior use of a Hickman catheter, and isolation of *Candida* species from nonblood body sites. A third matched case–control study by Bross et al. *(116)* drew similar conclusions concerning the use of central lines and antibiotics; moreover, the presence of a urinary catheter, azotemia, diarrhea, candiduria, and the transfer of the patient from another hospital also were associated with an increased risk of candidemia. These studies will help determine high-risk populations and preventive approaches that may reduce the incidence of healthcare-associated candidemia.

In another study, Richet et al. *(9)* showed that significantly granulocytopenic patients with acute lymphocytic leukemia were predisposed to candidemia following administration of vancomycin and/or imipenem. This study also found that, in these patients, proliferation of *Candida* species in the gastrointestinal tract as a result of vancomycin therapy was associated with an increased risk for candidemia, and that concurrent prophylactic oral amphotericin B therapy was protective. Thus, in granulocytopenic patients, receipt of specific antimicrobial agents for prophylaxis of bacterial infections may itself predispose these patients to invasive candidiasis. A better understanding of the risk factors for invasive candidiasis will await future studies.

Turner et al. *(117)* examined healthcare-associated candidemia in pediatric patients at two university hospitals over a 5-year period. Forty percent of the patients with candidemia were premature infants, 38% had gastrointestinal and hepatic disorders, and 15% had underlying malignancies. The infection was related to intravenous lines in 90% of cases.

A few studies have examined the role of preexisting colonizing *Candida* species strains in patients who subsequently develop invasive candidiasis. Solomkin et al. *(118)* reported that, in patients undergoing elective abdominal surgical procedures, there was evidence of sequential spread of colonizing yeasts from the abdominal cavity to the bloodstream and other body sites. Pittet et al. *(119)* used electrophoretic karyotyping to delineate *Candida* species strains isolated from critical care unit patients. In this study, *Candida* species carriage was found to be patient specific rather than site specific; each patient was colonized with *Candida* species with identical karyotype patterns. Colonization always preceded infection that occurred a mean of 25 days after initial surveillance cultures grew yeast. These investigators further determined that, among surgical patients heavily colonized with *Candida* species, the three significant risk factors for candidemia were the length of previous antibiotic therapy, an Acute Physiology and Chronic Health Evaluation (APACHE II) score >20, and the degree of *Candida* colonization *(119)*. In another study, Reagan et al. *(110)* used restriction endonuclease digests of chromosomal DNA and a DNA probe to demonstrate the sequence of initial colonization of patients with *Candida* species followed by their infection with strains considered identical with these techniques. These studies highlight the importance of using molecular epidemiologic tools for further understanding of the pathogenesis and mode of transmission of candidal infections.

Infections with *Candida* species that are resistant to antifungal agents used in prophylaxis for severely immunocompromised patients were initially identified with the widespread use of fluconazole in the therapy of nonhospitalized AIDS patients, which was associated with the emergence of *Candida* species strains resistant to the drug. As early as 1991, a report of a significant association of fluconazole prophylaxis and *C. krusei* opportunistic infections was documented among patients in the Johns Hopkins University's Hospital BMTU *(28)*. These *C. krusei* isolates demonstrated innate resistance to fluconazole. In a follow-up study from this institution, the administration of early empiric amphotericin B plus flucytosine therapy to febrile neutropenic BMTU patients colonized with *C. krusei* was associated with a reduction in the proportion of *C. krusei* fungemias in patients receiving fluconazole *(120)*. However, in the same study, a higher proportion of fungemias attributable to fluconazole-resistant *C. glabrata* was noted among patients receiving fluconazole. Since these preliminary studies, several epidemiologic reports have shown that the widespread use of fluconazole-suppressive therapy for patients at high risk for disseminated *Candida* species infections in these and other hospital critical care units has presaged the emergence of infections caused by less pathogenic but innately resistant *Candida* species (*121*,122,123).

HEALTHCARE-ASSOCIATED *CANDIDA* SPECIES INFECTIONS IN SPECIAL PATIENT POPULATIONS

Neonatal Candidiasis

Prenatally acquired *Candida* species infection resulting in congenital cutaneous candidiasis in premature neonates has been discussed (see above), and the condition must be distinguished from neonatal invasive candidiasis.

Colonization with *Candida* species in hospitalized neonates is thought to result most commonly from acquisition of microorganisms that are part of the maternal vaginal flora. The infant's gastrointestinal tract then becomes the predominant site of colonization with these fungal microorganisms. Alternatively, hospital personnel may be colonized with *Candida* species on their hands; transmission of these yeasts from personnel to infant and from infant to infant via the hands of NICU personnel may be important. In a prospective study of *Candida* species colonization of hospitalized infants, Reef et al. *(124)*, using molecular typing techniques, found evidence that acquisition of *Candida* species was healthcare-associated rather than maternally derived. Another unusual mode of acquisition of *Candida* species was demonstrated in an NICU outbreak of *C. parapsilosis* fungemias that was traced to probable extrinsic contamination of a multiuse bottle of liquid glycerin *(12)*.

Neonatal invasive candidiasis is predominantly a disease of low birth weight infants, in particular, very low birth weight infants. Because of modern advances in medical technology since the 1960s, NICUs have proliferated and have contributed to the prolonged survival of more critically ill infants. *C. albicans* is the most frequently identified fungal species to cause disseminated disease in neonates; however, potentially fatal infection may also be due to *C. tropicalis* and *C. parapsilosis*, and rarely *C. glabrata*, *C. guillermondii*, and *C. lusitaniae*. In a review of 111 cases of candidemia in their NICU during 1981 to 1995, Kossoff et al. *(125)* noted a more than 11-fold increase; a shift in the prevalent *Candida* species from *C. albicans* to *C. parapsilosis*, and a significantly higher mortality associated with *C. albicans* than with *C. parapsilosis*.

Both prior colonization with *Candida* species and these infants' degree of underlying immunologic immaturity are important in the subsequent development of fungal infection. Oral thrush and perineal rash are the most frequent clinical presentations of *Candida* species involvement in this population. Invasive disease, which is usually fungemia, occurs in approximately 1% to 3% of NICU infants. Risk factors identified as important for the development of fungemia in this population include intravascular catheters, total parenteral nutrition, prior receipt of antimicrobial agents, necrotizing enterocolitis and surgery specific for this condition, and medications such as steroids and aminophylline *(126)*. Recently, pulmonary hemorrhage and intrauterine growth restriction were identified as independent risk factors for fungemia in neonates *(127)*.

Invasive candidiasis in infants usually has a nonspecific clinical presentation *(128)*. Signs of respiratory deterioration and apnea predominate (70%); however, other manifestations include temperature instability, irritability, lethargy, carbohydrate intolerance, abdominal distention, and rash. Despite the tendency for blood cultures in these infants to be only intermittently positive, the rate of positivity may be higher than that seen for adults; in critically ill neonates, the incidence of catheter-related BSIs can be as high as 18 cases per 1,000 catheter days *(129)*. In addition, the clinical and laboratory definitions of catheter-related infection established for adults may not be easily applied to children. Difficulty obtaining blood samples in infants and young children may mean there are only results from blood samples obtained via the catheter available to guide patient management (130). As with adults, antifungal therapy should be initiated when yeast is isolated from a blood culture or when suspicion of fungemia is high (130). The selection of an appropriate antifungal agent depends on the microorganism that is isolated and the drug characteristics, including pediatric dosing information, toxicities, route of administration, and formulations (130). Meningitis in neonates is a well-recognized complication of *Candida* species sepsis, with an incidence ranging from 27% to 59% *(127)*. Therefore, a critical requirement for all fungemic infants is the performance of a CSF tap to examine CSF; these cultures may be positive without positive blood cultures *(128)*.

Evidence of *Candida* species meningitis requires early institution of antifungal therapy and may affect both the choice and duration of antifungal therapy and the infant's prognosis and follow-up. In addition, positive urine cultures may be found in 50% of infants with disseminated candidiasis and may be the initial indicator of disseminated infection *(127)*. However, in infants, the presence of yeast skin contamination may invalidate a urine specimen collected in a bag as a diagnostic tool for *Candida* species urinary tract infection, and suprapubic aspiration may be needed. When such an aspirate is culture positive

for *Candida* species, antifungal therapy may be indicated *(128)*. The importance of a screening ophthalmologic examination for infants with suspected *Candida* species fungemia is underscored by the finding that endophthalmitis occurs in as many as 50% of these infants *(131)*. In infected infants, the classic ophthalmologic lesion is described as a yellow-white, fluffy patch of retinitis with indistinct margins that may develop more gradually than lesions caused by bacterial sepsis. Resolution of the infection usually follows the introduction of systemic amphotericin B therapy; however, prolonged therapy is needed to prevent recurrences *(131)*.

The hematologic profile in infants with invasive candidiasis may also be nonspecific. Thrombocytopenia ($\leq$100,000/mm^3) may occur in up to 70% of infants with fungemia *(128)*, and the leukocyte count may be variable. Abnormal liver function test results may suggest hepatic involvement in infected infants *(128)*.

Reports of healthcare-associated outbreaks of *Candida* species infections have identified various sources for these infections in infants. In an investigation of a cluster of *C. albicans* fungemias involving seven preterm infants in a Canadian NICU, Vaudry et al. *(132)* failed to identify any significant risk factors for these infections in a case–control study, and further laboratory evaluation of the case-patient isolates using DNA restriction enzyme digests identified two different strains. A small outbreak of fungemias caused by *C. parapsilosis* in an Albany, New York, hospital was traced to defective filters for hyperalimentation fluids, and outbreak strains showed a single electrophoretic karyotype *(133)*. A pseudo-outbreak caused by *C. guillermondii* resulted from flushing needles with a contaminated heparin solution *(20)*. Contaminated retrograde intravenous medication was found to be the cause of an outbreak of *Candida* species fungemia involving five infants in an NICU, and molecular typing revealed identical *C. albicans* strains from patients and medication syringe fluid *(109)*. A report by Fowler et al. *(134)* of an outbreak of *C. lusitaniae* infections used molecular subtyping methods to establish that person-to-person transmission of the yeast had occurred among neonates in their NICU. Roilides et al. *(135)* reported a 4-year trend with increased isolation of non–*C. albicans* species as causes of fungemia in the absence of routine use of antifungal drug prophylaxis in their NICU. When these investigators studied a cluster of *C. tropicalis* colonization and fungemia cases using molecular subtyping methods, they concluded that cross-colonization was the likely mechanism for transmission possibly via transient hand colonization of personnel.

Postsurgical Infections

Patients demonstrating a variety of postsurgical invasive infections caused by *Candida* species have been described by several investigators. In most reported patients, these infections have been associated with surgical procedures involving all levels of the gastrointestinal tract *(136)*. However, there have also been reports of unusual outbreaks of postsurgical *Candida* species endophthalmitis and candidemia traced to intrinsically contaminated ophthalmologic irrigating solution and extrinsic contamination of an intravenous anesthetic agent without preservative (Table 40-1). Localized infections caused by *Candida* species in postsurgical patients have included sternal surgical site infections, abdominal abscesses, peritonitis, anastomotic breakdown, and intestinal necrosis; however, candidemia and disseminated candidiasis may also occur. Cultures of blood and deep incisional or organ/space surgical sites may be positive for *Candida* species in infected postsurgical patients. However, postoperative patients tend to be a heterogeneous population that is often critically ill with underlying medical conditions, which often makes it difficult to ascribe a specific role to the surgical procedure in the development of invasive candidiasis. Important underlying conditions in these patients may include malignancies and gastrointestinal, cardiac, and renal system disease; such patients may also have multiple exposures to risk factors for candidemia and invasive *Candida* species infections (e.g., vascular catheters, hemodialysis, total parenteral nutrition, and broad-spectrum antimicrobial agents and corticosteroids). *Candida* species has been isolated from CSF in patients following neurosurgery, most commonly in association with shunts. Pancreatic surgery may also be associated with an apparent increased likelihood of *Candida* infection. Hospitalized patients with burn wounds demonstrate frequent wound colonization with *Candida* species and are at particularly high risk for candidemia and potentially fatal disseminated candidiasis.

ANTIFUNGAL SUSCEPTIBILITY

Compared with other fungi, treatment of candidiasis can be better guided by *in vitro* susceptibility testing. Because the susceptibility of *Candida*, in general, is predictable based on species identification, it is currently not recommended to routinely test all *Candida* isolates for susceptibility (137). The 2004 Infectious Diseases Society of America (IDSA) guidelines recommend that susceptibility testing is most helpful in management of deep infection due to non–*C. albicans* species of *Candida* (137). In this setting, especially if the patient has been treated previously with an azole antifungal agent, the possibility of microbiological resistance must be considered. The 2009 IDSA guidelines recommend laboratories perform routine testing against fluconazole for *C. glabrata* isolates from blood and sterile sites and for other *Candida* species that have failed to respond to antifungal therapy or in which azole resistance is strongly suspected (38).

Although standards have been established by the Clinical and Laboratory Standards (formerly the National Committee for Clinical Laboratory Standards) for *Candida* species, interpretive breakpoints exist only for fluconazole, itraconazole, and voriconazole *(138,139)*. Furthermore, evidence supporting the association with MIC and clinical outcome of invasive candidal disease is limited (e.g., fluconazole breakpoints were based predominantly on mucosal candidiasis data). One further limitation of antifungal susceptibility testing for *Candida* is the variability in interpretation of results (e.g., misinterpretation of trailing growth at high drug concentrations) *(140)*.

Based on *in vitro* susceptibility testing performed on bloodstream isolates from around the world, *C. albicans*, *C. tropicalis*, and *C. parapsilosis* are considered to be susceptible to existing antifungal agents *(99,141)*. *C. glabrata* has

emerged as an important problem, sometimes even more commonly isolated than *C. albicans* in some institutions. Although it may be susceptible to fluconazole, this species can easily develop acquired resistance, particularly in patients who have received prior fluconazole prophylaxis or treatment *(71,142)*. *C. krusei* is intrinsically resistant to fluconazole and often demonstrates susceptibility to amphotericin B and flucytosine, although it remains susceptible to caspofungin, voriconazole, posaconazole, and ravuconazole *(143)*. In the severely immunocompromised patient population where fluconazole prophylaxis or therapy has been instituted, *C. krusei* has been problematic *(28)*. Some strains of *C. lusitaniae* can be resistant to polyene agents (amphotericin B, and nystatin) although they remain susceptible to triazoles (fluconazole, itraconazole, voriconazole, posaconazole, and ravuconazole) *(141,144)*. *Candida rugosa* has demonstrated decreased susceptibility to amphotericin B, nystatin, and fluconazole *(143)*. This property, as well as its propensity to colonize skin, may help explain this species emergence to cause difficult-to-control outbreaks of infection in hospitals *(145,146)*.

Results of antifungal susceptibility tests of *C. parapsilosis* clinical isolates (given the limitations of current methods) have generally shown them to be susceptible to amphotericin B, and this has been the most frequently used antifungal. Fluconazole is the most frequently administered alternative therapy to amphotericin B although clinical resistance in *C. parapsilosis* has rarely been reported. In addition, fluconazole has been widely used for targeted prophylaxis in infants who are either <1,000 g or ≤27 weeks. *In vitro* resistance to voriconazole is rare; however, resistance to the drug has developed among clinical strains previously exposed to fluconazole, and outbreak strains with reduced susceptibilities to both fluconazole and voriconazole have been identified *(13)*. The MIC levels for the echinocandins are significantly higher for *C. parapsilosis* than those for the other *Candida* species, and there have been reports of both echinocandidin treatment failures and "break through" infections with *C. parapsilosis* in individuals receiving echinocandins for other indications. In addition, a recent report has suggested an association between increasing caspofungin use and an increased incidence of *C. parapsilosis* candidemia *(16)*. Thus, echinocandins should be used with caution in invasive *C. parapsilosis* infection.

TREATMENT

In high-risk patients and patients in whom the diagnosis of invasive candidiasis is suspected or confirmed, the administration of antifungal drugs may be for prophylactic, empiric, preemptive, or specific therapy. A more aggressive approach to the management of candidal infections with antifungal agents has become the standard because of the potentially high mortality and morbidity associated with these infections and the wide availability of azole anticandidal agents as well as the echinocandins, which are less toxic than amphotericin B.

Echinocandins are the newest class of antifungals. They have a unique mechanism of action, and exhibit activity against a broad range of *Candida* species and strains, including those resistant to the azoles and polyenes. Few studies have directly compared the three approved echinocandins (caspofungin, micafungin, and anidulafungin) for efficacy, but the existing data have not suggested major differences to date. All the echinocandins possess excellent tolerability and safety, and although there are some pharmacokinetic differences, they are relatively minor and generally do not influence drug selection. Consequently, echinocandins are now considered to be the first-line treatment of invasive candidiasis in critically ill patients.

The choice of initial antifungal therapy in a patient who has proven or suspected invasive candidiasis is dependent upon several important considerations *(147)*. What is the patient's recent history of azole exposure? What are the susceptibility patterns of *Candida* spp. in this particular healthcare setting? What are the predominant *Candida* spp. in this particular unit/location and in this particular situation? What are the patient's comorbidities and underlying disorders? How acutely ill is this patient? Is there clinical evidence to suggest involvement of the CNS, cardiac valves, liver, spleen, or kidneys? Is there a patient history of intolerance to an antifungal agent? Each of these questions must be addressed specifically to make an informed choice relative to the most suitable antifungal agent.

The 2009 IDSA treatment guidelines for invasive candidiasis have clarified the indications and use of echinocandins, higher dosing of fluconazole, and lipid formulations of amphotericin B, each of which provides a safer alternative to conventional amphotericin B therapy with its associated toxicities (38). These guidelines identify echinocandins (caspofungin, micafungin, or anidulafungin) as a first-line therapy option for patients with moderately severe to severe nonneutropenic or neutropenic invasive candidiasis. The guidelines identify fluconazole as another first-line treatment option for patients with mild-to-moderate disease (i.e., hemodynamically stable patients) and no prior azole exposure, but state that echinocandins are the preferred choice for patients at elevated risk for infection with a fluconazole-resistant pathogen due to prior azole therapy. An echinocandin is also favored in nonneutropenic or neutropenic patients if the isolate is identified as *C. glabrata* or *C. krusei* (which exhibit increased resistance to triazoles).

The 2009 IDSA guidelines also provide recommendations for the treatment of *Candida* infection of the cardiovascular system, CNS, urinary tract, or vulvovaginal region, as well as candida osteoarticular infection, candida endophthalmitis, nongenital mucocutaneous candidiasis, neonatal candidiasis, and chronic disseminated candidiasis (38). There are some important changes in the most recent guidelines from earlier 2000 and 2004 IDSA guidelines. The most recent guidelines identify voriconazole as a suitable alternative treatment option for nonneutropenic or neutropenic patients with candidemia. In addition, traditional amphotericin B is no longer recommended as first-line therapy for nonneutropenic or neutropenic patients with established candidemia, although lipid formulations of amphotericin B are recommended as first-line treatment for nonneutropenic and as treatment for neutropenic patients. These changes are due to the increased incidence and severity of nephrotoxicity associated with

traditional versus lipid formulations of amphotericin B and the associated cost of this adverse side effect. The 2009 IDSA guidelines recommend either traditional or lipid formulations of amphotericin B as first-line empiric treatment for neutropenic patients or as alternative empiric treatment for nonneutropenic patients with suspected candidiasis (38). Major changes from earlier versions of the guidelines include the introduction of all three echinocandins as first-line or primary treatment options for nonneutropenic or neutropenic patients with candidemia or nonneutropenic patients with suspected candidiasis and the recommendation of voriconazole (as well as caspofungin or lipid formulations of amphotericin B) as a first-line empiric treatment option for neutropenic patients with suspected candidiasis.

The 2009 IDSA guidelines generally do not make any distinction among the available echinocandins (caspofungin, micafungin, or anidulafungin) (38). However, caspofungin was the first member of the class approved for use in the United States and has the largest database, as well as the greatest number of approved indications. Caspofungin is the only echinocandin with an indication for use as empiric treatment of presumed fungal infections in febrile, neutropenic patients and pediatric patients. Similarly, micafungin is the only echinocandin currently approved for the prevention of invasive candidiasis in patients undergoing hematopoietic stem cell transplantation. The efficacy of all three echinocandin agents for treatment of candidemia has been demonstrated in clinical trials including caspofungin was found to be noninferior to amphotericin B deoxycholate for treatment of nonneutropenic and neutropenic patients with invasive candidiasis *(148)*, anidulafungin was found to be noninferior to fluconazole for treatment of candidemia *(149)*, and micafungin was shown to be noninferior to both liposomal amphotericin B and caspofungin) in two separate studies *(150,151)*.

The 2009 IDSA guidelines recommend removal of CVC when candidemia is documented, if at all possible (38). The data to support this are strongest among nonneutropenic patients and show that catheter removal is associated with shorter duration of candidemia *(152)* and reduced mortality in adults *(152,154)* and neonates *(155)*. The management of intravascular catheters in neutropenic patients is more complicated than in nonneutropenic patients, the data for catheter removal is less compelling, and significant access problems may be a consequence of catheter removal (38). Intravascular catheter removal is strongly recommended in neonatal candidiasis, and there is evidence that delayed removal or replacement of a CVC for infants with candidemia places them at increased risk of prolonged infection, mortality, and long-term irreversible neurodevelopmental impairment *(155,156)*. The guidelines provide recommended candidemia treatment performance measures that include the need to perform ophthalmological examinations in all patients with candidemia to exclude *Candida* endophthalmitis (in neutropenic patients, this should be performed after recovery of the neutrophil count), the need to start antifungal therapy on all candidemia patients within 24 hours after the blood culture is positive for yeast, and the requirement that follow-up blood cultures be obtained for all patients with candidemia to ensure clearance of *Candida* from the bloodstream (38).

PREVENTION AND CONTROL

Effective control and prevention strategies for healthcare-associated *Candida* species infections must use available epidemiologic information, be targeted at patients who are at highest risk for these infections, and aim at interrupting or preventing transmission of infection. Strategies for control and prevention of *Candida* HAI differ importantly from guidelines for the control and prevention of healthcare-associated mold infections.

Proper implementation and strict adherence to established infection control guidelines remain the best means to prevent healthcare-associated candidiasis. Specific measures to prevent intravascular fungal infections include strict aseptic technique in the insertion and maintenance of intravenous lines. All the established risk factors for developing healthcare-associated bacterial BSIs also apply to candidemia, and established prevention guidelines for the prevention of BSI should be applied routinely to prevent candidemia (see also Chapter 19). CDC's HICPAC has no specific guidelines for the prevention of candidemia in general hospitalized patients apart from the approaches outlined in the "Guidelines for Prevention of Intravascular Catheter-Related Infections" (157). Regardless, there are several factors that can be considered if a healthcare setting detects a persistent problem with *Candida* BSIs or other forms of healthcare-associated candidiasis.

Reducing gastrointestinal colonization. Colonization with *Candida* is the overriding risk factor associated with developing healthcare-associated candidiasis. Removing the endogenous reservoir should reduce a patient's risk for subsequent disease substantially. Oral nonabsorbable antifungal drugs, including oral amphoterin B suspension, nystatin, and clotrimazole troches, might reduce superficial colonization and control local mucosal candidiasis, but have not been shown to reduce invasive candidiasisis (158). Utilizing systemic antifungals before there is any evidence of active disease (prophylaxis) is one well-studied method to accomplish this. Mounting evidence on the efficacy of preventing candidemia in the subset of patients at highest risk for invasive disease has resulted in specific recommendations by HICPAC and IDSA and an expert panel for the HSCT population (158,159) and the neutropenic population (160). Because candidiasis usually occurs in the period after transplantation but before engraftment, fluconazole, the drug of choice, should be started on the day of HSCT and continued until at least engraftment (158,159). The appropriate duration of prophylaxis is not known, but at least one study has shown there is a survival benefit when prophylaxis is extended for at least 75 days *(161,162)*. Because autologous recipients generally have a lower risk for invasive fungal infection than allogeneic recipients, only autologous recipients with particular conditions (underlying hematologic malignancies, prolonged neutropenia, and mucosal damage from manipulation, or recent treatment with fludarabine or 2-CDA) should receive antifungal prophylaxis (158,159).

Solid organ transplant recipients, especially patients undergoing orthotopic liver transplantation, have also been identified to be at high risk for invasive candidiasis (38,137,*163–165*). Various antifungal therapies, including amphotericin B deoxycholate, itraconazole, liposomal

amphotericin B, and fluconazole, have been studied as prophylactic regimens post transplantation (160). At this time, IDSA recommends that high-risk liver (with at least two risk factors for invasive fungal disease), pancreas, and small-bowel transplant patients receive antifungal prophylaxis in the early postoperative period (38). Prophylaxis in patients receiving liver transplants who are considered low risk as well as patients receiving kidney or heart transplantations is not currently recommended (38).

Prophylaxis may be warranted in ICUs with very high incidence rates of invasive candidiasis compared with normal rates of 1% to 2% *(166)* where aggressive infection control procedures are failing to reduce rates (38,137,*167,168*). Selected ICU patients who are at highest risk (incidence >10%) may also benefit from antifungal prophylaxis *(169)*. However, studies to date have not shown a survival benefit associated with this strategy *(170,171)*. The use of prophylaxis in ICUs with only low risks of candidiasis may be inappropriate due to the increased risk of adverse drug events as well as selection of resistant microorganisms *(172)*. For example, it is possible that the proportion of infections with *Candida* species exhibiting reduced susceptibility to fluconazole, such as *C. glabrata* and *C. krusei*, may increase as a consequence of the introduction of fluconazole prophylaxis *(173–175)*.

A patient population in which the role of antifungal prophylaxis is under increasing study is the neonatal population, specifically extremely low birth weight infants (<1,000 g). Although several studies have documented decreased rates of infection with antifungal prophylaxis *(156,176–178)*, there are many unanswered questions with regard to which variables are most apt for selection of patients requiring prophylactic treatment and there is no consensus among practitioners on the specific subset of patients in which this approach should be used *(71,179)*. IDSA currently recommends routine fluconazole prophylaxis for premature infants and infants with extremely low birth weights in nurseries that have a high incidence of invasive candidiasis (38). Fewer studies have evaluated this approach in surgical ICU patients. A recent meta-analysis evaluating these studies determined overall there was no survival benefit among treated patients compared with untreated patients *(174)*.

Preventing cross-transmission. Currently, Standard Precautions should be utilized for all patients with candidemia (157). Although transmission via healthcare workers' hands may be the pathway for some acquisition of *Candida*, most candidemia is thought to be derived from the patient's own flora, so enhanced precautions to prevent person-to-person spread are not justified. If local authorities identify a microorganism of epidemiologic concern (e.g., a particular *Candida* species of high virulence or resistance), Contact Precautions may be justified. However, outbreaks of candidemia that have involved cross-transmission have been associated with substandard hand hygiene and have been interrupted by improved compliance with Standard Precautions *(13)*. Efforts to improve hand hygiene, such as those described in HICPAC guidelines for hand hygiene (180), are therefore relevant to prevention and control of candidemia. Use of waterless antiseptic agents (alcohol-based solutions) has gained acceptance. Importantly, studies have shown that alcohol-based hand washes are effective against *Candida* species *(71,181)*, but efficacy may vary based on the concentration of alcohol in the products, the amount of contact time, and the burden of yeast present *(182,183)*. Other hand-hygiene antiseptic agents such as chlorhexidine (2% and 4% aqueous), iodine compounds, iodophors, and phenol derivatives also have some activity against fungi (180).

Antifungal prophylactic strategies using the oral azole drugs have been extensively studied, in high-risk granulocytopenic or HSCT patients, and fluconazole has been shown to be effective not only for the prevention of superficial and/or invasive candidal infections (see below), but also for prolonging overall patient survival *(147)*; however, this therapy may also select for less susceptible or resistant *Candida* species. The usefulness of newer antifungal agents and classes has also been evaluated. Micafungin is an alternative prophylactic agent, shown in one study to be comparable with fluconazole for preventing possible or documented fungal infection *(184)*; however, its use is limited by the necessity for intravenous infusion and cost (158). The optimum duration of prophylaxis is unknown but should, at a minimum, include the period of risk of neutropenia (38).

The experimental prophylactic therapies such as the cytokines, including granulocyte colony-stimulating factor (G-CSF), and granulocyte-macrophage colony-stimulating factor (GM-CSF), may lessen the extent and duration of the patient's chemotherapy-induced immunosuppression (granulocytopenia). However, a meta-analysis showed that the use of growth factors did not reduce the attack rate of invasive fungal disease *(185)*, and, therefore, these are not recommended for prophylaxis against invasive fungal disease (158). Further, a recent trial showed that early G-CSF corrects neutropenia but does not reduce sepsis in extremely preterm infants *(186)*. Cytokine administration to patients, together with antifungal agents, as well as transfusion of cytokine-upgraded phagocytes, are promising immunotherapeutic modalities for further research.

Routine surveillance cultures have also been suggested to aid in determining which high-risk patients will develop invasive candidiasis. Sandford et al. *(187)* assessed the usefulness of surveillance colonization cultures for predicting the development of systemic fungal infection in patients with prolonged granulocytopenia. These researchers found that, despite the frequent occurrence of stool colonization with *Candida* species (80% of study patients), this finding was not a reliable predictor for the development of invasive candidiasis in these patients. The data also suggested that any benefit conferred by surveillance cultures applied only to *C. tropicalis*–infected patients and not to *C. albicans*–infected patients. Colonization in particular high-density colonization is the most universally accepted predictive variable with regard to invasive candidiasis. However, it remains to be clarified whether colonization can be used in isolation to identify high-risk patients or if it should be combined with other variables indicating high risk and if determination of multisite colonization is required or whether detecting colonization at one or two specific sites (e.g., candiduria) is sufficient for identification of high-risk patients *(179)*. Definitive evidence of a correlation between candiduria and invasive candidiasis is currently still lacking as the few

published studies thus far have yielded conflicting results. Nevertheless, candiduria may be reliably considered as a surrogate marker for high density of colonization, thereby representing a more practical, and less resource-intensive screening marker than is currently possible using parameters such as the multiple site-colonization index *(179)*. Future studies are needed to better elucidate the role of these cultures and validate risk predictive models using a combination of clinical risk factors and *Candida* colonization parameters (188). There is no evidence to support routine use of surveillance cultures for asymptomatic HSCT recipients in the prevention of candididemia outside of an outbreak setting *(189,190)*.

MOLECULAR TYPING OF *CANDIDA* SPP.

Molecular epidemiology has proven useful for implicating the gastrointestinal tract as the most important endogenous reservoir for candidal infections *(110,191–194)*, documenting transmission via hands of healthcare workers *(13,195–198)* and for confirming the source (e.g., contaminated infusates, biomedical devices) during outbreak investigations *(15,29,193,199,200)*. In addition, molecular typing methods have documented that strains of *Candida* surviving on environmental surfaces within the hospital can also be acquired by patients in the hospital *(111,201)*.

Molecular typing methods are rapidly evolving. A variety of methods have been described in detail elsewhere *(201,202)*. Techniques used in the past include those based on restriction fragment length polymorphism with Southern blot hybridization, electrophoretic karyotyping, multilocus enzyme electrophoresis, and PCR-based techniques (random amplified polymorphic DNA). Newer techniques such as (MLST) has performed at least comparably to other established DNA fingerprinting techniques for *C. albicans (203–205)*. It is emerging as a powerful tool for subtyping *C. albicans* since it has a high degree of resolution, can characterize large numbers of isolates rapidly, and does not require subjective interpretation of banding patterns *(203–205)*. MLST is also available for *C. glabrata* and *C. tropicalis*. Other methods, including use of microarrays, which offer the hope of reproducible, high-throughput typing, are under development.

CONCLUSION

Healthcare-associated *Candida* species infections continue to present clinicians with considerable diagnostic and therapeutic challenges. The epidemiology of invasive candidiasis is complex and, although incompletely elucidated, is characterized by considerable regional and temporal variability. Of particular concern is an overall increase in incidence and an increase in the proportion of *C. glabrata*, infections, which is associated with reduced susceptibility to azole antifungal agents. The management of invasive candidiasis has been aided by the availability of several new effective antifungal agents. However, although the poor clinical outcomes associated with invasive candidiasis are, in part, related to the severity of underlying host factors, optimization of treatment-related factors is also important. In particular, the most difficult challenge is early initiation of effective antifungal therapy, given the lack of sensitivity and delay inherent in conventional culture-based diagnostic techniques. New non–culture-based rapid and specific diagnostic tests for invasive fungal infections in severely immunocompromised patients and validated clinical risk-predictive models are required to better target prophylactic, preemptive, and empirical antifungal strategies. In addition, the successful application of molecular typing methods in outbreak investigations has improved documentation of modes of transmission of healthcare-associated *Candida* species pathogens, and, together with new diagnostic and therapeutic advances, they may aid considerably in the development of effective prevention strategies for these important infections.

CHAPTER 41

Filamentous Fungi

Luis Ostrosky-Zeichner and John H. Rex

Healthcare-associated infection by filamentous fungi was a minor issue for infection control until the frequency of these diseases began to increase in the 1970s (1,2,*3*). This increased incidence is attributed to a larger immunocompromised population in relation to advances in invasive medical technology and highly immunosuppressive therapies (1,*3*). These infections have very high mortality rates and are also associated with significant morbidity in the hospital in relation to therapy and diagnostic procedures. The increased incidence, high mortality, and recent advances in diagnosis and therapy have made these infections a more attractive and "surveillance-worthy" target for infection control programs. Important observations have been made regarding the incidence of these diseases and the presence of their causative agents in the hospital environment. This chapter focuses on the cause, epidemiology, and prevention of these infections while addressing infection control considerations.

CAUSE AND FORMS OF DISEASE

Although there are many reports of virtually any fungal species causing some form of healthcare-associated disease in humans, the most often encountered diseases caused by filamentous fungi are invasive aspergillosis and mucormycosis (1,*4*,5). There are also numerous reports of agents of hyalohyphomycosis such as *Acremonium* spp. and *Fusarium* spp. (1,*6*,7,*8*,*9*), but these are usually associated with an outbreak related to the use of contaminated patient-care materials or in the case of *Fusarium* with environmental sources and dissemination from sites of onychomycosis (10). Their frequency is much lower than *Aspergillus* and the Zygomycetes; thus, this chapter concentrates on the latter.

Aspergillus spp. are the most often encountered filamentous fungi in clinical practice, causing invasive, allergic, and toxic diseases. They are ubiquitous filamentous fungi found in soil, plant debris, and air. There are over 180 described species, although only 20 or so have been reported to be pathogenic for humans (1,2). Table 41-1 summarizes the *Aspergillus* spp. that are most commonly isolated from clinical specimens. Invasive disease can be found in almost any organ, but the most commonly affected are lungs, brain, paranasal sinuses, heart, and bones. *Aspergillus* fungemia is very rare, even in the setting of disseminated disease. It occurs in <10% of cases *(11)*. Aspergillosis can also be related to medical devices such as intravenous or peritoneal catheters and prosthetic materials (*12*–*14*,15). Invasive aspergillosis occurs almost exclusively in patients with a high degree of immunosuppression, such as that seen in leukemia and in bone marrow and solid organ transplantation. However, there are recent reports of invasive pulmonary aspergillosis in otherwise immunocompetent hosts and in patients with chronic obstructive pulmonary disease. Its incidence has been on a steady rise, as evidenced by epidemiologic and postmortem studies. Mortality is very high, reaching nearly 90% in some series of disseminated disease or in deeply immunocompromised patients, and therapy often requires intensive medical treatment with amphotericin B (or its lipid formulations), caspofungin, or voriconazole, alone or in combination, in addition to aggressive surgical debridement when appropriate (2).

Fusarium species are becoming exceedingly important in medical practice, particularly for centers that care for cancer and transplant patients. This agent is usually regarded as an agent of onychomycosis and has been implicated in an extensive outbreak of fungal keratitis related to contaminated ophthalmologic solutions; however, it can cause invasive and disseminated disease, particularly in immunocompromised patients (16). While this mold can produce invasive lung involvement, the typical presentation will be that of disseminated disease characterized by fever and disseminated skin lesions of violaceous appearance. As opposed to disseminated aspergillosis, disseminated fusariosis is one of the few mold infections that can have positive blood cultures. Healthcare-associated infection and transmission are rare, but as with other mold pathogens, environmental contamination has been implicated. Mortality is extremely high, despite antifungal therapy.

The terms *mucormycosis* or *zygomycosis* comprise a class of filamentous fungi that cause highly invasive disease in humans. The terms can be used interchangeably. The class Zygomycetes includes three orders: Mucorales, Entomophthorales, and Mortierellales. The most often encountered clinical pathogens fall in the order Mucorales, and their species are shown in Table 41-1. They are all ubiquitous fungi found in soil and decaying fruits, vegetables,

TABLE 41-1

Aspergillus spp. and Zygomycetes as Causes of Healthcare-Associated Infection

Aspergillus spp.	*Zygomycetes*
Common	**Mucorales**
Aspergillus fumigatus	*Absidia* spp.
Aspergillus flavus	*Apophysomyces* spp.
Aspergillus terreus	*Cokeromyces* spp.
Aspergillus niger	*Cunninghamella* spp.
Aspergillus nidulans	*Mucor* spp.
Rare	*Rhizomucor* spp.
Aspergillus oryzae	*Rhizopus* spp.
Aspergillus ustus	*Saksenaea* spp.
Aspergillus avenaceous	*Syncephalastrum* spp.
Aspergillus candidus	**Entomophthorales**
Aspergillus carneus	*Basidiobolus* spp.
Aspergillus caesiellus	*Conidiobolus* spp.
Aspergillus clavatus	**Mortiellerales**
Aspergillus quadrilineatus	*Mortierella* spp.
Aspergillus restrictus	
Aspergillus sydowi	
Aspergillus versicolor	

TABLE 41-2

Risk Factors for Invasive Aspergillosis and Zygomycoses

Risk Factor	*Aspergillosis*	*Zygomycoses*
Prolonged neutropenia	X	X
Cytotoxic chemotherapy	X	X
Bone marrow transplantation	X	X
Solid organ transplantation	X	X
Congenital or acquired immunodeficiency	X	X
Hematologic malignancy	X	X
Renal failure	X	X
Diabetes (ketoacidosis)		X
Chronic obstructive pulmonary disease	X	
Steroids and tumor necrosis factor blockers	X	X
Iron overload and chelators		X
Trauma	X	X

and food. These microorganisms affect immunocompromised patients, such as those with diabetic ketoacidosis, iron overload, malnourishment, leukemia, bone marrow transplant, solid organ transplant, and burns. They are also seen in patients with acquired immunodeficiency syndrome and patients receiving immunosuppressive therapies such as corticosteroids or tumor necrosis factor blockers (1,*4*,5). Although they can affect almost any organ or body system, the most common forms of invasive disease are rhinocerebral, pulmonary, cutaneous, and gastrointestinal. They have also been associated with medical devices such as intravascular and peritoneal catheters. Mortality is very high and prognosis is poor, even in the face of aggressive treatment.

FILAMENTOUS FUNGI IN HEALTHCARE: ECOLOGY AND EPIDEMIOLOGY

The body of information on healthcare-associated reservoirs, transmission, and infection by filamentous fungi is constantly growing. Although the early years of studying this problem were characterized by debate, today there is little question that these microorganisms are present and can be transmitted in the hospital. Healthcare-associated acquisition of infection by filamentous fungi is extremely important for centers that have a large immunocompromised population, such as cancer or transplant centers, and great efforts and advances have been undertaken to control them.

Acquisition of these diseases is a function of a susceptible host and the presence of a pathogenic microorganism in the environment. Table 41-2 summarizes host risk factors for invasive aspergillosis and zygomycosis. As seen in the table, varying degrees of immunosuppression and underlying illness are required for the host to be susceptible.

As for the presence of the microorganisms in the hospital environment, it is now known that the main source for them is environmental contamination, which can include various surfaces, air, and water (1,*4*,5,*12*,15,*17*,*18*,19,20). Disturbances in the hospital environment, such as construction, can cause wide dissemination of the microorganisms and even outbreaks. Much of the evidence linking aspergillosis to the healthcare-associated environment comes from outbreak investigations (7,*21–25*).

Patterson et al. (26) defined healthcare-associated aspergillosis as that occurring more than 1 week after admission or <2 weeks after discharge. Setting those temporal limits allows for community-acquired cases to be excluded from any analysis. Most cases are pneumonias; thus, the most likely route of infection is by direct inhalation of spores by a susceptible host. Although the primary source of *Aspergillus* spp. spores is soil and decaying vegetation, its main form of healthcare-associated spread is through hospital air (*12*,15,*18*,19,20,*27*). The spore concentration in outdoor air ranges from 0.2 to 15.0 spores/m^3, and the density of spores in hospital air is a direct function of the level of filtration that is used in a particular unit (1,*3*,*14*,20,*21*,*28*). High-efficiency particulate air (HEPA) filtration and laminar airflow (LAF) are highly effective methods to reduce spore content in hospital air (*3*,19,*28*), but the quality of output air is a function of the quality of the input air and the filtration system cannot effectively control spores generated within the hospital environment. Assessment of hospital air for fungal contaminations is often done using two methods: particle counts and air cultures. Particle counts are very sensitive for *Aspergillus* spores (2–5 μm diameter), but not very specific. Air culture using fungal culture media at 35°C is very useful for identifying real pathogens, but it is more expensive and time-consuming and results are not available for several weeks. Thus, one often uses particle counts initially and reserves air cultures for special situations. The relationship between hospital air spore burden and development of aspergillosis

is controversial. However, most of the research indicates that there may be a direct relationship between spore density and disease. Although no firm threshold value has been established, spore concentrations >1/m^3 are thought to be associated with an increased incidence of disease in susceptible immunocompromised hosts (1,20,*22*,*28*). Extensive molecular epidemiology studies have linked the strains isolated from the patients to those found in the hospital environment (1,*13*,*18*,*21*). Other sources of *Aspergillus* in the hospital may include food, plants, and flowers. A recent source of concern has been hospital water. Anaissie et al. (10,*17*,*29*,*30*,31,*32*) have reported isolation of spores in hospital water and showers identical to those isolated from the patients, both for *Aspergillus* and *Fusarium* spp.

The reservoir and modes of transmission for the Zygomycetes are similar to those of *Aspergillus* (1). Nevertheless, there are numerous reports of infection by direct inoculation from contaminated materials, such as bandages, intravenous or peritoneal catheters, and even tongue depressors. Because outbreaks of zygomycosis from these sources have been reported, such sources should be considered when a cluster of infections resulting from Zygomycetes occurs in a hospital (1,*4*,5,*33*).

PREVENTION: ENVIRONMENTAL AND PHARMACOLOGIC INTERVENTIONS

Preventive strategies work best when the hosts at highest risk are protected with the interventions that have shown the best efficacy and safety. This is as true for healthcare-associated filamentous fungal infections as for any other area of medicine. Interventions that protect against these infections can be classified in two categories: environmental and pharmacologic. Table 41-3 summarizes current preventive strategies for healthcare-associated acquisition of filamentous fungal infections. Environmental measures are safe and generally presumed effective in preventing these types of infections, although their cost can range from very affordable (e.g., plain surgical masks) to highly expensive (e.g., modifications in hospital infrastructure and physical plant). Pharmacologic measures have been extensively studied, and they do not necessarily pertain to the specific prevention of healthcare-associated acquisition of these diseases but to general prophylaxis of fungal infection in susceptible hosts.

As discussed previously, *Aspergillus* is ubiquitous in the environment, but there are certain conditions that may cause it to overgrow or disseminate: humidity and construction. Environmental control measures are designed to avoid these two phenomena and minimize patient exposures to spores. The simpler measures include avoiding, limiting, or containing construction in patient care areas; using plain surgical masks or high-efficiency masks (there are no clear data to support one over the other) when patients are transported through construction areas (34); prohibiting live plants and flowers in patient rooms; disinfecting showers and wet surfaces; and repairing faulty air handlers (31). The more sophisticated and highly effective measures include HEPA air filtration and LAF, which are generally reserved for the rooms or wards housing bone marrow transplant patients or patients undergoing induction chemotherapy. These measures have data to support their use, but their high cost makes them only worthwhile for programs or facilities with a high volume of high-risk patients, such as cancer and transplant centers (*3*,19,*22*).

TABLE 41-3

Preventive Measures in High-Risk Hosts for Healthcare-Associated Infections Caused by Filamentous Fungi

- High-efficiency particulate air filtration
- Laminar airflow rooms
- Limitation or containment of hospital construction
- Use of plain surgical masks or high-efficiency masks when traveling outside protected environments, particularly through construction areas
- Mold remediation for air ducts, carpets, wall panels, showers, etc.
- Antifungal prophylaxis in high-risk hosts
- Control of underlying risk factors
- Limitation of duration of neutropenia with less immunosuppressive regimens

Pharmacologic prophylaxis has also been shown to be effective and safe in selected populations at high risk. Again, these interventions are not specific to healthcare-associated transmission, but they are becoming the standard of care for selected immunocompromised populations, which include induction chemotherapy, patients with prolonged neutropenia *(35)*, organ transplant recipients, hematopoietic stem cell transplant recipients, and patients with hematologic malignancies (36,*37*,38). Current prophylaxis options relevant to filamentous fungi include amphotericin B (intravenous, low dose at 0.1 mg/kg daily or full doses at 0.7–1.0 mg/kg weekly), nebulized amphotericin B and its lipid-based preparations *(39–41),* and the use of new agents such as voriconazole *(42)*, posaconazole *(43)*, and the echinocandins (*44*).

INFECTION CONTROL CONSIDERATIONS

As stated previously, the frequency of these infections is on the rise, and the problem becomes relevant mostly for centers that handle large volumes of immunocompromised patients. These centers should organize active surveillance programs to detect clusters of filamentous fungal infection, which may indicate environmental contamination. Such centers should consider HEPA filtration and LAF units and have construction, environmental sampling and cleaning, and patient transport policies designed to minimize exposure. It is also helpful to have prophylaxis protocols in place for the patients at highest risk.

Environmental sampling is not routinely recommended, but may be indicated during investigations of suspected clusters or outbreaks of infection. There are no standards for indoor quality of air in hospitals. As noted previously, particle counts and air cultures for molds are useful tools in those selected situations in which one must identify and

remediate contaminated areas. The principal goal of testing is to ensure that the hospital's air filtration equipment is functioning correctly and, thus, delivering the cleanest air possible for the system.

For general acute-care hospitals, appropriate general healthcare-associated infection surveillance should be enough to detect clusters of fungal infections. Investigation of such clusters of infection should include a search for possible reservoirs for the filamentous fungus, evaluation of the hospital ventilation system, moisture problems, and sites where outside air may be mixing with the inside air (see also Chapters 82–84).

As medical technology and interventions advance and patients live longer, these filamentous fungal infections will become more common. Infection control programs will increasingly acknowledge their relevance as healthcare-associated infections.

PART D. Viral Infections

CHAPTER 42

Influenza Viruses

William M. Valenti

Influenza continues to be an important cause of morbidity and mortality in hospitalized and long-term care patients, particularly among the elderly and those with chronic underlying diseases. Effective strategies for influenza prevention must be multifaceted because of the uniqueness of the influenza viruses, including their seasonal nature, antigenic drift, and antigenic shift. Because all known influenza A subtypes exist in aquatic bird reservoirs, influenza is not an eradicable disease *(1,2)*. Instead, prevention by vaccination and containment are the most realistic public health strategies for influenza control. Continued public health surveillance of influenza in humans and in animal reservoirs is a key element of these prevention and control strategies *(1)*. In healthcare settings, the best approach to seasonal influenza prevention is a vaccination program starting in the fall of each year or as soon as the vaccine is available. Limitations for prevention by vaccination include inconsistent use and underuse of vaccines and problems with incomplete immunity despite vaccination, especially in the elderly, people with chronic underlying illnesses, immunosuppression (e.g., human immunodeficiency virus [HIV] infection and bone marrow suppression), and young children (3).

BACKGROUND

The subtypes of influenza A virus are classified on the basis of their surface antigens, called hemagglutinins (H) and neuraminidases (N). There are three hemagglutinins (H1, H2, and H3) and two neuraminidases (N1 and N2). Immunity to these antigens reduces the likelihood of infection and reduces the severity of illness if it does occur. However, antigenic drift and antigenic shift (i.e., subtle and marked changes, within a subtype, respectively) make long-lasting immunity difficult to achieve. Of the two antigenic changes, antigenic drift is the more gradual, with the H and N subtypes retaining some similarity as changes occur. Antigenic shift is a more abrupt change in H or N subtype, which occurs at longer intervals (e.g., approximately every 10 or more years). When the marked changes of antigenic shift occur, infection or vaccination with one strain may not necessarily induce immunity to distant strains, even though they are of the same subtype. Influenza B is more antigenically stable than influenza A and undergoes antigenic drift, but not the major structural changes of antigenic shift.

Effectiveness of influenza vaccine is determined by the closeness of the vaccine-induced antibody to the H and N surface antigens of influenza A and B. Influenza vaccine loses its protective effects as more major shifts of influenza H and N surface antigens or subtypes occur.

The nomenclature for influenza strains is a useful way to better understand that particular strain. The standard way of describing strains includes the serotype, host of origin (human unless otherwise specified), geographic origin, strain number, year of isolation, and the H and N designation.

Recommendation for trivalent influenza vaccine (TIV) components is based on surveillance data related to epidemiology and antigenic characteristics *(4)*, serological responses to previous vaccines, and the availability of candidate strains and reagents (3,*4*). For the 2010–2011 influenza season, TIV will include a component of the recently emerged H1N1 strain *(4)*. For the H1N1 component, an A/California7/2009-like virus (the pandemic strain) will replace the Brisbane/59/2007 strain. For H3N2, the A/Perth/16/2009-like virus will replace A/Brisbane/10/2007. For type B, the B/Brisbane/60/2008-like strain (the same as 2009–2010) will be used.

VACCINATION AND INFLUENZA-RELATED VIRUS MORBIDITY AND MORTALITY

The so-called high-risk groups for influenza and its complications include older persons (i.e., 65 years of age or older), very young children, and persons of any age with certain underlying health conditions, who are at increased risk for hospitalization, death, and other complications. During major epidemics, hospitalization rates for high-risk persons may increase two- to fivefold. Despite this, only about 30% of people aged 65 years or older are vaccinated

with influenza vaccine every year (3). Many outbreaks are reported from nursing homes and long-term care facilities *(5–7)*, in part because of underuse of vaccine in these vulnerable, closed populations (see Chapter 97). In addition to underuse of vaccine, many high-risk people fail to develop a protective antibody response to vaccination *(5,6)*. Outbreaks have also occurred in general hospitals, psychiatric units, and medical and pediatric services (3). This underuse of vaccine is a major contributor to outbreaks of influenza in healthcare facilities with associated morbidity and, on occasion, mortality.

As the population ages, the risk of seasonal influenza death increases. Thompson et al. reported that the death rate from influenza rose markedly in the 1990s, and in 2001 it exceeded the number of deaths due to acquired immunodeficiency syndrome (AIDS) *(7)*. Annual estimates of influenza-associated deaths increased significantly between the 1976–1977 and 1998–1999 seasons, with a mean of 20,000 and 36,000 deaths, respectively. Ninety percent of respiratory and circulatory deaths occurred in persons aged 65 years or older. Since its emergence in the 1960s, type A (H3N2) epidemics have caused approximately 400,000 deaths in the United States alone, and >90% of these deaths have occurred in people older than 65 years *(8)*. Prior to the reemergence of influenza A (H1N1) in 2009, the H3N2 had the most severe overall impact (*2*,9). An unexpected trend with the 2009 pandemic influenza H1N1 strain, on the other hand, was a higher attack rate in people younger than 65 years, outside the traditional high-risk groups (10). Early data from the 2009 pandemic influenza A (H1N1) outbreak in Mexico indicated that attack rates among persons aged 65 years or older were lower than those in other age groups and that anti-influenza A antibodies that cross-react with 2009 H1N1 could be detected in up to one third of healthy adults aged older than 60 years (*11*,12,*13*).

Despite this new trend with pandemic influenza A (H1N1), it is important to keep in mind the impact of influenza on elderly and chronically ill patients. Gross et al. characterized two typical nursing home outbreaks of seasonal influenza A *(5,6)*. One began in November, peaked in February, and ended in April. The outbreak progressed slowly and was complicated by concurrent infections with respiratory syncytial virus, parainfluenza virus, and *Mycoplasma pneumoniae*. The patient population in this case had an immunization rate of 59%, affording it some degree of herd immunity. The authors contrast the pattern of slow spread in this closed, partially immunized population to the more explosive outbreaks described in open, unimmunized populations (e.g., acute care settings and psychiatric services) (*8*,9). In the outbreak, influenza illness was significantly more common in the unvaccinated group, as was mortality (17.7% in the unvaccinated group and 7.2% in the vaccinated group). When controlled for sex and severity of illness, influenza vaccine reduced mortality by 59% in this closed, partially vaccinated population *(6)*.

Patriarca et al. developed a useful model to project morbidity, mortality, and costs associated with type A influenza illness in nursing homes *(14)*. The model used demographics similar to the real world of long-term care: 100 residents and a 60% rate of vaccination in the fall of the prior year. In this model, the combination of previous vaccination and amantadine during outbreaks was associated with significantly fewer cases compared with vaccine alone, probably because of the <100% efficacy of vaccine. The authors predicted an increase in herd immunity as more patients were vaccinated beyond the 60% receiving it initially, and when 70% received vaccine, the risk of an outbreak approached zero. They concluded that influenza control programs in nursing homes are beneficial, clinically sound, and cost-effective and have a modest increase in program costs with the addition of amantadine. More recent studies have shown that vaccination of both healthcare providers (HCPs) and patients is associated with fewer deaths among nursing home patients *(15)* and elderly hospitalized patients *(16)*. These data support the Advisory Committee on Immunization Practices' (ACIP) target of 90% vaccine use in populations at risk (3) and the 2005 requirement from Centers for Medicare and Medicaid Services (CMS) that nursing homes participating in the CMS programs offer all residents influenza and pneumococcal vaccines and document the results *(17)*. Each resident is to be vaccinated unless contraindicated medically, the resident or a legal representative refuses vaccination, or the vaccine is not available because of shortage. This information is to be reported as part of the CMS Minimum Data Set, which tracks nursing home health parameters (*18*,19).

CLINICAL MANIFESTATIONS

Typical influenza illness in the adult is characterized by sudden onset of fever, myalgia, sore throat, headache, retroorbital pain, and nonproductive cough. Unlike most other viral respiratory infections, influenza causes myalgias and other constitutional symptoms that can last a week or more. However, the sensitivity and the positive predictive value of fever, cough, and/or other symptoms for the diagnosis of influenza virus infection in severely ill or hospitalized patients are lower than those in the community *(20)*. The use of these common symptoms for treatment decisions and infection control management will probably be insufficient to contain a healthcare-associated outbreak, because many influenza cases will remain unidentified.

Some patients with influenza A may develop additional complications of primary influenza pneumonia or secondary bacterial pneumonia most often resulting from *Streptococcus pneumoniae* or *Staphylococcus aureus (21)*. These complications are not associated with influenza B infection, which is usually a milder illness.

Influenza in adults is first and foremost a respiratory disease. The term "intestinal flu" in adults is generally a misnomer *(22)*. The illness in children, on the other hand, may have a major gastrointestinal component or may mimic sepsis *(22,23)*. In an influenza A outbreak on a pediatrics ward, 7 of 12 infected children (58%) developed pulmonary infiltrates and 5 of the 7 went on to develop a secondary bacterial pneumonia. In the young infant, influenza may mimic sepsis with fever and no localizing findings *(23)*.

DIAGNOSIS

Diagnostic tests available for influenza include viral isolation (culture), rapid antigen testing, nucleic acid amplification testing by the polymerase chain reaction (PCR)

TABLE 42-1

Summary of Diagnostic Tests for Influenza

Method	*Influenza Types Detected*	*Acceptable Specimens*	*Time for Results*
Virus isolation (culture)	A and B	Nasopharyngeal swab, throat swab, nasal wash, bronchial wash, nasal aspirate, sputum	3–10 d
Immunofluorescence	A and B	Nasopharyngeal swab, nasal wash, bronchial wash, nasal aspirate, sputum	2–4 h
Polymerase chain reaction	A and B	Nasopharyngeal swab, throat swab, nasal wash, bronchial wash, nasal aspirate, sputum	2–4 h
Enzyme immunoassay	A and B	Nasopharyngeal swab, throat swab, nasal wash, bronchial wash	2 h
Serology	A and B	Paired acute and convalescent serum samples 2–4 wk apart	2 wk or more
Rapid diagnostic tests			
Multiple manufacturers	Depends on manufacturer—may distinguish between A and B or may be positive for influenza virus, type not specified	Nasal wash, nasopharyngeal swab, throat swab, and other specimens, depending on manufacturer	≤15 min

(Adapted from Centers for Disease Control and Prevention. H1N1 flu: interim guidance for the detection of novel influenza A virus using rapid influenza diagnostic tests. Available at *http://www.cdc.gov/h1n1flu/guidance/rapid_testing.htm*. Accessed May 9, 2011.)

method, and immunofluorescence (3,24) (Table 42-1). The two latter tests are the most useful laboratory techniques for prospective, real-time diagnosis of influenza. Sensitivity and specificity of these tests may vary with the laboratory performing the test, the type of test used, and the type of specimen tested. The preferred specimens for testing are nasopharyngeal specimens whenever possible; these are typically more sensitive than throat swab specimens (25). Clinical judgment plays an important role, and as with any diagnostic test, results should be evaluated in the context of the available clinical information.

A positive rapid diagnostic test allows for more timely institution of therapy and infection control precautions. However, the specificity (90%–95%) and the sensitivity (50%–75%) of rapid tests vary by manufacturer and are lower than those for viral culture. Because of the lower sensitivity of rapid tests, providers should consider confirming negative tests with PCR testing based on their clinical judgment.

Rapid tests differ in several important respects. Some distinguish between influenza A and B viruses, and others cannot. Some tests are waived from requirements under the Clinical Laboratory Improvement Amendments of 1988. Most tests can be used with a variety of specimen types (Table 42-1), but the accuracy of the tests may vary based on the type of specimen collected (e.g., throat vs. nasal swabs). The additional advantage of PCR testing over rapid tests is their ability to provide specific information regarding circulating influenza subtypes and strains. If PCR testing is not readily available locally or via reference laboratory, immunofluorescence tests or virus isolation are good alternatives.

Acute- and convalescent-phase serologies (antibody determination) are a helpful epidemiologic or public health tool retrospectively, but may be neither widely available nor useful for clinical real-time decision making or for prospective surveillance.

Diagnosis of influenza can also be made using epidemiologic parameters in combination with clinical and laboratory findings. When influenza is prevalent in the community, adult patients with acute febrile respiratory illness can be assumed to have influenza virus (3,*26*), keeping in mind that other viral respiratory illnesses such as respiratory syncytial virus and adenovirus can overlap with influenza disease (3). This approach to diagnosis and empiric therapy may be necessary during periods of widespread influenza activity when laboratory capacity is exceeded, as was the case with the novel H1N1 influenza in 2009–2010 *(27)*.

EPIDEMIOLOGY

Surveillance and Monitoring

The Centers for Disease Control and Prevention (CDC) conducts influenza surveillance year round in the United States as part of a worldwide collaborative surveillance system (*2*,3). This activity monitors a variety of state and local health departments, public health and clinical laboratories, sentinel physician practices, and reports of pneumonia and influenza deaths from a sampling of vital statistics offices throughout the United States. These so-called FluView data are reported weekly on the Internet *(28)*.

Once influenza establishes itself in the community, sporadic cases may be seen in both HCPs and patients. In healthcare settings, employee absenteeism for influenza-like illness (ILI) often precedes an outbreak by several weeks, suggesting transmission from healthcare worker

(HCW) to patients *(2,13,29)* or the opposite *(29,30)*. Either way, healthcare-associated influenza increases hospital days and costs of hospitalization; in one study the cost was $3798 per infected patient in 2002 US dollars *(29)*. Cost-effectiveness studies of adults younger than 65 years indicate that vaccination can reduce both direct medical costs and indirect costs from work absenteeism *(31)*, resulting in 13% to 44% fewer HCP visits, 18% to 45% fewer lost workdays, 18% to 28% fewer days working with reduced effectiveness, and a 25% decrease in antibiotic use for ILI *(31)*. Among healthy persons aged 18 to 64 years, vaccination can save an estimated $60 to $4000 per illness, depending on the cost of vaccination, the influenza attack rate, and vaccine effectiveness against ILI *(32)*. Among studies of healthy young adults, >70% of the costs prevented were associated with reductions in lost work productivity *(32)*.

In healthcare settings, prospective monitoring and surveillance of influenza-like respiratory illness are of greatest value when accompanied by an influenza vaccination program to prevent illness in HCPs. Monitoring local or regional influenza and respiratory virus surveillance data can provide key indicators of the need for heightened awareness of influenza in healthcare settings.

Influenza as an Emerging Infectious Disease

In April 2009, a novel H1N1 influenza A virus, the so-called pandemic H1N1/09 virus (former designations include swine influenza, novel influenza, swine-origin influenza A [H1N1] virus [S-OIV], Mexican flu, and North American flu), was identified in Mexico (*2*,9,10). The virus subsequently reached pandemic level 6—the World Health Organization's highest designation—based not on mortality, but on geographic distribution *(33)*. This represents the first influenza A virus pandemic since the emergence of H3N2 (Hong Kong flu) in 1968. Although the pandemic H1N1/09 virus originated from the triple-reassortment swine influenza (H1) virus circulating in North American pigs, it is not epidemic in pigs. The initial waves of the H1N1/09 virus were relatively short-lived, and concerns remain that it may become more aggressive during spreading, based on the historical behavior of pandemic H1N1 strains (9,*34*).

Novel influenza viruses have the potential to initiate global pandemics if they are sufficiently transmissible among humans (*1*,9,*34*). Recent experience with the avian H5N1 influenza A strain—first identified in 1995 in Asia—supports the value of continued public health surveillance and containment *(35)*. Both the avian H5N1 and H1N1/2009 outbreaks demonstrate that influenza is still a serious public health issue and that global epidemiologic surveillance is an important public health tool for prevention and control of influenza, and early detection by global surveillance played an important role in tracking and containing these outbreaks.

Modes of Transmission

Influenza A and B viruses are among the most communicable viruses of man and have produced explosive epidemics. Transmission of both influenza A and B in healthcare settings is well documented. In healthcare settings, HCPs, patients, or visitors can be a reservoir of infection. Once infection is established and infection is being transmitted, infection control interventions, including vaccination, need to include all three groups as part of an outbreak control plan.

Humans are reservoirs of infection, and person-to-person transmission is thought to occur primarily via fomites (droplet spread) and hands contaminated with virus (3,19,*34*). Larger droplets require closer person-to-person contact for virus transmission, generally <3 ft separating two persons. These large droplets are produced by coughing or sneezing and can infect the susceptible host directly or indirectly. Direct transmission involves direct inoculation of mucous membranes of the eye or nose. Indirect transmission refers to contamination of the donor's hands, which spread infectious material to the skin or mucous membranes of a susceptible host.

In other cases, small-particle aerosols (<10 μm median diameter) containing infectious virus particles are produced and disseminated by coughing or sneezing. These small-diameter infectious virus particles can be transmitted over long distances (>6 ft). The aerosol mode of transmission may be responsible for the explosive nature of influenza transmission, with one infected person shedding large numbers of infectious virus particles and subsequently infecting a large number of susceptible people (3,*35*).

CONTROL AND PREVENTION OF INFLUENZA

Control of influenza requires herd immunity, which requires that large numbers of people in a particular group at risk be immune to infection (9,*14*). There are two approaches to reduce the impact of influenza infection: inactivated influenza vaccine (immunoprophylaxis) and antiviral drugs (chemoprophylaxis). Antiviral drugs are a useful adjunct when herd immunity is not present because of underuse of vaccine and/or inadequate protective antibody response to vaccination (36).

Vaccination

As influenza viruses continue to evolve through antigenic shift and antigenic drift, new strains emerge to which the population is susceptible. Therefore, annual vaccination is recommended using the current TIV for that year, even if the current vaccine has one or more antigens administered in the previous year's formulation (3,*4*). This is because immunity declines over a year's time, and an annual booster dose is required to maintain immunity to influenza strains that appear in the general population each year.

Influenza vaccination is the cornerstone of prevention and control of healthcare-associated influenza. Vaccine efficacy (i.e., the rate of reducing influenza infections in those who receive it) ranges from 80% to 90% in healthy individuals *(2)* to 50% in some nursing home populations (3).

During the preparation of TIV, the vaccine viruses are made noninfectious (i.e., inactivated or killed) (37). Only subvirion and purified surface antigen preparations of TIV (often referred to as "split" and subunit vaccines, respectively) are available in the United States. TIV contains killed viruses and thus cannot cause influenza. It is administered intramuscularly by injection for use among persons aged 6 months or older, including those who are healthy and those with chronic medical conditions. The

live attenuated influenza vaccine (LAIV) discussed below has the potential to cause mild signs or symptoms (e.g., runny nose, nasal congestion, fever, or sore throat). This formulation is administered intranasally by sprayer and is licensed for use in nonpregnant women aged 2 to 49 years; safety has not been established in persons with underlying medical conditions that confer a higher risk for influenza complications (37).

Beyond the obvious benefits of decreasing the risk of influenza transmission to patients, influenza vaccination of HCPs contributes to increased worker productivity and decreased absences (38). Using trivalent, seasonal vaccine, 264 HCPs from two Baltimore teaching hospitals were enrolled in a randomized trial of influenza vaccine versus placebo (meningococcal vaccine). Subjects were followed for clinical illness and were tested for serologic evidence of influenza A and B infections at baseline and at the end of the influenza season. The investigators conducted 359 person-winters of serologic surveillance (99.4% follow-up) and 4746 person-weeks of illness surveillance (100% follow-up). Twenty-four (13.4%) of 179 control subjects and 3 (1.7%) of 180 influenza vaccine recipients had serologic evidence of influenza type A or B infection during the study period. Vaccine efficacy against serologically defined infection was 88% for influenza A ($p = .03$).

In general, the passive approach to vaccination that announces vaccine availability in anticipation of employees being vaccinated does not achieve meaningful vaccination uptake. More active approaches include making vaccine available to staff on all shifts on patient units and education of HCPs that dispels misinformation and emphasizes the importance and safety of influenza vaccination.

A program that administered TIV in a neonatal intensive care unit (NICU) targeting parents of patients was attributed to an increase in vaccine uptake in NICU staff *(39)*. Among parents, 95% were vaccinated (with informed consent). Of 120 neonatal HCPs, 112 (93%) were screened during the 2005–2006 season; 80 (67%) were vaccinated, compared with 49 (41%) prior to the implementation of this program ($p = .03$); 54 (45% of the study population, which included senior neonatologists, fellow and resident physicians, nurses, respiratory therapists, X-ray technicians, and clerical staff) received TIV in the NICU, compared with the 17 (14%) of 120 HCWs the previous year; and 20 (46%) of 43 HCWs of the nursing staff were vaccinated in the NICU, whereas only 3 (7%) of 43 HWCs were vaccinated outside the unit.

Overall, the effort was judged an effective means of increasing the vaccination rate among NICU HCWs. Still, attending physicians had the lowest vaccination rate (1 of 7 [15%]), and most cited efficacy issues and/or side effects as reasons for deferral. Nurses refused vaccination most often because of fear of injection (20 of 43 [46%]).

To increase vaccination uptake, educational efforts for nurses should emphasize the risk of influenza transmission to neonates as motivation for vaccination. Physician-directed efforts should include tolerability of vaccine side effects. LAIV, administered intranasally, should be considered to increase vaccination rates among healthy HCPs who have fear of injections.

However, vaccination on patient units is not always a guarantee of success. Weinstock et al. reported on their efforts in a bone marrow transplant unit *(40)*. After an outbreak on the unit in January 1998, they took a "new, more rigorous approach" during the following influenza season. Their approach focused on HCP education accompanied by vaccination on the transplant unit. Vaccine uptake improved from 12% in the prior season to 58%. The 42% of staff who remained unvaccinated is particularly sobering in view of an influenza outbreak in patients on the unit the year before. While this increase is significant, this degree of vaccine acceptance probably falls short of the optimal herd immunity needed to impact influenza prevention.

One study reviewed vaccine use in HCWs systematically by comparing responses to questionnaires from vaccine recipients and nonrecipients. Vaccine recipients were significantly more likely to believe that influenza disease and its complications were more serious to high-risk patients, that influenza vaccine was effective and uncommonly associated with side effects, and that influenza vaccination was important for HCPs to decrease transmission to high-risk patients *(41)*. The authors concluded that these issues were the major educational components of a vaccination program for HCWs. However, a European study showed that even educational interventions targeted to specific HCPs' misinformation or misunderstandings only increased vaccine use by HCWs in three targeted departments from 13% to 37% *(41,42)*.

The challenge for healthcare facilities involves overcoming barriers to unacceptably low rates of vaccination of both HCWs (including physicians) and patients. The general public and HCPs alike have misconceptions that the vaccine can cause illness (37) (e.g., that vaccine can "cause the flu" and/or the—[GBS]). The possible link between influenza vaccine and GBS first emerged during the nationwide swine influenza vaccination program (A/New Jersey/76) in 1976 and was raised again during the H1N1/2009 vaccination campaign (43).

Influenza vaccines are made from egg-grown viruses that are rendered inactive as part of the vaccine-manufacturing process and cannot cause influenza (3,37). Also, education programs should include a reminder that influenza vaccine provides immunity to influenza only and that it does not provide protection from other respiratory viruses such as respiratory syncytial virus or the rhinoviruses (37).

GBS appears to have been unique to the A/New Jersey/76 vaccine strain, with an overall rate of 4.9 to 5.9 cases of GBS per million vaccinees among 45 million people vaccinated *(44)*. The nature of the association of A/New Jersey/76 vaccine with GBS remains unclear *(45)*, but the association is likely multifactorial, according to more contemporary analyses (*45*,46). In retrospect, the data on the swine flu vaccination program of 1976 did made a case for a "slight increase" in the risk of GBS *(45)*. That experience was an aberration, since the risk increased only in 1976 and only among civilians in the United States. Vaccines containing swine flu virus that were prepared in England and the Netherlands were associated with no such increase in risk. Moreover, 1.7 million US servicemen who received double doses of the vaccine against swine influenza had no adverse effects *(45)*.

One argument for a direct relation between GBS and preceding infections derives from experience with the enteric pathogen *Campylobacter jejuni*, which precedes GBS in

30% to 40% of cases as detected by serologic tests, even in the absence of enteritis *(45)*. The hypothesis is that *C. jejuni* is a contaminant in chicken eggs that may also contaminate influenza vaccine during the vaccine-manufacturing process. The presence of a lipopolysaccharide antigen on some *C. jejuni* strains is shared with ganglioside epitopes of peripheral nerves. The connection between campylobacter infection and the GBS supports a theory of cross-reactivity, or "molecular mimicry," in which the immune response directed toward an infectious agent spills over to involve a neural antigen *(47)*.

However, in recent years, GBS has not been reported as a complication of H1N1 monovalent vaccine use (37). One reason may be that vaccine formulations in years subsequent to the 1976 H1N1 vaccine have not been associated with vaccine-associated GBS (*2*,37,46).

With underuse of vaccine in major populations at risk (i.e., HCPs, the elderly and chronically ill, and persons likely to spread influenza to high-risk people), influenza prevention programs in many healthcare settings are often haphazard and incomplete and, instead, react when clusters or outbreaks of infection occur. Even though a substantial number of HCWs and patients have not been vaccinated at the time of the first report of influenza, the arrival of influenza in the community and/or hospital is still a good time to vaccinate these groups, keeping in mind that the time from vaccination to protective antibody response is about 2 weeks.

Other Strategies to Improve Vaccination Uptake

Despite the efficacy of vaccine and a public health commitment to childhood and adult immunization, fewer than 30% of persons aged 65 years or older receive the influenza vaccine each year (3). The collective experience of public health and infection control experts is that promoting influenza vaccination, or any other kind of vaccination, requires more than just posters announcing the availability of vaccine (3,*41*,*42*). A recent review of strategies for management of influenza in the elderly provides a comprehensive review of this important subject *(42)*.

Beyond recommending universal influenza vaccination, other more active strategies are being discussed and adopted in some healthcare settings. Standing orders for vaccination is an effective strategy for increasing influenza vaccine uptake in patients (3,*18*). In 2002, CMS relaxed their physician signature requirement for influenza and pneumococcal vaccination, allowing nurses and pharmacists to administer vaccination using standing orders in accordance with state rules on the matter (*17*,*18*,19). In a university ambulatory setting, larger numbers of patients whose physicians used standing orders for influenza vaccination received vaccine compared with patients whose physicians did not (63% vs. 38%, respectively) *(48)*. Guidance on standing orders is available for mass vaccination clinics as well *(18)*.

Efforts should be made to administer vaccine where people receive their medical care, generally physicians' offices, clinics, and urgent care settings, to name a few. Vaccine administered during an inpatient admission avoids another "missed opportunity." Other elements of a successful vaccination program are education for HCWs, a plan for identifying the highest risk patients (often by review of medical records), and efforts to remove administrative and financial barriers that prevent people from receiving vaccine (3). In primary care settings, computer-generated reminders to physicians have been effective *(49)*. Physicians who received such reminders as a part of a study were twice as likely to vaccinate their patients as those physicians who did not receive the reminders.

The optimal time to receive seasonal influenza vaccine is during October and November, or as soon as vaccine becomes available. However, because of vaccine distribution delays, the ACIP recommends a staggered approach so that early vaccination efforts focus on persons at greatest risk followed by other high-risk people as more vaccine becomes available (3).

In HCPs, vaccine should be administered in the workplace (e.g., patient units, at large conferences, cafeterias, ambulatory clinics, and physician private offices) to maximize participation. Making influenza vaccine available to employees is no guarantee of acceptance. However, offering free vaccine, addressing employee concerns about vaccine safety and adverse events, and making vaccination more convenient and accessible to employees reduce some of the barriers to an effective program for HCWs.

Simultaneous use of other vaccines with influenza vaccine is safe, effective, and eliminates the need for a return visit for additional vaccines. Influenza vaccine can be included as part of any healthcare encounter that includes other adult or childhood vaccinations. Because the target groups for influenza and pneumococcal vaccines overlap, both vaccines can be administered at the same time at different sites without increasing side effects of either vaccine (3). Children at high risk for influenza may receive influenza vaccine at the same time as measles—mumps—rubella, Haemophilus influenzae B, pneumococcal, and oral polio vaccines. Vaccines should be administered at different sites on the body, and influenza vaccine should not be given within 3 days of administration of pertussis vaccine (3).

Innovative Influenza Vaccination: LAIV

The LAIV is another option for HCPs who are healthy, younger than 50 years old, and not pregnant. This vaccine, delivered by an intranasal spray, has been shown to be equivalent to the injectable trivalent formulation in terms of safety and efficacy *(50)*.

Healthcare professionals who provide care to newborn infants (including neonatal intensive care patients), pregnant women, persons with a solid organ transplant, persons receiving chemotherapy, and persons with HIV/AIDS may receive LAIV if otherwise eligible (51). However, LAIV should not be used for HCPs who care for patients undergoing bone marrow transplantation. Although these immunocompromised patients have not been shown to be harmed by use of LAIV among HCPs, the recommendation against the use of LAIV in HCWs with this type of patient contact is an extra precaution for fragile immunocompromised patients. HCWs with this type of patient contact who receive LAIV should wait for 7 days after being vaccinated before returning to caring for bone marrow transplant recipients. No special precautions (e.g., masks or gloves) are necessary for healthcare personnel who have been vaccinated with the LAIV and who do not work with patients undergoing bone marrow transplantation (51).

Influenza Vaccination as a Measure of Quality

Healthcare administrators should consider the level of vaccination coverage among HCPs as a measure of a patient safety/quality program and consider obtaining signed declinations from personnel who decline influenza vaccination for reasons other than medical contraindications. Influenza vaccination rates among HCPs within facilities should be regularly measured and reported, and ward-, unit-, and specialty-specific coverage rates should be provided to staff and administration. Studies have demonstrated that organized campaigns can attain higher rates of vaccination among HCPs with moderate effort and by using strategies that increase vaccine acceptance (3).

Efforts to increase vaccination coverage among HCPs are supported by various national accrediting and professional organizations and in certain states by statute (3,*52*). The Joint Commission on Accreditation of HealthCare Organizations (2007) has approved an infection-control standard that requires accredited organizations to offer influenza vaccinations to staff, including volunteers and licensed independent practitioners with close patient contact. In addition, the Infectious Diseases Society of America has recommended mandatory vaccination for HCPs, with a provision for declination of vaccination based on religious or medical reasons. Some states have regulations regarding vaccination of HCPs, that require that healthcare facilities offer influenza vaccination to HCPs or require that HCP either receive influenza vaccination or indicate a religious, medical, or philosophic reason for not being vaccinated (3).

Other Approaches to Influenza Vaccination

The increased H1N1 influenza activity of 2009–2010 has resulted in a reevaluation of our approach to influenza vaccination. Previously, the ACIP recommended that annual influenza vaccination should include all people aged 6 months or older. Beginning with the 2010–2011 influenza season, the ACIP recommends that everyone who is 6 months or older should receive influenza vaccine *(53)*. This recommendation is an effort to expand protection against influenza to more people, seeks to remove barriers to influenza immunization, and signals the importance of preventing influenza across the entire population *(53)*. This new recommendation comes against a backdrop of incremental increases in the numbers and groups of people recommended for influenza vaccination in recent years and lessons learned from the H1N1 pandemic. Key points in favor of this new guidance are shown in Table 42-2.

Because of the benefits to patients and employees, and the additional implications for increased employee productivity, healthcare settings of any type should offer influenza vaccine to all employees, regardless of their degree of patient contact. Babcock et al. have described a mandatory influenza vaccination program in a large healthcare system in St. Louis, MO, which included approximately 25,000 employees (54). This approach resulted in vaccine uptake of 98.1%, with exemptions allowed for health or religious reasons only. Interestingly, a large number of employees who had previously signed a waiver declining vaccine accepted vaccination once it was mandated. While mandatory vaccination raises the issue of duty to patients versus employee autonomy, the St. Louis experience suggests that duty to patients, patient safety, and quality of care take precedence. In his accompanying editorial, Pavia calls the mandate a clear effort to protect patients from healthcare-associated influenza and describes some of the barriers to implementing such a program, including recent legal challenges (55).

TABLE 42-2

Rationale for Recommendation for Universal Influenza Vaccination

- Previous recommendations for seasonal vaccination already applied to about 85% of the US population
- Protection of people 19–49 y of age, who were hard hit by the 2009 H1N1 pandemic virus, which is likely to continue circulating into next season and beyond
- Many in currently recommended "higher risk" groups are unaware of their risk factor or that they are recommended for vaccination
- Conveys a practical, simple, and clear message regarding the importance of influenza vaccination
- Experience during 2009 H1N1 pandemic indicates that some people who do not have a specific recommendation for vaccination may also be at higher risk of flu-related complications, including those who are obese, postpartum, and in certain racial/ethnic groups

(From Centers for Disease Control and Prevention. CDC's advisory committee on immunization practices [ACIP] recommends universal annual influenza vaccination. Press release: Feb 24, 2010. Available at *http://www.cdc.gov/media/pressrel/2010/r100224.htm.* Accessed May 9, 2011.)

Others have described the role of mandatory influenza vaccination in a larger context (*56*,57). Using mandatory school vaccination programs as a starting point, Malone and Hinman offer an historical and balanced discussion of the public health benefits of vaccines versus individual rights, including the legal precedents supporting mandatory vaccination *(56)*. Orenstein et al. discuss the matter from a different viewpoint, but make a compelling case for vaccines as public health tools (57). Jefferson offers a counterpoint to the mandatory influenza vaccination, citing a gap between policy and evidence *(58)*.

Antiviral Agents for Influenza

Two classes of antiviral drugs are approved by the U.S. Food and Drug Administration (FDA) for treatment and prevention of influenza virus: M2 ion channel blockers (adamantanes) and neuraminidase inhibitors (NAIs). Historically, these agents are adjuncts to vaccination and not a substitute (*59*,60). The M2 blockers are effective against influenza A viruses, but not influenza B viruses, which lack the M2 protein. The use of the M2 blockers has been associated with the rapid emergence of drug-resistance mutations of the M2 protein among human influenza A viruses of H3N2 subtype; and in H1N1 subtype, viruses circulating in certain geographic areas (60,*61*).

Since 1960s, H3N2 has tended to dominate in prevalence over H1N1, H1N2, and influenza B, at least prior to the reemergence of the pandemic H1N1/2009 strain. Measured resistance to the standard antiviral drugs amantadine and rimantadine in H3N2 has increased from 1% in 1994

to 12% in 2003 to 91% in 2005 (9). Adamantane resistance has also been detected in A (H5N1) viruses in Southeast Asia (10,*11*). This rapid increase in resistance has reduced the usefulness of this class of drugs for the management of influenza A infections, and since 2005, CDC has not recommended their use *(61,62)*; the emergence of resistance to oseltamivir in seasonal influenza viruses circulating during the 2008–2009 season also led to changes in CDC recommendations *(63)*.

Two NAIs, oseltamivir (Tamiflu [Hoffman-La Roche]) and zanamivir (Relenza [GlaxoSmithKline]), are FDA-approved drugs for use against type A and type B influenza infections *(64,65)*. The two drugs differ structurally so that oseltamivir is orally bioavailable, whereas zanamivir must be inhaled. A third NAI, peramivir (BioCryst, Inc.), is formulated for intravenous administration and is undergoing clinical trials *(66)*. A fourth, called A-315675 (Abbott Laboratories) has only been investigated in preclinical studies.

The dosages, indications, and duration of use for the FDA-approved drugs are summarized for patients older than 1 year in Table 42-3 and for children younger than 1 year in Table 42-4.

TREATMENT

When administered within 2 days of illness onset to otherwise healthy adults, these can reduce the duration of uncomplicated influenza illness (67).

In 2009, the FDA issued an Emergency Use Authorization for peramivir, which may be used in certain hospitalized adult and pediatric patients with confirmed or suspected 2009 H1N1 influenza *(66)*. It is the only intravenous option for the treatment of patients with 2009 H1N1 influenza. Other guidance for use of these agents is discussed in more detail elsewhere (67).

TABLE 42-3

Dosing of Oseltamivir and Zanamivir for Treatment and Prevention for 2009 H1N1 Influenza

	Ages 1–12 y	*Ages 13 ≥ 65 y*
Oseltamivir tablets[a]		
Treatment twice daily × 5 d	<15 kg, 30 mg	75 mg
Prophylaxis once daily × 10 d	16–23 kg, 45 mg	
	24–40 kg, 60 mg	
	>40 kg, 75 mg	
Zanamivir inhalation[b]		
Treatment twice daily × 5 d	NA, <7 y	10 mg, ≥7 y
Prophylaxis once daily × 10 d	NA, <5 y	10 mg, ≥5 y

Note: Zanamivir is manufactured by GalxoSmithKline (Relenza—inhaled powder). Oseltamivir is manufactured by Hoffman-LaRoche, Inc. (Tamilflu—tablet). This information is based on data published by the Food and Drug Administration (FDA), which is available at www.fda.gov.
NA, not approved.
[a]A reduction in the dose of oseltamivir is recommended for persons with creatinine clearance <30 mL/min.
[b]Zanamivir is administered through inhalation by using a plastic device included in the medication package. Patients will benefit from instruction and demonstration of correct use of the device.
(Adapted from Centers for Disease Control and Prevention. Guidance on the Use of Influenza Antiviral Agents During the 2010–2011 Influenza Season—Use of Antivirals. Available at *http://www.cdc.gov/flu/professionals/antivirals/antiviral-use-influenza.htm*. Accessed May 9, 2011.)

PROPHYLAXIS

Antivirals for prevention of influenza are not a substitute for vaccination, although they are critical adjuncts for prevention and control. Influenza antivirals are approximately 70% to 90% effective in preventing illness from influenza infection (3,60). Because of widespread resistance of both H1N1 and H3N2 to the adamantanes, the NAIs, oseltamivir and zanamivir, are the first-line drugs for influenza prevention (3). When used as prophylaxis, these agents can prevent illness and still permit subclinical infection and the development of protective antibody against circulating influenza viruses (3). Both drugs have been studied extensively among nursing home populations as a component in influenza outbreak control and can limit the spread of influenza within chronic care facilities

TABLE 42-4

Recommended Doses of Oseltamivir Oral Suspension for Infants Younger than 1 Year of Age

Age (mo)	*Dose (mg)*	*Volume per Dose, 12 mg/mL*	*Treatment Dose (5 d)*	*Prophylaxis Dose (10 d)*
6–11	25	2 mL	2 mL twice daily	2 mL once daily
3–5	20	1.6 mL	1.6 mL twice daily	1.6 mL once daily
<3	12	1.0 mL	1.0 mL twice daily	Not recommended unless critical

(Data from US Food and Drug Administration. Emergency use of Tamiflu in infants less than 1 year of age. Available at *http://www.fda.gov/Drugs/DrugSafety/PostmarketDrugSafetyInformationforPatientsandProviders/ucm183870.htm.* Accessed May 9, 2011.)

(3,*59*). Both NAIs, zanamivir and oseltamivir, are approved for prophylaxis, and community studies of healthy adults indicate that both drugs are similarly effective in preventing febrile, laboratory-confirmed influenza illness (efficacy: zanamivir, 84%; oseltamivir, 82%) (3,*64*,*65*).

To be maximally effective, preventive treatment must be taken each day during the period of peak influenza activity in the community. This approach contributes to managing the development of resistance and helps avoid unnecessary costs and supply chain issues (3,60). Persons for whom prophylaxis is indicated are high-risk persons vaccinated after influenza activity has begun, HCPs who are unvaccinated or were vaccinated after influenza activity has begun who provide care to high-risk patients, immunosuppressed persons who may not respond to vaccination, and persons for whom vaccine is contraindicated (e.g., persons with allergy to egg protein) (3).

None of the four antiviral agents has been demonstrated to be effective in preventing serious influenza-related complications (e.g., bacterial or viral pneumonia or exacerbation of chronic diseases). Data are limited and inconclusive concerning the effectiveness of influenza antivirals for treatment of persons at high risk for serious complications of influenza (3,60). Fewer studies of the efficacy of influenza antivirals have been conducted among pediatric populations compared with adults (3,60). One study compared oseltamivir with the adamantanes and did not identify any new safety signals in terms of neurotoxicity *(68)*, although later, central nervous system toxicity was identified in children in Japan taking oseltamivir. The US FDA advises that persons receiving NAIs be monitored for abnormal behavior and notes that a direct link between behavioral changes and oseltavmivir has not been established *(69,70)*.

Other Therapeutic Options

Recently, the statin class of lipid-lowering agents was reported to be associated with decreased mortality in hospitalized patients with seasonal influenza *(71)*. The use of statins for influenza was first proposed in 2006 as part of the treatment for H5N1 avian influenza *(72)*. Fedson's hypothesis is that influenza is associated with inflammation and an increased risk of cardiovascular diseases. Therefore, the anti-inflammatory and immunomodulatory effects of statins might also help patients with influenza.

More recently, in a retrospective review, statin use was associated with reduced mortality in patients hospitalized with laboratory-confirmed seasonal influenza *(71)*. In these patients, 17 of 801 (2.1%) treated subjects died of influenza or its complications. In the untreated group, 64 of 1999 (3.2%) of the subjects died of influenza or its complications; this represents a 54% decreased risk of death, considering other risk factors, such as age and use of antiviral drugs. The investigators concluded that their results were not sufficient to recommend statins for treatment of influenza. Instead, these data need to be confirmed by more rigorous studies.

OUTBREAK CONTROL

Antiviral administration as an outbreak control measure requires considerable coordination to implement with a minimum of delays (3,*73*). For outbreak control, it is recommended that in closed populations such as nursing homes, patients with influenza taking one of these drugs for treatment be isolated or cohorted from the asymptomatic patients who are taking antivirals for prophylaxis (3,*59*,60,*74*). High-risk individuals can still be vaccinated after an outbreak of influenza A has begun. Because the development of antibodies in adults after vaccination takes 2 weeks, prophylaxis should be administered during the 2 weeks following vaccination while waiting for maximum vaccine antibody production (3,60).

Children being vaccinated for the first time may need 6 weeks for antibody development after vaccination or 2 weeks after the second vaccine dose. In either case, influenza antivirals do not interfere with antibody response after vaccination (3).

LIMITATIONS ON ANTIVIRAL USE

Outbreak-initiated use of influenza antivirals is usually problematic *(73,74)*. Often, the spread of influenza among patients and HCPs outpaces the best intentions and efforts to provide prophylaxis and treatment to those who might benefit from it (3). Additional considerations involve drug availability, distribution, staff education, compliance, and financial considerations.

It is not known whether these drugs are effective if they are given >48 hours after the onset of illness, although CDC guidance in response to the pandemic H1N1/2009 strain during the 2009–2010 influenza season offered a more flexible approach for initiating therapy later in very ill patients *(75)*. This means that unless rapid diagnostic techniques are readily available, treatment decisions will be based on clinical and/or epidemiologic diagnosis of influenza because of delays in establishing a laboratory diagnosis of influenza A.

Side effects include mild central nervous system symptoms (nervousness, anxiety, insomnia, and difficulty in concentrating) or gastrointestinal symptoms (anorexia and nausea). These side effects often improve after a week on the drug or can be reduced by an appropriate dosage adjustment (3). Dosage adjustments are needed for these drugs in patients with renal or hepatic failure (3,60).

In addition to known resistance of influenza A H3N2 to adamantanes, sporadic resistance has been reported to the NAIs as well *(61–63,76)*. It is advisable, therefore, to monitor local, regional, and national resistance trends to support proper drug selection.

ISOLATION PRECAUTIONS AND INFECTION CONTROL

The components of a comprehensive approach for healthcare-associated influenza infection, detailed extensively as a result of pandemic H1N1 2009 influenza (77), include immunization of HCWs and patients at high risk, early identification, isolation and/or cohort isolation (cohorting) of infected patients and personnel, and the flexibility to offer vaccine later in the year when influenza is first identified in the community or hospital (3,*75*). In addi-

tion, isolation in private rooms with negative pressure, if possible, is best for known or suspected cases of influenza.

Cohorting may be useful when larger numbers of patients or personnel are infected with influenza (3,*35*). Cohort isolation attempts to separate different groups of people in an effort to reduce disease transmission (3,*35*). In this case, cohorts of infected and uninfected individuals are identified and separated as a means of reducing spread of influenza. Because most facilities have only a limited supply of private rooms or rooms equipped with negative pressure, more than one patient with proven influenza may be cohorted or isolated together. Depending on the severity of the outbreak, it may also be necessary to restrict ill HCWs from work, curtail visitation, and reschedule some elective admissions and surgical procedures (3,*35*).

Obviously, the infection control fundamentals, especially hand hygiene, are critical and should not be overlooked *(78)*. Droplet Precautions, with a mask, preferably a fit-tested disposable N95 respirator, for direct patient contact (i.e., within 3 ft of the patient) are recommended whenever possible (3,*35*,77).

Precautions for patients with influenza should be maintained for 7 days or the duration of clinical illness, whichever is longer. Because the duration of clinical illness in antiviral-treated patients is shortened if the drug is given in a timely fashion (i.e., within 48 hours of onset of illness), the period of isolation precautions, especially the use of a mask, may be shortened accordingly.

CONCLUSION

The approach to prevention and control of influenza in healthcare settings relies heavily on vaccine use as the cornerstone of an infection control program for influenza. This is in conjunction with early identification, isolation, and/or cohort isolation. To reduce the risk of an outbreak, vaccine use must be high enough to yield some degree of herd immunity. Therefore, the ACIP recommendation of 90% vaccine use is appropriate when one considers the scientific basis from outbreak experience and sophisticated projection models.

Antiviral drugs are an important adjunct to vaccine during outbreak periods to increase the potential for developing herd immunity, especially when vaccine use is less than optimal. When vaccine use is low and/or influenza infection occurs, additional measures such as restriction of personnel, visitors, and certain procedures may also be indicated.

Despite the ACIP's new recommendation for universal vaccination, innovative programs promoting HCP education and awareness are still needed to reach this goal in healthcare settings. Mandatory influenza vaccination programs, although controversial and debated, play a role in improving patient safety and quality of care further. Whether voluntary or mandatory, either vaccination option requires administrative and financial commitment at a time of limitations on healthcare resources. The return on investment, however, will come over the long term in the form of reductions in morbidity, mortality, and hospital use, and the added benefit of more appropriate use of essential infection control program resources.

CHAPTER 43

Varicella-Zoster Virus

John A. Zaia

HISTORICAL BACKGROUND AND CURRENT SCOPE OF THE PROBLEM

Varicella is a vesicular exanthema caused by primary infection with varicella-zoster virus (VZV) and is commonly termed chickenpox in English because of the itching observed, derived from the Old English word *gican*, meaning to scratch *(1)*. Herpes zoster (HZ) is the clinical syndrome of segmental vesicular exanthema and pain associated with reactivation of latent VZV infection in a dorsal nerve ganglion. This is commonly called "shingles" in English because of the way the rash encircles the body, derived from the Latin word *cingulum*, meaning a girdle *(2)*. Varicella had been known for centuries as a relatively benign infection of childhood. It was first differentiated from smallpox in recorded medical texts in the ninth century AD by the Persian physician Rhazes, who noted that the mild pustular skin eruption was not protective against smallpox *(3)*. From an epidemiological standpoint, much of what we know and practice regarding management of disease prevention derives from the clinical descriptions that linked varicella and HZ *(4,5)*.

It is with modern medicine that these two entities took on new significance. With the advent of immunosuppression, severe VZV infection, with visceral dissemination after both primary and reactivated infection, became common *(6,7)*. Because of the resultant morbidity and mortality associated with VZV infection, immunologic and chemotherapeutic antiviral methods were developed to minimize this outcome in high-risk individuals. Today, the availability of anti-VZV chemotherapy and VZV vaccination assists in minimizing or preventing the complications of this important healthcare-associated infection. It is important that persons involved in the control of healthcare-associated infections remain knowledgeable about these methods of intervention as well as about the vast informational background upon which many of the recommendations are based.

DISTINCTION BETWEEN VARICELLA AND HERPES ZOSTER

Prior to the modern methods for virologic diagnosis, clinical observation had suggested that the causative agents of varicella and HZ were related *(8,9)*. Varicella was observed to occur not only following exposure to zoster, but also after vesicle fluid was purposely inoculated into susceptible children *(10)*. In addition, the pathologic description of the two clinical entities was similar (*11*,12). The major significant advance in understanding the nature of these agents was contributed by Weller (13,*14*,*15*), who demonstrated the method for isolation and serial propagation of VZV. These investigators demonstrated that virus isolates made from persons with chickenpox or zoster were identical in terms of cytopathic effect (CPE) in tissue culture (13) and antigenic analysis *(14,16)*. Subsequently, others demonstrated that the VZV strains isolated from these two clinical syndromes were identical by morphology *(17,18)* and by DNA analysis *(19,20)*.

NATURE OF VZV

VZV Strain Clades

Like the other members of the herpes virus family, VZV is an enveloped virus that contains double-stranded DNA within its protein core. The viral particle is an icosahedron, and the complete enveloped virion measures between 150 and 200 nm in diameter, while the naked particle is about 95 nm in diameter. The VZV genome contains approximately 125-kb pairs *(21)*, with approximately 71 open reading frames. There is a geographic distribution of sequence variations of VZV, and these are grouped into clades (22,23). The VZV vaccine strain Oka is a clade 2 strain, and the ability to distinguish VZV outbreaks by clade type has become an important epidemiologic tool *(24,25)*.

The CPE of VZV infection appears as syncytial cells with intranuclear inclusion bodies (13). In clinical disease, a similar inclusion body is observed in infected tissue, and, as noted, this CPE is identical for both chickenpox and HZ *(15)*. Electron micrographic analysis of vesicle fluid from children with chickenpox demonstrates cell-free enveloped virions *(17)*. It is presumed that VZV acquires an envelope by budding out of the nucleus and into a cytoplasmic Golgi vesicle *(26)*. The membrane of these Golgi vesicles contains viral glycoproteins, and thus the virus obtains the surface glycoproteins to which the immune system will be targeted. The molecular aspects of VZV replication has been reviewed (27).

IMMUNE RESPONSE TO VZV INFECTION

The antibody response to VZV has been measured by several methods with varying degrees of sensitivity since the initial isolation of the virus. In the 1950s and 1960s, the usual procedure was the complement fixation (CF) test. Although most children developed VZV antibody by the second week of illness, CF antibody is present in only approximately 80% of adult populations in which the serostatus would be expected to be >90% positive, indicating that CF antibody is lost over time *(28)*. Thus, the CF test is a poor assay to determine humoral immune status in the general population. Instead, the use of an indirect fluorescence antibody for membrane antigen (FAMA) method that uses VZV-infected cells as a substrate *(29,30)* permits the determination of the humoral immune status in high-risk populations *(31)*. This has been widely used for effective approaches to control of healthcare-associated VZV infection. In addition, enzyme-linked immunosorbent assays (ELISAs) *(32–35)* are available that are at least as sensitive as the immunofluorescence assays *(34)*.

VZV encodes nine glycoproteins, of which gB, gE:gI, and gH:gL are abundantly expressed, are important in virus infectivity, and serve as targets of the immune response (36). The humoral immune responses to these glycoprotein antigens can be assessed by immunoprecipitation reactions between crude radiolabeled VZV antigens *(37)*, by ELISA *(38,39)*, and by latex agglutination (LA) *(40)*. Using these methods, antibody to at least one of the major VZV glycoproteins is easily demonstrable within 1 week after onset of chickenpox. By 2 weeks, antibodies to two more viral glycoproteins are present. The amount of glycoprotein antibody reaches a peak by 4 to 8 weeks, before a gradual decline occurs over the years after the episode of chickenpox *(37)*. The LA assay has a sensitivity and specificity similar to the FAMA assay, and, because it can be performed in minutes and is commercially available, this assay can be particularly helpful to the healthcare epidemiologist *(40,41)*.

Cellular Immunity to VZV

It is well recognized that iatrogenic or natural reduction in cellular immunity is associated with both severe varicella and increased reactivation of latent VZV *(42–47)*. Cellular immunity to VZV has been classically measured by VZV-specific lymphocyte proliferation assays *(48,49)* and by quantitative measures of cytotoxic T lymphocytes *(50,51)*. Susceptible individuals fail to have an *in vitro* response either to crude VZV antigens or to individual VZV protein, but those with prior history of chickenpox develop a cell-mediated immune response to the individual VZV glycoproteins *(48)*. Analyses suggest that VZV proteins gI (ORF68) and immediate-early protein 62 (IE62; ORF62) are important for induction of a protective immune response to VZV *(50)*. Several methods for quantitative T-cell immune assays are available in research laboratories, as described *(52–54)*.

CLINICAL MANIFESTATIONS OF VZV INFECTION

Primary Infection: Varicella

In healthy children, the clinical features of VZV infection present as a mild exanthema often associated with prodromal malaise, pharyngitis, and rhinitis, appearing at a median time of 15 days after exposure (*55*,56). The rash is characterized as a vesicular eruption that emerges in successive crops over the first 3 to 4 days of illness, usually with concomitant exanthema. Each skin vesicle appears on an erythematous base, thereby giving rise to the descriptive "dewdrop on a rose petal." It can be difficult to see this stage of infection because of the rapid progression of the skin changes. A quick progression from stage to stage is characteristic of varicella in the otherwise healthy child and allows it to be distinguished from certain other vesicular eruptions and from varicella in the immunosuppressed person. Within 12 hours, the initial lesion becomes an umbilicated papule, and the crusted area then undergoes leukocyte infiltration and develops into a pustule. This then evolves into a hardened, crusted papule. The exanthema usually begins on the head, quickly progresses to the trunk and arms, and finally appears on the legs. Because of the rapid progression of individual lesions, it is common to see all stages of the exanthema, including macules, vesicles, papules, and crusts, in the same region of the skin. Fever can be expected to be elevated for the first 4 days of the exanthema, and much of the morbidity is associated with the extent of the cutaneous exanthema *(55)*.

Reactivation Infection: Herpes Zoster

In 1900, Head and Campbell (57) described the anatomic pathology of this syndrome and its precise localization to sites of single dermatomes, which permitted a mapping of the cutaneous distribution of the spinal nerves. Immunosenescence *(51)* and stress *(58)* are associated with risk factors for HZ. The clinical morbidity of HZ is determined in large part by the spinal ganglion involved. The most common area of involvement is the trunk, presumably because this is the area of greatest VZV infection during the primary infection, followed by cranial dermatomes and then by cervical and lumbar dermatomes (57,*59*,60). The involvement of cranial nerves is usually associated with the most clinically severe syndromes.

The pain associated with this disease is usually its major complication, although motor incapacitation can also be significant in the symptom complex (61,62). The pain of HZ, called postherpetic neuralgia, occurs with increasing frequency in older persons and can be a significant problem, lasting for many months *(59,63–65)*. This is presumably due to the fact that virus reactivation occurs in the dorsal spinal ganglion, which becomes a site of intense inflammation, often with hemorrhagic necrosis of nerve cells and eventual destruction of portions of the ganglion and with poliomyelitis of posterior spinal columns and leptomeningitis *(66)*. Certainly there is intense inflammation and nerve damage manifested clinically by meningitis and myelitis, with or without paresis of limbs, face, gut, or urinary bladder *(64,66–72)* in some cases. Recently, the role of the IE62 of VZV, which is a major transactivator of viral genes, has been suggested as an activator of brain-derived neurotrophic factor (BDNF). BDNF is involved in the pathogenesis of neuropathic pain, and antibody to IE62 augmented BDNF activity in neurons in an allodynia model in mice *(73)*. If this is confirmed, the role of inflammation in pain induction during HZ could be mediated via IE62-specific VZV immune responses, and this could become an important target area for improving treatment of postherpetic neuralgia.

Historical Complications and Mortality Rates for VZV Infection

Prior to the licensure of VZV vaccine in the United States in March 1995, there were an estimated approximately 11,000 VZV-related hospitalizations annually in the United States, 80% of which occurred in otherwise healthy children, and approximately 100 deaths per year *(74,75)*. The rate of complications was highest for persons <1 year old and >15 years old. Hospitalization rates relating to varicella, calculated from the Michigan Inpatient Database from 1983 to 1987, were 10 per 1,000 cases below age 1 year, 2 per 1,000 for ages 1 to 14 years, 5 per 1,000 for ages 15 to 19 years, and 8 per 1,000 for age 20 years and above. The types of complications that lead to hospitalization in VZV infection have been reviewed *(74,76–78)* and consisted of bacterial superinfection of skin, dehydration, pneumonia, encephalitis, and hepatitis. Bacterial skin infections and bacterial pneumonias occur in the youngest groups; prior to the antibiotic era, severe bacterial infections, including osteomyelitis, were not uncommon in association with varicella. With the development of antibiotics, but prior to the recognition of an association between aspirin and Reye's syndrome *(79)*, the major fatal complications of VZV infection in childhood were encephalitis and Reye's syndrome. Encephalitis occurred in approximately 1 in 11,000 cases in the age group 5 to 14 years and is described below. Reye's syndrome was associated with varicella and formerly occurred at a rate as high as 1 in 6,600 cases in certain regions of the United States *(80)*. With the reduction in occurrence of Reye's syndrome after varicella, VZV-associated mortality decreased from an average of 106 deaths per year in 1973 to 1979, to 57 per year for the period 1982 to 1986 (81) and finally to 43 per year in 1990 to 1994 *(82)*. This reduction also coincided with the prohibition of aspirin use in children with chickenpox and then with the availability of acyclovir and of varicella-zoster immune globulin (VZIG), and undoubtedly each contributed to this reduced mortality. The pre-VZV vaccine age-specific case-fatality ratios were reported as 6.23/100,000 at ages <1 year, 0.75/100,000 at ages 1 to 14 years, 2.72/100,000 at ages 15 to 19 years, and 25.2/100,000 for ages 30 to 49 years (81). Mortality rates in the postvaccine era have fallen dramatically (see "VZV Vaccine," below).

Bacterial Infections

Clusters of severe, occasionally fatal, group A streptococcal infection have historically been associated with varicella, and therefore aggressive management of bacterial infection is warranted *(82,83)*. Although not usually considered a healthcare-associated infection, pyoderma, the most frequently observed bacterial complication of varicella *(77,78)*, should be considered a healthcare-associated infection if it complicates the course of the hospitalized patient with VZV infection. This problem can be minimized by attention to good hygiene, including daily bathing with bacteriostatic soap, trimming of children's fingernails to minimize excoriation of itchy skin, and early recognition and treatment of superinfection.

Respiratory Tract Infection

In addition to the occasional laryngitis and laryngotracheobronchitis that can occur during varicella, bacterial superinfection can also involve the lower respiratory tract, producing pneumonia and bronchitis. Treatment should be directed toward the usual respiratory pathogens, including *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Staphylococcus aureus (78)*. Viral pneumonia is more likely to be a problem in older persons with varicella. In persons of ages 15 to 19 years, varicella-related pneumonia occurred in 1 in 3,000 cases, but in adults, clinically significant disease has been reported in 1 in 375 cases of varicella *(80)*. Asymptomatic pulmonary disease with radiographic changes has been reported to occur in 16% of adults *(84)*.

Mucositis

Varicella is a generalized infection involving all epithelial areas, including mucosal surfaces of respiratory, alimentary, and genitourinary systems. Involvement of the bladder and urethra can result in severe dysuria with functional bladder obstruction. Urinary analgesics and bladder drainage may be required.

Gastrointestinal Complications and Reye's Syndrome

When death occurs during VZV infection, the gastrointestinal system is often involved. Bleeding requires specific attention, particularly in the immunosuppressed subject. In addition, vomiting is not a usual part of the clinical course of this infection, and this symptom should alert the physician to look for abdominal or central nervous system (CNS) complications. As with other viral infections, surgical emergencies such as appendicitis and intussusception can occur during varicella. Mild hepatic involvement is seen in most children with varicella and is usually manifested by asymptomatic elevation of hepatic enzymes, for which no treatment is necessary *(85)*. As noted above, Reye's syndrome was described in association with varicella, often with concomitant use of aspirin in the child older than 5 years *(79,86,87)*. Reye's syndrome and other metabolic diseases must be excluded in any child with varicella in whom there is vomiting and changes in mental status *(88)*.

Encephalitis/Myelitis

VZV is trophic for epithelial tissue, and the CNS is not spared from this trophism, with encephalitis and myelitis appearing as important complications of VZV infection. It is important to note that with both varicella and HZ, neurologic disease can occur either before or after the acute infection *(89,90)* and can even occur with VZV reactivation in the absence of skin eruption, an entity called *zoster sine herpete (91)*. Several CNS syndromes, including aseptic meningitis, polyneuropathy, myelitis, and encephalitis, have been observed in normal persons in association with otherwise occult VZV infection *(92)*. VZV infection involving the CNS is of two types: cerebellar or cerebral complications during varicella and cranial or peripheral nerve complications during HZ. Cerebral complications present equally as either cerebral or cerebellar abnormalities, the latter being more benign *(69,89,90)*. Cerebellar ataxia is the most common syndrome associated with varicella encephalitis in children and is generally a benign entity that is thought to be due to postinfectious demyelination *(89,90,93)*. In older teenagers and adults, encephalitis occurred in approximately 1 in 3,000 cases of varicella *(80)*. Rarer CNS syndromes, such as granulomatous angiitis and stroke-syndromes, have been observed following HZ,

but these are poorly understood syndromes that have not been etiologically related to reactivation of VZV. As with varicella, CNS disease in immunodeficient persons is an important problem in HZ, and progressive CNS disease can occur in persons with HIV infection (*94–96*,97).

Bleeding Disorders

Bleeding disorders can occur during varicella and are due to disseminated intravascular coagulation, vasculitis, or idiopathic thrombocytopenic purpura. The syndrome of purpura fulminans must be treated with supportive therapy and with antibiotic therapy until bacterial sepsis is ruled out. Anaphylactoid purpura can follow an otherwise uncomplicated course of varicella and must be managed with appropriate attention to the status of renal function and the possibility of occult intra-abdominal hemorrhage. Idiopathic thrombocytopenic purpura can occur during active infection or during convalescence and usually responds to treatment with intravenously administered immune globulin *(98)*.

Infection in the Immunocompromised Host

The era of aggressive anticancer chemotherapy and acquired immunodeficiency syndrome has been associated with progressive VZV infection (*4*,*5*,*94–96*,97,*99*,*100*). VZV infection in the immunosuppressed individual is associated with progression of infection from skin to internal organs. Severe skin eruption occurs with or without hemorrhage; there is high fever and spread of virus to visceral organs, producing hepatitis, pneumonitis, pancreatitis, small bowel obstruction, and encephalitis *(100,101)*. A major manifestation of visceral dissemination in addition to fever is severe abdominal and/or back pain *(101,102)*. In the preantiviral era, visceral dissemination occurred in 30% of children with chickenpox while on active cancer therapy *(100)*. Pneumonitis occurred between 3 and 7 days after onset of chickenpox in 25% of such patients; without antiviral therapy, the overall mortality rate in such patients was approximately 7%. In the placebo-controlled trials of antiviral agents in similar patients, a fatal outcome occurred in 17% and visceral dissemination occurred in 52% of the placebo groups (*103*,104,*105*). In addition to viral dissemination, bacterial superinfection was a problem in these patients, and bacteremia accounted for significant morbidity during VZV dissemination *(100)*.

The severity of HZ is less predictable in patients receiving immunosuppressive agents. Historically, VZV will reactivate in 35% to 50% of persons with Hodgkin's disease, and those undergoing bone marrow transplantation during the first year of treatment *(106,107)* and persons undergoing other forms of chemotherapy are at increased risk for zoster *(108,109)*. The rates have not changed with intensive anticancer chemotherapy, and antiviral therapy significantly reduces this morbidity (62). When used early in reactivation, acyclovir can usually eliminate mortality (104,110,*111*).

PATHOGENESIS OF VZV INFECTION AND DISEASE

Pathogenesis of Chickenpox

The events that lead to the clinical syndrome of chickenpox are thought to be similar to those that were first proposed by Fenner to explain an animal model of viral exanthem *(112)*. In this schema, virus enters the host from an exogenous source and spreads locally to a site of initial augmentation and then, by a primary viremia, to a location of subsequent viral growth. After several days of replication, the virus then spreads by means of a second viremia to the skin and mucosal surfaces, where the exanthema and enanthema occur *(112)*. The entire time course for such virus replication and spread varies from 10 to 21 days, the range observed for the incubation period of varicella (*55*,56,*113*). The existence of the primary viremia has not been documented, but the secondary viremia is well described *(114)*. Virus spreads to endothelial cells of the skin and then infects the basal and deep malpighian layers of the epidermis. The role of T-cell tropism of VZV in the transmission of virus to skin and nerve ganglia has been proposed *(115)*. In addition, the VZV glycoprotein E contains an N-terminal region important for binding to the insulin-degrading enzyme (IDE) of cells in skin and other organs and glycoprotein E/IDE could be the critical ligand—receptor necessary for spread to the skin (36,116). Once in the skin, ballooning degeneration of these cells occurs and local collection of extracellular edema results in unilocular and multilocular vesicles (*2*,12). In addition to swelling of infected cells, multinucleation occurs, forming the basis for the Tzanck assay, and condensation of viral proteins within the nuclei results in intranuclear inclusions.

Pathogenesis of Herpes Zoster

The two important events in the pathogenesis of HZ are the development of latent VZV infection in dorsal spinal ganglia following primary VZV infection *(18,117,118)* and subsequent reactivation of latent VZV with disruption of ganglionic structure and spread to the areas distributed by this spinal nerve *(71,119)*. The virus is thought to reactivate in either the ganglion cell or the perineuronal cells *(120)*; when reactivation occurs, the virus then spreads within the ganglion and within the distribution of that spinal nerve. Because of VZV tropism for nervous tissue, in persons with profound immunodeficiency, VZV can spread transsynaptically within specific neuronal systems, producing necrosis of brain *(121)*. In addition, recent studies have shown that VZV is present in saliva of HZ patients *(25)*, and this is associated with acute stress, as has been shown in astronauts during space flight *(58)*. As noted above, the immune system plays a role in pathogenesis as suggested by an intense inflammation at the initial site of virus reactivation *(66)* and a resultant tissue reaction that leads to nerve damage with pain syndrome and to damage in the epidermal structures with the functional abnormalities *(68)*. The hypothesis that an IE62-specific antibody response induces BDNF and leads to the neuropathic pain syndrome remains to be confirmed *(73)*.

Of concern for healthcare-associated infection control, a generalized vesicular rash appears during the first week of HZ in approximately 10% of normal adults (*59*,60,*122*), suggesting that failure to control the virus at the initial site of reactivation permits spread of virus, much as in chickenpox. This rash consists of a single crop of vesicles that lacks the polymorphism of chickenpox, unless continued dissemination occurs *(123)*. Furthermore, in

recipients of marrow transplantation, disseminated vesicular exanthema without primary dermatomal skin eruption can follow reactivation *(106)*.

DIAGNOSIS OF VZV INFECTION AND IMMUNITY

Diagnosis by Direct Antigen or by DNA Detection

VZV infection can be diagnosed reliably on clinical grounds alone when there is a history of close exposure to chickenpox or HZ in the past 10 to 21 days and a vesicular eruption consistent with chickenpox (Table 43-1). However, in many situations, particularly those involving immunocompromised persons, no clear historical data support the diagnosis. In this situation, since treatment will be of paramount importance, laboratory diagnosis is necessary. For HZ, the clinical appearance of rash consistent with HZ on clinical grounds can be confirmed by polymerase chain reaction (PCR) in approximately 75%, and zosteriform herpes simplex infection occurs in 3% to 4% (61).

The earliest method for diagnosis was light microscopic examination of the vesicle contents to demonstrate multinucleated giant cells when stained with Wright–Giemsa stain. This method, called a Tzanck prep, has now been superseded by a fluorescent antigen detection assay, which is available in a commercial kit for confirmation of the diagnosis. This assay consists of a direct fluorescent antigen stain of samples of cells that are scraped from the base of a vesicle and dried onto a glass slide. Rapid diagnosis by antigen detection can also be performed on punch biopsy specimens of vesicular lesions. These tests take only 1 to 2 hours and can quickly differentiate between vesicular rashes caused by VZV or herpes simplex virus infection.

The most specific method for diagnosis of VZV infection is by DNA hybridization techniques or by PCR (124). PCR is the more sensitive assay and can discriminate between vaccine strain VZV and wild clades of VZV, and this is now the preferred tool for the healthcare epidemiologist, once the diagnosis is established by rapid antigen detection using VZV-specific monoclonal antibodies.

TABLE 43-1

Diagnosis of Varicella-Zoster Virus (VZV) Infection

History of exposure to varicella or herpes zoster in past 3 wk
Physical examination of rash indicates
For varicella: lesions in all stages of development from vesicle on red base to umbilicated pustule to crusted lesion
For zoster: dermatome distribution of lesions
VZV-antigen detection using lesion scraping
Culture of vesicle or PCR for VZV (optional if antigen-positive)
Antibody assay on acute/convalescent paired sera (optional if antigen-, culture-, or PCR-positive)

PCR, polymerase chain reaction.

Viral Culture for Isolation of VZV

For confirmation of laboratory diagnosis or to obtain the virus strain for research purposes, VZV infection is isolated in cell culture (13). Vesicular fluid is collected in sterile capillary tubes or tuberculin syringes, which are subsequently evacuated into culture medium. The medium is then layered over cultured cells, and in 3 to 5 days, CPE is visible in the monolayer. In human fibroblast cells, the CPE consists of multiple foci of swollen, rounded refractive cells. A definitive diagnosis of VZV infection is made by immunostaining of the infected monolayer with a VZV-specific monoclonal antibody.

Detection of Susceptibility to VZV

The simplest method for reliably determining susceptibility to varicella is to take a history for previous chickenpox. A positive history from adults correlates with serologic confirmation 97% to 99% of the time *(125–127)*. A positive history of previous chickenpox in a child with recent household VZV exposure is associated with subsequent disease in only 7% *(55)*. Conversely, a negative history from an adult does not correlate with serostatus in 72% to 93% *(125–128)*. Thus, serologic tests of immunity are most useful in adults with a negative history of chicken pox. The FAMA, radioimmunoassay, ELISA, LA, and hemagglutination antibody assays, because they are sufficiently sensitive, are reliable methods for demonstration of prior infection with VZV *(33,34,38)*. For this reason, these tests are widely used as presumptive evidence of immunity following exposure to chickenpox, for preemployment evaluation, or for follow-up after vaccination. It should be noted that these assays are not reliable in persons who have received blood products and who might have acquired passive antibody. As mentioned above, the CF test, because it is an insensitive test for antibody, should not be used for determination of prior infection. The immediate availability of the radioimmunoassay, ELISA, or FAMA assays can be problematic when the question of susceptibility must be determined quickly, as is usually the case in matters relating to healthcare-associated infection. The LA assay is commercially available *(40)* and reliably determines immune status to VZV *(40,41)*. A VZV skin test, which has shown promise as a test of susceptibility, is not generally available *(129,130)*.

EPIDEMIOLOGY OF VZV INFECTIONS

Transmission and Communicability of VZV

Early observations suggested that chickenpox was an airborne disease *(131,132)*, but this was subsequently confirmed using sophisticated methods of air-flow analysis *(133,134)*. The spread of infectious VZV from a person with chickenpox is by air droplets from nasopharyngeal secretions, which usually requires face-to-face exposure but can also occur via air currents to susceptible individuals without direct contact *(133,134)*. For HZ, the accumulation of VZV in hospital rooms *(135)* and the presence of VZV in saliva of HZ patients *(25)* may play a role in spread of infection.

The period of infectivity is generally considered to be between 48 hours prior to exanthema and 4 days after exanthema, a range derived from published observations

of chickenpox in cohorts of children quarantined for other infections. In this setting, it was rare to observe spread of chickenpox from a child who exposed other ward-mates >2 days prior to the onset of rash (56,*136*). Although there is a single report that infectivity could occur 4 days prior to exanthema *(137)*, this case is suspect and would be the exception to the common experience, which suggests that exposure for >1 day prior to exanthema is unlikely to be infectious (56,*136*). The usual recommendation is to consider the period of infectivity as 48 hours prior to rash until the skin lesions are crusted.

HZ can cause spread of VZV by direct contact with lesions or by exposure to airborne infectious material *(25)*. The incubation period for chickenpox following exposure to zoster *(113)* is the same as that following exposure to varicella (56) (median time 15 days, range 10–21 days). However, the clinical varicella attack rate following household HZ is only 25% among history-negative children *(113)*, compared to an attack rate of 87% following exposure to household chickenpox *(55)*.

Age-Specific Incidence of VZV Infection

Postvaccine era incidence of varicella in the United States is not known with certainty, but using index counties as representative, the number of cases and the complications requiring hospitalization have been reduced by 80% (138). Historically, the estimated incidence of chickenpox in the United States in the prevaccine era was based on the size of the birth cohort and on the assumption that nearly everyone developed chickenpox over a lifetime. Thus, for example, with approximately 4 million births in the United States annually, approximately 3.7 million cases of varicella occurred each year *(74)*. More than 90% of all cases of varicella occurred in persons under the age of 15 years, and nearly half of all cases in children occurred between the ages of 5 and 9 years. Age-specific incidence data were reported for the years 1980 to 1990 from the National Health Interview Survey, indicating that 33% of cases occurred in preschool children of ages 1 to 4 years, in whom the incidence was 82.2/1,000/year (*74*,81). In the age group 5 to 9 years, the incidence was estimated to be 91.1/1,000/year *(74)*.

In the pre-HZ vaccine era, it is estimated that there were approximately 1,000,000 cases of HZ in the United States per year (62). Based on public records, the incidence of HZ is constant for each age group through midadulthood. Thereafter, the incidence of zoster increased with age such that persons in their 80s have a 1 in 100 chance per year of developing zoster *(65)*. When adjusted for prior occurrence of varicella, there is a known association of HZ in children who have acquired varicella prior to their first year of life *(139)*. In the VZV vaccine era, with less circulating wild-type VZV, there is the potential for increased rates of HZ in the non-HZ-vaccine immunized adult population (62,*140*), and it remains to be determined whether this is a real concern that would stimulate wider use of the HZ vaccine.

VARICELLA-ZOSTER VACCINE

Background

The VZV vaccine is the single most important tool in prevention and control of healthcare-associated VZV infection. The live attenuated VZV vaccine was developed by Takahashi in 1974 *(141)* and was prepared by attenuation of a VZV isolate (Oka strain) in human embryonic cells and then in human diploid fibroblasts (142). The vaccine virus, which is a clade 2 virus, is biologically different from wild VZV in its growth characteristics, DNA restriction enzyme profile *(143,144)*, and single nucleotide polymorphisms (23). The Oka-strain vaccine was used extensively in Japan in healthy children and was effective for the prevention of varicella after exposure and for curtailment of outbreaks of VZV infection prior to its near-world-wide approval *(141,145)*.

Recommended use of VZV vaccine

A live attenuated VZV vaccine (Varivax) was approved in the United States in 1995 (146). Vaccine is administered at any routine visit at or after age of 12 months for susceptible children, that is, those without prior history of prior chickenpox, and susceptible persons ≥13 years old should receive two doses at least 4 weeks apart *(147)*. The vaccine is particularly important in chickenpox history-negative teens and adults, especially college students, healthcare and daycare workers, prisoners, military recruits, nonpregnant women of childbearing age, and international travelers. For adolescent and adult patients, serologic testing for VZV antibody is usually cost effective prior to vaccination *(148,149)*. The vaccine is not recommended for infants younger than 1 year, for immunosuppressed persons, for those receiving salicylate therapy, for pregnant women, or for persons allergic to components of the vaccine, including neomycin, gelatin, and monosodium glutamate *(147)*. Severe VZV vaccine infection has been observed in immunodeficient children *(94,96,97)*. Despite this, VZV vaccine can be administered in HIV-infected children *(150)*, and, because of the likely severity of chickenpox in children with acquired immunodeficiency syndrome, the vaccine is recommended for consideration on a case-by-case basis for asymptomatic or mildly symptomatic patients with age-specific CD4 T-lymphocyte percentages of 25% or more. Other immunosuppressed individuals such as solid organ transplant recipients who are on continuous iatrogenic immunosuppression are not recommended for receipt of VZV vaccine, and it is unlikely that these patients will have an effective immune response to the vaccine *(151)*. However, in children with leukemia studied in the United States, vaccination given to those in remission produced a 5-year seropositivity of 70% and an attack rate of chickenpox after household exposure to VZV of only 14% *(152,153)*.

The protection of at-risk patients from varicella exposure requires use of VZV vaccine in healthcare workers, and the safe use of this vaccine in this population has been described *(21)*. For healthcare workers, screening for prior VZV infection should be done at the time of employment, and seronegative persons should receive the two-dose VZV vaccine immunization schedule. For patients about to undergo intensive immunosuppression, the healthy family members who have no history of VZV infection or who are seronegative for VZV antibody should be vaccinated. For severely immunocompromised patients, for example, hematopoietic cell transplant recipients, the recommendation states that ideally patients should not have contact with vaccinees at times of severe immunosuppression until ≥4 weeks after completion of vaccine doses *(154)*.

However, in practice, the more important concern is that the patient should not have contact with any vaccinee who experiences a rash after vaccination. At present, transmission from a healthcare worker to a patient has not been documented, and vaccine virus is susceptible to acyclovir which many immunosuppressed patients receive during intense immunosuppression. Thus, most centers allow the employee to start work prior to the completion of VZV immunization as long as they will not have contact with immunosuppressed patients and only when there is no postvaccine rash.

The effectiveness of the VZV vaccine has been reported in long-term follow-up studies (138,*145*,*155*,*156*). A single dose of vaccine results in seroconversion in 97% of susceptible children 1 to 12 years old, in 79% of children 13 to 17 years old, and in 82% of adults. Two doses of vaccine result in seroconversion in 94% of adults *(145,155,156)*. Vaccine effectiveness in preventing chickenpox is approximately 85% and the effectiveness for preventing severe disease is approximately 97%. As noted above, the number of chicken pox cases and hospitalizations has decreased between 1995 and 2000 by approximately 80%, based on analysis of representative counties in the United States (138). Breakthrough varicella occurs in approximately 20% of vaccinees after household exposure, and the risk factors for such breakthrough are close contact with varicella, age ≤14 months at vaccination, and receipt of low titer vaccine *(153)*. In this regard, subjects with low serological immune response to the vaccine appear to reactivate the vaccine virus, resulting in persistent increasing serum antibody titers, suggesting that the vaccine virus persisted *in vivo* and reactivates in the presence of low antibody titers *(152)*. If this is true, the vaccination should result in long-term immunity.

HZ due to vaccine strain virus is very rare but does occur (97,*157*). Chickenpox has been contracted in a child 5 years of age after exposure to a sibling who developed zoster 5 months after immunization with VZV vaccine *(158)*. The inadvertent exposure of susceptible women to VZV vaccine during pregnancy has been monitored since 1995 in the United States, and to date, there has been no congenital varicella syndrome or other VZV-specific birth defects in this group *(159)*. Other aspects of VZV vaccine have recently been reviewed *(160)*.

HERPES ZOSTER VACCINE

Risk for developing HZ is thought to be related, not to low levels of anti-VZV antibody but to inadequate cellular immunity to VZV (61,*161*). Cellular immunity to VZV increases with age after primary VZV infection until age approximately 40 years and then lessens with advancing age *(51)*, consistent with the increased rate of HZ with advancing age *(162)*. It had been shown that persons of age >60 years could respond to VZV vaccine *(163)*, paving the way for a large prospective placebo-controlled study showing that a modified Oka-strain-based VZV vaccine (Zostavax, Merck Inc.), with approximately 14-fold increase in plaque-forming units, would prevent HZ and postherpetic neuralgia (61). This study of 38,546 adults of age >60 years showed that the HZ vaccine reduced the incidence of HZ by 51.3% and reduced the incidence of postherpetic neuralgia by 66.5%. Based on these data, as well as on a thorough analysis of benefit, including economic impact of HZ, the HZ vaccine was licensed in the United States in 2006 (62).

The HZ vaccine is recommended for use in all persons ≥60 years old with no other contraindications (62). The vaccine is given as 0.65 mL/dose subcutaneously in the deltoid region of the upper arm. Contraindications include (a) allergy to components of the vaccine, for example, gelatin and neomycin, (b) immunocompromised persons (see discussion in Ref. 62), (c) pregnant women, (d) concomitant severe acute illness, and (e) use of antiviral medications active against VZV (e.g., acyclovir, famciclovir, and valacyclovir), which cannot be safely stopped for 24 hours prior to vaccination and for 14 days thereafter. A prior history of HZ is not relevant, since the HZ vaccine is immunogenic and safe in those with a prior history of HZ *(164)*. The availability of the HZ vaccine is a new tool for control of VZV spread by HZ exposure and a means of lessening this disease in the older population *(165)*. The HZ vaccine is likely to be approved for use in younger populations.

PREVENTION AND CONTROL OF HEALTHCARE-ASSOCIATED VZV INFECTION

Employee Policy Regarding VZV Infection

The control of healthcare-associated VZV infection begins with the development of a rational employment policy for the healthcare worker (Table 43-2). It cannot be overemphasized that healthcare workers are a significant source of exposure to primary healthcare-associated VZV infection *(125,128,166–168)*; therefore, one of the first lines

TABLE 43-2

Varicella-Zoster Virus (VZV) Policy for Healthcare Workers

Determine history of prior varicella at initial intake interview
Obtain serologic information of immune status for persons with negative or unknown history of varicella and consider such workers susceptible
Seronegative healthcare workers should receive VZV vaccine (alternatively, vaccinate all persons with negative or unknown history of varicella)
Unvaccinated susceptible employees should avoid contact with patients having varicella or herpes zoster
Susceptible or recently vaccinated healthcare workers must report any VZV exposure to the infection control department
After valid exposure:
Susceptible, unvaccinated workers must be furloughed away from direct patient care from days 10 to 21 after exposure; consider administration of VZV vaccine
Recently vaccinated workers can be assigned to patient care responsibility if (a) VZV-seropositive upon retesting and (b) seronegative workers can be retested 5–6 d later and, if still seronegative, furloughed away from direct patient care from days 10 to 21 after exposure

of protection of susceptible patient populations is to minimize spread of infection from hospital workers. This begins with the initial employment history and physical examination, which should include history regarding prior chickenpox *(128)*. If this history is negative, appropriate serologic testing should be performed to confirm antibody status if the employee will be involved in interactions with patients. VZV-seropositive employees will not be at risk for primary VZV infection. VZV history-negative/seronegative employees who receive VZV vaccine should be restricted from patient responsibilities involving VZV-infected individuals and should be counseled to recognize VZV infection and the appropriate isolation methods.

In the past, the practice of furloughing healthcare workers known to be susceptible to VZV, after exposure to this virus, was less than satisfactory because of both cost to the healthcare institution *(84)* and lost time for the employee. With the approval of the VZV vaccine in the United States, there is an opportunity to reduce the potential for employee-mediated healthcare-associated VZV infection. Healthcare institutions are advised to consider the use of the VZV vaccine for control of employee-related healthcare-associated infection (81). In addition to healthy children aged 12 months to 12 years, the vaccine is recommended for healthy adolescents and adults with no prior history of chickenpox (Table 43-3). The vaccine is given in two doses of 0.5 mL subcutaneously 4 to 8 weeks apart. It is recommended for all such healthcare workers, especially those having contact with susceptible children, pregnant women, and immunocompromised individuals.

In the policy recommendation, it is noted that individual institutional policies should be developed in regard to the use of the VZV vaccine, and these will need to consider certain factors about which there is imprecise information. In addition, 5.5% of adolescents and adults develop a rash after the first injection, and there is the rare instance of transmission of virus from healthy vaccinee to susceptible household contact. Hence, it is recommended that recent vaccinees who develop a rash following vaccination avoid contact with immunosuppressed patients. As a practical matter, recent vaccines with or without a rash should avoid contact with high-risk persons (e.g., newborns, pregnant women, and immunocompromised persons). In addition, testing for seroconversion at the completion of immunization is not recommended, because approximately 99% will be seropositive; however, consideration should be given to testing vaccinated healthcare workers at the time of a subsequent VZV exposure, since detection of antibody could become a method for identifying employees who are at minimum risk for breakthrough infection. It should be noted that breakthrough cases of varicella in vaccinated persons are mild, but the rate of transmission of disease from vaccinees who develop varicella is not well studied (81). For this reason, daily monitoring for rash while employees continue at work is suggested for vaccinated healthcare workers, following VZV exposure (81). In addition, VZV serostatus should be determined by LA assay, and seronegative workers should be retested 5 to 6 days later, prior to the 10th day postexposure; if the worker is still seronegative, he or she should be furloughed away from direct patient care during days 10 to 21 postexposure. VZV-seropositive healthcare workers can be assigned patient-care duties but should be monitored daily for rash and removed from such duties if breakthrough rash appears (81). For susceptible healthcare workers who have been exposed to varicella, removal from patient contact is recommended beginning on the 10th day following initial exposure and continuing until day 21 after the last exposure. Although postexposure vaccination has been shown to have a 90% protective effect in children vaccinated within 3 days of close exposure, vaccination is not recommended as a means of limiting healthcare-associated VZV infection after a healthcare worker exposure (81).

TABLE 43-3

Indication for VZV Vaccination[a]

Healthy children aged 12 mo to 12 yr
Healthcare workers
Persons working in day care or pediatric institutions
College students
Prisoners
Military recruits
Nonpregnant women of childbearing age
International travelers

[a]Vaccine (Varivax, Merck) recommended for healthy children over age 12 mo and for healthy adolescents and adults with no prior history of varicella.

INFECTION CONTROL OF VZV INFECTION IN HOSPITALIZED PATIENTS

Initial Containment Response: Isolation Precautions

Prior to the VZV vaccine, pediatric patients, especially those under the age of 5 years, formed a population in which most were susceptible to chickenpox, and VZV infections spread and endured over many months within an institution *(137)*. When immunocompromised pediatric patients existed in the same setting, the need was heightened for control of such healthcare-associated infections *(169,170)*. Guidelines for prevention and control of such infections have been published, and there is advice for managing such problems (81,*171–173*). However, with the use of VZV vaccine, the pediatric inpatient population >1 years old should be immune to VZV, and such institutional outbreaks could be a thing of the past.

If the exposure is from a patient, the patient should be discharged if possible. If this is not possible, then for patients with either varicella or disseminated HZ or for immunosuppressed patients with localized HZ, isolation precautions designed to prevent spread of infection by both air and direct contact are recommended. Optimally, this will consist of a private room with negative air pressure relative to the corridor *(171)*. Immunocompromised individuals with HZ are unlikely to disseminate infection after 24 hours of treatment with acyclovir (110), and for that reason, continued strict isolation is not necessary for this subgroup. The precaution guidelines should be posted on the door to restrict entry for susceptible persons.

Immunocompetent patients with localized zoster should be placed on precautions to prevent transmission by direct or indirect contact with infectious material/drainage from an infected body site. For varicella and disseminated HZ, isolation should remain in effect until all skin lesions are crusted. For localized HZ, Contact Precautions should continue until all drainage from the lesions has ceased.

Secondary Response: Control of Extended Infection

After initiating control of the source of VZV infection, the problem then is to quickly access three types of information: (a) the nature of the VZV exposure and whether this exposure is likely to result in secondary infections, (b) a list of susceptibility of the exposed patients, and (c) a list of patients at risk for life-threatening VZV-related complications. The types of exposures that are likely to lead to varicella transmission are those involving close contact. A close contact is defined as one in which there is >1 hour in the same area indoors with the infected source (e.g., exposure in the same two to four bed hospital room or indoor play area). However, even <1 hour of exposure should be taken seriously when exposure is direct face-to-face contact with the infectious person (81). As noted earlier (see "Detection of Susceptibility to VZV," above), positive or negative history of prior varicella can be highly reliable in the first assessment of who is susceptible. Pediatric admission records should indicate whether the exposed patients have received the VZV vaccine. Serologic tools can be used to clarify the status of those with ambiguous history. Thus, the initial step is to define the hospital area(s) in which a definite VZV exposure occurred and then to focus on which patients in this area are at risk for infection. Finally, among these exposed patients, immunosuppressed individuals are considered to be at high risk for VZV-related complications, and these persons should be given separate attention (see below).

Once this information is available, those susceptible patients who are exposed should be discharged if possible. Those who cannot be discharged should be isolated beginning 10 days from initial exposure through 21 days from last exposure. Those who must remain in the hospital who were not exposed to varicella should be placed in a cohort to keep them away from the VZV-exposed susceptible patients in order to prevent further spread of infection. It has been shown that the use of the VZV vaccination in this situation can stop an extended round of varicella in a pediatric setting *(174)*. At present, however, except for use in children with leukemia under a special protocol, the vaccine is only recommended for use in healthy individuals, and hence this modality is not recommended for healthcare-associated control of VZV in US institutions.

Approach to Protection of Immunocompromised Persons

An institution's policy regarding healthcare-associated spread of VZV infection is designed in large part to minimize the possibility of immunocompromised persons becoming infected with VZV in the hospital. Those at risk are defined as patients who have primary and acquired immunodeficiency disorders, have neoplastic diseases, have recently received immunosuppressive treatment, are premature newborns of varicella-susceptible mothers, or are premature infants born at <28 weeks' gestation or weighing <1,000 g (81). As noted above, these individuals should receive special attention in the form of antiviral prevention. This type of prevention should begin before there is a known problem. The clinic staff and inpatient personnel should become familiar with and enforce visiting policy that minimizes the exogenous introduction of infection into the patient areas. As mentioned, the employee policy should serve to protect the patients from exposure to VZV infection. In addition to employee vaccination, the children with acute leukemia should have access to VZV vaccine, and the infection control office should work with the pediatric hematology clinic to provide vaccination for appropriate clinic patients.

Of greatest concern, of course, are those who are both susceptible and immunocompromised. In the past, these children were provided exogenous antibody to VZV in the form of VZIG, an immune globulin prepared from pooled blood plasma containing high antibody titers to VZV *(28)*. Since VZIG is not generally available, antiviral chemotherapy with acyclovir or valacyclovir could be the only practically available approach for VZV prophylaxis in susceptible high-risk patients after exposure to VZV. Although not approved for this use, acyclovir has been shown to significantly decrease, but not completely eliminate chickenpox when used in healthy children after household exposure *(175,176)* or in the setting of renal transplantation *(177)* or leukemia *(178)*. A cautionary note is made because of a case of fatal VZV infection that occurred weeks after prophylactic acyclovir was stopped in one immunosuppressed child *(179)*. Thus, if there is a decision to use prophylactic antiviral chemotherapy, this should be made on a case-by-case basis, and with the recognition that VZV can remain inactive and then reappear after the suppressive therapy is stopped. When used for this purpose, acyclovir is given at an oral dose of 20 mg/kg (not to exceed 800 mg per dose) four times daily and valacyclovir is given at an oral dose of 1 g three times daily if body weight is >40 kg.

Management of Adult Patients with VZV Exposure

More than 95% of all adults have been infected with VZV, and these persons do not develop disease after repeat exposure to the virus *(125–127)*. Nevertheless, it has been shown by Arvin et al. *(7)* that normal adults frequently are reinfected by VZV after exposure to chickenpox. But, despite this finding, recurrent varicella is sufficiently rare that for practical purposes, it need not be considered in the construction of guidelines for management of healthcare-associated VZV. Susceptible adults do develop chickenpox, provide the source for unexpected epidemics, and are at increased risk for life-threatening complications. The susceptible individual needs to be identified and appropriately managed. One population that is at risk for varicella is adults from subtropical climates, where varicella can occur well into adult life *(180,181)*. Since immigrants from these areas can be found in health-related employment, attention should be addressed to any such person in order to confirm varicella immunity and provide VZV vaccine before that person has contact with high-risk patients.

With the availability of the VZV vaccine, vaccination is recommended for all healthy persons after 12 years of age

who do not have a reliable history of chickenpox at the time of any routine healthcare visit. As noted for healthcare workers, the vaccine is given to adolescents and adults in two doses, subcutaneously, 4 to 8 weeks apart. Vaccination is particularly recommended for susceptible persons (a) who live or work in settings with high transmission of VZV, including day care and institutional settings; (b) who live or work in environments in which VZV transmission might occur, including college dormitories, correctional institutions, and the military; (c) who are nonpregnant women of childbearing age and who will avoid pregnancy for 1 month following each dose of vaccine; and (d) who are international travelers likely to have close contact with local populations (81). If acyclovir is used prophylactically in adults, the VZV vaccine should not be given until after the acyclovir is stopped. As noted with children, the vaccine should not be given to persons with neomycin allergy or to individuals with immunodeficiencies. If the vaccine is to be used for adults for whom there is an immunodeficient child in the family, then the same precautions exist as for hospital employees, and the adult should not stay with the child for the first week postvaccination.

MANAGEMENT OF THE PREGNANT WOMAN AFTER VZV EXPOSURE

Congenital Varicella Syndrome

The congenital varicella syndrome was first described in 1947, and <100 cases have been described *(76,182–185)*. The syndrome consists of low birth weight, cutaneous scarring, limb hypoplasia, microcephaly, cortical atrophy of brain, chorioretinitis, and cataracts. Intrauterine VZV infection can occur following maternal varicella in all trimesters of gestation, but teratogenic or developmental damage results from infection prior to the third trimester *(186,187)*. The rate of transplacental infection is 24%, but clinically apparent disease occurs in only about 2% to 3% after maternal varicella in early pregnancy *(76,182,187)*.

Perinatal VZV Infection

Perinatal infection can occur in late third trimester chickenpox, and newborns are considered at risk if chickenpox occurs in the mother from 5 days before to 2 days after delivery (81,*187*,*188*). The precise risk of severe disease is not known, and the initial report *(188)*, which showed a mortality rate of 31%, is probably inflated compared to the risk in a modern neonatal intensive care unit. The risk of severe VZV infection appears to be a function of the presence of transplacental maternal antibody to VZV in the baby *(186,189)*. In the absence of VZIG, acyclovir prophylaxis should be considered, but the best reported result is with the combination of immunoglobulin and acyclovir *(190)*. Unlike varicella exposure of the neonate, maternal HZ is not a risk since it occurs only in the setting of prior maternal antibody which appears to be protective *(187)*.

Approach to the Pregnant Woman Exposed to VZV

A pregnant woman with significant exposure to VZV infection should be evaluated for susceptibility to VZV with an appropriate antibody assay, if she has a negative or unknown history of varicella as a child. But congenital infection is rare, and the woman should be reassured. The most significant risk is to the health of the mother rather than to the infant *(187)*, and therefore, guidance on management should be directed toward protecting the health of the mother.

CHAPTER 44

Herpes Simplex Virus

Stuart P. Adler

Herpes simplex virus (HSV), a common cause of morbidity among humans, has two distinct serotypes: HSV-1 and HSV-2. HSV-1 primarily causes cold sores, with oral or labial lesions being the most common manifestation. HSV-1 is presumably transmitted by contact with infected saliva or cutaneous lesions. HSV-2 is found predominantly in the genital areas and causes vesicular lesions with red borders that often appear in crops or clusters with satellite lesions. Both oral and genital lesions are often swollen and painful but eventually crust over and heal. HSV-2 transmission can be reduced with the use of condoms.

Newborns under 1 month of age are especially susceptible, because infection of the skin and mucous membranes by herpes simplex leads to viremia with viral dissemination to multiple organs, including the central nervous system. Newborns usually become infected at birth via contact with maternal cervical—vaginal secretions infected with HSV-2, but occasionally become infected via contact with infected personnel or contaminated equipment in the nursery.

In adults, HSV usually causes an asymptomatic infection, but occasionally HSV-1, or less commonly HSV-2, invades the central nervous system, causing encephalitis. This occurs when virus in the upper respiratory tract migrates along the olfactory nerve through the cribriform plate, most typically into the frontal or temporal lobes. The most common manifestations of herpes infection, however, are cutaneous, mucocutaneous, or oculocutaneous lesions.

BIOLOGY OF HERPES SIMPLEX VIRUS

HSV particles contain a double-stranded DNA genome enclosed in a nucleocapsid surrounded by enveloped glycoprotein. HSV may survive in humans for decades in spite of circulating neutralizing antibodies. After a primary infection, the virus usually remains latent in neuroganglion cells. Reactivation from these cells, with or without symptoms, is the hallmark of HSV infection. Reactivation of HSV may occur frequently over time and can be induced by stimuli noxious to the skin, such as ultraviolet radiation.

EPIDEMIOLOGY OF HERPES SIMPLEX

The prevalence of HSV infections among humans has been determined by virologic and seroepidemiologic surveys. Based on serologic surveys of adults (antibodies to either HSV-1, HSV-2, or both), seroprevalence ranges from 15% to 100% *(1–5)*. Seroprevalence is associated with many variables including socioeconomic status, crowded living conditions, age, geographic location, and sexual practices. Surveys using viral isolation from healthy individuals without HSV disease, to determine prevalence of HSV infection, have found that between 1% and 20% of asymptomatic children and adults are shedding HSV-1 in saliva at any given time. However, in populations in which individuals are cared for or live together for a long time, the prevalence may increase to over 30% *(6)*.

Immunocompromised patients, particularly those with acquired immunodeficiency syndrome or receiving a stem cell or solid organ transplant, will shed HSV either symptomatically or asymptomatically following infection. Estimates on the frequency of asymptomatic infection and seropositive patients after transplantation range up to 80%.

Between 0.1% and 7.3% of men attending sexually transmissible diseases clinics have HSV-2 infections *(7)*. In pregnant women from lower socioeconomic groups, the cumulative incidence of asymptomatic shedding varies between 1% and 4% *(8)*. The cumulative incidence is significantly higher in high-risk populations such as prostitutes, who may have a cumulative incidence up to 12% *(9)*. Asymptomatic genital shedding of HSV-2 is intermittent, and serial studies have found that the virus is not persistently present and varies from individual to individual.

HSV TRANSMISSION IN HOSPITALS

Prevalence of Herpes Simplex Shedding Among Hospital Personnel and Adult and Pediatric Patients

No studies have addressed the prevalence of asymptomatic shedding of HSV among hospitalized adults or children. Among institutionalized children, however, one

6-year study that used serologic testing and viral isolation at a children's home found that, of 70 initially seronegative children, 8 (11.4%) had a primary infection while at the home and 6 were symptomatic *(6)*. In another study in Australia, in a home for children under age 3 years, 29 of 43 seronegative children developed HSV antibodies over 1 year *(10)*. The prevalence of HSV infections among any hospitalized group will depend highly on whether the patients are immunocompromised and on socioeconomic background, the presence of risk factors for HSV, and the history of previous HSV infection. Hence, for practical purposes, hospital personnel should assume that all patients are potentially infectious for HSV.

In 1980, Hatherley and coworkers (11) studied the frequency of asymptomatic HSV excretion in the saliva of 384 asymptomatic members of the staff of an obstetric hospital. HSV was isolated from 10% of the employees.

Healthcare-Associated HSV Transmission

HSV transmission in the hospital is an infrequent but serious problem when it occurs. Documented hospital transmission of HSV has been confirmed in numerous studies, with the virus being transmitted from patient to patient, from personnel to patient, and from patient to personnel.

The patients at highest risk for healthcare-associated acquisition of HSV are infants <30 days of age (see Chapter 52). Several studies have documented acquisition of HSV by hospitalized infants, occasionally with fatal outcomes. The first cluster of cases was reported in 1975 by Francis and colleagues (12), who identified four fatal infections that occurred over a 2-month period in a pediatric intensive care unit. Each patient was infected with HSV-2.

In the late 1970s, DNA fingerprinting of HSV became possible. Halperin and associates (13) first determined that each epidemiologically unrelated strain had a different endonuclease pattern and thatepidemiologically related strains had identical DNA fingerprints. This technique has been applied to a number of outbreaks of HSV infection in the hospital and is a potent epidemiologic tool to confirm HSV transmission.

Infants who acquire HSV infection during the first month of life always do so postnatally. The usual source of acquisition is the maternal genital tract, although infants may acquire HSV-1 from labial lesions of either parent; occasionally, infections have been acquired by nursing infants from breast lesions. In 1978, Linnemann and coworkers (14) observed two infants in a nursery infected within 1 month with HSV-1. The two isolates had identical DNA fingerprints. The source of infection for one child was the father's labial lesion, implying that the second child had acquired HSV virus via horizontal transmission in the nursery.

In 1983, Hammerberg and colleagues (15) described an HSV outbreak in a nursery in which four infants acquired HSV-1 infection over 10 days. DNA patterns of each of the four isolates were identical, indicating the strong possibility of horizontal transmission. In 1984, Van Dyke and Spector (16) reported a case of apparent transmission of HSV-1 from a physician with a labial lesion to an infant who had received endotracheal suctioning for meconium aspiration. This was the first reported case of transmission of HSV from hospital staff to a patient.

In 1986, Sakaoka and associates (17) reported an unusual outbreak in Japan. They identified three infants who were infected with the same HSV-1 isolate, although the three cases occurred over 2.5 years. None of the mothers of these infants had a history of any genital herpes, and HSV could not be obtained from the genital tract of the mothers. All three infants were infected with a strain with the same restriction endonuclease pattern. This suggested that a single individual in the nursery with recurrent asymptomatic HSV may have infected infants intermittently in the nursery. In a second outbreak, the same authors isolated HSV-1 from three infants in the same room of a hospital within 1 month (17). One of the infant's mothers had herpetic lesions at a genital site at delivery. The infant of this infected mother was the source of infection for the other two infants. The three infants had occupied a common radiant warmer, which was thought to be a potential source of HSV transmission.

The DNA technique has also been used to exclude horizontal transmission. Halperin and coworkers (13) reported two infants who were cared for side by side in a hospital nursery who both developed HSV infections with HSV-2. DNA patterns of the two isolates were different, indicating that healthcare-associated transmission had not occurred.

In addition to hospitalized newborns, other patients at risk include surgical patients, particularly burn patients. Any patient with a breakdown in the skin has an increased risk for serious HSV infection because it is easy for HSV to enter the wound and thus the bloodstream. In 1985, Brandt and colleagues (18) used DNA patterns to determine that three HSV wound infections that occurred on a burn unit over 6 weeks were caused by unrelated isolates, although temporarily there appeared to be an outbreak in the unit. In 1981, Adams and associates (19) described two outbreaks of HSV-1 infection in a pediatric intensive care unit, one in early summer and one in late summer. In one outbreak, three nurses had herpetic whitlow (cutaneous infection of the fingertip and/or nail bed). The husband of one of the nurses had an acute HSV gingival stomatitis, and a fourth nurse had acute recurrent oral ulcers associated with HSV infection. DNA analysis of the HSV showed that each nurse was infected with the same isolate. In the second outbreak, two different isolates were transmitted in the intensive care unit. In both outbreaks, a patient was identified as the possible source of infection.

In 1992, Perl and coworkers (20) described an outbreak in a hospital unit caring for adults with cancer. The index patient was a 64-year-old man immunocompromised by lymphoma. He developed perioral HSV-1 infection. He subsequently required intubation, and the physician who intubated him developed herpetic keratoconjunctivitis. The nurse caring for the patient and a family member visiting the man both developed HSV infections with the same strain as the one found in the infected patient. There is one report of a physician acquiring HSV via a needle stick. The needle had be used to deroof a child's HSV infected vesicle (21).

Thus, there is little doubt that HSV infection is a potentially serious problem for both patients and personnel. Personnel are more likely to acquire HSV from immunocompromised patients who shed high titers of HSV for long periods. Outside the hospital a mohel infected two infants with HSV-1 during ritual circumcisions (22).

PREVENTION AND CONTROL

Prevention and control of HSV infections in the hospital is easily accomplished by rigorous adherence to standard hygienic practices. Of nine adults with HSV labialis, Turner and colleagues *(23)* found HSV in the oral secretions of seven and on the hands of six. HSV survives for as long as 2 hours on skin, 3 hours on cloth, and 4 hours on plastics. HSV is an enveloped virus and therefore is easily inactivated by standard denaturing agents such as alcohol, soaps, and detergents. Its survival on fomites and on hands means that rigorous care must be taken to protect both personnel and patients from infection from both environmental surfaces and hands *(24,25)*.

Currently, there is no evidence that hospital personnel with genital infections pose a high risk to patients if infected personnel follow good patient care practices. The risk to patients by personnel with oral labial herpes is unknown. Personnel with nonexposed oral infections, however, can reduce the risk of infecting patients by wearing an appropriate barrier, such as a mask over the lesions and avoiding hand contact with the lesions. Hand washing is absolutely essential to prevent transmission from personnel to patients. Personnel with either oral lesions or active cutaneous lesions on the hands should not care for high-risk patients such as neonates and patients with severe malnutrition, burns, or immunodeficiencies.

Personnel who have exposed active lesions of herpes simplex should not work with newborn infants (term or preterm), burn patients, or immunocompromised hosts until all lesions have dried and crusted. Personnel with herpetic whitlow may be more likely to transmit infection by contact *(26–28)*. For personnel with herpetic whitlow, the effectiveness of gloves in preventing transmission is unknown; in general, personnel with herpetic whitlow should not work with patients while they have active lesions. There is no evidence that the treatment of infected personnel with oral acyclovir, although it may reduce the titer of virus shed, will eliminate the risk of transmission *(24,29,30)*.

Several guidelines for preventing infection of personnel by infected patients have been published. Personnel can prevent infection by avoiding contact with contaminated oral secretions. Such exposure is a hazard for nurses, anesthesiologists, dentists, respiratory personnel, and others who usually have hand contact with the respiratory secretions from patients. Patients in an immunodeficiency state with active HSV infections are more likely to be infectious over a longer period than are immunocompetent individuals. Personnel can protect themselves from such infections by (a) avoiding direct contact with active lesions, (b) wearing gloves on both hands or using no-touch techniques when handling oral and vaginal secretions, and (c) thorough hand washing after patient contact.

Management of Obstetric Patients with HSV Infections

Women on an obstetric ward with proven or suspected genital herpes should be assigned to a private room with a private bath (*31*). Standard Precautions should be used by personnel who have contact with such women. Meticulous hand washing is important. The infant of a woman who has an active HSV infection or who is asymptomatic but HSV culture positive may be allowed to visit the mother, provided the mother washes her hands, wears gloves, and wears a clean gown before handling the child. The patient should sit in a chair while holding the infant, and the neonate should not be placed in a bed with the mother. The patient may walk in the hall if she wears a clean gown, but may not visit the nursery. Mothers with active genital HSV infections should be treated with acyclovir. These precautionary measures should be maintained for at least 7 days. Also, linens from patients with HSV infections should be considered contaminated and promptly and appropriately bagged for transport to the laundry (see also Chapter 55).

Management of Neonates with Active or Suspected HSV Infection

Infants born of mothers with active HSV infections should be cultured for HSV 48 hours after birth and should be kept in special care under close observation in a nursery unit. The infant should be placed on Contact Precautions along with proper disposal and containment of all articles coming in contact with the infant. The infant should be kept in isolation until at least 96 hours have passed since birth and until cultures for HSV including conjunctivae, urine, blood, skin, posterior pharynx, and nose are negative. The infant may go home with the mother and should be followed closely for the first 30 days of life. Prophylactic use of acyclovir in infants exposed to HSV at birth has no known benefit.

Pregnant personnel may care for patients with HSV infections but must observe strict hand washing techniques *(32)*.

CONCLUSION

HSV infections in the hospital are uncommon, but transmission from patient to patient, patient to personnel, or personnel to patient may occur. In a survey done by Perl and associates (20), the annual rates of healthcare-associated HSV-1 infection at a large hospital were between 9 and 15 per 10,000 admissions. When clusters of cases occur temporally within a given unit, transmission should be suspected and isolates gathered and typed by genome analysis to determine the source of the infection. This is important, because occasionally the source is an asymptomatic patient or staff member. HSV transmission is easily prevented by appropriate barrier methods and decontamination of surfaces with standard soaps, detergents, and alcohols. HSV is very labile and easily eliminated from both hands and inanimate surfaces.

CHAPTER 45

Cytomegalovirus

Stuart P. Adler

During pregnancy, if a woman acquires a primary infection with cytomegalovirus (CMV), the fetus is placed at highest risk for symptomatic congenital disease. Because of this risk and because acquisition of a primary CMV infection is frequently associated with morbidity and mortality in very low birth weight infants, immunocompromised patients, and transplant recipients, concern is often raised about the possible transmission of CMV within hospitals. Several studies of the hospital transmission of CMV have been completed. To accurately interpret these studies and understand the hospital transmission of CMV, one must first develop a basic understanding of the virus and the way it is transmitted within the general population.

BIOLOGY, DIAGNOSIS, AND CLINICAL FEATURES

Human CMV and the other human herpesviruses share certain common features. All human herpesviruses contain large DNA genomes, and CMV has the largest with a DNA molecular weight of 150 million. In addition, they all feature a nucleic acid core, a nucleocapsid, and an envelope glycoprotein derived primarily from the cell membrane when mature virions bud from within one cell to another. This cell membrane makes the virus very susceptible to inactivation by common disinfectants.

A transient viremia is produced by a primary infection with CMV. For immunocompetent individuals, primary CMV infections are usually always asymptomatic, although CMV occasionally causes an infectious mononucleosis syndrome in adults often consisting of fatigue and low-grade fever. For immunocompromised patients, particularly those immunosuppressed because of the acquired immunodeficiency syndrome (AIDS) or stem cell transplantation, CMV infections may cause severe disease in almost any organ system. CMV replicates in all tissues and organs, and when cell-mediated immunity is deficient, reactivation of latent CMV infections is common. The severity and location of tissue inflammation associated with CMV depend on the degree of immunosuppression. Among transplant recipients of solid organs, those who are seronegative before transplantation and acquire CMV via a donor organ or infected blood have the most severe CMV disease after transplantation. This disease is often associated with fever, neutropenia, and accelerated organ rejection.

CMV infections are best diagnosed by recovery of the virus from infected tissues or organs. In tissues with high titers of virus, histopathologic examination may reveal the presence of CMV inclusion cells. In immunocompromised patients, viremia is very common. In immunocompetent individuals, viremia occurs only transiently during a primary infection. The virus eludes antibody neutralization within tissues when it buds from cell to cell, thus causing, in most cases, a focal infection. Viral excretion in saliva or urine of the original infecting strain may resume at any time; therefore, CMV apparently becomes latent. Such latency is most frequently noted in individuals with severely impaired cellular immunity; in these individuals, a secondary viremia may disseminate the virus to all organs and tissues. Not only can a latent infection recur, but reinfection with a second strain of CMV may occur in both immunocompetent and immunocompromised individuals. To date, no studies have revealed the precise frequency of reinfection among immune (seropositive) individuals (1,*2–6*).

EPIDEMIOLOGY

Because CMV is ubiquitous in the human population, nearly all individuals eventually become infected. The percentage of seropositive individuals in central Virginia increases with age approximately 1% or 2% per year, and a mean of about 50% of the population possesses antibodies to the virus *(7)*. Nearly 100% of these individuals are seropositive by age 70. Around the world, the mean seropositivity rate for particular populations varies with location, the frequency of breast feeding, and socioeconomic status; regardless of location, however, nearly all individuals eventually become seropositive *(8–13)*.

One can also examine the prevalence of CMV infection within a particular population by determining the frequency of viral excretion. The rate of excretion for any age group depends on many factors, including geographic location, and is extremely variable. The congenital infection rate worldwide, however, is remarkably constant; in any population, between 0.5% and 2% of newborns will be excreting CMV (14,*15–18*).

For the most part, CMV produces no disease when acquired postnatally. Adults occasionally develop an infectious mononucleosis syndrome. Viremia will persist for a few days or weeks following a primary infection. CMV DNA in the blood detected by polymerase chain reaction and prolonged viral excretion in saliva and urine may persist for weeks or months. After infection, young children excrete CMV in saliva and urine for a period of 12 to 40 months, significantly longer than adults do (1). Immunoglobulin G antibodies to CMV appear 2 to 3 weeks following a primary infection and persist for life in both children and adults.

When, where, and how is CMV transmitted? In up to 2% of all pregnancies, transplacental transmission will occur. In the majority of cases of transmission, the mother is seropositive prior to becoming pregnant, and the infants become congenitally infected *in utero* following a recurrence of the mother's infection. Although primary maternal infection during pregnancy is responsible for only a small percentage of the total number of congenitally infected newborns, it is responsible for the majority of the symptomatic infections and severe handicaps caused by congenital infection (14,*15–18*). Perinatal transmission rather than transplacental transmission accounts for the majority of CMV infections acquired by infants. Breast milk is the most common form of transmission of CMV from seropositive mothers and accounts for up to 50% of transmitted infections; 10% to 20% transmit the infection via cervical and vaginal secretions *(19)*. Also, CMV can be acquired postnatally from other children, as in a day care setting; intrafamilial transmission is frequent following a primary infection in a single family member, with a rate of transmission of about 50% *(20)*.

CMV is frequently excreted in semen and cervical secretions. In addition, CMV infections are more prevalent among those who have multiple sex partners. However, the frequency of sexual transmission of CMV is problematic, because the virus can be transmitted orally or by close and frequent contact.

There is clear evidence of how slowly CMV is transmitted, even under optimal circumstances, which has been documented in studies of CMV transmission among children in day care. Children initially shed CMV at a concentration of about 10^4 plaque-forming units per milliliter of urine following a primary infection; this titer declines slowly thereafter *(21)*. Those under 2 years of age shed CMV for between 6 and 40 months, with a mean of about 2 years (1).

Our group monitored three day care centers in Richmond for 3 years (1). At the three centers, 14%, 27%, and 45% of the children became infected, with the majority becoming infected in the second year of life. The most significant data indicate that even at the center with the highest rate of infection, on average only one child per month acquired a primary CMV infection. Therefore, even under ideal transmission conditions of close, intimate daily contact (i.e., children playing daily together in the same room), the virus is transmitted slowly.

The period for CMV transmission from infected children to their mothers or caregivers is also very slow and depends on the age of an infected child (22). We observed that among the seronegative mothers of infected children, 16 (57%) of 28 mothers with infected children 20 months of age or younger acquired CMV from their children, while only 3 (14%) of 22 mothers with infected children over 20 months of age acquired the infection ($p < .007$). In the group of mothers with infected children <20 months of age, the average interval between identification of the child's infection and transmission to the mother was 8 months (SD = ±6 months).

Caregivers can also be infected with CMV through transmission from children (23–25). We studied 614 caregivers in Richmond, and the rate of CMV infections among caregivers was independently associated with the age and race of the caregiver and the ages of children for whom they cared. The highest rate of CMV infections occurred in women caring for children younger than 2 years independently of age and race (23,24). For the caregivers in our study, the annual seroconversion rate was 11% for a group of 202 initially seronegative women, compared with a 2% rate for hospital employees during the same period.

CMV TRANSMISSION IN HOSPITALS

Prevalence of CMV Excretion among Hospitalized Adults and Children

The above short review of CMV transmission outside the hospital describes the relative rates of transmission and indicates why nearly all the hospital transmission studies have been conducted in pediatric units.

In general, children have higher excretion rates than adults, as indicated by published reports on the prevalence of CMV excretion among hospitalized adults and children. In a home care setting, 8% of children younger than 5 years excrete CMV *(26–29)*. This rate increases to between 9% and 75% for children in day care, depending on the day care center (1,*21,30–39*). Between 1% and 7% of hospitalized children beyond the newborn period shed CMV (*28,29,40–43*,44,45). From 1% to 3% of infants in newborn nurseries shed CMV at any time, although an Egyptian study found 12.5% of 175 infants in a neonatal intensive care unit shedding CMV (44,46–48).

Viremia is rare among healthy adults and <1% are viruric. Likewise, in a study completed on a general oncology ward in Richmond, <1% of adult patients excreted CMV *(49)*. Published data suggest that up to 45% of stem cell recipients may excrete CMV, but this percentage may be decreasing because of the selection of seronegative donors and the frequent use of ganciclovir *(50–52)*. Among AIDS patients, rates of CMV excretion vary widely, but it is probable that at least 25% of symptomatic patients will shed CMV *(53)*. In the 1970s, between 38% and 96% of kidney recipients excreted CMV *(54–60)*, but current rates are probably much lower because immunosuppressive therapy is less intense. Finally, 8% to 35% of pregnant women will excrete CMV from one or more sites in the third trimester *(61,62)*.

An examination of CMV infection at eight different hospital units in two children's hospitals was completed by Demmler and her colleagues (44) in Houston, TX. The group surveyed each unit at least three times and surveyed the chronic care unit 18 times. Infection rates in the units ranged from 3% to 6%, but the chronic care units had much higher rates of CMV infection (15%). In these units, the

children were together for many months, were chronically ill, and had multiple blood transfusions. Overall, infection rates among hospitalized children in Houston were similar to those observed in an earlier study of hospitalized children in Richmond.

CMV on Surfaces

Where is CMV found in a hospital setting besides in the urine and saliva of infected patients? In Houston the Demmler group (44) obtained numerous environmental samples and surface swabs for CMV culture, including toys, Ambu bags, scales, intravenous tubing, crib rails, and thermometers. The swabs did not recover CMV from any inanimate object. However, the virus was isolated from the hands of a patient, a nurse, and a laboratory worker. Hands are a known reservoir for CMV. In Birmingham, AL, a similar survey done in day care centers recovered CMV from the hands of children and caregivers *(63)*.

It is easy to deactivate CMV with products such as soaps, detergents, and alcohol; CMV will also wash off surfaces with plain water (64). The virus is not very stable in the environment (65). CMV has a half-life of 2 to 6 hours on surfaces, but low titers of virus may persist for 24 hours.

Transmission from Patients to Personnel—Published Rates of CMV Infection among Pediatric Nurses and Controls

Table 45-1 lists the published rates of CMV infection among pediatric nurses and control subjects (women without patient contact). Relatively low numbers of primary CMV infections and low numbers of total subjects have affected the results of each survey. In the early 1970s, Yeager (66) first reported data that suggested a healthcare-associated infection risk for pediatric nurses. Her group observed infection in 3 of 31 ward nurses, 2 of 34 nursery nurses, and 0 of 27 control subjects. Studies in Sweden and Philadelphia showed similar results, but low rates of CMV infection were found in studies in Richmond, Birmingham, Houston, and Minneapolis (see Table 45-1).

One observation that has been consistent among all the studies is a relatively low infection rate among the control subjects. When the infection rates (number of persons infected per 100 person-years observed) for each of the studies listed in Table 45-1 were averaged, a higher annual infection rate was found among those who worked in pediatric hospitals than among the control subjects. Ward nurses display an annual average infection rate of 3.1 infections/100 person-years (24 infections for 778 person-years); this does not differ statistically from the 2.1 infections/100 person-years (45 infections for 2,126 person-years) observed for the control group. In nursery nurses the average annual infection rate is 3.9 infections/100 person-years (21 infections for 534 person-years), which is a significantly higher rate than that observed in the control group ($p < .05$; chi-square = 4.8; 1 degree of freedom).

The above analysis should be approached with skepticism for several reasons. First, the statistical analysis depends on the large group of pregnant women who served as controls in the Birmingham study. If this control group had not been available, the analysis would lack sufficient statistical power to detect small differences among groups. Second, in three of the studies, nursery nurses did not acquire CMV from infected infants in their care, according to genome analysis data. This was true of one woman in the Richmond study, of two in the Birmingham study, and of two in the Houston study. Third, one may be comparing

very dissimilar groups when combining studies because nurses engage in many different activities, and these activities and their relative frequencies may vary widely among hospitals. Fourth, the highest rate of infection occurs in nursery nurses, and these nurses care for children with the lowest rate of CMV excretion. Summarizing the data in Table 45-1, under the worst circumstance the rate of CMV infection for nursery nurses is probably no more than three times higher than the rate for control subjects (relative risk = 1.83; 95% confidence interval = 1.01–3.04).

Patient-to-Patient Transmission

A powerful tool for studying CMV transmission is DNA genome analysis of viral DNA. Table 45-2 lists the results of studies that applied this technique to epidemiologic studies of CMV in the hospital. Between 1982 and 1985, my colleagues and I monitored the number of children in the newborn nursery in Richmond who were shedding CMV virus and the periods they were viruric while hospitalized (47). We monitored 40 seronegative women over the course of this study. One of this group seroconverted, but she shed an isolate that had a DNA genome pattern different from 34 of the isolates excreted by the children in the nursery for that period. Also, no infant-to-infant transmission occurred.

In Durham, it was believed that a house officer had acquired CMV from a child in her care, but the DNA of her isolate differed from that of the isolate shed by the child *(71)*. Surveys revealed similar observations for nurses in Houston and Birmingham (46,*72*).

In 1983, Spector (73) used DNA analysis of viral isolates to conclude that two babies in a neonatal nursery in Oakland had probably acquired CMV from another infected infant in that nursery. Infants became infected after being located side by side for approximately 6 weeks. They received care from common caregivers, but did not receive blood from common donors.

In another study in Houston, Demmler and her team (44) studied the DNA patterns of 27 viral isolates, 24 from children and 3 from nurses, derived from 18 sets of samples obtained for culture from children and staff on a pediatric chronic care unit. Four children produced two pairs of identical isolates. Because one pair of children had shared a common blood donor, it is uncertain whether the CMV was acquired from the blood donor or via horizontal transmission. The second pair of children who shed identical isolates had been given care for 20 weeks or more side by side in the same unit, and they had not received blood from a common donor. One nurse had cared for both children for 3 weeks. Therefore, it is reasonable to assume that these children shed isolates with identical DNA patterns because patient-to-patient transmission occurred.

Based on analysis of genome DNA, there have been no documented instances of CMV transmission from patients to hospital caregivers, but, at least in the two reports cited above, patient-to-patient transmission probably did occur. In both cases, patient-to-patient transmission occurred in chronic care units with children crowded side by side for long periods; this is an institutional setting similar to that of day care.

PREVENTION AND CONTROL

According to published data, CMV transmission from patients to hospital personnel occurs rarely, if at all, and has never been documented. An analysis of the seroconversion data shows that there may be an annual infection rate 1% to 4% greater for nursery nurses than for the general population, but, as noted above, there are many problems with this type of analysis of published data.

CMV may be transmitted between hospitalized patients, but transmission is easily prevented. Soap and water readily inactivate the virus, and simple handwashing techniques should prevent transmission. One study we completed showed that susceptible pregnant women but not nonpregnant women could protect themselves from acquiring CMV from their infected child by following simple hygienic precautions (74). Thus if strictly adhered to, standard precautions will protect both patients and personnel *(75,76)*. One should not be concerned about patient-to-patient transmission unless dealing with immunocompromised patients or premature infants. In either of those situations, one should be very careful about the kinds of contact these patients have with other patients and personnel; one should adhere to frequent and adequate handwashing techniques and to standard precautions.

It is not necessary to routinely test hospital personnel for CMV immunity either before or during pregnancy

[a]NICU, neonatal intensive care unit.

because of the low incidence of infection. If, however, a pregnant woman working in a healthcare setting is especially concerned about CMV, serologic testing for immunity can be done. Seronegative pregnant women who are susceptible should be especially attentive to good hygiene at work and at home if they care for a young child at home (74). Serial serologic testing during pregnancy should be offered as an option to concerned pregnant seronegative healthcare workers.

Pregnant women also should not be furloughed or transferred with the idea that their exposure frequency would decrease on different units. They should instead assume that all patients may be infectious and are best advised to practice frequent handwashing and strictly adhere to standard precautions. Standard precautions apply to blood and all body fluids, secretions, and excretions. Pregnant hospital personnel should assume that all body fluids are possibly infectious. As stated above, they should practice frequent handwashing after patient contact. When they perceive that they are most likely to be exposed to body fluids or when they are handling urine and respiratory secretions, they should wear gowns and gloves.

While CMV is seldom, if ever, transmitted via respiratory droplets, the polymerase chain reaction—a very sensitive method for detecting minute quantities of DNA—has detected CMV DNA in the filtered air near immunosuppressed patients with CMV pneumonia and other respiratory infections *(77)*. Because the infectivity of aerosols from such patients is unknown, use of a mask by pregnant women is appropriate when prolonged or frequent exposure to aerosolized urine or respiratory secretions is likely to occur.

CHAPTER 46

Hepatitis Viruses

Adelisa L. Panlilio, Melissa K. Schaefer, and Nicola D. Thompson

Three hepatitis viruses are of clinical significance in healthcare settings in the United States because of healthcare-related transmission: hepatitis A virus (HAV), hepatitis B virus (HBV), and hepatitis C virus (HCV). This chapter discusses the epidemiology, clinical presentation, diagnosis, and prevention of transmission of these viruses, focusing on transmission from patient to patient in healthcare settings. Transmissions from patient to patient in dialysis settings, through transfusion or transplantation, and to and from healthcare personnel are covered elsewhere.

Patient-to-patient transmission of HAV, HBV, and HCV has been detected in a variety of healthcare settings, both in developed and less developed countries (1,*2–8*). Such transmission generally occurs indirectly through lapses in infection control practices of caregivers, and almost all of the transmissions reported were preventable through adherence to recommended practices for infection control.

Worldwide, exposures associated with healthcare delivery account for many HBV and HCV infections. Therapeutic injections, which are commonly overused and administered in an unsafe manner in developing and transitional countries, are estimated to account for over 21 million new HBV infections and 2 million new HCV infections each year *(9)*. Historically, in the United States, surveillance data have suggested that healthcare-associated HBV and HCV transmission was unusual; however, mounting data compiled from public health outbreak investigations suggest that transmission of viral hepatitis related to healthcare procedures is more common than previously recognized *(8,10,11)*.

HEPATITIS A

Epidemiology

Hepatitis A is caused by HAV, an RNA virus, classified as a picornavirus (12). HAV infection can cause both acute disease and asymptomatic infection, does not cause chronic infection, and confers lifelong immunity from future HAV infection *(13)*. HAV is transmitted primarily by the fecal–oral route, by either person-to-person contact or ingestion of contaminated food or water (12).

While hepatitis A occurs worldwide, major geographic differences exist in its endemicity and resulting epidemiologic features. The degree of endemicity is closely related to sanitary and living conditions and other indicators of the level of development. Historically, most US cases have resulted from person-to-person transmission, and infection often occurred in the context of community-wide and child daycare center outbreaks (12,*14*). In a majority of reported cases, risk factors for infection have not been identified *(10,14,15)*.

The national incidence rate of hepatitis A has declined steadily since the introduction of licensed hepatitis A vaccines in the United States in 1995 and the issuance of the first public health recommendations for the use of vaccine to prevent transmission of HAV in 1996 *(16)*. In 2007, a total of 2,979 acute symptomatic cases of hepatitis A were reported; the national incidence (1.0 case per 100,000 population) was the lowest ever recorded *(10)*. The most frequently reported risk factors for hepatitis A were international travel (18%), and sexual and household (8%) or other (9%) contact with another person with hepatitis A. (Risk factors are not mutually exclusive.) The majority of cases have no risk factor data available. After asymptomatic infection and underreporting were taken into account, an estimated 25,000 new infections occurred in 2007 *(10,17)*.

Rarely, HAV infection has been transmitted by transfusion of blood or blood products collected from donors during the viremic phase of their infection, before they are symptomatic or jaundiced (1,*18–29*). Transmission has not been reported to occur after inadvertent needlesticks or other contact with blood, although transmission of HAV among injection drug users (IDUs) may be through both percutaneous and fecal–oral routes (12,*30*).

Depending on conditions, HAV can be stable in the environment for months *(31)*. Heating foods at temperatures >185°F (85°C) for 1 minute or disinfecting surfaces with a 1:100 dilution of sodium hypochlorite (i.e., household bleach) in tap water is necessary to inactivate HAV *(32)*. Laboratory studies have demonstrated that HAV can survive on human hands for up to 4 hours and that the quantity of HAV transferred from hands to animate and inanimate surfaces can be increased by the application of pressure and friction *(33)*. This study suggests that human hands and environmental surfaces may serve as sources of HAV dissemination.

Clinical Illness

The average incubation period for hepatitis A is 28 days (range 15–50 days) *(34)*. Typically, acute hepatitis A starts abruptly with symptoms that can include fever, malaise, anorexia, nausea, abdominal discomfort, dark urine, and jaundice. The severity of clinical disease associated with HAV infection increases with age. In children <6 years of age, most (70%) infections are asymptomatic; if illness does occur, it is usually anicteric *(35)*. Among older children and adults, infection is usually symptomatic, with jaundice occurring in >70% of patients *(36)*. Signs and symptoms usually last <2 months, although 10% to 15% of symptomatic persons have prolonged or relapsing disease lasting up to 6 months *(37)*.

Fulminant hepatitis is a rare complication of hepatitis A; the case-fatality rate for all ages is 0.3% to 0.6%, but reaches 1.8% among adults >50 years *(10)*. Persons with chronic liver disease who acquire hepatitis A are at increased risk for acute liver failure and death *(10,38)*. Other complications include cholestatic hepatitis, with very high bilirubin levels that can persist for months, and relapsing hepatitis, in which exacerbations can occur weeks to months after apparent recovery. Chronic infection does not occur following HAV infection (12).

In infected persons, HAV replicates in the liver, is excreted in bile, and is shed in the stool. Feces can contain up to 10^8 infectious virions per milliliter and are the primary source of HAV *(39,40)*. Fecal excretion of HAV and, hence, peak infectivity are greatest during the incubation period of disease before the onset of jaundice or elevation of liver enzymes *(39,40)*. The concentration of virus in stool declines after jaundice appears; once disease is clinically obvious, the risk of transmitting infection is decreased. However, some patients admitted to the hospital with HAV, particularly immunocompromised patients, may still be shedding virus because of prolonged or relapsing disease, and such patients are potentially infectious *(41)*. Fecal shedding of HAV, formerly believed to continue only as long as 2 weeks after the onset of dark urine, has been shown to occur as late as 6 months after diagnosis of infection in premature infants (who are more likely to be anicteric). Children and infants can shed HAV for longer periods than do adults, up to several months after the onset of clinical illness *(28)*. Viremia occurs soon after infection and persists through the period of liver enzyme elevation *(42,43)*. The amount of virus in the blood is several orders of magnitude lower than that in stool *(42–44)*. Although virus has also been found in saliva during the incubation period in experimentally infected animals, transmission by saliva has not been reported *(44)*.

Diagnosis

Hepatitis A cannot be differentiated from other types of viral hepatitis on the basis of clinical or epidemiologic features alone. The diagnosis of acute HAV infection is confirmed during the acute or early convalescent phase of infection by the presence of immunoglobulin M (IgM) anti-HAV. In most persons, IgM anti-HAV becomes detectable 5 to 10 days before the onset of symptoms and can persist for up to 6 months after infection *(43,45)*. Immunoglobulin G (IgG) anti-HAV, which also appears early in the course of infection, remains detectable for the lifetime of the individual and confers lifelong protection against infection *(13)*. Although commercial tests are available for the detection of IgM and total (IgM and IgG) anti-HAV in serum, IgM HAV testing should be limited to persons with evidence of clinical hepatitis or to those who have had recent exposure to an HAV-infected person to avoid the possibility of false-positive test results *(46)*.

HAV RNA can be detected in the blood and stool of most persons during the acute phase of infection by using nucleic acid amplification methods, and nucleic acid sequencing has been used to determine the relatedness of HAV isolates *(47)*. However, these methods are available in only a limited number of research laboratories and generally are not used for diagnostic purposes.

HAV Transmission in Healthcare Settings

Transmission of HAV from patient to patient in healthcare settings has been reported infrequently, usually occurring when the source patient had unrecognized hepatitis and was fecally incontinent or had diarrhea (1). Other risk factors for HAV transmission include activities that increase the risk of fecal–oral contamination, such as eating or drinking in patient-care areas, inadequate hand hygiene after handling an infected patient and/or the patient-care environment, and sharing food, beverages, or cigarettes with patients, their families, or other staff members. Healthcare-associated hepatitis A outbreaks are summarized in Table 46-1 in chronological order of the date they were reported. The table shows the number of patients, staff, and family contacts infected, the country and healthcare setting in which each outbreak occurred, and factors contributing to transmission such as asymptomatic viral shedding, gross fecal environmental contamination, and hospitalization during the prodrome of hepatitis A *(18,20,22,23,25–29,48–61)*. The majority of reports are from the 1980s, with the last published report from 2002. Two illustrative outbreaks will be described in greater detail.

Several outbreaks have occurred in neonatal intensive care units (NICUs), often involving transfusion of neonates with infected blood and subsequent transmission of HAV infection to other infants and staff *(22,23,26–29,48)*. The first such reported outbreak resulted from exchange transfusion of blood from a donor in the prodrome of hepatitis A *(18)*. (The donor became ill 4 weeks after donation.) The infant had received an exchange transfusion at birth for Rh incompatibility and developed subclinical HAV infection. She was subsequently nursed on a surgical ward for treatment of *Staphylococcus aureus* osteitis for 4 weeks, during which period she had to be turned every hour. Transmission to her mother, to nine staff who provided care to the index patient, and to one other patient on the same ward as the index case was documented.

In many of the NICU outbreaks, lapses in infection control practices, including smoking, eating, and drinking in patient-care areas, not wearing gloves as appropriate when providing patient care, and inadequate hand hygiene, facilitated transmission of HAV from patient to patient and from patient to staff, contributing to propagation of the outbreaks *(22,23,26–29,48)*. NICUs provide a setting that has been conducive to further spread of HAV once it

is introduced. The combination of frequent contact with soiled diapers, asymptomatic infection in neonates, and prolonged HAV excretion among preterm infants may facilitate HAV transmission.

Most patients hospitalized for symptomatic hepatitis A are admitted after onset of jaundice, when they are beyond the point of peak infectivity (1,*62*). Consequently, most source patients for outbreaks of hepatitis A outside of NICUs were usually admitted for diagnoses other than hepatitis A, were incubating hepatitis A, and developed subclinical or symptomatic hepatitis after hospitalization *(20,25,49–61)*. Patient-to-healthcare personnel and patient-to-patient transmission of HAV in such situations was usually associated with fecal incontinence and/or gross environmental contamination with feces *(20,25,49–54,56–58,61)*. One such outbreak involved an adult hospitalized for elective cholecystectomy who developed fever, abdominal pain, vomiting, and diarrhea postoperatively *(51)*. She had several episodes of fecal incontinence with gross contamination of her bed linen and floor. Despite developing jaundice, she was discharged without a specific diagnosis. However, on readmission for further diagnostic evaluation of her jaundice, she was confirmed to have acute hepatitis A. Five nurses who were exposed to the patient during her first admission became clinically ill with laboratory-confirmed hepatitis A. As part of a serologic survey of exposed personnel, a sixth nurse was found to have asymptomatic infection. The index patient's hospital roommate, who had assisted the index patient in the bathroom postoperatively, also developed clinical illness.

Other healthcare-associated outbreaks of hepatitis A had features similar to the outbreak just described *(25,50,52–61)*. In many of these outbreaks, the index patient was admitted for a condition other than hepatitis, for example, malaria, amebic hepatic abscess, burns, or cardiac surgery. When the index patient developed symptoms consistent with hepatitis A, the diagnosis was often not suspected until after his or her contacts, usually personnel, developed symptomatic hepatitis A.

Prevention of Healthcare-Related HAV Transmission

The primary means of preventing HAV transmission in healthcare settings is by observing Contact Precautions with patients with acute hepatitis A who are in diapers and/or incontinent and by avoiding fecal–oral contact (63). Continent patients can be managed with Standard Precautions alone (63). Meticulous hand hygiene after touching the patient, the patient's feces, or the environment around the patient (64) and not eating, drinking, or smoking in patient-care areas are essential to preventing HAV transmission in healthcare settings (63). In addition, cleaning and disinfection of all patient-care areas is important for frequently touched surfaces, especially those closest to the patient, which are most likely to be contaminated (e.g., bedrails, bedside tables, commodes, doorknobs, sinks, surfaces, and equipment in close proximity to the patient) (63). The frequency or intensity of cleaning may need to change based on the patient's level of hygiene and the degree of environmental contamination (63). An Environmental Protection Agency (EPA)—approved hospital disinfectant/detergent designed for general housekeeping surfaces is preferred (65).

Inactivated hepatitis A vaccines are available for prevention of hepatitis A (12,*66–68*). The vaccines containing HAV antigen that are currently licensed in the United States are the single-antigen vaccines HAVRIX (manufactured by GlaxoSmithKline, Rixensart, Belgium) and VAQTA (manufactured by Merck & Co., Inc., Whitehouse Station, NJ) and the combination vaccine TWINRIX (containing both HAV and HBV antigens; manufactured by GlaxoSmithKline). These vaccines are highly immunogenic as well as highly effective in the prevention of clinical hepatitis A *(67,68)*. With universal childhood immunization with hepatitis A vaccine, catch-up vaccination of older children in geographic regions with historically high incidence, and broader vaccination coverage of at-risk groups, the overall population level of immunity will continue to rise. Already, increased vaccination coverage for hepatitis A among children has led to the lowest rates of hepatitis A in the United States, consistent with herd immunity *(69)*. Healthcare-associated hepatitis A transmission is likely to remain a rare event.

Because serologic surveys among healthcare personnel have not shown greater prevalence of HAV infection than in control populations, healthcare personnel are not considered at increased risk for acquiring HAV infection, and routine administration of vaccine in healthcare personnel is not recommended (12,*70,71*). Vaccine is recommended for some persons because of occupational risk, including those who handle HAV-infected primates or are exposed to HAV in a research laboratory (12). Hepatitis A vaccine is also recommended for all children at age 1 year (12–23 months), for persons at increased risk of infection, such as those traveling or working in countries with high or intermediate endemicity of infection, men who have sex with men, injection and noninjection illicit-drug users, persons with clotting factor disorder, and for persons with chronic liver disease who are at increased risk for severe complications from hepatitis A (12).

Immune globulin (IG) is available for preexposure and postexposure prophylaxis (12,72). IG provides protection against hepatitis A through passive transfer of antibody, and is 80% to 90% effective in preventing clinical hepatitis A when administered before exposure or early in the incubation period after exposure, that is, within 14 days. The recommended dose of IG for hepatitis postexposure prophylaxis is a single dose of 0.02 mL/kg administered intramuscularly as soon as possible after exposure (12,72).

Hepatitis A vaccine administration was recommended as preferred over IG for postexposure prophylaxis by the Advisory Committee on Immunization Practices in 2007 (72). For healthy persons aged 12 months to 40 years, single antigen hepatitis A vaccine at the age-appropriate dose is preferred to IG because it offers long-term protection and is more easily administered. For persons aged >40 years, IG is preferred because of the absence of information regarding vaccine performance and the more severe manifestations of hepatitis A in this age group; vaccine can be used if IG cannot be obtained. The magnitude of the risk for HAV transmission from the exposure should be considered in decisions to use IG or vaccine. IG should be used for children aged <12 months, immunocompromised persons, persons who have had chronic liver disease diagnosed, and persons for whom vaccine is contraindicated. Persons given IG, for whom hepatitis A vaccine is also

recommended for other reasons, should receive a dose of vaccine simultaneously with IG. For persons who receive vaccine, the second dose should be administered according to the licensed schedule to complete the series (72). The efficacy of IG or vaccine administered >2 weeks after exposure has not been established.

Hepatitis A postexposure prophylaxis is not routinely indicated when a single case occurs in an elementary or secondary school, an office, or in other work settings, and the source of infection is outside the school or work setting (12,72). Similarly, when a person who has hepatitis A is admitted to a hospital, staff should not routinely be administered hepatitis A postexposure prophylaxis; instead, Standard Precautions and careful hygienic practices should be emphasized. Hepatitis A postexposure prophylaxis should be administered to persons who have close contact with index patients if an epidemiologic investigation indicates that HAV transmission has occurred among students in a school or among patients or between patients and staff in a hospital. When outbreaks occur in hospitals, use of hepatitis A vaccine or IG for persons in close contact with infected patients is recommended (12,72).

HEPATITIS B

Epidemiology

HBV belongs to the family Hepadnaviridae, a group of DNA viruses. The only known hosts for HBV are humans, although some nonhuman primates can be infected under laboratory conditions (73). HBV infection can cause both acute disease and asymptomatic infection and may result in chronic infection. Worldwide, HBV is the most common cause of chronic viremia; there are an estimated 360 million chronic carriers worldwide who are at risk for HBV-related liver disease (73), and there are 500,000 to 700,000 deaths each year due to acute and chronic liver disease (73,*74*). In the United States, approximately 0.3% to 0.5% of the general population, or 800,000 to 1.4 million persons, are chronically infected with HBV; they provide a reservoir for infection in the population *(75,76)*.

HBV is transmitted by percutaneous or mucosal exposure to blood and other body fluids from infected persons. Blood contains the highest HBV titers of all body fluids and is the most important vehicle of transmission in the healthcare setting. Hepatitis B surface antigen (HBsAg) is also found in several other body fluids, including breast milk, bile, cerebrospinal fluid, feces, nasopharyngeal washings, saliva, semen, sweat, and synovial fluid *(77)*. However, the concentration of HBsAg in body fluids can be 100- to 1,000-fold higher than the concentration of infectious HBV particles. Therefore, most body fluids are not efficient vehicles of transmission, because they contain low quantities of infectious HBV, despite the presence of HBsAg.

Children born to infected mothers are at high risk for perinatally acquired HBV infection. Persons parenterally exposed to blood, particularly IDUs, are also at significant risk. Sexual contact with infected partners is another efficient mode of HBV spread. In most industrialized countries, adult infections usually are acquired sexually or by injection drug use (*10*,73,*78*).

HBV is a relatively hardy virus, resistant to drying, ambient temperatures, simple detergents, and alcohol. It has been found to remain viable and infectious on environmental surfaces for at least 7 days and can be present in high concentrations on inanimate objects, even in the absence of visible blood *(76,79,80)*. Thus, indirect contact transmission can occur through inanimate objects (e.g., contaminated medical equipment or environmental surfaces). Transmission in households is well documented, and, in part, may be attributable to contact with fomites or environmental surfaces contaminated with secretions or blood from infected persons. HBV has been shown to be inactivated by several intermediate-level disinfectants, including 0.1% glutaraldehyde and 500 parts per million (ppm) free chlorine from sodium hypochlorite (e.g., household bleach) *(81,82)*. Heating to 98°C for 2 minutes also inactivates HBV *(83,84)*.

Clinical Illness

The average incubation period (time from exposure to onset of jaundice) for acute HBV infection is 90 days with a range of 6 weeks to 6 months *(76)*. The period of infectivity precedes the development of jaundice by 2 to 7 weeks and correlates with the presence of HBsAg in the serum. Symptoms of acute hepatitis B include fatigue, poor appetite, nausea, vomiting, abdominal pain, low-grade fever, jaundice, dark urine, and light stool color. Clinical signs include jaundice, liver tenderness, and possibly hepatomegaly or splenomegaly. Fatigue and loss of appetite typically precede jaundice by 1 to 2 weeks. Acute illness typically lasts 2 to 4 months. Most newly infected infants, children aged <5 years, and immunosuppressed adults are typically asymptomatic, while 30% to 50% of children aged >5 years and adults will have initial clinical signs or symptoms. The case-fatality rate among persons with reported acute hepatitis B is approximately 1%, with the highest rates (~5%) occurring in adults aged >60 years *(10)*.

The risk of developing chronic HBV infection varies inversely with the age at infection. Chronic infection occurs in 90% of infants infected at birth, 25% to 50% of children infected at 1 to 5 years of age, and about 5% to 10% of people infected as older children and adults *(76,85)*. However, immunosuppressed persons (e.g., hemodialysis patients and persons with HIV infection), persons with diabetes, and the elderly are also at increased risk of developing chronic HBV infection (*86*,87). An estimated 15% to 25% of persons with chronic HBV infection will die prematurely of either cirrhosis or primary hepatocellular carcinoma (HCC) (73,*76*,*88*).

Diagnosis

Hepatitis B is differentiated from other causes of hepatitis by serologic assays. Several well-defined antigen–antibody systems are associated with HBV infection, including HBsAg and antibody to HBsAg (anti-HBs); hepatitis B core antigen (HBcAg) and antibody to HBcAg (anti-HBc); and hepatitis B e antigen (HBeAg) and antibody to HBeAg (anti-HBe). Serologic assays are commercially available for all of these except HBcAg, because no free HBcAg circulates in blood. These markers of HBV infection change over time, with different patterns seen in patients with acute infection that resolves and patients with chronic infection (Table 46-2) *(76)*.

TABLE 46-2

Interpretation of Patterns of HBV Serologic Markers

Serologic Marker				
HBsAg[a]	*Total Anti-HBc*[b]	*IgM*[c] *Anti-HBc*	*Anti-HBs*[d]	*Interpretation*
–	–	–	–	Susceptible, never infected
+	–	–	–	Acute infection, early incubation[e]
+	+	+	–	Acute infection
–	+	+	–	Acute resolving infection
–	+	–	+	Recovered from past infection, and immune
+	+	–	–	Chronic infection
–	+	–	–	False positive (i.e., susceptible), past infection, or "low-level" chronic infection
–	–	–	+	Immune if titer is ≥10 mIU/mL

[a]HBsAg, hepatitis B surface antigen.
[b]Anti-HBc, antibody to hepatitis B core antigen. The total anti-HBc assay detects both IgM and IgG antibodies.
[c]IgM, immunoglobulin M.
[d]Anti-HBs, antibody to hepatitis B surface antigen.
[e]Transient HbsAg positivity (lasting ≤18 days) might be detected in some patients during vaccination.
+, positive; –, negative.
(Adapted from Centers for Disease Control and Prevention. Recommendations for identification and public health management of persons with chronic hepatitis B virus infection. *MMWR Morb Mortal Wkly Rep* 2009;57(RR-8):1–20, Table 2.)

The presence of HBsAg is indicative of active HBV infection and all HBsAg-positive persons should be considered infectious *(76)*. In newly infected persons, HBsAg is the first marker present in serum. The average time from exposure to HBsAg detection is 30 days (range 6–60 days) and persists for variable periods. Transient HBsAg positivity (usually lasting ≤18 days) can be detected in some patients after the receipt of hepatitis B vaccination and is clinically insignificant *(89,90)*. Anti-HBc develops in all HBV infections, appearing at onset of symptoms or liver test abnormalities in acute HBV infection, rising rapidly to high levels, and persisting for life *(76)*. Acute or recently acquired infection can be distinguished by presence of the IgM class of anti-HBc, which persists for approximately 6 months if the infection resolves. Persons with exacerbations of chronic HBV infection can test positive for IgM anti-HBc *(76)*. The positive predictive value of the IgM anti-HBc test is low in asymptomatic persons, and its use for diagnosis of acute hepatitis B should be limited to persons with evidence of acute hepatitis or epidemiologic link to a person with HBV infection *(76)*.

In persons who recover from HBV infection, HBsAg and HBV DNA are eliminated from the blood, usually in 3 to 4 months, and anti-HBs usually develops during convalescence. The presence of anti-HBs indicates immunity from HBV infection. After recovery from natural infection, most persons will be positive for both anti-HBs and anti-HBc, whereas only anti-HBs develops in persons who are successfully vaccinated against hepatitis B. Persons who do not recover from HBV infection and become chronically infected remain positive for HBsAg (and anti-HBc) and HBV DNA, although a small proportion of persons with chronic HBV infection (0.5%–2% per year) spontaneously resolve infection, clear HBsAg and HBV DNA, and develop anti-HBs *(76,91)*. The persistence of HBsAg for 6 months after the diagnosis of acute HBV is indicative of progression to chronic HBV infection.

HBeAg can be detected in serum of persons with acute or chronic HBV infection. The presence of HBeAg correlates with more active disease and high levels of HBV DNA (i.e., high infectivity), and the presence of anti-HBe correlates with lower HBV DNA levels. However, all HBsAg-positive persons should be considered infectious, regardless of their HBeAg or anti-HBe status.

Testing can be performed to assess the presence or concentration of circulating HBV DNA. HBV infection can be detected using qualitative or quantitative tests for HBV DNA. Highly sensitive single-sample nucleic acid tests can detect HBV DNA in the serum of an infected person 0 to 10 days before detection of HBsAg. A number of HBV DNA tests approved by the Food and Drug Administration (FDA) are available. HBV DNA tests are most commonly used for patients being managed with antiviral therapy *(88)*.

HEPATITIS C

Epidemiology

HCV is an RNA virus of the Flaviviridae family. Worldwide the estimated prevalence of HCV infection is 2%, representing 123 million people (92). HCV infection is the most common chronic blood-borne infection in the United States, affecting an estimated 1.3% of the US general population or 3.2 million persons *(93)*. There are six HCV genotypes and more than 50 subtypes. Genotype 1 accounts for 70% to 75% of all HCV infections in the United States; subtype 1a predominates over subtype 1b *(94–96)*. HCV-associated end-stage liver disease is the most frequent indication for liver transplantation among US adults *(97)*. As with HBV, persons with chronic HCV infection provide a reservoir for new infection in the population.

The highest prevalence of HCV infection (70%–90%) is reported among persons with substantial or repeated direct percutaneous exposures to blood (e.g., IDUs,

recipients of blood from unscreened donors, and persons with hemophilia treated with clotting factor concentrates that did not undergo viral inactivation) (92,*93*). Risk factors associated with acquiring HCV infection in the United States have included transfusion of blood and blood products and transplantation of solid organs from infected donors, occupational exposure to blood (primarily contaminated needlesticks), birth to an infected mother, sex with an infected partner, and multiple heterosexual partners. The incidence of acute hepatitis C in the United States has declined by ≥90% since 1990, primarily as a result of a decrease in cases among IDUs; however, these declines have plateaued since 2003 *(10)*. Injection drug use remains the primary mode of HCV transmission in developed countries (92).

Degradation of HCV occurs when serum containing HCV is left at room temperature. Specific animal infectivity studies have shown survival up to 16 hours but not as long as 4 days *(98)*. The potential for environmental survival of HCV suggests that environmental contamination with blood containing HCV can pose a risk for transmission in the healthcare setting. The risk for transmission from exposure to fluids or tissues other than HCV-infected blood has not been quantified but is expected to be low. HCV is not known to be transmissible through the airborne route or through casual contact in the workplace.

Clinical Illness

The average incubation period for acute HCV infection is 6 to 7 weeks and ranges from 2 to 24 weeks. HCV infection produces a spectrum of clinical illness similar to that of HBV infection and is indistinguishable from other forms of viral hepatitis based on clinical symptoms alone. Most adults with acute HCV infection will be asymptomatic; about one-third of adults develop clinical symptoms and jaundice *(99)*. The course of acute hepatitis C is variable, although elevations in serum alanine aminotransferase (ALT) levels, often in a fluctuating pattern, are its most characteristic feature. Normalization of ALT levels might occur and suggests full recovery, but this is frequently followed by ALT elevations that indicate progression to chronic disease *(100)*. After acute infection, 15% to 25% of persons appear to resolve their infection without sequelae as defined by sustained absence of HCV RNA in serum and normalization of ALT levels *(101)*. Fulminant hepatic failure following acute hepatitis C is rare *(10,99)*.

The lack of a vigorous T-lymphocytic response and the high propensity of the virus to mutate appear to promote a high rate of chronic infection *(94,99)*. HCV preferentially replicates in hepatocytes but is not directly cytopathic, resulting in persistent infection. During chronic infection, HCV RNA reaches high levels, generally ranging from 10^5 to 10^7 international units per milliliter (IU/mL), but the levels can fluctuate widely. Within the same individual, however, RNA levels are generally relatively stable.

Chronic HCV infection develops in most (75%–85%) persons; 60% to 70% of these chronically infected persons have persistent or fluctuating ALT elevations, indicating active liver disease *(99)*. The course of chronic liver disease is usually insidious, progressing slowly without symptoms or physical signs in the majority of patients during the first 2 or more decades after infection. Chronic hepatitis C frequently is not recognized until asymptomatic persons are identified as HCV-positive during screening, or elevated ALT levels are detected during routine physical examinations. Most studies have reported that cirrhosis develops in 10% to 20% of persons with chronic hepatitis C over 20 to 30 years, and HCC in 1% to 5%, with striking geographic variations in rates of this disease *(102–106)*. However, when cirrhosis is established, the rate of development of HCC might be as high as 1% to 4% per year.

Diagnosis

As with other types of viral hepatitis, laboratory testing is necessary to establish a specific diagnosis of hepatitis C (107,*108*). The two major types of tests available for the laboratory diagnosis of HCV infection are serologic assays for anti-HCV and the nucleic acid test to detect HCV RNA *(109)*. Testing for anti-HCV is recommended for initially identifying persons with HCV infection, and includes initial screening with an immunoassay, and if positive, confirmation by an additional more specific assay or a high screening-test–positive signal-to-cutoff ratio (107). Assays for anti-HCV detect only IgG antibody; no IgM assays are available. With the third-generation enzyme immunoassays used at present, anti-HCV can be detected 4 to 10 weeks after infection *(110)*. Anti-HCV can be detected in 97% of persons by 6 months after exposure. False-negative results can occur in persons tested early in the course of acute infection due to the prolonged interval between exposure and seroconversion, and among immunosuppressed individuals (*111*,*112*,113).

There are several FDA–licensed diagnostic tests for qualitative and quantitative detection of HCV RNA *(109)*. HCV RNA can be detected in serum or plasma within 1 to 2 weeks after exposure to the virus and weeks before onset of liver enzyme abnormalities or appearance of anti-HCV. HCV RNA tests are commonly used in clinical practice in the early diagnosis of infection, for determining the presence of chronic infection, and for monitoring patients receiving antiviral therapy. However, false-positive and false-negative results can occur from improper handling, storage, and contamination of the test specimens. Viral RNA may be detected intermittently, and thus, a single negative assay result is not conclusive. Genotype determination is used in clinical management to determine the appropriate antiviral therapy regimen and also in epidemiologic studies.

TRANSMISSION OF HBV AND HCV IN HEALTHCARE SETTINGS

The delivery of healthcare has the potential to transmit both HBV and HCV to patients if infection control or disinfection procedures are inadequate and contaminated equipment is shared among patients. Settings in which HBV and HCV transmission from patient to patient has occurred include hospitals, outpatient medicine and surgery clinics, private physicians' offices, hemodialysis centers, and long-term care facilities (LTCFs) *(3,5,7,8)*. Incidents of HBV and HCV transmission can be grouped by their presumed mechanism of transmission.

Transmission Related to Blood Sampling

Multiple episodes of HBV, and one of HCV, transmission to patients through contamination of equipment used by

healthcare personnel or other staff during blood sampling have been reported, both internationally and in the United States (114). These episodes have occurred in hospitals, LTCFs, and in residential care or assisted living facilities. Almost all of the reported outbreaks have been associated with the use of reusable fingerstick devices and/or blood glucose testing meters; many have also involved the gloves or hands of personnel performing procedures being contaminated with blood. In two HBV infection outbreaks, a reusable spring-loaded fingerstick device was used for several patients, and the disposable platform used to stabilize the patient's finger during the procedure was either not changed or cleaned and disinfected between uses *(115–117)*. During the investigations, visible blood contamination was observed on the platform and was believed to be the probable mechanism of transmission. Failure to change the disposable platform of shared spring-loaded fingerstick devices for monitoring of capillary blood glucose between patients also led to HCV transmission in a ward for cystic fibrosis and diabetes *(118)*. During 1986 to 1988, 18 patients with cystic fibrosis and four with diabetes acquired HCV infection through this mechanism.

In two other HBV infection outbreaks, reusable pen-like fingerstick devices that included both disposable and reusable components were implicated in transmission *(119,120)*. In these outbreaks, the device used had a separate lancet and end cap that rested on the skin during the procedure and could have become contaminated after the lancet retracted. Both the lancets and end caps were disposable and should have been replaced after each use. However, only the lancet was routinely replaced, suggesting that exposure of subsequent patients to residual blood on the end cap contributed to transmission.

Numerous other HBV infection outbreaks in long-term care settings have been attributed to sharing of reusable pen-like fingerstick devices that were intended for individual patient use *(121–126)*. In these outbreaks, lancets were reported to have been changed between each patient; however, contamination of the reusable barrel and its use on multiple patients likely contributed to HBV transmission. In one outbreak investigation *(124)*, a multi-lancet pen-like fingerstick device, containing six lancets in a drum and obviously intended for individual patient use, was used on multiple patients for blood glucose monitoring by 16 of 38 nursing home staff. Although it was not known if the lancets were reused, contamination of the reusable barrel component between patients most likely contributed to HBV transmission.

In four other outbreaks in long-term care settings, HBV transmission between patients occurred in facilities where reusable fingerstick devices were not present (i.e., single-use safety lancets were used exclusively) (*121*,*127*,128). Implicated factors for transmission in these outbreaks were blood contamination of shared blood glucose meters that were not cleaned and disinfected between each patient use, and failure to routinely change gloves or perform hand hygiene between each patient. In one outbreak facility, the staff in a nursing home reported they were discouraged from wearing gloves in order to decrease the sense of a clinical environment *(121)*.

Contamination of unused blood glucose monitoring equipment and supplies when stored with used items has also played a role in HBV transmission. In one outbreak, 17 nursing home patients, all undergoing blood glucose monitoring by the same general practitioner, were found to have acute HBV infection *(129)*. During blood glucose monitoring procedures, both clean and used supplies were stored on a common tray and carried between patients' rooms, and gloves were not routinely changed between patients. The same opportunities for cross-contamination were found during the investigation of an outbreak in a drug trials unit where visible blood contamination of hands or gloves and lack of hand hygiene between individual blood sampling procedures were recalled by staff and volunteers *(130)*.

Transmission Related to Improperly Cleaned, Disinfected, or Sterilized Equipment

Lapses in reprocessing of endoscopy equipment have previously been described as contributing to both HBV and HCV transmission *(131,132)*. However, in an investigation of HBV transmission linked to endoscopy equipment, other factors such as anesthesia administration and the potential for shared medications were not explored *(131)*. In an investigation of HCV transmission that led to infections in two patients undergoing endoscopy following a known HCV-infected patient, the same colonoscope was noted to be used for all three patients. Lapses in endoscope reprocessing included failure to clean the biopsy-suction channel with a brush and failure to autoclave biopsy equipment after use *(132)*. However, the source patient shared biopsy equipment with only one of the index patients. Additionally, evaluation of anesthesia practices revealed that the anesthetist routinely used the same syringe to administer anesthetic to multiple patients. The anesthetist stated that he discarded syringes only after they were used on a patient known to be infected and that he used a check valve to avoid backflow of blood into the syringe. The source patient in this outbreak was known to have HCV infection and the anesthetist reported discarding that patient's syringes. However, the possibility exists that this did not occur and syringes were reused on the index patients or that the vials of medication became contaminated and served as a potential reservoir of infection.

HCV transmission has been described in six patients receiving computed tomography (CT) scanning with contrast at three separate facilities in Spain *(133)*. These patients' procedures had followed CT scans of HCV carriers. The exact mechanism of transmission was not determined. However, one piece of equipment shared by patients was an injector that was loaded automatically from a 500-mL bottle containing contrast solution. Furthermore, the bottle of contrast solution was shared by four or more patients and the injector was used from 8 hours to several days before being replaced. An extension tube from the injector to the patient's intravenous (IV) line was fitted with a nonreturn valve and was supposed to be changed for each patient. Observations made during the investigation identified potential for blood contamination of the equipment when the extension tube was changed. Two sets of control measures were introduced at all facilities and included use of a separate contrast injection syringe for each patient and introduction of written protocols for performing the procedure to avoid transmission of infectious diseases.

HBV transmission has previously been reported in association with improper sterilization of acupuncture needles *(134–136)* and with use of a jet injection gun for administering daily injections in a weight reduction clinic in the United States *(137)*.

Transmission Related to Medication Administration

Episodes of HBV and HCV transmission related to medication administration have resulted when providers have failed to use aseptic technique and/or to adhere to the principles of Standard Precautions when preparing and administering injections to patients. Circumstances documented to have led to HBV and/or HCV transmission include using the same syringe to administer medications to more than one patient (i.e., direct syringe reuse), contaminating medication vials that were used for more than one patient by reusing syringes to access and administer medications, and preparing injections in blood-contaminated environments or near contaminated medical equipment.

Direct Syringe Reuse One of the largest healthcare-associated viral hepatitis outbreaks in the United States was identified during an investigation at a pain remediation clinic (*138*,139). In total, 31 HBV and 71 HCV infections were identified among patients attending the clinic. Patient-to-patient transmission resulted from direct reuse of needles and syringes by a certified registered nurse anesthetist. The nurse anesthetist prepared a single needle and syringe at the beginning of each clinic session for each of the three sedation medications: Versed (midazolam HCl), fentanyl, and propofol. These same three syringes and needles were then used to administer these medications to as many as 24 consecutively treated patients at each clinic session. These medications were administered through heparin locks that were connected directly to IV cannulae. This was a long-standing practice by the nurse anesthetist, who reported believing that the heparin lock provided a sterile field.

Additional outbreaks of HCV transmission through direct syringe reuse have also been described in patients undergoing sclerotherapy of varicose veins by a physician in France *(140)* and in research study participants in Canada and Sweden *(141,142)*. In the research study in Sweden, blood sampling of study participants was performed on several occasions from an indwelling IV catheter during a 24-hour period *(142)*. Syringes for flushing the IV catheter were labeled only with the patient's study number and were used repeatedly instead of being discarded after each flushing. It was theorized that syringes could have gotten mixed up during the flushing process, particularly since the study participants overlapped in the same room on multiple occasions.

Contamination of Medications through Syringe Reuse Reuse of syringes for withdrawal and administration of medications can lead to contamination of both single-use and multidose medication vials used for more than one patient. This mechanism of infection transmission has led to several recent large outbreaks of HBV and HCV transmission. A recent US investigation of acute HCV infections among patients who attended the same endoscopy center in Nevada identified seven patients with newly diagnosed HCV infection; their infections were associated by epidemiologic data and viral sequencing to unsafe injection practices at the facility (143,*144*,*145*). Nurse anesthetists at the endoscopy center routinely reused syringes on the same patient, after changing the needle, to obtain additional doses of the anesthetic propofol when further sedation was required. The needle and syringe were discarded at the end of each procedure and not used for subsequent patients. However, any medication remaining in the single-dose vial of propofol was then, contrary to labeling, used as a source of anesthetic for subsequent patients (Fig. 46-1). The investigation at the endoscopy center identified these long-standing infection control breaches, resulting in a large public health response. Approximately 50,000 patients who had received

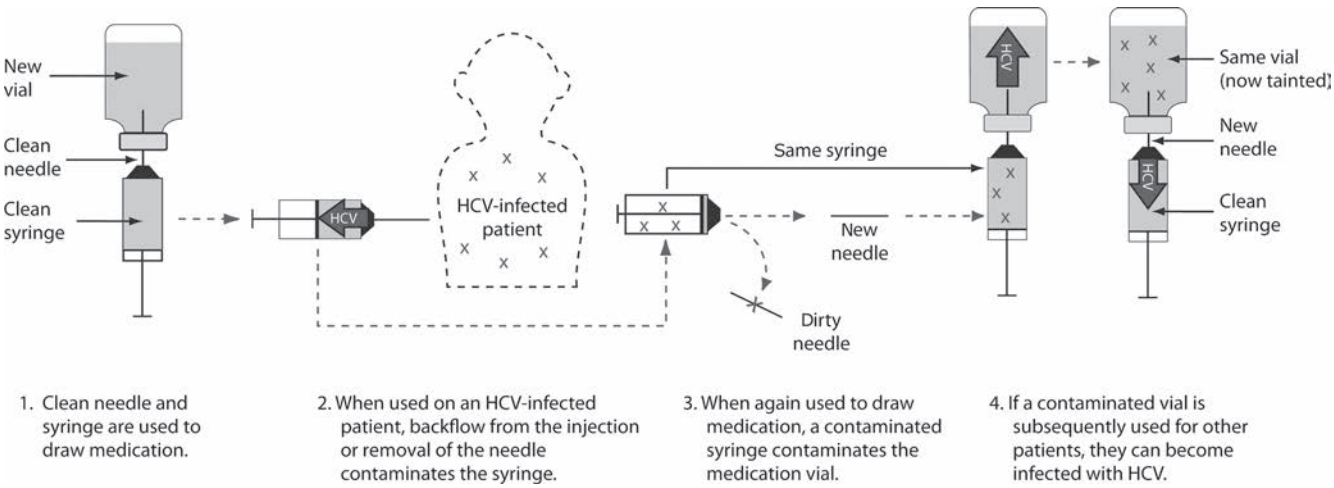

FIGURE 46-1 Unsafe injection practices that likely resulted in HCV transmission during endoscopy. (From Centers for Disease Control and Prevention. Acute hepatitis C virus infections attributed to unsafe injection practices at an endoscopy clinic—Nevada, 2007. *MMWR Morb Mortal Wkly Rep* 2008;57:513–517.)

sedation at the center were notified and recommended to undergo blood-borne pathogen testing. As a result of this testing as well as further investigation, an additional 101 patients with HCV infection were potentially linked to the receipt of healthcare at this center (143,*144*,*145*).

In another US example, a large HCV infection outbreak occurred among patients receiving treatment in a hematology/oncology clinic (113,*138*). Through this investigation, 99 patients were found to be infected with HCV. Among the 95 patients for whom HCV genotype was available, all were genotype 3a. An assessment of practices at the clinic found that a nurse would use the same syringe to draw blood from a patient's central venous catheter and then draw catheter-flushing solution from a single 500-mL saline bag used for multiple patients. A patient known to have chronic infection with HCV genotype 3a began attending the clinic at the beginning of the 22-month period investigated. After dismissal of the implicated nurse and introduction of prefilled syringes of saline flush, no further HCV transmission was identified.

Multiple other instances of HBV and HCV transmission clearly linking reuse of syringes to access medication vials used for more than one patient have been described. They include HBV transmission at a primary care office in Belgium where needles and syringes were reused to access a vial of local anesthetic that was used as a common source for multiple patients *(146)* and also in Sweden where syringes were reused to withdraw multiple doses of local anesthetic for the same patient from a shared multidose vial in which a permanent aspiration needle was left in place *(147)*. Syringe reuse to withdraw medication through a needle permanently left in the vial for aspiration was also described as one of the lapses contributing to HBV transmission at a dermatology practice in the United States *(148)*. Other lapses potentially contributing to this outbreak included failure of the provider to wear gloves or wash his hands between patients and the reuse of electrocautery tips that were neither changed nor cleaned between patients. HCV transmission due to contamination of shared medications through syringe reuse has also been described in patients at a surgery clinic in France *(149)*, in patients undergoing arthroscopy procedures in Australia *(150)*, and in patients receiving chemical stress tests at a cardiology clinic in the United States *(151)*.

Similar infection control breaches and subsequent HBV and HCV transmission have also been reported at alternative medicine practices where autohemotherapy and ozone enrichment have been performed *(152–155)*. At a clinic in the United Kingdom, the procedure involved drawing blood from the patient, mixing the blood with saline, and reinjecting the autologous blood mixture *(152)*. Here, saline was drawn directly after venipuncture with a syringe containing the patient's blood from a bottle used for multiple patients.

Environmental or Other Sources of Medication Contamination HBV transmission has been documented at a private physician's office in the United States when medication vials used for more than one patient were stored and injections were prepared on the same work surface where syringes were dismantled and injection equipment was discarded after use (*138*,156). Similar practices were described as part of an outbreak investigation in a pediatric hematology and oncology ward in Denmark where medication vials used for more than one patient were placed next to the disposal container for used infusion bags and lines, syringes, needles, and blood samples *(157)*. The outbreak ended when infection control staff dedicated vials to a single patient and established a separate disposal area.

In three outbreaks of HBV infections associated with endomyocardial biopsy (EMB), environmental contamination was felt to be the most likely mechanism of HBV transmission *(158–162)*. Simulation of EMB in one of the investigations demonstrated the plausibility of viral contamination of instruments or solutions placed up to 1 to 2 m from the EMB table through droplets of blood generated when inserting and withdrawing biopsy forceps *(158)*.

An outbreak of acute HCV infection was identified among patients undergoing myocardial perfusion studies at three separate outpatient cardiology clinics in the United States *(163)*. An epidemiologic investigation traced the source of transmission back to a common lot of radiopharmaceutical prepared at a nuclear pharmacy. Blood from a patient with chronic HCV and HIV infections was processed for a radiolabeled white blood cell study approximately 12 hours before the lot of radiopharmaceutical was prepared for the cardiac patients. Sixteen doses were prepared and administered from the first lot of radiopharmaceutical prepared at this pharmacy. All 16 patients who received doses from this lot became infected with HCV. The HCV quasispecies sequences from the presumptive source patient and the case-patients were nearly identical. The exact mechanism of contamination was not identified, but opportunities for cross-contamination included reuse of syringes and needles during dilutions and use of common medication preparation hoods for some steps in the preparation of sterile and blood-derived products.

At least 12 additional outbreaks of HBV and HCV infections have been attributed by investigators to contamination of medication vials, primarily of local anesthetic and flush solutions that were used for more than one patient. Settings have included an endoscopy clinic *(138)*, pain clinic *(164)*, emergency department *(165)*, and both adult *(166–172)* and pediatric *(173,174)* wards in hospitals. Syringe reuse was not reported and the exact mechanism of contamination in these outbreaks was not identified by investigators. However, in some instances, other lapses such as failure to change gloves after each patient may have contributed to medication contamination *(173)*.

A further seven outbreaks of HCV infection in inpatient and outpatient settings, including a fertility clinic, had no clear lapse or route contributing to HCV transmission identified *(3,175–180)*. Although the outbreaks, unlike those mentioned above, were not clearly attributed to contamination of shared medications, the presence of vials used for multiple patients was described in all but one of these settings.

Transmission Related to Other or Unknown Mechanism

Hepatitis transmission has also been described through single case-reports of acute infection in individuals who lacked traditional risk factors and had discrete healthcare encounters during the exposure period. HCV transmission was identified in a routine blood donor who

lacked traditional risk factors and whose only healthcare exposure was at an outpatient IV clinic that provided antibiotic therapy to patients *(181)*. Standard practice at the clinic involved labeling and storing patient-specific IV solution bags and tubing in a cupboard in the clinic, using the same equipment each time the patient returned for a dose of antibiotics, and only changing that equipment at 72-hour intervals. Multidose vials were not used at the facility. The index patient's clinic visits overlapped with visits to the same clinic by an HCV-infected patient, whose HCV isolate demonstrated a high degree of relatedness to the index patient. The exact mechanism of transmission was not identified. However, investigators postulated that the IV bag and tubing previously used by the source patient could have been connected to the index patient in error.

HBV transmission was identified at an outpatient oral surgery clinic when a patient without other risk factors developed acute HBV infection after undergoing oral surgery following an HBV-infected patient *(182)*. An infection control assessment identified no breakdowns in procedures, including those related to handling of medications and processing of shared patient equipment. The source patient was HBeAg positive with a high viral load and cross-contamination from an environmental surface was postulated as one possible mechanism for transmission.

Prevention of Healthcare-Related HBV and HCV Transmission

Because HBV and HCV have similar modes of transmission in healthcare settings, the same infection control principles apply to preventing their transmission. In all of the outbreaks described above, it was not the medical or surgical procedures themselves that led to hepatitis transmission, but rather lapses in infection control by the healthcare providers *(7)*. The outbreaks described above could have been prevented through adherence to basic infection control practices (63–65).

Patient-to-patient transmission of HBV and HCV during blood glucose monitoring can be prevented by consistent adherence to recommended practices, which include the following: use of single-use auto-disable lancets for fingersticks; assignment of blood glucose meters to individual patients; cleaning and disinfecting monitors between each use; preventing blood contamination of clean equipment and supplies; and changing gloves and performing hand hygiene between patients (Table 46-3) (114,*121*,*183*).

Prevention of outbreaks linked to unsafe injection practices and medication handling must focus on adherence to Standard Precautions and ensuring that healthcare personnel understand and use aseptic technique when preparing injectables for patient administration (Table 46-3). Needles and syringes are single-use devices that should never be used for more than one patient nor reused to access medication vials. Providers have attempted to justify syringe reuse through the incorrect belief that changing the needle on the syringe or injecting through IV catheters, intervening lengths of tubing, or use of a check valve eliminates any risk of transmission. However, decades-old experiments have demonstrated blood contamination of syringes even after the needle has been changed *(184–186)*. One of these studies also demonstrated contamination of IV tubing, only a third of which was visible by direct observation, and determined that the presence of a check valve made no difference in the incidence of contamination *(186)*.

Providers should limit the use of shared medication vials for multiple patients. Single-use medications, which were inappropriately used for multiple patients in some of the described outbreaks, should not be used for more than one patient. Multidose vials should be dedicated to a single patient whenever possible. If they are used for multiple patients, they should be stored according to manufacturer's instructions and kept outside of the patient-care environment in a centralized medication area that is separate from used or contaminated equipment. The need for adherence to these infection control practices is not negated by the presence of preservative, which offers no protection against viruses such as HBV and HCV.

Standard sterilization and disinfection procedures recommended for patient-care equipment are adequate to sterilize or disinfect items contaminated with blood or other body fluids from people infected with bloodborne pathogens, including HBV and HCV *(187)*. Because organic material, salts, and visible soils can interfere with the sterilization or disinfection procedure, devices must first be adequately cleaned *(188)*. This is particularly important for devices such as endoscopes that may become heavily soiled and may not tolerate heat sterilization *(189,190)*.

HBV and HCV have been demonstrated to remain infectious in dried blood on environmental surfaces for at least 7 days and 16 hours, respectively *(80,98)*. Therefore, all spills of blood and bloody body fluids should be cleaned promptly by a person wearing gloves and using an EPA–registered disinfectant (65). (Visibly bloody material should first be removed with disposable towels or other means to prevent direct contact with blood. The area should then be decontaminated with an appropriate disinfectant (65,*187*).

HBV infection is largely preventable through vaccination. Hepatitis B vaccine provides both preexposure and postexposure protection against HBV infection (87). The currently available vaccines in the United States are produced by recombinant DNA technology. There are two single-antigen vaccines available in the United States—Recombivax HB (Merck & Co., Inc., Whitehouse Station, NJ) and Engerix-B (GlaxoSmithKline Biologicals, Rixensart, Belgium)—and three licensed combination vaccines—one (Twinrix [GlaxoSmithKline Biologicals]) is used for vaccination of adults and two (Comvax [Merck & Co., Inc.] and Pediarix [GlaxoSmithKline Biologicals]) are used for vaccination of infants and young children (87). Three intramuscular doses of hepatitis B vaccine induce a protective antibody response in >90% of healthy recipients. Adults who develop a protective antibody response are protected from clinical disease and chronic infection. The duration of vaccine protection is under investigation. Most data suggest that protection persists even when anti-HBs concentrations fall below the level of detection, and routine screening and boosting are not currently recommended (87).

There is currently no vaccine against HCV, and postexposure prophylaxis is not recommended for exposures to HCV *(187)*.

TABLE 46-3

Recommended Infection Control, Safe Injection and Blood Glucose Monitoring Practices to Prevent Patient-to-Patient Transmission of Blood-Borne Pathogens

1. Hand hygiene and glove use
   a. Perform hand hygiene (i.e., handwashing with soap and water or use of an alcohol-based handrub) before preparing and administering an injection, before and after donning gloves for obtaining blood samples, after inadvertent blood contamination, and between patients.
   b. Wear gloves for procedures that may involve contact with blood and change gloves between patients.
2. Injection safety
   a. Use a sterile, single-use, disposable needle and syringe for each injection and dispose intact in an appropriate sharps container after use. Syringes and needles should not be used for more than one patient or reused to draw up additional medication.
   b. Use single-dose medication vials, prefilled syringes, and ampoules when possible. Do not administer medications from single-dose vials to multiple patients or combine leftover contents for later use.
   c. If multidose vials are used, restrict them to a centralized medication area or for single patient use. Store vials in accordance with manufacturer's recommendations and discard if sterility is compromised.
   d. Do not use bags or bottles of intravenous solution as a common source of supply for multiple patients.
   e. Use aseptic technique to avoid contamination of sterile injection equipment and medications.
3. Blood glucose monitoring and other patient-care equipment
   a. Restrict the use of fingerstick devices for blood sampling to individual patients. Select auto-disabling single-use fingerstick devices that permanently retract upon puncture.
   b. Handle all patient-care equipment that may be contaminated with blood in a way that prevents skin and mucous membrane exposures, contamination of clothing, and transfer of microorganisms to other patients and surfaces.
   c. Evaluate equipment and devices (e.g., blood glucose testing meters) for potential cross-contamination of blood. Establish procedures for safe handling during and after use, including cleaning and disinfection or sterilization as indicated.
4. Work environment
   a. Dispose of used lancets, needles, and syringes at the point of use in a sharps container that is puncture-resistant and leakproof and that can be sealed before completely full.
   b. Maintain physical separation between clean and contaminated equipment and supplies.
   c. Prepare medications in areas physically separate from those with potential blood contamination.
   d. Use barriers to protect surfaces from blood contamination during blood sampling.
   e. Clean and disinfect blood-contaminated equipment and surfaces in accordance with recommended guidelines.
5. Administrative
   a. Infection control measures should be tailored to the individual practices setting.
   b. Responsibility for oversight and monitoring should be clearly designated.
   c. Periodic reviews of staff practices should be conducted.
   d. Procedures and responsibilities should be established for reporting and investigating breaches in infection control policy.

Identification of Healthcare-Associated Viral Hepatitis Transmission or Infection Control Breaches

Healthcare professionals can play a key role in the identification and containment of healthcare-associated HBV and HCV infections by reporting potential clusters or newly diagnosed cases to their local or state public health officals. When diagnosing new HBV and HCV infections, physicans should consider the role of healthcare exposures in transmission, especially among older adult populations or others who do not report traditional risk factors (e.g., injection-drug use, high-risk sexual behaviors) for infection (191). Potential clusters involving two or more patients with a common healthcare exposure during the likely exposure period should immediately be reported to public health authories. Single cases of acute hepatitis B or C (or documented seroconversion) occurring in a cancer, dialysis, or transplant patient, a long-term care resident, or a routine blood donor represent a "red flag" for medical transmission that deserves thorough investigation (192). In addition, the identification of infection control breaches in the absence of disease transmission requires futher assessment to determine whether patient notification and testing for blood-borne pathogens is required (193).

CONCLUSION

HAV, HBV, and HCV have different routes of transmission; yet all have been involved in healthcare-related transmissions, primarily due to breaches in basic infection control practices. Transmissions of HBV and HCV have frequently involved unsafe injection or blood glucose monitoring practices.

Preventing transmission of these viruses in healthcare settings requires careful attention to aseptic technique and consistent adherence to infection control practices, including hand hygiene and appropriate use of gloves.

Since a large proportion of patients with acute HAV, HBV, or HCV infection are asymptomatic, newly acquired infections may not come to the attention of healthcare providers, and clusters of infected patients with common risk factors may not be recognized and reported to public health authorities. In addition, when cases do occur, they may not be reported or adequately investigated. Healthcare-related transmission should be suspected when cases without traditional risk factors for infection are detected.

In many of the HBV and HCV outbreaks reported above, healthcare workers violated fundamental principles related to safe injection practices, which suggests that they failed to understand the potential of their actions to lead to disease transmission. In some of these outbreaks (113,*138*,139,*145*,156), the relevant healthcare worker reported performing the implicated practices routinely over a period of years.

Awareness of fundamental infection control principles, aseptic techniques, and safe injection practices is essential to prevent healthcare-related transmission of hepatitis viruses. These principles, techniques, and practices need to be reinforced in training programs; added to institutional policies and in-service education for healthcare staff, including those in outpatient settings; and monitored as part of the oversight process (191,192). Episodes of such transmission should be viewed as sentinel events for the detection of breaches in infection control practice. They are reminders that such lapses have important public health and patient safety implications.

PART E. Other Pathogens

CHAPTER 47

Uncommon Causes of Healthcare-Associated Infections

Michael S. Gelfand and Kerry O. Cleveland

Some community-acquired infections are seen infrequently in hospitals either because they are rare (e.g., rabies) or because they are not endemic to the United States (e.g., hemorrhagic fever virus infections). Some of these infections are potentially lethal and have been transmitted in hospitals. Thus, the diagnosis of these infections can cause great concern and even panic among healthcare workers and infection control personnel. This chapter discusses such uncommon healthcare-associated infections.

RABIES

Etiology and Pathogenesis

Rabies is a severe encephalitis caused by the rabies virus, a rhabdovirus, that infects mammals, including humans. In most areas of the world, rabies is almost always transmitted by the bite of an infected mammal. In the United States, most cases are now cryptic; that is, they occur without a clear exposure to the rabies virus *(1–4)*. Of the 39 human cases reported in the United States since 1995, only 12 had reported bites *(5)*. Many of these are believed to result from inapparent bites from bats or from rabies virus that comes into contact with a break in the skin or mucous membranes *(2,4)*. The virus is believed to multiply at the inoculation site and then spread via peripheral nerves to the spinal cord and the central nervous system. By the time systemic symptoms develop, the virus has traveled peripherally down efferent nerves to nearly every organ and tissue including, most importantly for the life cycle of the virus, the salivary glands *(1)*. The incubation period is usually 20 to 90 days but has varied from 5 days to many years *(3,4)*. Antigenic and genetic analyses have demonstrated different viral strains that are endemic to different areas of the world and even to different animal species *(3,4)*.

Epidemiology

Human rabies has been acquired on all continents except the Antarctic. The epidemiology of rabies reflects that of local animal rabies. Dogs are the most important rabies reservoir for humans in underdeveloped countries. In the United States, wild carnivorous animals such as skunks, raccoons, bats, coyotes, and foxes are the most important reservoirs for rabies *(3)*. Hawaii is the only state that remains rabies-free.

In the United States, rabies in humans has decreased from an average of 22 cases per year in 1946 to 1950 to 0 to 5 cases per year since 1960. The number of rabies cases among domestic animals has decreased similarly. However, approximately 16,000 to 39,000 persons receive rabies prophylaxis every year because of animal exposures, about half of which are nonbite exposures *(6)*. The risk of rabies from nonbite exposures is extremely low. Scratches, abrasions, open wounds, or mucous membranes contaminated with saliva or other potentially infectious material (such as brain tissue) from a rabid animal are the usual nonbite exposures requiring prophylaxis. If the material containing the virus is dry, the virus can be considered noninfectious. Since 1980, an increasing number of human rabies cases have been associated with rabies variants that circulate in bats *(2–4)*. The nonbite exposures of highest risk appear to be exposures to large amounts of aerosolized rabies virus or to organs or tissues (i.e., corneas) transplanted from patients who died of rabies and to scratches from rabid animals (7). Two cases of rabies have been attributed to airborne exposures in laboratories, and two cases of rabies have been attributed to probable airborne exposures in a bat-infested cave in Texas (7).

Human-to-human transmission of rabies has occurred among 16 transplant recipients from corneas ($n = 8$), solid organs ($n = 7$), and vascular tissue ($n = 1$). Each donor died from rabies or a rabies-compatible illness (7). Two patients who received corneal tissue and one patient who received a liver from a rabies-infected donor did not develop clinical rabies *(8)*.

The risk for rabies transmission to healthcare workers is low *(9,10)*. Apart from organ and tissue transplants, bite and nonbite exposures inflicted by infected humans could theoretically transmit rabies, but no laboratory-diagnosed cases occurring under such situations have been documented *(11)*. Two human-to-human transmissions of rabies by saliva (a bite and a kiss) are not laboratory confirmed (7).

Clinical Manifestations

The early manifestations of rabies are usually nonspecific and can be difficult to differentiate from other encephalitic diseases. These consist of malaise, fatigue, headache, anorexia, and fever. Rabies progresses to one of two distinct presentations: the most common is the furious form characterized by hydrophobia, aerophobia, or episodic agitation and anxiety; the least common is the paralytic form. Rabies should be considered in any patient with rapidly progressive encephalitis of unknown etiology, particularly in patients who have lived in an area with enzootic canine rabies. Only one human with documented rabies infection is known to have survived the illness *(12)*.

Diagnosis

In the United States, the rapid fluorescent focus inhibition test is the standard test for measuring rabies-neutralizing antibody. The results from this *in vitro* cell culture neutralization test are available within 24 hours. In one study of antibody titers of rabies patients who did not receive postexposure treatment, 50% had serum antibodies by the 8th day and 100% by the 15th day of illness *(13)*. Rabies virus may be demonstrated by immunofluorescent antibody staining of brain and skin tissue. The most reliable and reproducible of the direct immunofluorescent studies that can aid in patient diagnosis is that performed on neck skin obtained by biopsy *(1)*. In this test, a 6- to 8-mm full-thickness wedge or punch biopsy specimen containing as many hair follicles as possible is obtained from the posterior aspect of the neck above the hairline. Histologic examination of brain tissue from human rabies cases typically shows perivascular inflammation of the gray matter, various amounts of neuronal degeneration, and, in many cases, characteristic cytoplasmic inclusion bodies (Negri bodies). A reverse transcriptase-polymerase chain reaction (PCR) test may be the diagnostic procedure of choice for suspected rabies *(4)*.

Prevention and Control

Patients who have suspected rabies should be placed on Contact Precautions (see Chapter 89) to minimize the number of possible healthcare worker exposures and to minimize anxiety, although Standard Precautions are adequate (14). Possible cases should be reported to public health officials immediately, so that they can assist with an epidemiologic and diagnostic workup. Healthcare workers who have had a significant exposure should receive postexposure prophylaxis (15). Casual contact with a person with rabies (i.e., touching the patient) or contact with noninfectious fluid or tissue (e.g., blood or feces) does not constitute an exposure and is not an indication for prophylaxis (7). Postexposure prophylaxis is recommended after contact with human rabies only if a bite or nonbite exposure (e.g., contamination of abraded skin or mucous membranes with saliva, nerve tissue, urine sediments, or other potentially infectious material) can be documented. Because postexposure prophylaxis after the onset of disease is of no known benefit, such treatment for patients after onset of clinical rabies is not recommended.

CREUTZFELDT–JAKOB DISEASE/ TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES

Etiology

Prion diseases, or transmissible spongiform encephalopathies (TSEs), are rare, progressive, invariably fatal neurodegenerative disorders (16). This family of diseases includes classic or sporadic Creutzfeldt–Jakob disease (CJD) and variant CJD (vCJD) in humans. The purported unconventional causative agents are prions, which induce abnormal folding of cellular prion protein through a mechanism that remains debatable *(17)*. The extremely small prions exhibit great resistance to chemical and physical agents (e.g., sterilization procedures), fail to induce either an inflammatory or an immune response, and lack demonstrable nucleic acid or nonhost protein *(18)*. Although CJD is clearly transmissible to animals and humans *(19,20)*, most cases of CJD occur sporadically and are of unknown cause (16), but CJD is also a genetic disorder inherited as a familial dominant trait *(21)*.

A new form of CJD in humans, called vCJD, emerged in the 1990s and may be related to bovine spongiform encephalopathy (BSE) *(20,22,23)*. BSE is also known as "mad cow disease" and may be transmitted to humans by consumption of beef products contaminated by central nervous system tissue. An outbreak of BSE in cattle in the United Kingdom occurred from the early 1980s to the late 1990s *(20)*. As of March 2010, a total of 216 cases of vCJD have occurred in humans, most of them in the United Kingdom *(24)*. Strong laboratory and epidemiologic evidence indicates that vCJD is linked causally with BSE. The epidemics of BSE and vCJD in the United Kingdom have prompted blood-collection agencies in the United States to refuse donors who have lived or traveled in Europe for an extended period of time. vCJD occurs at an unusually young age compared with classic CJD (median age 26 years vs. 68 years) *(22)*.

Pathogenesis

Infection by prions causes central nervous system degeneration with spongiform degeneration of gray matter, severe loss of neurons, vacuolization of neuronal cytoplasm, marked proliferation of astrocytes, and little inflammation. The actual mechanisms by which prions cause neurologic disease are unknown, but they appear to induce an abnormal irreversible folding of normal prion protein. There is no significant humoral or cell-mediated immune response to any known infectious agent. However, a characteristic brain protein can sometimes be detected in spinal fluid and used for diagnosis *(25,26)*. Prions have been found in lymph nodes, liver, kidney, spleen, lung, cornea, and cerebrospinal fluid, although less regularly and in far lower titers than in the brain and spinal cord. The brain may contain at least 10^8 infectious units per gram *(27)*.

Epidemiology

The incidence of CJD in the United States is about one case per million persons per year (16). This incidence appears to have become stable since 1979. The age-specific incidence peaks at 65 to 69 years, but occasional cases occur as early

as the second decade and as late as the ninth decade of life. vCJD cases occur at a younger age *(22)*.

More than 250 iatrogenic cases of CJD have been reported worldwide *(28)*. Most of these have been associated with the use of cadaveric dura mater grafts, growth hormone, and corneal grafts. Six cases are linked to contaminated invasive equipment, four with neurosurgical instruments, and two with stereotactic electroencephalographic depth electrodes. All of these equipment-related cases occurred before the routine implementation of sterilization procedures currently used in healthcare facilities. No such cases have been reported since 1976. There is no evidence of occupational transmission to healthcare workers *(28)*.

Clinical Manifestations

Patients with CJD usually present with progressive mental deterioration. In about half the patients, cerebellar or visual signs dominate the clinical presentation with only moderate to minimal mental deterioration. Abnormal movements, usually including myoclonus, are found late in the illness. The progression of disease is usually relentless. Most patients die within 6 months. There are no verified recoveries.

Diagnosis

Diagnosis can often be inferred by clinical features of the illness and by an immunoassay for protein 14-3-3 in the cerebrospinal fluid of patients with rapidly progressive dementias accompanied by myoclonus or ataxia *(25)*. A magnetic resonance imaging study may show characteristic findings for vCJD *(22)*. However, a brain biopsy or autopsy may be needed to confirm the diagnosis *(18,23)*.

Prevention and Control

Any program to prevent transmission of CJD and TSEs from patients in hospitals should first seek to detect all such patients before brain or other high-risk tissues (dura mater, spinal cord, and eyes) are biopsied. Such patients can be identified by screening patients for "unexplained dementia without a detectable brain mass." Any patient meeting this description should be considered to have CJD until proven otherwise even if another diagnosis such as vasculitis is being considered. The neurosurgeons, pathologists, and others in the operating room, the pathology department, and the infection control department should be alerted about such a patient if a biopsy of high-risk tissue is being considered. Some neurosurgeons may elect not to biopsy potential CJD patients unless an alternate, treatable diagnosis is also under consideration. Hospitals should develop a CJD protocol for nervous system tissue biopsies done on such patients (*28*–*30*,31). Disposable surgical instruments should be used when possible. Reusable instruments should be discarded or sterilized according to a CJD protocol or the instruments should be quarantined until another diagnosis is made. Powered instruments, such as drills and saws, should be avoided or covered by a disposable protective shield. Brain and other high-risk tissues should be labeled as "suspected CJD" before being sent to pathology. The pathology department should have a plan to track such tissue and quarantine and disinfect instruments, such as microtomes, that contact CJD tissue. It is important to note that formalin- and glutaraldehyde-fixed tissues may be infectious indefinitely *(29)*. Confirmed CJD tissue can be managed as regulated medical waste per state regulations. No one suspected of having CJD should serve as a blood or tissue donor even though transmission of classic CJD has never been linked to blood, but vCJD has been transmitted via blood transfusion *(32,33)*. Blood or blood products from such patients should be disposed of per state regulations for regulated medical waste.

CJD patients should be cared for using Standard Precautions (14). Sharps injuries involving spinal fluid or high-risk tissues can be cleansed using 0.5% sodium hypochlorite or 1 N sodium hydroxide *(28,29)*. During an operation or autopsy, disposable surgical caps, water-repellant gowns, aprons, double gloves, and face visors (covering eyes, nose, and mouth) should be worn *(29)*. Autopsies should be done only if the pathologist is aware of the potential diagnosis of CJD and uses the Precautions mentioned previously for the autopsy suite and pathology laboratory *(29)*. When the patient dies, the morgue and funeral home should be notified that the patient had suspected or confirmed CJD.

VIRAL HEMORRHAGIC FEVER

The term *viral hemorrhagic fever* (VHF) refers to the illness associated with a number of geographically restricted viruses. This illness is characterized by fever and, in the most severe cases, shock and hemorrhage *(34)*. Although a number of other febrile viral infections may produce hemorrhage, only the agents of Lassa, Marburg, Ebola, and Crimean–Congo hemorrhagic fevers (CCHFs) are known to have caused significant outbreaks of diseases with person-to-person transmission.

None of these viruses are endemic to the United States. However, increasing levels of international travel result in rare cases of VHF imported into the United States, and there is concern that these viruses may be used for bioterrorism (*34*,35,*36*–*39*). When cases are hospitalized, there is often concern about the potential for healthcare-associated transmission. However, evidence shows that transmission of these viruses does not occur through casual contact and is rare in hospitals if adequate Standard Precautions are used *(34,36,40)*. Hantaviruses can cause hemorrhagic fever and are endemic in the United States but are not spread person-to-person or in hospitals *(41)*.

Lassa Fever Virus

Lassa fever virus is spread in Africa by a rodent not present in the United States. Person-to-person spread requires close personal contact or contact with blood or excreta. Careful follow-up of household and other close contacts of cases imported into Western Europe and North America has shown no evidence of secondary transmission from casual contact, in stark contrast to earlier reports from African hospitals *(34,36)*. The clinical spectrum of Lassa fever is wide, and the likelihood ratio of illness to infection is 9% to 26% *(42)*. After an incubation period of 1 to 3 weeks, illness begins insidiously with fever, sore throat, weakness, and malaise. The long incubation period increases the likelihood that asymptomatic cases will be imported into the

United States. The infection often progresses over several days to a generalized toxic syndrome with pharyngitis (often severe and exudative); retrosternal pain; vomiting; abdominal tenderness; and signs of vascular instability and capillary leakage including hypotension, bleeding, and edema of tissues. High levels of viremia and aminotransferase concentrations are associated with mortality and probably infectiousness of body fluids. The virus is present in blood and, sporadically, in the throat and urine of patients *(40)*. Overall, the case-fatality rate is about 1% to 2% *(42)*. Diagnosis can be made by viral isolation or by demonstrating immunoglobulin M (IgM) antibodies to Lassa fever virus or a fourfold rise in titer of IgG antibody between acute- and convalescent-phase serum specimens *(34,43)*. Treatment with ribavirin effectively reduces mortality *(44)*.

Marburg and Ebola Viruses

Marburg and Ebola hemorrhagic fever viruses are closely related, as is their endemic geographic area. The mode of acquiring natural infection is unknown. Secondary person-to-person transmission results from close personal contact. Healthcare-associated transmission has occurred with both viruses and appears to depend on contact with blood, secretions, and excretions *(34,45)*. There is no evidence of spread by casual contact or aerosol. The onset of illness is abrupt, and clinical manifestations include fever, headache, general malaise, myalgia, arthralgia, and sore throat. These symptoms are often followed by diarrhea, abdominal pain, a desquamating morbilliform rash, and hemorrhagic manifestations including petechiae and frank bleeding. Diagnosis requires isolating the virus from blood, detection of nucleic acids using PCRs, or demonstrating IgM or rising IgG antibodies *(46,47)*. Treatment is supportive. In one epidemic of Marburg hemorrhagic fever in Europe related to an imported African green monkey, the case-fatality rate was 23% for primary cases, but no deaths were reported among the six secondary cases *(48)*. The incubation period ranges from 3 to 10 days for Marburg hemorrhagic fever. For Ebola hemorrhagic fever, the case-fatality rate is even higher, generally greater than 50% in reported epidemics. The incubation period ranges from 2 to 21 days and averages about 7 days *(34)*.

Crimean–Congo Hemorrhagic Fever Virus

The CCHF virus is present in many wild and domestic animals in the endemic areas. Ticks act both as a reservoir and a vector for CCHF; ground-feeding birds may disseminate infected ticks *(34)*. Humans become infected by being bitten by ticks or crushing them. Contact with blood, secretions, or excretions of infected animals or humans may also transmit infection. Healthcare-associated transmission is well described *(34)*. Evidence suggests that blood and other body fluids are highly infectious and that airborne transmission is unlikely. Initial symptoms include fever, headache, myalgia, arthralgia, abdominal pain, and vomiting. Sore throat, conjunctivitis, jaundice, photophobia, and various sensory and mood alterations may develop. A petechial rash is common and may precede a hemorrhagic diathesis including hemorrhage from multiple sites. The case-fatality rate is estimated to range from 15% to 70%, but more than 15% of cases may be asymptomatic. The incubation period is 2 to 9 days. Diagnosis requires isolating the virus from blood or detecting rising IgG antibody or nucleic acids using PCR *(49)*. Treatment is supportive.

Diagnosis

The patient's travel history, symptoms, and physical signs provide the most important clues to the diagnosis of any of the causes of VHF. Travel exclusively to urban zones in endemic areas or an interval of greater than 3 weeks from travel in an endemic area to onset of symptoms make VHF unlikely *(34)*. Other patients at risk for VHF include those who, within 3 weeks before onset of fever, have had direct contact with blood or other body fluids, secretions, or excretions of a person or animal with VHF or who worked in a laboratory or animal facility that handles hemorrhagic fever viruses. A single case of any VHF in the United States should suggest bioterrorism unless there is an appropriate travel history *(45)*.

Initial symptoms are flu-like and nonspecific. The differential diagnosis includes influenza, arboviral, and other viral infections; bacterial infections such as typhoid fever, toxic shock, streptococcal pharyngitis, and rickettsial diseases; and parasitic infections such as malaria. Symptoms and signs supporting the diagnosis of VHF are pharyngitis, conjunctivitis, a skin rash, and, later, hemorrhage and shock.

Prevention and Control

If clinicians feel that VHF is likely, they should take two immediate steps: (a) notify local and state health departments and the Centers for Disease Control and Prevention (CDC) and (b) institute special precautions, including the use of a private room and use of gloves for all patient and specimen contact. The CDC in 1988 recommended precautions for VHF that were updated in 1995 and 2005 (*34*,35,*50*). Blood, urine, feces, vomitus, and respiratory droplets should be considered infectious. Gloves, gowns, face shields, and goggles should be used as necessary to prevent exposures to these body fluids. Patients should be placed on Contact Precautions (see Chapter 95) (14). In addition, the following measures should be implemented: (a) eye covering (goggles or shields) for all contact within 3 ft, (b) a negative pressure room and use of a high-efficiency particulate air respirator (mask) if aerosolization of virus is likely (e.g., patients who have a prominent cough), (c) use of class II biologic safety cabinet following biosafety level 3 practices for laboratory specimens, and (d) pretreatment of serum specimens with polyethylene glycol *p-tert*-octylphenyl ether (10 μL of 10% Triton X-100 per mL of serum) for 1 hour *(50)*. All specimens should be marked with the biohazard symbol, so that all persons handling these specimens will be alerted to use proper precautions, including gloves. If a patient with any VHF dies, all unnecessary handling of the body, including embalming and autopsy, should be avoided. The corpse should be placed in an airtight bag and cremated or buried immediately.

Patients who likely have Lassa fever should be treated with ribavirin, as should all individuals who have had unprotected contact with the patient's body fluids or excretions *(44)*. Examples of unprotected contact include sexual intercourse, shared use of eating or drinking utensils, and failure to use gloves to handle items known to be contaminated with the patient's blood or secretions.

MENINGOCOCCAL INFECTIONS, INCLUDING PNEUMONIA

Infections caused by *Neisseria meningitidis* are endemic throughout the world, but also occur in epidemics. Among civilians in the United States, meningococcal disease occurs primarily as single isolated cases or, infrequently, in small localized clusters. One third of all cases of meningococcal disease occur among patients 20 years of age or older. Healthcare-associated spread of the meningococcus is rare, but hospitalization of a case of invasive meningococcal disease is often associated with severe anxiety among healthcare workers caring for the patient.

Etiology

N. meningitidis is a gram-negative diplococcus that produces a polysaccharide capsule that forms the basis for the serogroup typing system. There are at least 13 serogroups, but serogroups B and C cause most cases of meningococcal disease in the United States, with serogroup Y increasingly seen and serogroup W135 accounting for most of the rest *(51)*.

Epidemiology

Carriage of meningococci in the pharynx is common. One study found a 4.9% to 10.6% prevalence of carriage in a nonepidemic situation involving crowded living conditions *(52)*. No disease was noted in this population. The median duration of carriage was 9.6 months, and a 5.7% to 12.5% yearly incidence of acquisition was noted. Crowding appears to be one important factor influencing the prevalence of meningococcal carriage. The risk of acquisition of carriage is also increased if the index carrier is ill rather than asymptomatic *(53,54)*. Acquisition of a new meningococcal serotype can result in asymptomatic colonization (the carrier state), local infection, or, rarely, invasive disease. The recent acquisition of carriage, rather than chronic carriage, may be the factor associated with the greatest risk of disease, because carriage longer than 2 weeks results in the development of apparently protective type-specific antibody *(55)*. Transmission is believed to occur by direct contact, including contact with large droplets from the nose and throat of infected or colonized carriers. Generally, close live-in or intimate contact (e.g., mouth-to-mouth contact) is required to transmit meningococci effectively, especially if the index carrier is asymptomatic *(52)*.

Risk to hospital personnel and patients from casual contact with an infected patient appears to be small. Epidemics of disease and colonization related to meningococcal pneumonia have been reported *(56)*. However, most *N. meningitidis* pulmonary infections apparently are not associated with serious illness or transmission. Transmission from patients who have meningococcemia or meningitis to hospital personnel is rare but can occur to personnel who have intimate contact with respiratory secretions from infected patients *(57–60)*. Laboratory workers are also at risk for meningococcal disease *(61)*. Laboratory workers should follow biosafety procedures and consider meningococcal vaccination (*61*,62) (see also Chapter 77). It is not clear why transmission of meningococcal disease in hospitals is so rare compared with community transmission. Perhaps, transmission is limited because of the rapid institution of barrier precautions, treatment of the patient, and prophylaxis of exposed persons. The incubation period for disease varies from 2 to 14 days and is commonly 3 to 4 days.

Clinical Manifestations and Diagnosis

Meningococcal disease includes bacteremia without sepsis, meningococcemia without meningitis, meningitis with or without meningococcemia, and the meningoencephalitic presentation. A petechial rash is often present in invasive disease. Diagnosis is made by appropriate cultures and detection of antigen in spinal fluid, blood, or urine *(63)*.

Prevention and Control

Droplet Precautions should be used to minimize transmission from patients with invasive meningococcal disease (see Chapter 90). Confirmed cases should be promptly reported to public health authorities to limit illness in prehospital contacts.

In addition, antibiotic prophylaxis should be considered for those with intimate contact with an untreated patient. This group potentially includes (a) community contacts, including family; (b) rarely, hospital personnel; and (c) possibly, hospitalized patients who are close contacts of a patient with untreated meningococcal pneumonia. When prophylaxis is necessary, it is important to begin it immediately, often before results of antimicrobial susceptibility testing are available (*63*,64). Ceftriaxone can be used for pregnant women. In the absence of a known exposure to meningococcal illness, personnel found to be colonized with meningococci should not be treated or removed from patient care activities.

Laboratory scientists with percutaneous exposure to an invasive *N. meningitidis* isolate from a sterile site should receive treatment with penicillin; those with known mucosal exposure should receive antimicrobial chemoprophylaxis (*61*,64). Microbiologists who manipulate invasive *N. meningitidis* isolates in a manner that could induce aerosolization or droplet formation (including plating, subculturing, and serogrouping) on an open benchtop and in the absence of effective protection from droplets or aerosols should also consider meningococcal vaccination and antimicrobial chemoprophylaxis when indicated (see also Chapter 77) (62).

PLAGUE

Etiology

Plague is a zoonotic infection caused by *Yersinia pestis (65). Y. pestis* is a gram-negative, facultatively anaerobic, asporogenous bacillus that belongs to the bacterial family Enterobacteriaceae. It grows aerobically on most culture media, including blood agar and MacConkey's agar *(65). Y. pestis* produces numerous virulence factors, including V and W antigens and endotoxin *(65–67)*.

Pathogenesis

Plague bacteria are inoculated by the bite of an infected flea and migrate by cutaneous lymphatics to the regional lymph nodes. *Y. pestis* resists destruction within mononuclear phagocytes and multiplies intracellularly. Acute

necrotizing suppurative lymphadenitis develops in the involved lymph nodes (the bubo) *(66)*. Transient bacteremia is common in bubonic plague and may result in metastatic lesions (liver, spleen, meninges) and endotoxemia with hypotension, oliguria, altered mental status, and subclinical disseminated intravascular coagulation.

Epidemiology

Plague is an ancient disease. Epidemics of plague brought devastation to many societies, including medieval Europe, with a massive loss of population. Humans, however, are an accidental host and have no role in the maintenance or propagation of plague in nature. Rats, which were the reservoir of epidemic plague, no longer are subject to epizootics of plague as they were in the past. Now, infected sylvatic rodents are the primary reservoir in the southwestern United States and have become entrenched in rural areas of many countries *(65,66)*. Plague occurs worldwide, with most of the human cases reported from developing countries of Asia, Africa, and South America. Several hundred cases are reported annually to the World Health Organization (WHO) *(65–67)*. From 1989 through 2003, 38,310 cases of plague and 2,845 deaths (7%) were reported to the WHO by 25 countries in Africa, the Americas, and Asia *(68)*.

In the United States, most of the human plague (except for rare laboratory accidents and imported cases) is contracted in nonurban sylvatic foci in the states of New Mexico, Arizona, Colorado, Utah, and California. Each year, 10 to 40 cases are reported in the United States *(65–67,69,70)*. From 1970 through 2007, 415 cases of plague were reported in the United States (a mean of 11 cases per year), with 59 deaths (14%) *(65)*. Cases in travelers, acquired in endemic areas but manifested elsewhere, have been reported *(71)*. A delay in diagnosis and poor outcome may result if travel history is not ascertained. Most of the cases are diagnosed during the months of May to October. A disproportionately large number of cases occur in American Indians *(72)*.

Plague is primarily a zoonotic infection. It is perpetuated in the natural animal reservoirs of urban and sylvatic rodents by flea bites or by ingestion of infected animal tissues. Worldwide, rats are the most important reservoirs of plague bacillus. In sylvatic foci of plague, such as in the southwestern United States, the important reservoirs are the ground squirrel, rock squirrel, and prairie dog. Humans become infected when bitten by rodent fleas and occasionally by handling of contaminated animal tissues *(73)*. Transmission from domestic cats has been reported in the United States *(74–76)*. Direct person-to-person spread of plague is rare and occurs during epidemics of pneumonic plague.

Clinical Manifestations

Bubonic plague is the most common clinical presentation. The incubation period is 2 to 7 days following the bite of an infected flea. Patients present with a sudden onset of high fever, chills, weakness, headache, and, at the same time or shortly thereafter, a swollen and intensely painful regional group of lymph nodes (the bubo) usually in the groin, axilla, or neck *(65–67)*. Hematogenous spread may result in secondary pneumonia characterized by a rapid course and high mortality. The sputum is purulent and contains plague bacilli. Plague pneumonia is highly contagious by droplet transmission. Primary inhalation pneumonia is rare, but it is always a potential threat following exposure to a patient or a cat with plague pneumonia *(74,75)*. Any patient with plague and cough should be suspected of having pneumonia until proven otherwise.

Other clinical syndromes include septicemia, meningitis, pharyngitis, and cutaneous plague. Gastrointestinal symptoms (nausea, vomiting, and diarrhea) may dominate the clinical picture and lead to diagnostic confusion.

Diagnosis

Diagnosis of plague should be suspected in febrile patients with a history of exposure to rodents or to other mammals in endemic areas. The aspirate from the bubo should be stained with Gram and Wayson (or Giemsa or Wright) stains and also cultured. Several blood cultures should be obtained. Blood smears may be positive in patients with septicemia. Smears and cultures of the sputum, cerebrospinal fluid, and skin lesions should be done when appropriate. Rapid diagnostic tests, such as F1 antigen detection, IgM enzyme immunoassay, immunostaining, PCR, and serological testing of specimens of acute and convalescent phases of illness, are available only at some state health departments, the CDC, and military laboratories *(65,67)*. Chest radiography should be done in every patient with suspected plague. Testing of clinical specimens and isolates from suspected plague patients should be coordinated through state health departments and sent to CDC's Diagnostic and Reference Laboratory Section, Division of Vector-Borne Infectious Diseases, National Center for Infectious Diseases (telephone: 1-800-232-4636). The CDC, Plague Branch (telephone: 1-800-232-4636), can perform the fluorescent antibody stain, PCR testing, the definitive culture identification, and serologic testing on acute- and convalescent-phase sera (*http://www.cdc.gov/ncidod/dvbid/plague/diagnosis.htm* [cited January 7, 2010]).

Prevention and Control

No healthcare-associated transmission of plague has occurred in the United States in modern times, but the potential danger demands prompt institution of infection control measures any time the disease is suspected. Plague is an internationally quarantinable disease. All patients with suspected plague must be immediately reported to the health department.

All patients with plague must be placed on Droplet Precautions for the first 72 hours after start of effective treatment because of the possibility that pneumonia may supervene (14,77). Standard Precautions are then adequate for the duration of hospitalization. In patients with pharyngitis or a positive throat culture, Droplet Precautions should continue until a negative throat culture is obtained for *Y. pestis*. For patients who have plague and have a cough or pneumonia, Droplet Precautions plus eye protection should be continued for at least 72 hours after the initiation of effective antimicrobial therapy. Respiratory isolation is not necessary as the droplet nuclei do not play a significant role in transmission of plague pneumonia *(78)*. All contacts of plague pneumonia patients should be rapidly identified. Individuals with a direct face-to-face contact (<2 m) with a person with plague pneumonia who has not

had antibiotic treatment for at least 48 hours should be given prophylactic or abortive treatment *(79)*. Doxycycline 200 mg/day for 5 to 10 days is recommended in nonpregnant adults. Streptomycin, gentamicin, chloramphenicol, ciprofloxacin, or, in pregnant women, trimethoprim-sulfamethoxazole may also be used for abortive therapy (*79*,*80*,81). All contacts should be instructed to have their temperature taken twice daily and to report fever, cough, or other symptoms. Surveillance may terminate 7 days after the last contact with the case–patient. Isolation of asymptomatic close contacts is not recommended. All laboratory specimens should be handled with gloves. Laboratory personnel should be alerted to the possibility of plague to avoid skin contact with and aerosolization of cultures. A previously used formalin-killed vaccine was discontinued in 1999 by its manufacturers and is no longer available.

Bioterrorism Potential

Plague outbreaks following use of an aerosolized plague bacillus as a biologic weapon are a plausible threat (see Chapter 102) *(79)*. The occurrence of cases and clusters of cases of primary pneumonic plague in locations not known to have enzootic infection or in persons without risk factors should lead to a suspicion of bioterrorism. Recommendations on the management of bioterrorism-related plague outbreaks have been published *(79)* (see also Chapter 102).

PSITTACOSIS

Etiology

Psittacosis (ornithosis) is a disease of birds caused by *Chlamydophila* (*Chlamydia) psittaci* and is transmissible to humans. *C. psittaci* is an obligate intracellular parasite and is considered a specialized bacterium *(82)*.

Pathogenesis

C. psittaci enters the body via the upper respiratory tract after the inhalation of infectious material. The microorganism spreads to the reticuloendothelial cells of the liver and spleen and, after replication, invades the lungs and other organs by hematogenous dissemination *(82)*. Psittacosis is a systemic illness with predominantly pulmonary involvement.

Epidemiology

Dried excreta of birds is the main source of infection. Human-to-human transmission is rarely reported but may result in more severe disease. Human-to-human transmission has also been reported with the related species *Chlamydophila pneumoniae (82–84)*. Clusters of possible healthcare-associated transmission of *C. psittaci* have been reported, but possible serologic cross-reactivity with *C. pneumoniae* complicates the evaluation of these reports *(85–87)*.

Psittacosis is reported worldwide and is associated with exposure to infected birds and other animals *(82–88)*. There has been a recent decline in psittacosis cases in the United States associated with effective control of the disease in domestic and imported birds, but 100 to 250 cases are reported annually, and small outbreaks continue to occur (*82*,89,*90*). Psittacosis is an occupational hazard for people working with birds, including veterinarians, and poultry-processing plant employees and bird fanciers are also at risk of infection *(91,92)*. A minority of patients have no history of bird contact and may have had only an exposure to a contaminated environment or to an infected human *(93)*.

Clinical Manifestations

The incubation period is 6 to 20 days. The severity of illness ranges from a mild flu-like illness to an overwhelming lethal infection. In the preantibiotic era, the mortality rate was 20%. Chills, fever, headache (often severe), malaise, anorexia, myalgias, and persistent cough are the usual symptoms *(94–96)*. Pneumonia is the major clinical manifestation. Hepatosplenomegaly is common and should lead to a consideration of psittacosis in a patient with pneumonia. Asymptomatic seroconversion can occur.

Diagnosis

A compatible clinical illness in a patient with a history of exposure to birds should lead to a suspicion of psittacosis. Chest radiography usually shows a pulmonary infiltrate but is nonspecific. A fourfold rise in titer of complement-fixing antibodies to *Chlamydia* antigen to at least 1:32 between acute and convalescent specimens is diagnostic. A single titer of 1:32 in a compatible clinical setting is presumptive evidence of psittacosis *(82)*. Effective antibiotic therapy may blunt the antibody response. The isolation of *C. psittaci* by culture of respiratory secretions is possible but not routinely available except in reference laboratories *(82)*. PCR analysis of human and bird clinical specimens for *C. psittaci* has been successfully used in the management of outbreaks of psittacosis, but the assay is not commercially available *(97,98)*. Laboratory diagnostic criteria and commercially available laboratory tests for psittacosis in humans have been summarized in a recent publication (99).

Prevention and Control

Prevention of psittacosis consists of control of avian infection and prevention of bird-to-human transmission (99). Human respiratory secretions may be infectious, but human-to-human transmission is very rare, and healthcare-associated psittacosis is only a remote possibility. CDC guidelines do not recommend isolation of hospitalized patients with psittacosis or the use of a private room, masks, gowns, or gloves (14). Pet-assisted therapy in healthcare facilities is gaining in popularity in the United States. The introduction of birds as pets into hospitals is undesirable *(100)* (see Chapter 93). Psittacosis is a notifiable disease, and cases should be reported to the local health department *(83)*. The mortality rate in treated patients is low (<1%) *(82)*.

TETANUS

Tetanus (lockjaw) is a disease caused by a neurotoxin tetanospasmin produced by *Clostridium tetani*. Tetanus is manifested by uncontrolled muscle spasms, results in high mortality, and is preventable by immunization. It is more common in developing countries but continues to occur in the United States, especially in unimmunized or inadequately immunized elderly persons *(101)*.

Etiology

C. tetani is a motile, gram-positive, strictly anaerobic, nonencapsulated, spore-forming rod. The drumstick-shaped spores are highly resistant to chemical disinfection and heat but are destroyed by autoclaving. *C. tetani* can be found in human and animal feces, and the spores can survive in dry soil for years. *C. tetani* is a noninvasive microorganism and depends on the introduction of its spores into damaged or devitalized tissue to provide the anaerobic conditions favorable for its growth.

Pathogenesis

The potent neurotoxin tetanospasmin is produced by vegetative *C. tetani* in a localized site of infection and enters the nervous system at myoneural junctions of motor neurons either locally or after hematogenous and/or lymphatic spread. Tetanospasmin is carried by retrograde axonal transport to the neuraxis, where it binds to the presynaptic terminals of the inhibitory synapses, preventing transmitter release. The absence of inhibition results in increased muscle tone, rigidity, and simultaneous spasms of both agonist and antagonist muscles *(101)*.

Epidemiology

C. tetani resides harmlessly in the intestines of horses and other animals, including humans. Soil or fomites contaminated with human or animal feces serve as a source of infection. *C. tetani* spores are ubiquitous, and essentially any wound or infected area with an anaerobic environment can serve as a nidus for the disease *(101)*. The incidence of tetanus in a population is related to the prevalence of immunity and the frequency of trauma. In the United States, the incidence of tetanus has been 0.16 cases per 1,000,000 population in recent years *(102)*. A total of 40 to 50 cases are reported annually *(101–108)*. The disease in the United States occurs predominantly in older adults who are either unimmunized or inadequately immunized. Serologic analysis of the US population suggests that tetanus immunity wanes with age *(109)*. Women, Mexican-Americans, and immigrants from underdeveloped countries have a significantly lower rate of immunity than do non-Hispanic white males *(110)*. Neonatal tetanus is very rare in the United States. Tetanus is a major problem in developing countries, where the prevalence of immunity is low. Common predisposing factors in developing countries include wounds, contamination of umbilical stumps in neonates, postpartum manipulation of the placenta, chronic ear infections, nonsterile injections, unskilled abortions, ear piercing, scarification rituals, and female circumcision *(101,103)*.

Most of the cases are secondary to acute wounds. Other predisposing conditions include chronic wounds, skin ulcers, abscesses, burns, gangrene, parenteral drug abuse, body piercing, and surgery *(107)*. Tetanus occasionally follows surgical procedures, with gastrointestinal surgical procedures most often reported *(101,108,111,112)*. Several small outbreaks of postoperative tetanus have been reported. Both exogenous surgical site contamination in the operating room and endogenous sources (intestinal flora of the patient) of *C. tetani* have been implicated. Standard surgical instrument sterilization techniques are effective against *C. tetani* spores *(101)*. Rarely, the patient has no recognizable tetanus-prone wound.

Clinical Manifestations

The incubation period is usually within 2 weeks but may range from 2 days to months. Early manifestations include localized or generalized weakness, stiffness or cramping, difficulty in chewing and swallowing food, and trismus resulting from increased masseter muscle tone (lockjaw). The disease progresses to generalized muscle rigidity and reflex spasms. Tonic contractions of muscles may result in painful opisthotonos, abdominal rigidity, and the characteristic facial expression called risus sardonicus. Laryngospasm and/or respiratory muscle involvement may interfere with ventilation. Aspiration may result from difficulty in swallowing. Reflex tetanic spasms may be precipitated by stimuli such as noise, light, or touch and may result in opisthotonos, apnea, fractures, tendon separations, and rhabdomyolysis. The autonomic dysfunction with excessive catecholamine release is common and may result in labile hypertension, tachycardia, cardiac arrhythmias, peripheral vasoconstriction, sweating, elevated temperature, toxic myocarditis, and cardiac arrest *(101,104)*. The mortality rate is high in severe tetanus, especially in infants and the elderly, and may exceed 40% *(101,106)*.

Diagnosis

The diagnosis of tetanus is primarily clinical and is based on history and examination. *C. tetani* is rarely seen in Gram stains from a wound or recovered on culture. A definite history of having received a complete immunization series and/or a serum antitoxin level of 0.01 units/mL or higher makes the diagnosis very unlikely *(101)*. The differential diagnosis of tetanus includes meningitis, dental abscess, peritonitis, rabies, hypocalcemic tetany, epilepsy, decerebrate posturing, alcohol and drug withdrawal, dystonic reactions to antipsychotic drugs, and strychnine poisoning.

Prevention and Control

Antibody to tetanospasmin is protective. Serum antitoxin levels of 0.01 units/mL or above are considered protective, although mild tetanus cases have been reported in patients with titers in the range of 0.01 to 1.0 units/mL *(101,104)*. Tetanus is a disease with no naturally acquired immunity but is preventable with appropriate immunization and wound care. Tetanus toxoid is an effective immunizing agent and is administered via intramuscular injections. Current recommendations for active immunization have recently been updated and include the use of Tdap (tetanus toxoid, reduced diphtheria toxoid, acellular pertussis vaccine) (113–115). Completion of the primary series confers immunity to tetanus for at least 10 years in 95% or more of vaccinees. Booster vaccinations are recommended every 10 years to maintain protective antitoxin levels. Healthcare employees can be immunized or given booster injections as part of the preemployment screening process.

Appropriate management of wounds is very important in preventing tetanus. Tetanus-prone wounds include those contaminated with dirt, feces, or saliva; puncture wounds (including accidental needle punctures); avulsions; and wounds resulting from missiles, crushing, burns, and frostbite. However, any wound can result in tetanus, including surgical sites and decubitus ulcers. Careful cleansing, drainage, and debridement of the wound and removal of foreign

bodies and necrotic tissue can reduce the likelihood of tetanus. Recommendations for specific immunoprophylaxis depend on the patient's prior immunization history and the nature of the wound (115). Patients who have received a full immunization series but who have not received a dose for more than 10 years should be given a booster vaccination with (or without) any type of wound. This is especially important in preoperative patients, pregnant women (to protect both mother and child), nursing home residents and paraplegics (risk of decubitus ulcer), patients with chronic foot ulcers, intravenous drug abusers, and healthcare personnel sustaining accidental needle punctures. If the patient is uncertain about prior vaccinations or knows that the full tetanus series has not been received, tetanus vaccine should be given for any type of wound (with arrangements made to complete the series), and additional passive immunization with tetanus immune globulin (TIG) should be given for tetanus-prone wounds. When vaccine and TIG are given concurrently, separate syringes and separate sites of administration should be used. One study demonstrated that the antitetanus prophylaxis given in hospital emergency rooms is often inadequate *(116)*.

Tetanus is not directly transmissible from person to person, and no isolation precautions are indicated for the management of a patient with tetanus. Cases of tetanus must be reported to the health department. Hospitalization or a visit to an emergency room may be the only contact of an unimmunized or inadequately immunized individual with the healthcare system, and routine review of tetanus immunity status should be considered for all hospitalized patients but especially for the elderly, children, pregnant women, preoperative patients, patients with wounds (including burns and decubitus ulcers), and parenteral drug abusers.

BOTULISM

Etiology

Botulism is a disease caused by *Clostridium botulinum* exotoxin. *C. botulinum* is a gram-positive spore-forming anaerobic bacillus. The neurotoxin produced by the microorganism causes a paralytic illness.

Pathogenesis

The toxin can cause the disease by (a) being preformed in the food (botulism food poisoning), (b) being produced in a traumatic wound contaminated by *C. botulinum* (wound botulism), and (c) being produced by *C. botulinum* in the gastrointestinal tract of infants (infant botulism) *(117–119)*. A potent neurotoxin is released after spores germinate and bacterial growth and autolysis occur under appropriate conditions. These conditions include an appropriate pH (>4.6), a temperature generally >10°C, sufficient availability of water, and a relatively anaerobic environment *(118)*. Seven toxin types have been described (A, B, C, D, E, F, and G). Types A, B, and E are the most common causes of disease in humans. Botulinum neurotoxins are the most potent known poison. The toxins interfere with neurotransmission at peripheral cholinergic synapses by binding tightly to the presynaptic membrane and preventing the release of the neurotransmitter acetylcholine.

Epidemiology

From 1990 to 2000, 17 to 43 cases of foodborne botulism have occurred annually in the United States *(120)*. The toxin, when ingested with food, is absorbed from the stomach, the small intestine, and, slowly, the colon. Food items contaminated by botulinum toxin may have a completely normal appearance and taste. If *C. botulinum* microorganisms or spores are ingested and reach the colon, toxin production and absorption can occur in the human gastrointestinal tract as in infant botulism *(117,121)*. The spores of *C. botulinum* are heat-resistant, but the toxins are heat-labile and are destroyed by boiling for 10 minutes or by heating at 80°C for 30 minutes. Thus, terminal heating of toxin-containing food can prevent botulism *(117)*.

Wound botulism occurs when *C. botulinum* contaminates a traumatic wound and produces toxin *in situ (122–124)*. The toxin is then absorbed systemically. The incubation period is 4 to 14 days from the time of injury. The wound may appear clean, but antibiotic therapy may not prevent intoxication. The clinical picture is similar to foodborne botulism but without gastrointestinal symptoms; fever may occur secondary to wound infection. Wound botulism is rare, with only a few cases reported annually *(117)*. Compound fractures and crush injuries to the extremity are the major types of associated wounds *(122)*. Postoperative cases have been reported *(124)*. Parenteral and/or intranasal illicit drug use has been reported as a risk factor for wound botulism *(125,126)*. The use of "black-tar" heroin has emerged as the main cause of wound botulism *(127)*.

Infant botulism is the most common form of botulism in the United States, with 2,419 cases identified in the United States from 1992 to 2006 (average: 2.1 cases per 100,000 live births) *(119,128,129)*. The infant gastrointestinal tract becomes colonized with *C. botulinum* (often from honey contaminated with spores), and toxin is produced *in vivo*. Infants younger than 1 year are usually affected. The illness typically begins with constipation followed by lethargy, listlessness, poor feeding, ptosis, difficulty in swallowing, loss of head control, hypotonia and generalized weakness (the floppy baby), and, in some cases, respiratory arrest. Occasionally, infant-type botulism can occur in adults with altered gastrointestinal anatomy or microbial flora that permits the proliferation of ingested *C. botulinum* and production of toxin *in vivo (130)*. With the availability of botulinum toxins A and B for therapeutic use in muscle spasm disorders, the possibility of inadvertent, surreptitious, or criminal misuse of the toxin should be considered in patients with an otherwise unexplained clinical syndrome consistent with botulism *(131)*. Iatrogenic botulism cases have been reported with therapeutic and unlicensed cosmetic use *(132–134)*.

C. botulinum spores are found in soil and marine sediment worldwide and, therefore, may easily contaminate food products. In the United States, type A spores predominate west of the Mississippi River and type B spores predominate in the eastern states. Type E disease is usually associated with fish products *(117,118)*.

Most cases of botulism food poisoning occur singly or in small clusters and are due to home-canned or home-prepared foods; commercial products and restaurant-prepared foods are implicated in some instances *(135,136)*.

Clinical Manifestations

The incubation period is 12 to 36 hours, with a range of 6 hours to 8 days. Early symptoms include weakness and dizziness. Nausea and vomiting are uncommon. The picture of cholinergic inhibition is manifested by diminished salivation, extreme dryness of the mouth and throat, ileus, constipation, and urinary retention. Cranial nerve involvement is manifested by diplopia, blurred vision, photophobia, dysphonia, dysarthria, and dysphagia. Symmetric descending weakness of the extremities and respiratory muscle weakness occur. The patient characteristically is alert, oriented, and afebrile. Orthostatic hypotension may be present. Ptosis, extraocular muscle palsies, and dilated fixed pupils usually (but not always) are present on eye examination. Oral mucous membranes are dry. Variable degrees of muscle weakness and deep tendon reflex abnormalities are observed. Sensory examination is normal. Respiratory failure may develop secondary to respiratory muscle weakness. The clinical course is often prolonged, and the recovery is gradual *(137,138)*.

Diagnosis

A characteristic clinical picture and history of exposure should lead to suspicion of botulism. Characteristic abnormalities are observed in electromyographic studies in patients with botulism *(117)*. The diagnosis is confirmed by detecting *C. botulinum* toxin (by bioassay in mice) in the blood, stool, gastric contents, or suspected food or by culturing *C. botulinum* from the food, stool, gastric contents, or wounds (in patients with wound botulism) *(139,140)*. These tests are usually performed by reference laboratories.

Prevention and Control

The health department should be promptly notified of all suspected cases of botulism. The source food should be identified, and all potentially exposed individuals should be informed. The disease is not communicable, and isolation is not indicated. The mortality rate for adult botulism is 10% to 25% with modern supportive care and is as low as 2% in infant botulism.

Bioterrorism Potential

An aerosolized or foodborne botulinum toxin weapon potential exists (Chapter 102). Botulinum toxin has been weaponized, and terrorists have tried to use botulinum toxin as a weapon *(141)*. Hospital personnel should be alert to a possibility of a deliberate attack with botulinum toxin when an outbreak of flaccid paralysis is detected.

SECTION VI

Epidemiology and Prevention of Healthcare-Associated Infections in Pediatric Patients

CHAPTER 48

Healthcare-Associated Viral Respiratory Infections in Pediatric Patients

Ronald B. Turner

Healthcare-associated viral respiratory infection has historically been an important cause of morbidity in pediatric patients. Studies based on virus isolation reported that viral pathogens caused 23% to 35% of all healthcare-associated infections in children and the incidence of healthcare-associated viral infections in this population ranged from 0.59 to 0.72 per 100 patients *(1,2)*. There have been no comprehensive studies of hospital-acquired viral respiratory infection using modern diagnostic techniques, but available data suggest that the apparent incidence has changed little in recent years (*3*,4). Whether these data truly reflect no improvement in healthcare-associated infection rates over the last 20 years or whether improvements in infection control are obscured by the increased sensitivity of polymerase chain reaction (PCR) for detection of viral pathogens is not clear.

The viral pathogens that have been most commonly associated with healthcare-associated respiratory infections in pediatric patients include respiratory syncytial virus (RSV), parainfluenza virus, adenovirus, rhinovirus, and influenza virus. Viruses that are spread via the respiratory tract but that produce more prominent symptoms in other organ systems (i.e., measles, varicella-zoster, and parvovirus B19) are not considered in this chapter (see Chapters 42 and 51). Bocavirus has recently been detected from the respiratory tract of children with respiratory symptoms in a number of studies. The role of this virus as a respiratory pathogen, however, is obscured by the frequent detection of this virus from asymptomatic individuals and the frequent codetection of other established respiratory pathogens in symptomatic individuals *(5)*. This virus will not be considered further in this chapter.

VIRAL PATHOGENS

Respiratory Syncytial Virus and Metapneumovirus

RSV is an enveloped virus with a genome composed of a single negative strand of RNA. The virion has a diameter of 150 to 300 nm. The nucleocapsid, 12 to 15 nm in diameter, is smaller than that of the other members of the paramyxovirus family; thus, the virus has been placed in the separate genus *Pneumovirus*. Human metapneumovirus (HMPV) was described in 2001 *(6)*. The virologic, epidemiologic, and clinical characteristics of this virus are similar to those of RSV *(6–12)*.

RSV is relatively quickly inactivated after exposure to different environmental conditions. In studies using partially purified virus, virus survival decreased as the temperature at which the virus was stored was increased over the range from 55°C to 65°C *(13)*. Virus survival was best at a pH of 7.5 with decreasing infectivity as pH was raised or lowered. RSV is rapidly inactivated by ether, chloroform, and detergents *(14,15)*. Studies of virus survival using nasal secretions from infected infants revealed that infectious virus could be recovered for approximately 0.5 hours on skin, 1 hour on porous surfaces, and 7 hours on nonporous surfaces *(16)*.

Both RSV and HMPV have a single serotype based on neutralization with human sera but have two subgroups *(17)*. The clinical and immunologic significance of these antigenic differences has not been clarified; however, the detection of different viral strains by monoclonal antibody testing and/or nucleic acid analysis is useful in epidemiologic studies *(18–20)*.

RSV infection is the most common cause of lower respiratory infection in young infants. Fifty percent to seventy percent of all infants are infected during the first year of life, and by the age of 4 virtually all infants have had at least one infection *(21,22)*. Reinfection with RSV is common and, despite the nearly universal experience with this infection, the attack rate is approximately 40% for exposed individuals in all age groups *(21,23)*. HMPV infection is also very common with most individuals infected in early childhood.

The seasonal occurrence of RSV infections is well defined. Epidemics of RSV occur annually in the winter or spring *(24)*. These epidemics are consistently associated with increased hospital admissions for pediatric respiratory infection, although the severity of the epidemic varies from year to year. RSV is transmitted by contact with infected respiratory secretions. A study of RSV transmission found that close contact with an infected infant, when virus may be transmitted directly or by large-particle aerosols, or contact with virus-contaminated fomites could transmit infectious RSV to volunteer recipients *(25)*. Transmission of virus by small-particle aerosols was not detected in this study. The role of environmental contamination in the transmission of RSV is not clear, although RSV can survive on environmental surfaces for hours *(16)* and can be recovered from the environment of infected infants *(25)*. Infection with RSV requires that the virus reach the respiratory mucosa. Inoculation of infectious virus into either the nose or the eye is equally efficient for initiation of infection and much more efficient than oral inoculation *(26)*. The incubation period of RSV infection is 2 to 8 days with an average of about 5 days *(27–29)*. Once virus infects the upper respiratory mucosa, it may spread to the lower respiratory tract. RSV infection is limited to the respiratory tract, and respiratory secretions are the only body fluids that contain infectious virus. Shedding of RSV can be detected for a few days before onset of symptoms and generally continues for approximately 1 week *(30)*. Shedding is detected for >2 weeks in approximately 10% of patients.

Immunoprotection against RSV appears to be conferred by serum and secretory antibody *(21,31,32)*. A role for cell-mediated immune responses in the termination of RSV infection is suggested by the observation that children with deficiencies of T-cell immunity have unusually severe infections and prolonged shedding of virus *(33)*.

RSV infection may result in clinical illness involving any level of the respiratory tract. The most severe manifestations of RSV infection are bronchiolitis or pneumonia. The incidence of lower respiratory symptoms is greatest during primary infections in young infants *(21,22)*. Both increasing age and recurrences of infection are associated with an increasing proportion of infections that are asymptomatic or limited to the upper respiratory tract. Hospitalization for RSV infection is generally due to lower respiratory tract infection or apnea. However, during the RSV season, many infants admitted to the hospital have an incidental, community-acquired, RSV infection. HMPV has a similar clinical presentation but generally produces milder illnesses than RSV *(34,35)*.

Parainfluenza Virus

The parainfluenza viruses are enveloped RNA viruses that are members of the genus *Paramyxovirus* in the family Paramyxoviridae. These viruses are susceptible to a variety of chemical disinfectants *(36,37)*. There are four different serotypes of parainfluenza, types 1 to 4, which can be differentiated by antibody to complement-fixing and hemagglutinating antigens. No antigenic variation in these serotypes has been recognized over many years of observation.

Early studies of the parainfluenza viruses reported that both parainfluenza type 1 and type 3 were endemic with infections reported in virtually all months of the year *(38)*. More recent data suggest that infection with parainfluenza type 1 occurs as a fall epidemic in 2-year cycles (39). Parainfluenza, type 2, is much less common and the epidemic peak is more variable. Infections with parainfluenza virus types 1 and 2 are most common in children between 6 months and 6 years of age. By 5 years of age, most children have been infected with both serotypes of virus *(38)*.

In contrast to the behavior of serotypes 1 and 2, infection with serotype 3 occurs in biennial peaks that may be moderated somewhat in the years of high parainfluenza type 1 activity (39). Parainfluenza virus type 3 is a common cause of infection in young infants. A serologic survey reported that 60% of infants were seropositive by 1 year of age and 80% were positive by the time they were 4 years old *(38)*. The actual incidence of infection may be somewhat higher because reinfection, which would not be detected by serology, occurs often in young infants *(40)*. Parainfluenza type 3 often produces illness in the first 6 months of life despite the presence of maternal antibody. The peak incidence of illness is in the second year of life. Primary infections occurring in the second year of life are more likely to be associated with lower respiratory tract infection than those that occur earlier or later. Reinfections with parainfluenza type 3 occur commonly but are generally associated with mild upper respiratory illness.

The parainfluenza viruses have an apparent incubation period of 2 to 8 days *(41,42)*. Viral shedding from the upper respiratory tract occurs 1 to 4 days before the onset of symptoms and continues for 7 to 10 days in most patients with primary infection *(30)*. Some patients with primary infection continue to have intermittent shedding of virus for 3 to 4 weeks. The duration of shedding following reinfection is generally shorter than that after primary infection; however, reinfected patients occasionally shed virus for longer than 2 weeks *(30)*. The mechanism of transmission of the parainfluenza viruses is not known; however, the route of spread is presumed to be by large droplets or direct person-to-person contact.

The serotype of the virus and the presence of preexisting homotypic antibody appear to affect the clinical manifestations of parainfluenza virus infection. Infection with parainfluenza type 1 is most commonly associated with a febrile upper respiratory infection. The most common lower respiratory tract manifestation of type 1 infection is croup. Parainfluenza type 2 is associated with similar clinical manifestations, although the illnesses are generally less severe. Preexisting nasal secretory antibody appears to offer some protection against infection *(42)*. Parainfluenza virus type 3 is associated with disease at all levels of the respiratory tract and is not associated with a predominant clinical syndrome (39). This virus is second only to RSV as a cause of bronchiolitis and pneumonia in young infants.

Adenovirus

The adenoviruses are nonenveloped viruses with a genome of double-stranded DNA. These viruses are not inactivated by ether or chloroform and are stable at temperatures of 4°C to 36°C and pH of 5 to 9. Adenovirus is inactivated by sodium dodecylsulfate, chlorine, ultraviolet (UV) radiation, or formalin. There are >40 distinct serotypes of adenovirus; types 1 to 7 are the most important in pediatric respiratory disease. Adenovirus type 14 has recently emerged as a cause of respiratory disease especially in military recruits but is not yet a significant threat for hospital-acquired infection (43).

Adenovirus infections are an important cause of illness in childhood *(44)*. Antibody to serotypes 1 and 2 is detected in the serum of 60% to 80% of children by 5 years of age, and approximately 40% also have antibody to serotypes 3 and 5 *(45,46)*. About one-half of the adenovirus infections in these infants are associated with illness. The peak incidence of adenovirus-related illness occurs between 6 months and 2 years of age *(47)*, and adenovirus causes 5% to 10% of all febrile respiratory illnesses in children younger than 7 years *(46,47)*. Adenovirus is a much less common cause of respiratory illness in older children or adults. Adenovirus infections are endemic and cause illness in all months of the year *(24)*; an increased incidence of infection has been noted between December and July in some studies *(45,46)*.

The fecal–oral route may be the most likely route of transmission of adenovirus between young children although transmission by aerosol can also occur. Transmission of infection has been documented in families following experimentally induced fecal excretion of adenovirus type 4 *(48)*. During adenovirus infections, fecal excretion of virus occurs in >75% of children *(46)*. Transmission of infection is relatively efficient; 46% to 67% of susceptible household and day care contacts were infected after exposure to adenovirus *(46,47)*. The incubation period of adenovirus in children is not known. However, in adults challenged by the aerosol route, the incubation period was 6 to 13 days *(49)*, and, in a hospital outbreak, the apparent incubation period was 2 to 18 days *(50)*. A unique feature of adenovirus among the pediatric respiratory viruses is that intermittent shedding of the virus may continue for years after infection. Approximately one-half of adenovirus infections are associated with only a single day of virus shedding. One-fourth of the infections, however, result in intermittent shedding of virus for >3 months, and almost 10% continue to shed virus for >1 year *(46)*. Homotypic antibody, whether actively acquired by previous infection or passively acquired by maternal transmission, is partially protective for both infection and illness.

The most common respiratory manifestation of adenovirus infection in young infants is a febrile upper respiratory syndrome *(44,47,51,52)*. Although conjunctivitis is widely recognized as a manifestation of adenovirus infection, only 12% of outpatients *(47)* and 4% of hospitalized patients i have this finding. Hospitalized patients with adenovirus infection often have high and prolonged fevers (*51*,*52*).

Rhinovirus

The rhinoviruses are small, nonenveloped, single-stranded RNA viruses in the picornavirus family. The human rhinoviruses are stable at a pH of 6 to 8 and are not inactivated by chloroform, ether, or detergents (*53–55*). These viruses are rapidly inactivated at a pH of 3 and by UV irradiation. Rhinovirus survives well under environmental conditions. Virus was recovered after 1 hour on porous surfaces, 3 hours on nonporous surfaces, and 3 hours on human skin *(56)*. Other reports have suggested that virus may remain viable in the environment for several days *(57)*. There are >100 distinct rhinovirus serotypes that all appear to have similar epidemiologic characteristics and produce a similar clinical syndrome.

In contrast to other viral respiratory pathogens of childhood, the incidence of rhinovirus infection varies little with age. Approximately two-thirds of children experience a rhinovirus infection each year *(58,59)*; about 60% of these infections are associated with illness. Rhinoviruses cause illness in all months of the year, but there are distinct epidemic peaks of illness in the early fall and in the late spring *(58–61)*.

The mechanism of transmission of rhinovirus has been studied extensively. In experimental models, rhinovirus is transmitted most efficiently by direct person-to-person contact *(62)*, although transmission by large-particle aerosols has also been documented *(62,63)*. A study of natural colds found that treatment of the hands with a virucidal compound prevented transmission of rhinovirus infection, suggesting that hand-to-hand transmission may be important in a natural setting *(57)*. Once virus is transmitted, the incubation period is generally short, with onset of symptoms in 2 to 3 days, although, in a family setting, rhinovirus was cultured from 15% of specimens collected 7 to 10 days before the onset of symptoms *(58)*. Rhinovirus is shed exclusively from the upper respiratory tract. Shedding is most efficient from nasal secretions, although lower titers of virus can be detected in saliva and pharyngeal secretions *(64)*. Virus can also be recovered from the hands of a high proportion of infected volunteers *(56)*. Shedding of virus from infected individuals continues for 2 to 3 weeks after the onset of illness *(58,65)*. Homotypic serum neutralizing antibody correlates with resistance to rhinovirus infection *(59,66,67)*. The characteristic clinical syndrome associated with rhinovirus infection is the common cold but rhinovirus is also an important cause of exacerbations of asthma. These infections are generally not associated with fever.

Influenza

The influenza viruses are discussed in detail in Chapter 42. These viruses are enveloped RNA viruses classified in the family Orthomyxovirus. The virus is classified as type A, B, or C based on antigenic differences in the nucleoprotein and the matrix protein. Heat (56°C), lipid solvents, acid, formaldehyde, and UV irradiation all inactivate influenza viruses. Influenza is capable of prolonged survival on fomites. On nonporous surfaces, the virus was detectable for >48 hours, and, on porous surfaces, virus was detectable for 8 to 12 hours *(68)*. The amount of virus present on hands decreases rapidly with drying but residual virus can be detected for at least 1 hour when the hands are contaminated with large quantities of virus (69). The protective immune response to the viruses is directed at the hemagglutinin and neuraminidase antigens on the surface of the virion. The epidemic behavior of influenza viruses

is a result of variation in the antigenicity of these surface antigens.

The incidence of influenza infections is highest in preschool and school-aged children, with infection rates of 20% to 50% per year *(70–72)*; 60% to 80% of influenza infections in the pediatric age group are associated with illness *(70,72)*. The seasonal epidemiology of influenza virus infection is well established, with annual midwinter and spring epidemics *(70,71)*. Transmission of influenza may occur by small-particle aerosols, by large-particle aerosols (droplets), or by direct contact. The role of small-particle aerosols in transmission has been controversial and resolution of this question has important implications for hospital infection control recommendations (73,74). The incubation period for influenza is 24 to 48 hours. Virus shedding is primarily from the respiratory tract, and most patients shed virus for <1 week after the onset of illness, although shedding may last somewhat longer in young children *(75,76)*. Influenza virus is present in the stool of some infected children *(77,78)*, but the significance of this observation for pathogenesis and transmission of the virus is not known. The clinical manifestations of influenza in children differ from adult infections in that children are less likely to have lower respiratory infection, more likely to have associated gastrointestinal symptoms, and tend to have higher fevers *(71,72)*.

HEALTHCARE-ASSOCIATED VIRAL RESPIRATORY INFECTION

Healthcare-associated viral respiratory infections have important implications for the patient. These infections are associated with an average increase of 5 to 6 days in the length of hospitalization *(1,79)*. The increased length of stay may be somewhat greater when only influenza and RSV are considered (*80*,*81*). In addition to the increased length of stay, many patients with healthcare-associated infection are subjected to additional diagnostic studies or administration of unnecessary antibiotics. Healthcare-associated respiratory infection frequently involves children with chronic underlying medical conditions, presumably because of their frequent and prolonged hospitalizations (4,*82*).

Patients with uncorrected congenital heart disease, chronic lung disease, compromised immune function, and premature infants are at increased risk from healthcare-associated viral infections. In 1982, MacDonald et al. *(83)* reported that healthcare-associated RSV infection was associated with a mortality rate of 44% in patients with congenital heart disease. More recent studies have reported much lower mortality rates in these patients *(84,85)*. Improvements in intensive care management and pediatric cardiac surgery may account for the reductions in the mortality in these populations. A high mortality rate has been associated with healthcare-associated adenovirus infections in patients with underlying pulmonary or cardiac disease in two studies *(86,87)*.

Immunosuppressed patients who acquire a viral lower respiratory infection have a mortality rate of 25% to 45% *(88)*. Infections with RSV and adenovirus are particularly dangerous in this population. The magnitude of the risk of severe illness associated with viral respiratory infections appears to be related to the intensity of the immunosuppressive therapy.

The impact of healthcare-associated viral respiratory infections in neonatal intensive care nurseries is inconsistent from study to study. RSV and adenovirus infections in these patients have been associated with a high (18–29%) mortality rate in some reports *(89–91)*. In contrast, other studies of neonatal healthcare-associated viral infection have reported low or no mortality *(92–100)*, and, in many of these studies, a large proportion of patients were asymptomatic. Most studies, however, have reported significant morbidity associated with healthcare-associated viral infections in neonates (see also Chapter 52 for additional information on healthcare-associated viral respiratory infections in neonates).

Healthcare-associated respiratory infections with a particular virus are temporally related to the presence of the virus in the community *(75,76,101–103)*. Thus, the incidence of hospital-acquired viral respiratory disease is seasonal and the risk of infection is greatest during community epidemics. Virtually all patients, visitors, and hospital personnel are at risk for infection with healthcare-associated viral respiratory pathogens and may serve as a source of infection in the hospital. A respiratory viral pathogen or *Mycoplasma* was detected in 61% of symptomatic pediatric patients admitted to the hospital during the respiratory virus season *(79)*. Furthermore, in this study, a viral pathogen was detected in almost 50% of patients who were asymptomatic or in whom respiratory symptoms were initially overlooked. The incidence of RSV infection in hospital personnel during community outbreaks has been reported to range from 5% to 61% depending on the personal protection measures used *(104,105)*. In one study, 18% of the infections were asymptomatic, and an additional 36% were associated only with mild illness *(106)*. Consistent with the multiple potential sources of virus, detailed studies of healthcare-associated outbreaks of viral respiratory pathogens have found that these outbreaks are usually caused by different strains of virus and are not true point-source outbreaks *(18,20,50,107–109)*.

Young children with underlying chronic medical conditions are most likely to be affected by healthcare-associated viral respiratory infections (4). Specific risk factors, such as intravascular lines or immunosuppression, appear to be less important but a few risk factors have been identified. Children with immunosuppression resulting from cancer have been found to have a higher incidence of influenza infection than children with normal immunity *(110)*. This increased incidence appeared to be related to a failure of preexisting antibody to protect from disease in immunocompromised patients. Specific procedures and devices such as orotracheal and orogastric intubation have both been associated with an increased risk of acquisition of infection *(93,98,111)*. Despite these reports, targeting high-risk patients for specific preventive measures would have little impact on the overall incidence of healthcare-associated viral respiratory infection.

DIAGNOSIS

Epidemiologic and clinical information can provide important clues to the specific etiology of viral respiratory infections. The occurrence of viral respiratory disease in a

community is the result of sequential and relatively discrete epidemics of individual pathogens *(112,113)*. The etiologic diagnosis of an individual patient is aided by knowledge of which viruses are prevalent in the community at a given time. Furthermore, although any of the viral respiratory syndromes may be caused by any of the pathogens, specific pathogens are often associated with particular clinical syndromes as described previously. The presence of a clinical syndrome characteristic of a virus known to be present in the community provides a reasonably reliable prediction of the etiologic diagnosis.

Laboratory Tests for Diagnosis

Laboratory confirmation of the etiologic diagnosis is usually not necessary for management of viral respiratory infections or for the institution of appropriate infection control measures. Specific identification of a pathogen is useful for cohorting of patients and for directing specific antiviral therapy. A specific viral diagnosis may be established by PCR, virus isolation, viral antigen detection in respiratory secretions, or detection of specific antiviral antibodies in acute and convalescent sera.

PCR assays for the detection of the parainfluenza viruses, RSV, and the influenza viruses are commercially available and have become the preferred method for detection of these pathogens. Assays for metapneumovirus, coronavirus, adenovirus, and rhinovirus/enterovirus are also available in some laboratories. These assays require only hours to perform and permit a sensitive and specific diagnosis. Nasal wash specimens appear to be most sensitive for detection of viral pathogens by PCR (114).

Virus isolation in cell cultures remains the standard method for diagnosis of the respiratory pathogens. Isolation of these viruses in cell culture, however, generally requires several days and, in some cases, may take >2 weeks. Recent studies of RSV, influenza, and rhinovirus have found that virus isolation has a sensitivity of 75% to 85% compared with detection of virus by PCR *(115–117)*. The time of collection in relation to the onset of symptoms, the method of specimen collection, and the handling of the specimen before inoculation into cell culture all affect the recovery of virus from infected individuals. Specimens for virus isolation should be obtained as early as possible in the course of the patient's illness. Although some individuals may shed virus for weeks *(30,65)*, virus is most consistently recovered in the first few days after the onset of symptoms. Nasal wash specimens are better than swab specimens for detection of respiratory pathogens *(118–120)*.

Detection of viral antigen in respiratory secretions has been reported for many of the respiratory viruses. Enzyme-linked immunosorbent assay reagents are commercially available as kit technologies for RSV and influenza. These assays provide rapid results but are less sensitive than cell culture or PCR. Many laboratories also offer antigen detection by fluorescent antibody methods; however, the accuracy of these techniques depends on the technical expertise of the laboratory and the quality of the specimen submitted for testing.

Serologic assays are available for most of the respiratory pathogens; however, the need for a convalescent serum limits the usefulness of the serologic tests in the clinical setting. Acute serum specimens should be obtained as soon as possible after onset of symptoms, and convalescent sera should be collected 2 to 3 weeks later. Sera may be stored at 4°C for short periods and may be stored at –20°C indefinitely.

Interpretation of Laboratory Results

Virus Isolation The isolation of a viral pathogen from the upper respiratory tract of a patient with respiratory symptoms is generally considered diagnostic. Virus isolation is absolutely specific if the laboratory confirms the identity of the virus by immunologic methods.

Viral Antigen Detection and PCR Detection of viral antigen in respiratory secretions allows rapid diagnosis of viral infection. The commercially available reagents for detection of RSV infection generally have a sensitivity and specificity of 85% to 95% compared with virus isolation, although individual studies have reported markedly lower sensitivities *(121,122)*. When antigen detection methods are compared with PCR, the sensitivity of antigen detection appears to be 65% to 75% *(116,123)*.

PCR is more sensitive than other methods for detection of viral respiratory pathogens. The sensitivity of PCR relative to virus isolation and antigen detection is consistently >90% *(115–117,124)*. The exquisite sensitivity of PCR can lead to false-positive results if meticulous care is not taken to prevent contamination of the assay.

Viral Serology Interpretation of serologic results depends on comparison of antibody levels in acute and convalescent sera. Antibody levels in a single serum specimen are generally not helpful for diagnosis of viral infection. A fourfold increase in antibody titer in a convalescent serum specimen compared with the titer in an acute serum specimen drawn early in the illness is evidence of infection with the virus.

PREVENTION AND CONTROL OF HEALTHCARE-ASSOCIATED INFECTIONS

Active Immunization

The influenza vaccine is the only vaccine available for the prevention of infection by the respiratory viruses. The influenza vaccine usually contains two type A strains and one type B strain selected to provide immunity to the virus expected in the following influenza season. The strains of virus in the vaccine are changed, as necessary, in response to the changing epidemiology of the influenza viruses. The vaccines available in the United States are trivalent inactivated vaccines and live-attenuated influenza vaccine. All children 6 months to 18 years of age, all adults ≥50 years of age, adults 19 to 49 years of age with underlying medical conditions, and anyone (e.g., healthcare workers and household contacts) who has contact with individuals at high risk for influenza-related complications should be immunized each year *(125)*. Immunization is not effective for intervention in healthcare-associated outbreaks of influenza *(126)* unless antiviral therapy is given for 2 weeks following vaccination to prevent infection while one waits for antibody titers to rise to a protective level (see also Chapter 42).

Passive Immunization

Palivizumab, a humanized monoclonal antibody to RSV, reduces the severity of illness in premature infants, but has no effect on the incidence of infection *(127)*. The role of this preparation for the prevention of healthcare-associated infection has not been studied. Because of the lack of effect on RSV infection, it is unlikely that passive immunization will be useful for prevention of transmission of virus. The use of palivizumab to protect appropriate high-risk patients during healthcare-associated outbreaks of RSV infection has been reported and appears to be effective *(128)*.

Antivirals

Effective antiviral therapy is available for the treatment or prevention of influenza infection (129). Amantadine and rimantadine are useful for prophylaxis of influenza A infections in children older than 1 year. Oseltamivir and zanamivir may be used for prevention of both influenza A and B infections. Oseltamivir is approved for in children over 1 year of age and zanamivir is approved for children 5 years of age or older. The drug resistance patterns of circulating influenza isolates will influence the appropriate choice for prophylaxis. These drugs are not a substitute for immunization but can be used in patients who cannot be immunized or who are immunized after influenza is already present in the community to prevent infection before development of a protective antibody response. These agents may also be used to prevent infections in patients who may have an impaired antibody response to the vaccine. Patients who are at high risk from influenza infections should be immunized or treated prophylactically before hospitalization when feasible; the cost–benefit ratio of prophylaxis for low-risk patients has not been established. Prophylaxis with antivirals in the setting of a healthcare-associated outbreak may be of use; however, detection of the outbreak in time to institute effective prophylaxis may be difficult *(126)* (see also Chapter 42).

Isolation

Respiratory viruses can be transmitted from person to person by aerosols or by hand contact with the virus followed by self-inoculation. Aerosols are readily produced by coughing, sneezing, and nose blowing *(130,131)*. Some aerosolized particles have also been detected during normal speech *(130)*.

Small-particle aerosols, composed of droplet nuclei 2 to 3 μm in diameter, account for approximately 95% of the total number of particles and 25% of the total volume of coughs and sneezes *(130)*. The small-particle aerosol fraction is slightly higher for coughs than for sneezes. These particles remain suspended in the air and can be transmitted over extended distances. Once a virus suspended in a small-particle aerosol contaminates an air space, only the circulation of the air and the ability of the virus to survive in the environment limit the time during which infection can be transmitted. Small-particle aerosols are not filtered by the nose and are inhaled into the lungs.

Large-particle aerosols are composed of particles larger than 10 μm in diameter. These particles settle quickly and are transmitted only a few feet. For this reason, transmission of infection by a large-particle aerosol requires relatively close contact between infected and susceptible individuals. Large-particle aerosols are effectively filtered in the nose and do not reach the lower respiratory tract.

Transmission of viral respiratory infections by direct contact requires that susceptible individuals contaminate their hands with virus by contact with either an infected individual or contaminated objects in the environment. The virus is then inoculated onto the mucous membranes by hand-to-nose or hand-to-eye contact. Respiratory viruses can conceivably be spread from infected to susceptible individuals by an uninfected intermediate person, but this has not been demonstrated. Spread of infection by direct contact is limited only by the ability of viruses to survive on skin and environmental surfaces.

Information about the mechanisms of spread of different viral pathogens under natural conditions is limited. Although it is likely that any of the different mechanisms of transmission may be involved in the spread of respiratory infection, studies in controlled settings suggest that for some viruses one route may be more efficient than another.

The viruses associated with healthcare-associated respiratory infections in children, with the possible exception of influenza, appear to require relatively close contact for transmission from person to person (*25*,*57*,73,74). Given the role of direct person-to-person contact in the transmission of these pathogens, strict compliance with good hand hygiene should theoretically be sufficient to control healthcare-associated spread. The alcohol-based hand cleaners recommended in recent guidelines *(132)* rapidly inactivate viral respiratory pathogens *(133–136)*, but the effectiveness of these preparations for prevention of healthcare-associated viral respiratory infections has not been studied. The efficacy of various other interventions for prevention of transmission of respiratory viruses, particularly RSV, in the hospital setting has been examined in a number of studies. The intensity of the interventions studied has ranged from the use of gloves to cohorting of patients based on universal preadmission testing for viral antigen. The use of gowns and masks does not appear to effectively interrupt transmission of RSV *(137,138)*. Cohorting of symptomatic infants also appears to contribute little to the control of healthcare-associated RSV *(105,106,139)*. Demonstration of self-inoculation of personnel by transfer of RSV from contaminated hands to the eyes *(25)* suggested the potential for the use of face shields as a control measure for prevention of these infections. Two studies have reported a significant reduction in infections in personnel when goggles were used *(104,105)*, and in one study this was associated with a decrease in healthcare-associated infections in patients *(105)*. Gloves might also be expected to reduce hand-to-face contact, and in one study strict enforcement of gloving effectively prevented healthcare-associated transmission of RSV *(140)*. A more recent study found that gloves were ineffective *(139)*; however, the mechanism by which compliance with glove use was enforced was not described. Two studies have shown that diagnostic viral testing of infants at the time of admission with subsequent cohorting to infected and uninfected cohorts effectively controls healthcare-associated RSV *(139,141)*, but this is not feasible as a routine infection control measure.

Several issues specific to the respiratory viruses present obstacles to the success of interventions for the prevention of healthcare-associated infections: (a) healthcare-associated

infections with these agents occur when there are large numbers of infected individuals in the community providing an opportunity for new introductions of the virus not only by patients but also by personnel and visitors; (b) a large proportion of the patient population is susceptible to infection; (c) many infected individuals will be asymptomatic; and (d) diagnostic testing for most of the viral pathogens of concern is either not sufficiently rapid or not sufficiently accurate to guide decisions for isolation. With these limitations in mind, all patients with symptoms consistent with viral respiratory illness should be placed on Contact Precautions. Patients with likely influenza or adenovirus infection should also be managed with Droplet Precautions. If a healthcare-associated outbreak of viral respiratory disease occurs, cohorting of infected infants (based on diagnostic testing if possible), cohorting of uninfected high-risk patients, and heightened surveillance of staff and visitors for symptomatic infections should be instituted.

Isolation for Prevention of Influenza The mechanism of transmission of influenza has been controversial, but there is some suggestion that small-particle aerosols may play a role (73,74). Transmission by small-particle aerosol has implications for both the type of mask (surgical vs. respirator) and the type of isolation that might be required. Contact and Droplet Precautions are currently recommended for patients with known or suspected influenza when healthcare personnel can be immunized and high-risk patients either immunized or treated with prophylactic antiviral therapy. UV radiation has been reported to reduce the incidence of influenza infections in the hospital setting *(142)*. However, carefully controlled studies of UV radiation for disinfection in the general hospital setting have not been done, and it is likely that this modality would be effective only under very limited conditions *(143)* (see also Chapter 90).

CHAPTER 49

Healthcare-Associated Bacterial Infections of the Central Nervous System, Upper and Lower Respiratory Tracts, and Skin in Pediatric Patients

W. Matthew Linam and Terry Yamauchi

Clinicians involved in the care of children must be alert for signs or symptoms of healthcare-associated infections in their pediatric patients. Infections involving the central nervous system, respiratory tract, and skin can occur even under optimal conditions. Clinicians must be aware of the potential infecting microorganisms and should understand the pathogenesis of these illnesses. An understanding of these factors allows for appropriate therapy and infection-control measures.

CENTRAL NERVOUS SYSTEM INFECTIONS

Healthcare-associated infections of the central nervous system include intracranial infections, meningitis or ventriculitis, and shunt infections. Central nervous system infections account for 2% to 17% of all healthcare-associated infections in infants in intensive care units (*1,2*,3,*4,5*,6,*7*). Most of these infections involve surgical procedures and/or manipulation/trauma within the central nervous system. Information concerning pediatric intensive care units is less readily available; although some investigators have demonstrated a central nervous system infection rate of 25% in their pediatric intensive care units, others have had no occurrences *(8,9)*.

Intracranial Infections

Pathogenesis Intracranial infections, such as brain abscesses, are not commonly encountered and should meet the criteria from the Centers for Disease Control and Prevention (CDC) in Table 49-1 for diagnosis (10). Brain abscesses commonly form via direct spread from a contiguous source or via hematogenous spread from a distant source. In approximately one-third of situations, however, no predisposing factors are identified. Respiratory diseases such as chronic sinusitis, otitis media, and mastoiditis account for the majority of sites from which microorganisms can extend directly into the brain *(11,12)*. Patients who develop abscesses resulting from contiguous spread usually have a single abscess in the proximity of the infected region. Abscesses acquired through the hematogenous route tend to follow the course of the middle cerebral artery and cause abscesses in the frontal and parietal regions. Cyanotic congenital heart disease with right-to-left shunts or pulmonary arteriovenous fistulas predisposes patients to brain abscess formation *(13,14)*. The most common lesion encountered in such patients is tetralogy of Fallot *(15)*. A healthcare-associated brain abscess is particularly likely in patients who have suffered head trauma or who have undergone neurosurgical procedures. Approximately 6% to 11% of abscesses are in patients with head trauma or neurosurgical procedures, and their symptoms usually develop within 10 days to 2 months following the inciting episode *(13,14,16,17)*.

Etiology Brain abscesses are often polymicrobial in origin, but when they occur in patients who have had head injuries or neurosurgical procedures, *Staphylococcus aureus*—including methicillin-resistant *S. aureus* (MRSA)—followed by the viridans streptococci and *Streptococcus pneumoniae* are the most common microorganisms isolated *(13–17)*. Abscesses in patients with complex congenital heart disease include anaerobes, viridans streptococci, microaerophilic streptococci, enterococci, and *Haemophilus* species. The etiologic agents in patients with a history of chronic sinusitis or otitis media are anaerobes, gram-negative rods (*Proteus*, *Pseudomonas*, *Haemophilus*), and *S. aureus*.

Clinical Manifestations Symptoms associated with a brain abscess include fever (68%), headache (66%), vomiting (59%), focal neurologic deficits (46%), seizures (44%), papilledema (39%), and meningeal signs (36%) *(18)*. Papilledema and meningeal signs may not be present in patients younger than 2 years *(13,14)*. The classic triad of symptoms—headache, fever, and focal neurologic deficits—is demonstrated in <30% of patients *(14)*.

TABLE 49-1

Definitions for Central Nervous System Infections in Pediatric Patients

Intracranial Infection

- Microorganism must be cultured from the brain tissue or dura
- Patient shows evidence of infection at surgery or by histopathologic examination
- Patient indicates two or more of the following without another recognizable cause: headache, dizziness, fever (>38°C), localizing neurologic signs, change in mental status; these symptoms must be followed by institution of appropriate antimicrobial therapy with the microorganism seen on microscopic examination, or there must be a positive antigen test, radiographic evidence of infection, or a diagnostic antibody test
- Criteria are similar for patients younger than 12 mo with the inclusion of hypothermia (<37°C), apnea, or bradycardia

Meningitis/Ventriculitis

- Microorganism is isolated from the cerebrospinal fluid
- Appropriate antimicrobial therapy is instituted, and the patient has one or more of the following: fever (>38°C), headache, stiff neck, meningeal signs, cranial nerve signs, irritability; *and* one of the following laboratory abnormalities: increased white cells, elevated protein, and/or decreased glucose in the cerebrospinal fluid; positive gram stain; positive blood culture; positive antigen detection; or a diagnostic antibody test
- Criteria are similar for patients <12 mo with the inclusion of hypothermia (<37°C), apnea, and bradycardia

(Adapted from Horan TC, Andrus M, Dudeck MA. CDC/NHSN surveillance definition of healthcare-associated infection and criteria for specific types of infections in the acute care setting. *Am J Infect Control* 2008;36:309–332.)

Diagnosis The diagnosis of a brain abscess can be established by cerebral imaging using cranial ultrasonography, computed tomography, or magnetic resonance imaging.

Prevention Prophylactic antimicrobial agents may prevent the development of brain abscesses in certain situations. Antimicrobial prophylaxis to prevent infective endocarditis is currently only recommended for patients with cardiac conditions that place them at the highest risk for complications from infective endocarditis (Table 49-2) (*19,*20). Antimicrobial prophylaxis is indicated in patients before dental procedures that involve the manipulation of the periapical region of the teeth or the gingival mucosa or the perforation of the oral mucosa. Prophylaxis should also be considered for invasive respiratory procedures that involve incision or biopsy of the respiratory mucosa and infected skin, skin structure, or musculoskeletal tissue *(19)*. Recommended prophylaxis regimens are outlined in Table 49-3.

Antimicrobial prophylaxis for neurosurgical procedures has been demonstrated to be effective for clean and clean–contaminated procedures *(21–26)*. Antibiotics should be started within 60 minutes of the skin incision with the exception of vancomycin and fluoroquinolones, which should be started 60 to 120 minutes before the skin incision. For procedures lasting longer than 4 hours, antibiotic redosing should be based on the half-life of the antibiotic, but antibiotics should be discontinued within 24 hours after surgery (27). Multiple regimens have been used involving vancomycin *(21)*, vancomycin/gentamicin *(24)*, cefazolin/gentamicin *(26)*, piperacillin *(22)*, cloxacillin *(25)*, and cefuroxime *(28)*. Despite the multiple combinations that have been used, all the regimens should include activity against staphylococci. It is recommended that patients undergoing clean or clean–contaminated neurosurgical procedures receive antimicrobial prophylaxis with cefazolin or vancomycin as the drugs of choice (*23,*29). Patients known to be colonized with MRSA should receive vancomycin for prophylaxis (27). In hospitals with high rates of healthcare-associated gram-negative infections, consideration should be given to including antimicrobial agents in the regimen that are active against the prominent gram-negative microorganisms as well.

TABLE 49-2

Cardiac Conditions Associated with the Highest Risk of Adverse Outcome from Endocarditis for which Prophylaxis with Dental Procedures is Reasonable

Prosthetic cardiac valve or prosthetic material used for cardiac valve repair

Previous IE

Congenital heart disease (CHD)[a]

- Unrepaired cyanotic CHD, including palliative shunts and conduits
- Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 mo after the procedure[b]
- Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)

Cardiac transplantation recipients who develop cardiac valvulopathy

[a]Except for the conditions listed above, antibiotic prophylaxis is no longer recommended for any other form of CHD.
[b]Prophylaxis is reasonable because endothelialization of prosthetic material occurs within 6 mo after the procedure.

TABLE 49-3

Regimens for a Dental Procedure

		Regimen: Single Dose 30–60 min before Procedure	
Situation	***Agent***	***Adults***	***Children***
Oral	Amoxicillin	2 g	50 mg/kg
Unable to take oral medication	Ampicillin	2 g IM or IV	50 mg/kg IM or IV
	OR		
	Cefazolin or ceftriaxone	1 g IM or IV	50 mg/kg IM or IV
Allergic to penicillins or ampicillin—oral	Cephalexin[a,b]	2 g	50 mg/kg
	OR		
	Clindamycin	600 mg	20 mg/kg
	OR		
	Azithromycin or clarithromycin	500 mg	15 mg/kg
Allergic to penicillins or ampicillin and unable to take oral medication	Cefazolin or ceftriaxone[b]	1 g IM or IV	50 mg/kg IM or IV
	OR		
	Clindamycin	600 mg/kg IM or IV	20 mg/kg IM or IV

[a]Or other first- or second-generation oral cephalosporin in equivalent adult or pediatric dosage.
[b]Cephalosporins should not be used in an individual with a history of anaphylaxis, angioedema, or urticaria with penicillins or ampicillin.
IM, intramuscular; IV, intravenous.

Meningitis and Ventriculitis

Pathogenesis Meningitis or ventriculitis is usually the result of a bacteremia. The bacteria gain access to the central nervous system from the blood in the region of the choroid plexus. Meningitis less commonly develops as a complication of endocarditis, pneumonia, or thrombophlebitis. There may also be a direct extension from a chronic respiratory source (i.e., mastoiditis) or as a complication of trauma (i.e., basilar skull fracture), an anatomic defect of the cribriform plate, or a direct communication between the skin and meninges (meningomyelocele) *(30)*. Some degree of ventriculitis can be demonstrated in most cases of bacterial meningitis, but ventriculitis is more common as an infectious complication of ventricular shunting. The predominant microorganisms involved in healthcare-associated meningitis or ventriculitis are different from those involved in community-acquired disease. Contributing factors include the age, immune status, and antibiotic history of the patient. The diagnostic criteria for healthcare-associated meningitis or ventriculitis are outlined in Table 49-1.

Etiology In children older than 3 months, the common pathogens causing meningitis have traditionally included *Haemophilus influenzae* type B, *S. pneumoniae,* and *Neisseria meningitidis*. Because of the efficiency of the *Haemophilus* vaccines, however, this microorganism is no longer the predominant pathogen *(31)*. For children younger than 3 months, group B β-hemolytic streptococci (GBS), *Escherichia coli,* and *Listeria monocytogenes* are the most frequent causes of meningitis *(32)*. Newborns become colonized with these microorganisms from passage through the birth canal and may develop illness within hours after birth. If illness occurs within the first 6 days of life, it is considered an early-onset illness. Infections that develop after 6 days of life are considered late-onset illnesses. Early-onset illnesses are due to microorganisms harbored in the mother's birth canal. Microorganisms that cause late-onset disease may have been transmitted from the mother or may have been acquired from caregivers or the environment.

Most healthcare-associated cases of meningitis in children older than 3 months are due to the staphylococci, although enterococcal and gram-negative enteric (*E. coli*, *Klebsiella*, *Enterobacter*, *Proteus*) infections do occur *(2,33)*. When staphylococcal meningitis occurs, there is an associated defect in the central nervous system resulting from surgery or trauma in approximately 75% of cases *(34,35)*. Therefore, most cases are due to direct extension of the microorganism instead of hematogenous spread. Spread of the more traditional microorganisms such as *N. meningitidis* and *H. influenzae* occurs via the respiratory route, and therefore, respiratory spread is a potential hazard for healthcare-associated transmission. These microorganisms are responsible for secondary diseases in family members but only rarely have been associated with healthcare-associated infections of the central nervous system *(36)*.

Early-onset GBS disease usually manifests itself as respiratory distress with bacteremia. Most early-onset disease, regardless of the microorganism, usually lacks meningeal involvement. Meningeal involvement is a common manifestation in late-onset disease *(37)* (see Chapter 32). Most

newborns who develop meningitis while hospitalized are in neonatal intensive care units. Therefore, clinicians should be concerned about the bacteria that are known to be present in each nursery. Outbreaks of meningitis in neonatal intensive care units have been attributed to several microorganisms, both gram-positive and gram-negative, including *S. aureus*, *Staphylococcus epidermidis*, *Serratia*, *Klebsiella*, and *Citrobacter (7,38–40)* (see Chapter 52).

Clinical Manifestations Children with meningitis usually have signs and symptoms relating to their central nervous system, whereas infants may not. The diagnosis of meningitis must be considered in any patient with fever, altered mental status, and meningismus.

Diagnosis A lumbar puncture is the method of choice for establishing this diagnosis. An increased number of white blood cells with a polymorphonuclear predominance, elevated cerebrospinal fluid (CSF) protein levels, and decreased glucose levels are typically found with bacterial meningitis. The CSF should be sent for gram staining, and CSF and blood should be cultured for bacteria to aid in finding the etiologic agent. Bacterial antigens are less helpful because the more common healthcare-associated pathogens are not included in such panels. Recently, polymerase chain reaction (PCR) has become more readily available for the detection of bacterial meningitis. Broad-range PCRs targeting the 16S rRNA gene and specific PCRs for the detection of pathogens such as *S. pneumoniae* and *Neisseria meningitides* can assist in diagnosing bacterial meningitis, particularly in situations in which the patient has received antibiotics prior to the collection of spinal fluid *(41–44)*.

Prevention To aid in the prevention of healthcare-associated disease, patients admitted to the hospital with meningitis resulting from *N. meningitidis* or *S. pneumoniae* should be placed on Droplet Precautions for the first 24 hours of hospitalization, and all contacts of the patient should observe strict hand washing *(45)*. Antibiotic prophylaxis may be indicated for household or day-care contacts who have had direct exposure to the oral secretions of patients who have an *N. meningitidis* infection. Only hospital personnel with exposure to a patient's respiratory secretions through situations such as unprotected mouth-to-mouth resuscitation, intubation, or airway suctioning should receive prophylaxis (see Chapter 76). Rifampin, 10 mg/kg (maximum of 600 mg), every 12 hours for 2 days is indicated for persons aged 1 month or older. Contacts who are younger than 1 month should receive 5 mg/kg every 12 hours for 2 days. Affected individuals should be alerted to the potential side effects of the medication: urine and other secretions are discolored (orange or red), contact lenses can become permanently discolored, and rifampin may alter the activity of birth control pills.

Pregnant women should be excluded from rifampin prophylaxis *(46)*. Options for individuals unable to take rifampin include ceftriaxone or ciprofloxacin (47). Ceftriaxone given in a single intramuscular injection at a dose of 125 mg for children younger than 15 years and 250 mg for others has been demonstrated to effectively eradicate the meningococcal carrier state with group A *N. meningitidis (48)*. A single oral dose of ciprofloxacin, 20 mg/kg (maximum dose 500 mg), has been demonstrated to be effective in adults but cannot be used in children or in pregnant or lactating women *(49)*. Ceftriaxone should be used in pregnant women. These options should only be considered in circumstances in which rifampin cannot be used.

Meningococcal vaccine can be used as an adjunct to chemoprophylaxis in outbreaks caused by serogroups that are included in the vaccine (A, C, Y, and W-135). For adults and children older than 2 years, the preferred vaccine is the tetravalent meningococcal (A, C, Y, and W-135) conjugate vaccine, but the tetravalent meningococcal (A, C, Y, and W-135) polysaccharide vaccine may also be used. Serogroup B is not contained in the vaccine. The tetravalent meningococcal (A, C, Y, and W-135) polysaccharide vaccine has been used in children younger than 18 months. This is given as 2 doses 3 months apart to control outbreaks *(50)*.

For trauma patients with basilar skull fractures, antimicrobial prophylaxis for the prevention of meningitis is controversial *(51)*. Currently, antimicrobial prophylaxis does not appear to decrease the incidence of meningitis after a basilar skull fracture *(51)*. Surgical intervention should be performed when there is no evidence of healing and/or repeated infection occurs. For open skull fractures, antibiotic prophylaxis is generally recommended *(52)*.

The prevention of early-onset meningitis in neonates begins with good prenatal care and intervention strategies to prevent the transmission of potentially harmful microorganisms to the newborn infant *(53)*. To prevent early-onset neonatal GBS disease, all pregnant women should have vaginal and rectal cultures for GBS at 35 to 37 weeks of gestation. Women identified as carriers during the current pregnancy should receive intrapartum antibiotic prophylaxis at the onset of labor or rupture of membranes. Intrapartum prophylaxis should be administered to all women who have had a previous infant with invasive GBS disease or who are found to have GBS bacteriuria during the current pregnancy. If the results of the GBS screen are not known at the onset of labor or rupture of membranes, intrapartum antimicrobial prophylaxis should be administered if any of the following risk factors are present: gestation of <37 weeks, prolonged rupture of membranes ≥18 hours, or intrapartum temperature ≥38°C. The antimicrobial agent of choice is penicillin G (5 million U initially and then 2.5 million U every 4 hours) given intravenously until delivery. Intravenous ampicillin (2 g initially, followed by 1 g every 4 hours until delivery) can be used, but penicillin is preferred because of its narrow spectrum. Intravenous cefazolin or vancomycin can be used for penicillin-allergic patients. Because of the increasing prevalence of resistance, clindamycin and erythromycin should not be used for antibiotic prophylaxis for GBS. The management of infants born to mothers who have received chemoprophylaxis should be based on the gestational age of the infant, the number of doses of the prophylactic agent received, and the clinical findings of the infant *(54)*.

Shunt Infections

Pathogenesis Approximately 4.5% to 25% of patients who have undergone CSF shunting procedures develop infectious complications *(55–59)*. Risk factors for infection include young age of the patient (<3 months), inexperienced surgeons, prolonged shunting procedures,

and distal catheter tip location *(60–63)*. Shunt infections usually occur within 2 months after placement; most of these infections are caused by transient or permanent bacterial inhabitants of the skin. The latter observations suggest that direct inoculation in the perioperative period is probably the pathogenesis of this infection *(64)*.

Etiology Staphylococci are responsible for approximately 75% of infections; *S. epidermidis* is the primary agent in 50% and *S. aureus* in 25% *(55,56,58)*. Infections with gram-negative enteric microorganisms (*E. coli*, *Klebsiella*, *Proteus*) and *Pseudomonas* account for approximately 20%; the remainder of infections are caused by less-common microorganisms such as *Enterococcus*, viridans streptococci, *N. meningitidis*, micrococcus, *H. influenzae*, diphtheroids, *Propionibacterium*, and *Corynebacterium (56,58,65–68)*.

Clinical Manifestations The most common symptoms of shunt infections are usually symptoms of shunt malfunction. Headache, irritability, lethargy, nausea, and change of mental status are common. Although fever is usually present, approximately 10% to 20% of children are afebrile *(56,58)*. In most shunt infections, signs of meningeal irritation are absent because there is no communication between the infected ventricle and the CSF.

Diagnosis Shunt infections should be suspected in any patient who has a ventricular shunt with complaints of malfunction. Fluid from the shunt or ventricle is needed to secure the diagnosis, and the fluid usually displays an increase in the white blood cell count (>10 cells/mm^3). CSF should be cultured aerobically and anaerobically and also plated on media for the isolation of fungi. Extreme care should be used when obtaining a CSF specimen from a ventricular shunt bubble. Neurosurgical consultation should be considered before attempting to violate the shunt. The area should be cleaned before penetration with a needle to avoid contaminating the shunt. If patients have concomitant complaints of abdominal distention, peritonitis, shunt wound infection, erythema, or swelling along the shunt tract or if they appear toxic, the shunt should be assumed to be infected.

Prevention The role of prophylactic antimicrobial agents for the prevention of shunt infections has been controversial with the protective efficacy demonstrated to vary widely (5–84%) *(23)*. A meta-analysis performed by Langley et al. *(69)* showed that antibiotic prophylaxis resulted in a 50% reduction in postoperative infections after cerebrospinal shunt insertion. In a recent systematic review, perioperative antibiotic prophylaxis was associated with a significant reduction in shunt infections (*70*). Based on current data, the use of antibiotic prophylaxis with an antistaphylococcal agent (i.e., nafcillin, cefazolin, vancomycin) beginning before the procedure and continuing for up to 24 hours after the procedure is recommended *(70)*. Recently, silicone catheters impregnated with rifampin and clindamycin have been developed to help reduce the incidence of shunt infections. Initial experience reveals that antibiotic-impregnated catheters appear to be well tolerated and can reduce the incidence of shunt infection in children and adults *(71–73)*.

Occasionally, patients require external ventricular drains. These drains may be placed for limited periods after surgery or trauma or when the release of ventricular fluid is required to combat increased intracranial pressure. Catheters are placed directly into the ventricle and drain into an external receptacle. Patients who require these drains are at an increased risk for infectious complications; therefore, CSF specimens should be carefully extracted when these devices are entered. Regular catheter exchange does not prevent infections associated with external ventricular drains *(74)*.

RESPIRATORY TRACT INFECTIONS

Upper Respiratory Tract Infections

Most healthcare-associated upper respiratory tract infections are nonbacterial and appear approximately 2 weeks after admission (*2*,6). Respiratory syncytial virus, adenovirus, and influenza virus account for most of these infections *(75)* (see Chapter 48). The role of bacteria in healthcare-associated upper respiratory tract infections is manifested predominantly in sinusitis and otitis media. Less commonly encountered problems include pharyngitis, bacterial tracheitis, and diphtheria.

Pharyngitis Group A *Streptococcus* is a common cause of community-acquired pharyngitis but not of healthcare-associated disease. Patients are rarely admitted to the hospital for a streptococcal throat infection but may be admitted for complications of this infection, such as a peritonsillar or retropharyngeal abscesses. When such complications occur, cultures often reveal multiple microorganisms including *S. aureus*, gram-negative microorganisms, and anaerobic microorganisms *(76,77)*. Secondary cases of disease resulting from *Streptococcus pyogenes* are higher among siblings than among adult contacts. Rates of infection may be as high as 50% for sibling contacts compared with 20% for adult contacts. Asymptomatic, culture-positive individuals (children and adults) are well documented and may be the source for some infections *(78)*. The most important means of controlling group A streptococcal infections, therefore, is early identification and treatment of the disease. Although many contacts develop illness, asymptomatic contacts should not be cultured or treated. Symptomatic contacts should undergo a throat culture and be treated if group A *Streptococcus* is isolated *(78)*.

Bacterial Tracheitis Bacterial tracheitis is a bacterial infection thought to be secondary to a primary viral respiratory infection, usually parainfluenza or influenza viruses *(79,80)*. The viral infection may cause local mucosal damage, alter the patient's immune response, or both, thus leading to a secondary bacterial infection *(81,82)*. The most common microorganism involved is *S. aureus*. Other implicated microorganisms include *S. pneumoniae, H. influenza,* and *S. pyogenes (79,80)*. Before the availability of *H. influenzae* conjugate vaccines, this disorder was as common as epiglottitis, but because of a dramatic decrease in the incidence of invasive *H. influenzae* disease, bacterial tracheitis may now be more common *(79)*. The patient with

bacterial tracheitis usually has a waning viral respiratory illness when the fever rises and stridor begins or worsens. Patients assume any position that maximizes their airflow, not just the sniffing position as demonstrated with epiglottitis. Patients can deteriorate quickly and frequently require intubation to maintain patency of the airway and facilitate frequent suctioning. Endoscopic examination, which should be performed in an operating room, reveals copious, tenacious, purulent secretions above the subcricoid trachea. No isolation is required. Early recognition and treatment is the only method to prevent life-threatening illness.

Diphtheria Diphtheria is a disease that usually manifests itself as a membranous nasopharyngitis and/or an obstructive laryngotracheitis resulting from *Corynebacterium diphtheriae*. This disease has been uncommon since the advent of the diphtheria vaccine. Specimens for culture should be obtained from the nose and throat; the culture requires special media from the clinical laboratory. Once the culture has been obtained, the laboratory should be alerted to facilitate the evaluation. Patients with pharyngeal diphtheria should be placed on Droplet Precautions until two cultures from both the nose and the throat are negative. Communicability is usually <4 days once effective antimicrobial treatment has started. Patients with cutaneous forms of diphtheria should be placed on Contact Precautions until two cultures of the skin are negative *(83)*. Close contacts of the patient should be cultured irrespective of their immunization status and should be given antimicrobial prophylaxis with orally administered erythromycin or intramuscularly administered penicillin. The efficacy of antimicrobial prophylaxis is presumed but not proven; therefore, these patients should be kept under surveillance for 7 days. Asymptomatic contacts should receive a booster of diphtheria toxoid if they have not received a booster in the preceding 5 years. The vaccine series should be started for unimmunized individuals. Diphtheria antitoxin for unimmunized close contacts is not generally recommended *(83)*. However, in the rapidly deteriorating patient with the presumptive diagnosis of diphtheria, a dose of equine antitoxin administered intravenously may be needed. Tests for sensitivity to horse serum should be performed before the antitoxin is given.

Sinusitis Most cases of acute sinusitis in children are due to *S. pneumoniae*, *H. influenzae*, and *Moraxella catarrhalis* (84). These agents are also recovered from patients with chronic sinusitis, but *S. aureus* and anaerobic bacteria (*Peptococcus*, *Peptostreptococcus*, and *Bacteroides*) are recovered more often from children with sinus symptoms that have lasted longer than 1 year *(85–87)*. Healthcare-associated sinusitis may be due to the major agents of acute or chronic sinusitis but also include pathogens endemic to the hospital, such as *Pseudomonas aeruginosa*, *E. coli*, *Klebsiella pneumoniae*, *Enterobacter*, and *Proteus* (88). *Aspergillus* species have also been recovered from hospitalized patients with sinusitis, in which the most likely source of the fungus was hospital construction or a faulty ventilation system (see the section on Lower Respiratory Tract Infections in this chapter).

The major predisposing factor for the development of healthcare-associated sinusitis is the use of obstructive devices in the nasal cavity. The paranasal sinuses are inflamed or infected because of the trapping of sinus secretions in closed spaces. Nasogastric and nasotracheal tubes are the most common instruments noted to predispose patients to sinusitis (88,*89–92*). This may occur in up to 40% of patients who have undergone nasotracheal intubation *(93)*. Other forms of instrumentation of the oropharynx, such as oropharyngeal intubation and tracheostomy, also contribute to this disease process. Other risk factors include nasal packing, high-dose corticosteroid therapy, prior antimicrobial treatment, and facial or cranial fractures.

The symptoms are nonspecific. Most patients develop illness during the first 2 weeks of intubation. Fever is usually the only complaint, although purulent rhinitis may be demonstrated *(90)*. Radiographic studies are usually needed to establish a diagnosis. The demonstration of mucosal thickening, opacification, or air-fluid levels of the sinuses is consistent with an inflammatory process. Computed tomography is superior to plain radiographs for the evaluation for sinusitis *(94)*. The diagnosis of sinusitis should be based on a combination of clinical, radiographic, and microbiologic findings.

Prevention of sinusitis includes maintaining good oral hygiene while patients are intubated. Proper hand hygiene of healthcare workers is also necessary to prevent the transmission of microorganisms to the patient. Patients should be regularly assessed for the continued need of nasal or oral tubes, and all tubes—particularly nasogastric and nasotracheal tubes—should be promptly removed when they are no longer indicated. Sinusitis occurs more frequently in patients with nasotracheal intubation compared to patients with oropharyngeal intubation; therefore, unless contraindicated, oropharyngeal intubation is preferred *(89,95)* (see also Chapter 23).

Otitis Media Otitis media is one of the most common illnesses of infants and children. Predisposing factors include lower socioeconomic groups, secondhand smoke exposure, bottle-feeding, day-care attendance, craniofacial abnormalities, gastroesophageal reflux, and atopy *(96–98)*. The most common microorganisms involved in acute otitis media are *S. pneumoniae, M. catarrhalis*, and *H. influenzae (99)*. Microorganisms that have been associated with chronic suppurative otitis media include coagulase-negative staphylococci, *P. aeruginosa,* and *S. aureus* (including MRSA) *(100,101)*. Healthcare-associated otitis media is a common entity, particularly in intensive care units. The bacteriology usually reflects that of the hospital environment and not that of the community *(102)*.

Healthcare-associated otitis media is usually due to prolonged dysfunction of the eustachian tubes. Like sinusitis, it is most commonly demonstrated with the use of devices that occlude the airways *(102)*. This dysfunction of the eustachian tube leads to the stasis of fluid and bacteria in the middle ear and allows infection. Fever is the most common symptom associated with otitis media. Older children may be able to verbalize a complaint of ear pain, and occasionally, there may be purulent otorrhea. The diagnosis can be established by physical examination. An absent light reflex, decreased tympanic motility, a retracted or bulging tympanic membrane, or purulence behind the tympanic

membrane can be demonstrated by otoscopy. In severely ill or immunocompromised patients, a diagnostic myringotomy may be indicated to direct therapy.

Many children who are admitted to the hospital have a recent history of antimicrobial therapy for otitis media. If the child develops this complication while hospitalized, there is always a question of whether this represents disease that was resistant to initial therapy or a new infection. Children presenting with symptoms of otitis media within 1 month after therapy may have an infection caused by a new microorganism *(103)*. The bacteria that cause most recurrences are also sensitive to the antimicrobial agent just completed *(104)*. Therefore, children who develop otitis media while hospitalized usually have a healthcare-associated infection rather than a relapse from a previously treated case of otitis media.

Since the risk factors for healthcare-associated otitis media are similar to those that cause healthcare-associated sinusitis, the same prevention strategies apply. Using devices that obstruct the nasopharynx and oropharynx, such as nasogastric, nasotracheal, or orotracheal tubes, for as short a time as possible may aid in the prevention of healthcare-associated otitis media.

Lower Respiratory Tract Infections

Healthcare-associated lower respiratory tract infections (LRTIs) account for approximately 15% to 22% of healthcare-associated infections of infants and children (*2*,6,*7*,105). These infections constitute a common but potentially life-threatening complication of hospitalization. Mortality rates associated with healthcare-associated LRTIs are estimated to range from 20% to 50%, and 15% of all deaths occurring in hospitalized patients of all ages are directly related to these infections (106). The increased risk of poor outcome with a healthcare-associated LRTI has become more obvious because of modern intensive care facilities. Intensive care units can support critically ill patients for prolonged periods with invasive life-support techniques. Healthcare-associated LRTIs that occur in intubated, mechanically ventilated patients are called ventilator-associated pneumonias (VAPs). Many of the patients undergoing prolonged support are very low birth weight infants, premature infants, or immunocompromised patients; these conditions enhance the risk of healthcare-associated LRTIs with subsequent increased morbidity and mortality. A recent study in children who developed VAP showed a mortality rate of 19% (107).

Pathophysiology The pathophysiology of healthcare-associated LRTIs is thought to involve the altered or circumvented pulmonary antimicrobial defenses of the upper and lower respiratory tract *(108)*. Although a few infections represent hematogenous seeding of the lungs from a distant suppurative focus (i.e., endocarditis, meningitis), most patients suffer from subclinical aspiration of oropharyngeal secretions containing bacteria that have colonized the upper airway of the patient. This flora includes aerobic gram-positive and gram-negative microorganisms commonly identified in the hospital where the patient is located *(109)*. Flora commonly found in the oropharynx of children admitted to the hospital include both gram-positive (i.e., staphylococci, streptococci) and gram-negative microorganisms (i.e., *Neisseria* species). In colder months, many healthy infants and children are commonly colonized with microorganisms considered to be pathogens (i.e., *S. pneumoniae, S. pyogenes)* (106). The flora commonly demonstrated on admission changes within 4 days to those microorganisms commonly found in the hospital (110). The risk factors for colonization include acidosis, endotracheal intubation, hypotension, breaks in the aseptic technique, and broad-spectrum antimicrobial therapy *(109,111)*. Turbulence in the nasal airways normally prevents the deposition of large particles in the lower respiratory tract. Nasotracheal, orotracheal, or tracheostomy tubes bypass this defense mechanism and allow colonization of the upper respiratory tract with healthcare-associated microorganisms. Without colonization of the upper airways, only a few patients develop healthcare-associated LRTIs as compared with colonized patients (3% vs. 23%) *(112)*.

Most healthcare-associated LRTIs are caused by gram-negative microorganisms (*2,8*,106,107). A fecal–oral route for bacterial contamination of the upper airways has been suspected but has never explained the frequency of colonization with microorganisms such as *P. aeruginosa* or the *Acinetobacter* species. These microorganisms are not the usual inhabitants of the human gastrointestinal tract. In studies addressing this, members of the Enterobacteriaceae family (i.e., *E. coli, Klebsiella*) were isolated from the hypopharynx and rectum before they were isolated from the trachea in patients undergoing prolonged intubation in whom daily cultures were monitored from rectal, hypopharyngeal, and tracheal sites. In contrast, non-Enterobacteriaceae (i.e., *P. aeruginosa*, *Acinetobacter*) were rarely demonstrated before their appearance in the trachea (106). This suggests that non-Enterobacteriaceae microorganisms have environmental sources and that colonization with Enterobacteriaceae occurs from the patient's endogenous flora. The hands of the healthcare worker and certain components of the respiratory therapy equipment, therefore, may be important factors in the transmission of microorganisms.

A healthcare-associated LRTI results when the colonizing microorganisms evade the mucociliary and cellular defenses of the lower respiratory tract. Microorganisms can then attack the respiratory epithelium and possibly disseminate disease. The most important factor predisposing infants and children to the development of a healthcare-associated LRTI is endotracheal intubation (105). Healthcare-associated LRTIs have been shown to occur 4 times more often in intubated patients than in nonintubated patients (106). Rates for patients with tracheostomy tubes appear to be even higher *(113)*. Although the critically ill patient requiring prolonged hospitalization in intensive care units is at increased risk for healthcare-associated infections, the endotracheal tube eliminates the most effective natural host defense mechanism of the upper airway. The filtration system of the upper airway and the mucociliary system of the large airways is bypassed during intubation. The loss of the mucociliary transport system is accentuated by mechanical irritation and damage to the respiratory epithelium, which predisposes the patient to colonization with potential pathogens. Other risk factors for healthcare-associated LRTIs in infants and children are premature and low birth weight infants, poor nutrition, underlying

pulmonary disease, length of hospitalization, general anesthesia, respiratory therapy, tracheal reintubation, transportation of intubated patients out of the PICU, and the use of total parenteral nutrition (107).

Any infant or child admitted to the hospital should be considered at risk for healthcare-associated LRTIs. However, patients who have problems with acidosis, hypotension, hypoperfusion, altered mental status, or who have tubes (nasotracheal, orotracheal, or nasogastric) are at increased risk for these infections *(112,114)*. Infants and children with symptomatic or asymptomatic aspiration are also at risk (106). Patients with tracheoesophageal fistulae, swallowing dyscoordination, gastroesophageal reflux, facial burns, cardiac disease (i.e., shunt lesions with pulmonary hypertension), pulmonary disease, malnutrition, immunodeficiencies, or who have undergone surgery with unprotected airways also risk aspirating the resident flora in the hypopharynx.

Etiology Healthcare-associated LRTIs can be categorized by time of onset. Early-onset LRTIs occur within the first days of hospitalization. Causative microorganisms are similar to those causing community-acquired pneumonia, *S. pneumoniae*, *M. catarrhalis*, and *H. influenza*. Late-onset LRTIs are typically caused by gram-negative bacilli and *S. aureus* (110). The specific etiologic microorganisms for healthcare-associated LRTIs vary from institution to institution. Clinicians, therefore, must be familiar with the common microorganisms and antimicrobial susceptibility of these microorganisms at their institutions. Gram-negative rods are the most common bacterial cause of a healthcare-associated LRTI in infants and children *(115)* (Table 49-4). Among gram-negative organisms, *P. aeruginosa* is the most common microorganism causing VAP (107). Among gram-positive microorganisms, staphylococci are the predominant microorganisms encountered, with MRSA increasing in occurrence. Less-common microorganisms include *Legionella* spp. *(116,117)*. In pediatric hospitals, community-acquired microorganisms such as *S. pneumoniae* and *N. meningitidis* may also be encountered. If these microorganisms are identified, however, a septic metastasis or direct respiratory tract spread should be considered, because these microorganisms are an uncommon cause of healthcare-associated LRTIs.

Other gram-negative bacilli

Pertussis is caused by the microorganism *Bordetella pertussis* and has been an important respiratory pathogen with high infectivity in children, which can result in death. More recently, the disease has had an increased incidence in older patients, specifically adolescents and adults *(118)*. Outbreaks of pertussis in the hospital setting have also been reported *(119)*. Because of decreasing immunity, the incidence of clinical disease has increased in certain populations, particularly in medical personnel. Adults are more effective disseminators and, therefore, serve as major reservoirs for disease. Even when pertussis is present in a community in epidemic proportions, it is rarely transmitted within the hospital if proper precautions are taken *(120)* (see also Chapter 76).

Children with pulmonary infections resulting from *Mycobacterium tuberculosis* (TB) rarely transmit this microorganism to other individuals. Children are generally ineffective coughers, and in most cases, pulmonary involvement in infants and children is manifested by closed caseous lesions that have lower numbers of acid-fast bacilli compared with the cavitary lesions commonly demonstrated in adults with pulmonary disease *(121)*. Although children with active TB infections are infrequently contagious, adult caregivers, including healthcare workers with unrecognized active TB, can be sources for spread within the healthcare setting *(122)*.

In neonatal intensive care units, coagulase-negative staphylococci (i.e., *S. epidermidis*) have emerged as a major cause of healthcare-associated infections, and patients infected with this microorganism should be treated aggressively (3,*123*). In hospitals undergoing renovation or nearby construction or ventilation changes, *Aspergillus* may cause LRTIs in the hospitalized patient. Other agents that can present a problem for premature infants include *Chlamydia trachomatis*, *Ureaplasma urealyticum*, and *Mycoplasma hominis (124–126)*.

Diagnosis Diagnosing healthcare-associated LRTIs remains difficult. Historically, clinical presentation, chest radiographs, Gram stains, and cultures of respiratory secretions have established the diagnosis. Unfortunately, this method of detection has probably overestimated the true incidence of disease, because other entities can be easily confused with LRTIs in critically ill patients. Entities such as chemical aspiration, respiratory distress syndrome, pulmonary hemorrhage, lung contusion, atelectasis, congestive heart failure, pulmonary edema, pleural effusion, pulmonary emboli, or tumor may be confused with an LRTI *(127)*. Other conditions that can be confused with LRTIs in infants and children include congenital heart disease, bronchopulmonary dysplasia, and cancer chemotherapy effects (106). Because of such difficulties in diagnosis, the CDC has provided clinicians with guidelines for the definition for healthcare-associated LRTIs and for VAP (10,110) (Table 49-5).

A change in clinical status that is unexplained by other events is helpful in diagnosing healthcare-associated LRTIs. Patients in intensive care units generally have abnormal chest radiographs regardless of whether infection is present (Fig. 49-1). Likewise, fever and leukocytosis are often present irrespective of the presence of an LRTI. Cough and sputum production are infrequently diagnostic of LRTIs in intubated infants and children. If tracheal secretions are

TABLE 49-5

Algorithms for Clinically Defined Pneumonia (Pnui)

Radiology	*Signs/Symptoms*
Two or more serial chest radiographs with at least one of the following: • New or progressive and persistent infiltrate • Consolidation • Cavitation • Pneumatoceles, in infants ≤1 y old Note: In patients without underlying pulmonary or cardiac disease, one definitive chest radiograph is acceptable.	For any patient, at least one of the following: • Fever • Leukopenia or leukocytosis *And* at least two of the following: • New onset of purulent sputum or change of sputum or increased respiratory secretions or increased suctioning requirements • New or worsening cough, dyspnea, or tachypnea • Rales or bronchial breath sounds • Worsening gas exchange Alternate criteria, for infants ≤1 y old: Worsening gas exchange *And* at least three of the following: • Temperature instability • Leukopenia or leukocytosis • New onset of purulent sputum, change in sputum, increased respiratory secretions, or increased suctioning requirements • Apnea, tachypnea, nasal flaring with retraction of chest wall or grunting • Wheezing, rales, or rhonchi • Cough • Bradycardia or tachycardia Alternate criteria, for child >1 y old or ≤12 y old, at least three of the following: • Fever or hypothermia • Leukopenia or leukocytosis • New onset of purulent sputum, change in sputum, increased respiratory secretions, or increased suctioning requirements • New onset worsening cough, dyspnea, apnea, or tachypnea • Rales or bronchial breath sounds • Worsening gas exchange

(Adapted from Horan TC, Andrus M, Dudeck MA. CDC/NHSN surveillance definition of healthcare-associated infection and criteria for specific types of infections in the acute care setting. *Am J Infect Control* 2008;36:309–332, with permission.)

purulent, the differentiation between tracheobronchitis and LRTIs may be difficult. Clinical suspicion, therefore, is needed to diagnose healthcare-associated LRTIs. The diagnosis of VAP is made based on a combination of clinical and radiographic findings. Changes such as a drop in oxygenation, increased oxygen requirements, or increasing ventilator requirements in combination with fever, leukocytosis/leukopenia, changes in respiratory secretions, wheezing, rales, or rhonchi should alert clinicians to a possible VAP. These factors, combined with a new or progressive infiltrate on a chest radiograph, are required to meet the clinical definition of a VAP. Although these criteria may lack sensitivity and specificity, they may be the only available parameters for clinicians (10,110).

Once a healthcare-associated LRTI is suspected, an attempt should be made to identify the specific etiologic agent. Microscopic examination of a gram-stained smear of upper airway secretions may reveal the presence of polymorphonuclear cells and bacteria. However, tracheal aspirations and endotracheal cultures are unreliable and do not help to identify the etiologic agent. Although rarely positive, blood cultures may help in identifying the etiologic microorganism. A culture of pleural fluid may also yield the etiologic agent (10). Culture results from specimens obtained from endotracheal tubes correlate poorly with those obtained from sterile sites such as the lung, blood, or pleural fluid. Qualitative culture of specimens obtained from endotracheal tubes has failed to predict the causative agent of respiratory deterioration in infants and children *(128)*. A positive quantitative culture from minimally contaminated lower respiratory tract specimen, such as protected specimen brushing (PSB) or bronchoalveolar lavage (BAL), may also be used to identify the causative microorganism(s). In adults, these specimens are often obtained via bronchoscopy (10,*129,130*). Unfortunately, bronchoscopic equipment for protected specimen collection cannot be used in infants and small children because of the small size of the airways. Therefore, the use of such

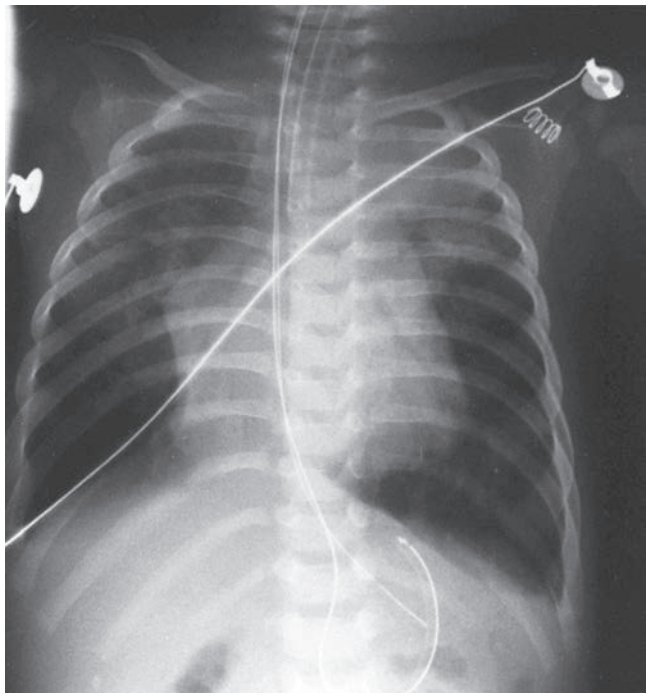

FIGURE 49-1 A chest radiograph demonstrating the difficulty in diagnosing a healthcare-associated lower respiratory tract infection in a child with respiratory distress syndrome.

techniques is severely limited in infants and children *(130)*. Nonbronchoscopically obtained PSB or BAL has been used with some success in ventilated children *(129,130)*. Thresholds used have been 10^3 colony-forming units (CFU)/mL for PSB and 10^4 CFU/mL for BAL *(130)*. *Legionella* can be diagnosed using special respiratory cultures, direct immunofluorescence of respiratory secretions, indirect immunofluorescent antibody assay, or urine antigen. Pertussis can be suspected in the unimmunized patient with a history of coughing to the point of vomiting, exposure to a known case, and lymphocytosis. Culture of *B. pertussis* is the "gold standard" and requires the inoculation of nasopharyngeal mucus onto special media (Regan–Lowe or Bordet–Gengou). Pertussis can also be diagnosed by PCR.

Prevention The prevention of healthcare-associated LRTIs and VAP should focus on two critical processes: the reduction of colonization of the upper airway by potential pathogens and the prevention of aspiration of microorganisms into the lower respiratory tract. The most important factor is strict compliance by healthcare workers with hand hygiene before and after contact with the patient or the patient's ventilator circuit. Physicians and nurses fail to perform hand hygiene before and after patient contact approximately 50% of time *(131)*. Effective hand hygiene can prevent healthcare-associated LRTIs, particularly in areas such as intensive care units. Despite this knowledge, the hand hygiene practices of healthcare workers have been difficult to improve *(132,133)*. Multimodal improvement interventions have shown success in a number of healthcare settings (see also Chapter 91). Healthcare workers should also wear a gown and gloves if they anticipate their hands or clothing becoming soiled with respiratory secretions. In addition to hand hygiene, employees should strictly comply with healthcare infection control policies and isolation techniques. Patients infected or colonized with antibiotic-resistant microorganisms, such as MRSA or extended-spectrum β-lactamase producing gram-negative bacilli, should be placed on Contact Precautions. In addition, patients should be placed in private rooms, if possible, or cohorted with other patients who are colonized or infected with the same microorganisms.

Intervention bundles that address both the reduction of airway colonization and the prevention of aspiration have successfully reduced VAP rates in both adult and pediatric institutions (107,*134*). There are a number of interventions recommended to reduce colonization of the upper airway (135). Comprehensive age-appropriate mouth care can help reduce the bacterial load in a patient's mouth. For children over 2 months old, institutions should consider using a chlorhexidine mouth care product. Condensate should be drained from the ventilator circuit every 2 to 4 hours. In addition, the use of heated ventilator circuits may reduce the amount of condensation that develops. Circuits should only be changed when they are visibly soiled or malfunctioning to prevent further contamination. In-line suction catheters should only be changed when visibly soiled, and open catheter systems should be considered single use. The next group of components is aimed at preventing the aspiration of microorganisms that are colonizing the upper airway and ventilator circuit (135). Elevation of the head of the bed between 30 and 45 degrees, unless contraindicated, is recommended. For neonates, the bed should be elevated between 15 and 30 degrees. It is important to drain ventilator circuits prior to repositioning the patient to prevent pooled fluid in the circuit from flowing into the patient's lower respiratory tract. For children older than 12 years, the use of an endotracheal tube with a dorsal lumen above the endotracheal cuff facilitates drainage and suctioning. The adult ventilator bundle recommended by the Institute for Healthcare Improvement includes four components geared toward preventing complications common in intubated patients including VAP *(136)*. The components include elevation of the bed between 30 and 45 degrees, daily "sedation vacation" and assessment of readiness to extubate, peptic ulcer disease prophylaxis, and deep vein thrombosis prophylaxis. "Sedation vacations" are not appropriate in children because of the risk of unplanned extubation, although assessing the readiness to extubate should be performed daily. Addition of the last two components in children should be based on the age and condition of the child (135).

Proper cleaning and disinfection of ventilator equipment is always important. Contaminated equipment has been incriminated in numerous outbreaks of respiratory infections (47). Such reports have pointed out that many respiratory devices are capable of harboring and spreading pathogenic microorganisms, including in-line medication nebulizers, ventilator tubing (particularly when condensate is present), bedside resuscitation bags, and endotracheal tubes. Only sterile fluids should be nebulized or used in a humidifier, and disposable equipment should not be reused. Although endotracheal suctioning may dislodge bacterial aggregates often found in the lumina of endotracheal tubes, endotracheal suctioning should be performed, as needed, to remove secretions *(137)*. The role of the gastrointestinal tract as a source for endogenous upper airway colonization cannot be overlooked. Much of the attention has centered

on the stomach, and it is quite clear that this organ can serve as a reservoir for pathogenic microorganisms. The esophagus may serve as a conduit for the transmission of these microorganisms to the upper respiratory tract. The use of enteral feeding, antacids, and H_2-blockers in critically ill patients can elevate the gastric pH and facilitate gastric microbial colonization and growth *(138,139)*. These medications are used in intensive care patients for prophylaxis against upper gastrointestinal bleeding. If these medications are indicated, it is important to choose an agent that does not elevate the gastric pH *(140)*. In patients who have received prophylaxis with sucralfate, for example, a lower gastric pH and fewer healthcare-associated LRTIs have been demonstrated *(141)*.

Patients admitted to the hospital with pertussis should be placed on Droplet Precautions for the first 5 days of antimicrobial therapy. This therapy does not change the course of the disease but renders the patient noninfectious. Early pertussis is indistinguishable from viral upper respiratory tract infections, which often results in a delay in diagnosis, treatment, and appropriate isolation. This delay results in frequent exposures of healthcare workers. In 2005, a tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine (Tdap), formulated for use in adults and adolescents, was licensed in the United States *(142)*. The Advisory Committee on Immunization Practices recommends that all healthcare workers who have direct patient contact should receive a single dose of Tdap if they have not previously received it *(142)*. The interval between the most recent tetanus, diphtheria vaccine and Tdap can be as short as 2 years *(142)*. For hospital personnel exposed to the patient before the diagnosis of pertussis, chemoprophylaxis with azithromycin, erythromycin, or clarithromycin is indicated. Patients may also receive prophylaxis with the latter macrolides. Trimethoprim-sulfamethoxazole (TMP-SMZ) may be used for healthcare workers or patients allergic to macrolides (Table 49-6). Therapies such as azithromycin have been well tolerated in treating hospital employees during hospital outbreaks *(119,143,144)*. Prompt erythromycin chemoprophylaxis effectively limits secondary cases and is recommended regardless of age or immunization status because pertussis immunity is not absolute. In addition to chemoprophylaxis, children younger than 7 years who are not immunized or who have had fewer than 4 doses of vaccine should undergo initiation or continuation of pertussis immunization according to schedule. If a child received the third dose of vaccine 6 months or more before exposure, the fourth dose should be given as soon as possible after the exposure *(144)*. Patients admitted

TABLE 49-6

Recommended Antimicrobial Treatment and Postexposure Prophylaxis for Pertussis by Age Group

	Primary Agents			*Alternate Agent*[a]
Age group	*Azithromycin*	*Erythromycin*	*Clarithromycin*	*TMP-SMZ*
<1 mo	Recommended agent. 10 mg/kg/d in a single dose for 5 d (only limited safety data available)	Not preferred. Erythromycin is associated with infantile hypertrophic pyloric stenosis. Use if azithromycin is unavailable; 40–50 mg/kg/d in 4 divided doses for 14 d	Not recommended (safety data unavailable)	Contraindicated for infants aged <2 mo (risk for kernicterus)
1–5 mo	10 mg/kg/d in a single dose for 5 d	40–50 mg/kg/d in 4 divided doses for 14 d	15 mg/kg/d in 2 divided doses for 7 d	Contraindicated at age <2 mo. For infants aged ≥2 mo, TMP 8 mg/kg/d, SMZ 40 mg/kg/d in 2 divided doses for 14 d
Infants (aged ≥6 mo) and children	10 mg/kg in a single dose on d 1, then 5 mg/kg/d (maximum:500 mg) on d 2–5	40–50 mg/kg/d (maximum: 2 g/d) in 4 divided doses for 14 d	15 mg/kg/d in 2 divided doses (maximum: 1 g/day) for 7 d	TMP 8 mg/kg/d, SMZ 40 mg/kg/d in 2 divided doses for 14 d
Adults	500 mg in a single dose on d 1 then 250 mg/d on d 2–5	2 g/d in 4 divided doses for 14 d	1 g/day in 2 divided doses for 7 d	TMP 320 mg/d, SMZ 1,600 mg/d in 2 divided doses for 14 d

[a]Trimethoprim-sulfamethoxazole (TMP–SMZ) can be used as an alternative agent to macrolides in patients aged ≥2 mo who are allergic to macrolides, who cannot tolerate macrolides, or who are infected with a rare macrolide-resistant strain of *Bordetella pertussis*.
(From Tiwari T, Murphy TV, Moran J; National Immunization Program, CDC. Recommended antimicrobial agents for the treatment and postexposure prophylaxis of pertussis: 2005 CDC guidelines. *MMWR Recomm Rep* 2005;54[RR14]:1–16.)

with *Legionella* infection do not need to be isolated (see also Chapters 22,36,90).

SKIN INFECTIONS

Cutaneous infections of infants and children have been reported to occur in 5% to 74% of healthcare-associated infections, with the highest rates occurring in neonatal intensive care units (*1,2*,3,*4,5*,6,*7–9*,145). Although most reported infections are associated with intravenous catheter sites, there is always a concern for the development of more invasive disease (i.e., bacteremia). Most of these infections are due to microorganisms already colonizing the patient or are transmitted to the patient via the hands of hospital personnel. In addition to poor hand hygiene practices by healthcare workers, improper cleaning of environmental surfaces can lead to an increase in infections. These infections commonly present as an intravenous catheter-site infection: impetigo, cellulitis, or less commonly, a life-threatening infection such as necrotizing fasciitis.

Catheter-Site Infections

Hospitalized infants and children usually require venous access while receiving medical therapy. Most venous access is obtained by cannulation of peripheral veins. Occasionally, more critically ill patients require cannulation of larger vessels. Semipermanent indwelling catheters (e.g., Infuse-a-port, Broviac, peripherally inserted central catheter [PICC] lines) are now widely used in children undergoing chemotherapy, long-term parenteral nutrition, or long-term antibiotic therapy. Phlebitis is the most common complication associated with peripheral vein cannulation *(146,147)*. Catheters in the antecubital fossa, the arm, or the leg and those used for hyperalimentation are among those most often complicated by phlebitis. Local infections such as exit-site infections or tunnel infections may develop. Microorganisms may gain access to the space between the catheter and the subcutaneous tissue during catheter insertion or migrate into the catheter tract after insertion. *S. aureus* or coagulase-negative staphylococci (i.e., *S. epidermidis*) cause the majority of these infections. The entrance site—the point at which the catheter enters the vein—or the intravascular portion of the catheter may also become infected. These latter infections are often associated with bacteremia.

Indwelling intravascular catheters become colonized when an overgrowth of microbes develops on either the external catheter surface below the skin or the endoluminal surface of the catheter. Semiquantitative cultures with a growth of at least 15 CFUs or quantitative cultures growing at least 100 CFUs of a microorganism are needed to confirm colonization. Colonization rates of between 4% and 13% occur after these catheters have been in place for 48 hours and increase to more than 30% if left in for longer than 6 days *(146–150)*. The coagulase-negative staphylococci are the most common microorganisms isolated, but colonization may occur with other microorganisms from the hospital flora. These colonized catheters then become a nidus for infection that may result in cutaneous infection or bacteremia. Local catheter-related infections usually present with signs of local inflammation such as erythema, warmth, tenderness, and/or purulent discharge from the catheter site. Cultures usually reveal the presence of colonization. There are two main types of local catheter-related infections: exit-site infections and tunnel infections. Exit-site infections are defined as erythema or tenderness within 2 cm of the exit site or purulent drainage from the exit site. In tunnel infections, the erythema and tenderness occur along the tract of the catheter at least 2 cm from the exit site. Inflammation or pus may or may not be present at the exit site *(151)*.

Materials used for venous catheters may affect colonization rates as well. Some microorganisms can actually metabolize components of the plastic catheters in the absence of other nutrients and use them to sustain growth on the surface of biomaterials *(152)*. Polyvinyl chloride and siliconized latex catheters have been demonstrated to have higher colonization rates than polyurethane, Vialon, or Teflon catheters *(153)*. Antibiotic and chlorhexidine–silver sulfadiazine coating of catheters may be anti-infective and prevent colonization for short periods (up to 1 week) *(154)*. Pediatric scalp vein needles, however, have been associated with a marked decrease in colonization and infections *(155)*. This may be true, because these needles cause less trauma to the vein, are shorter, and tend to stay in place for a shorter period.

Colonization of catheters is a key step to the development of catheter-site infections. Strict adherence to infection prevention strategies during both insertion and maintenance of the catheter is required to prevent catheter-site infections and more severe complications such as bloodstream infections. Intervention bundles have been developed to prevent the development of catheter-related infections with the primary focus on the prevention of bloodstream infections *(156)*. Adult intervention bundles have focused mainly on preventing infection at the time of catheter insertion. Successful implementation of these insertion bundles in adult hospitals has dramatically reduced infection rates (*157,158,*159). These bundles include hand hygiene; the use of maximum sterile barriers; cleaning the skin with chlorhexidine; attention to the site where the catheter is placed, such as avoiding femoral line placement; and the use of an all-inclusive catheter cart or kit *(160)*. Studies in pediatric settings have shown that focusing only on strategies to prevent contamination during catheter insertion is not enough; proper maintenance of the lines is also required *(161)*. Recently, a multicenter study that included 29 PICUs tested and implemented insertion and maintenance intervention bundles and showed considerable reduction in catheter-associated bloodstream infections (CA-BSIs) (162). The pediatric insertion bundle is similar to the adult bundle. The maintenance bundle includes daily assessment of catheter need; catheter-site care using a 30-second chlorhexidine gluconate scrub; only changing gauze dressings every 2 days or for clear dressings every 7 days unless they become soiled, dampened, or loosened; and specific instructions for catheter hub, cap, and tubing care (162). The focus of the adult and pediatric bundles has been to reduce CA-BSIs, but the various components work to prevent contamination and colonization. Therefore, these strategies should also prevent catheter-site infections. The catheter site and cannulated vein should be inspected daily for signs of inflammation and

the catheter removed promptly if they occur. If phlebitis or a local abscess should develop, the entire infusion system, including the bag of intravenous fluid, tubing, and needle or catheter should be removed. If purulent material is present, it should be sent for gram stain and culture (see also Chapters 17 and 18).

Impetigo

Impetigo contagiosa is a contagious superficial infection of the skin. The causative agent is usually *S. pyogenes* alone or in combination with *S. aureus*. Bullous impetigo is caused almost exclusively by *S. aureus*. Although this disorder is seen commonly in the community, impetiginous lesions often develop while patients are hospitalized, and the infection reflects the flora of the hospital. This infection occurs most often in the diaper region as a complication of diaper dermatitis. Usually, local care with soap and water or antimicrobial cream effectively eradicates the infection. Occasionally, parenteral therapy is indicated, and the agents chosen should be active against *Staphylococcus* species and *Streptococcus* species. Close attention to hand hygiene among hospital personnel and routine baths for the patients help alleviate this problem. Patients with impetigo should be placed on Contact Precautions until 24 hours of appropriate antibiotic therapy has been administered.

Staphylococcal scalded skin syndrome is an unusual skin infection caused by exfoliative toxin-producing strains of *S. aureus*. The syndrome starts as a bullous lesion and may spread to involve the entire body. The microorganism enters the skin through an area of trauma, such as a circumcision or other surgical procedure. It is generally spread on the hands of healthcare personnel or a family member. The microorganism is more likely to be recovered from the nares than the lesion itself. The preferred treatment is nafcillin or a first-generation cephalosporin, but MRSA isolates producing the exfoliative toxin have been identified; therefore, empiric therapy with vancomycin should be considered. Isolates should be saved for typing if an outbreak is suspected *(163)*.

Cellulitis

Cellulitis is an acute inflammation of the skin and subcutaneous tissues that may be associated with fever, warmth, erythema, edema, tenderness, lymphadenopathy, and an elevated peripheral leukocyte count *(164)*. This illness may represent a primary infection of the skin or may be secondary to bacteremia. *S. aureus* or *S. pyogenes* most commonly cause cellulitis of the extremities. In infants, in addition to *S. aureus*, GBS is a predominant microorganism. With facial involvement, *S. pneumoniae* is currently the most common cause, but *H. influenzae* type B should be considered as a potential pathogen in infants younger than 1 year who are not completely immunized. Healthcare-associated cellulitis most commonly involves microorganisms endemic to the hospital or endogenous to the patient. The diagnosis of cellulitis is based on physical examination. Aspiration of the leading edge or the area most intensely involved by the cellulitis may aid in identifying a microorganism. Most patients are not bacteremic unless they appear toxic.

Omphalitis is a severe form of cellulitis affecting the newborn infant. This usually results from colonization of the umbilical cord by *S. pyogenes*. In more recent years, gram-negative microorganisms have become more prominent causes of omphalitis because of the use of prophylactic agents on the umbilical cord *(165)*. Funisitis usually begins as a wet, malodorous umbilical stump with minimal inflammation. Inflammation may continue to develop and may spread to involve the wall of the abdomen. Patients with severe forms of omphalitis may develop necrotizing fasciitis. The infants become irritable, and a cellulitis surrounding the umbilical cord is noted on physical examination. Dissemination into the bloodstream is uncommon but may occur.

Adequate cord care is the key to preventing complications such as omphalitis. A single application of triple dye to the cord results in considerable reduction in all bacteria, including staphylococci, streptococcal species, and coliforms. However, triple dye has only limited effectiveness in preventing colonization with MRSA *(166)*. After the application of triple dye, the umbilical cord should be kept clean and dry. If the cord becomes wet or malodorous, it can be routinely cleaned with alcohol. Good hand hygiene technique should always be used, and immediate isolation of an infant who develops omphalitis due to *S. pyogenes* should be instituted. Infection control measures for identification and segregation of all colonized infants is necessary.

Methicillin-Resistant *Staphylococcus aureus*

MRSA has been an important cause of healthcare-associated infections for many years. Infections include cellulitis, soft tissue abscesses, wound infections, myositis, bone and joint infections, pneumonia, and bacteremia. Historically, these infections have resulted from healthcare-acquired strains, which often are resistant to multiple antibiotics. In recent years, community-acquired MRSA has become increasingly prevalent, resulting in infections in people who have not had recent healthcare or antibiotic exposures. Infections from community-acquired MRSA often result in skin and soft tissue abscesses. These strains are frequently susceptible to gentamicin, clindamycin, and trimethoprim/sulfamethoxazole, although local susceptibility patterns vary. Recently, the distinction between community-acquired and hospital-acquired MRSA has become blurred as patients have developed healthcare-associated infections with MRSA strains with resistance patterns that are more typical of community-acquired MRSA. To prevent transmission to other people, patients with MRSA infections should be placed on Contact Precautions. Because up to 80% of soft tissue abscesses in children are caused by MRSA, consider empirically placing patients with soft-tissue abscesses on Contact Precautions until another causative microorganism has been identified (167). Patients infected or colonized with MRSA should be placed in private rooms, if possible, or cohorted with other MRSA patients. In patients with MRSA infections, the environmental surfaces can become contaminated within a few hours (168,*169*). Thorough cleaning by environmental services is necessary.

Necrotizing Fasciitis

Necrotizing fasciitis is a rapidly progressive soft-tissue infection involving the skin, subcutaneous tissue, and superficial fascia. It is a rare but life-threatening complication following surgery or trauma in the infant or child. The infection may begin in an operative site or at the site of

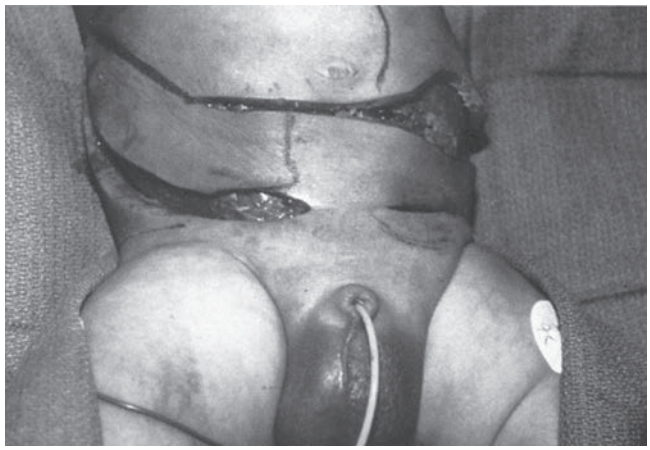

FIGURE 49-2 A patient has undergone the wide surgical debridement needed for treatment of necrotizing fasciitis.

an injury, or it may develop without apparent cause. The infection spreads rapidly along fascial planes, producing thrombosis of nutrient vessels, which results in the necrosis of overlying subcutaneous tissue and skin. Although *S. pyogenes* was initially described as the causative microorganism for this disorder, the infection in most individuals is polymicrobial *(170)*. This disorder has been described in postoperative cases after appendectomy, inguinal herniorrhaphy, and circumcision *(171)*.

The diagnosis of necrotizing fasciitis is based on clinical findings. Adults usually demonstrate a triad of cellulitis, crepitus, and the presence of gas in tissues on a radiograph. Children usually do not manifest these findings *(171)*. In infants and children, the diagnosis should be considered when a patient develops a new case of cellulitis with an area of induration that far exceeds the area of erythema. The patient appears toxic out of proportion to the area of cellulitis *(171)*. Gas or crepitus is uncommon in infants and children. The treatment for necrotizing fasciitis demands early wide surgical debridement and broad-spectrum antimicrobial agents (Fig. 49-2) *(172)*. To prevent necrotizing fasciitis, good hand hygiene and meticulous wound care are needed.

CHAPTER 50

Healthcare-Associated Gastrointestinal Tract Infections in Pediatric Patients

Douglas K. Mitchell

Gastrointestinal tract infections are a major cause of morbidity and mortality in children worldwide. Data from a group of private hospitals showed that gastroenteritis was the leading reason for the hospital admission of children in their population *(1)*. Children can develop diarrhea as the result of infections acquired prior to hospital admission or during hospitalization. Either mode of acquisition may result in considerable complications including dehydration, chronic diarrhea, prolonged hospitalization, and death. Each child infected with an enteropathogen may then become a potential source of further spread within the hospital population.

Healthcare-associated infection (HAI) refers to infections associated with healthcare in any setting. Nosocomial infection is a term that is now reserved specifically for infections acquired in a hospital (2). This approach in terminology now addresses the broader spectrum of infections related to multiple settings including hospitals, outpatient care settings, long-term care facilities, and home care.

The Centers for Disease Control and Prevention (CDC) defines healthcare-associated gastrointestinal system infections, as "gastroenteritis, hepatitis, necrotizing enterocolitis, gastrointestinal tract infections, and intra-abdominal infections not specified elsewhere." In this chapter, we address healthcare-associated gastroenteritis as defined by the CDC *(3)*:

Gastroenteritis must meet either of the following criteria:

1. Acute onset of diarrhea (liquid stools for more than 12 hours) with or without vomiting or fever (>38°C) AND no likely noninfectious cause (e.g., diagnostic tests, therapeutic regimen, acute exacerbation of a chronic condition, psychologic stress)
2. Two of the following with no other recognized cause: nausea, vomiting, abdominal pain, or headache AND any of the following:
   a. Enteric pathogen isolated from stool or rectal swab culture
   b. Enteric pathogen detected by routine or electron microscopy (EM) examination
   c. Enteric pathogen detected by antigen or antibody assay on feces or blood
   d. Evidence of enteric pathogen detected by cytopathic changes in tissue culture (toxin assay)
   e. Diagnostic single antibody titer (immunoglobulin M) or fourfold increase in paired serum samples (immunoglobulin G) for pathogens
   f. Enteric pathogen detected by molecular methods (polymerase chain reaction [PCR], reverse transcription PCR [RT-PCR], genotyping, etc.)

For an episode of diarrhea to be considered healthcare-associated, the onset of disease must occur during hospitalization or shortly after discharge, and the infection should not be present or incubating at the time of the patient's admission. This assessment of healthcare-associated versus community-acquired infection should also consider the expected incubation period for each possible enteropathogen. Most studies define healthcare-associated diarrhea as occurring more than either 48 or 72 hours after admission or within 48 hours after discharge. This definition is clearly fraught with difficulties because of the poor methods employed while screening for disease at the time of admission to the healthcare facility.

A review of 26 pediatric wards in 1949 revealed a cross-infection (nosocomial infection) rate of 7%, 21% of which was gastroenteritis *(4)*. Subsequent reports have described gastroenteritis as the first to the fifth most frequent type of HAI in children *(5,6)*. Gastroenteritis has been reported as the cause of 13% to 35% of HAIs in pediatric hospitals *(7–12)*. In addition, 5% to 14% of pediatric patients developed healthcare-associated gastroenteritis *(7,10)*. The incidence was from 0.68 to 6.1 cases per 100 inpatients with a rate of 0.11 to 1.1 episodes per 100 hospital days *(7,13–17)*.

A 9-year surveillance in a children's hospital identified diarrhea as the third most common HAI (15%) with 0.5 to 1.0 episodes per 1,000 patient days *(6)*. A pathogen was identified in 56% of episodes, including *Clostridium difficile* (32%), rotavirus (31%), adenovirus (30%), and other viral etiologies (7%). The median age of affected patients was 1.3 years, 0.8 years for viral diarrhea and 3.9 years with *C. difficile* diarrhea. Of the children with healthcare-associated diarrhea, 75% were diapered at the time of the episode. The ranges in incidence rates are attributable to studies with differing definitions, different age groups, and developing versus developed locations.

Reports by the CDC as part of the National Nosocomial Infections Surveillance (NNIS) system have included the incidence of nosocomial diarrhea in participating

hospitals. The NNIS system data from 1985 to 1991 demonstrated that nosocomial diarrhea occurred in newborn nurseries at a rate of 3 per 10,000 discharges. This rate is higher in high-risk nurseries, wherein the rate is 20 per 10,000 discharges. The NNIS system also reported that gastrointestinal tract infections cause 8% of all nosocomial infections in high-risk nurseries *(16)*. NNIS (1992–1997) reported gastrointestinal tract infections as 5% of nosocomial infections in pediatric intensive care units *(18)*. *C. difficile* was implicated in 52% of cases, and viruses were implicated in 44% of cases. Rotaviruses were the etiology in 74% of viral cases and enteroviruses were the etiology in 13%.

Data describing the ultimate economic or medical impact of pediatric healthcare-associated gastrointestinal tract infections in the United States are lacking. Two reports from developing countries indicated that healthcare-associated gastroenteritis increased the mean length of hospital stay by 7 and 20 days, respectively. Healthcare-associated rotavirus infection increased the length of hospital stay by 8 days in a French hospital *(19)*. An Austrian study estimated annual costs of 6.2 million EUR because of healthcare-associated rotavirus infections *(20,21)*. Many reports have described outbreaks of healthcare-associated gastrointestinal tract infections due to specific enteropathogens. These specific pathogens and their relative importance are discussed below *(8,9)*.

ETIOLOGY

Many viral, bacterial, and parasitic enteropathogens have been associated with HAIs (Table 50-1). The NNIS system reports for 1985 to 1991 indicate that an etiologic agent was identified in 97% of the adult and pediatric cases of nosocomial gastroenteritis and that bacteria accounted for 93% of the reported enteropathogens. *C. difficile* was the most frequent pathogen, but because this report included adults as well as children, it is not a true reflection of healthcare-associated gastroenteritis in children. In addition, most of the NNIS system participating hospitals lack diagnostic virology laboratories, so the relative importance of enteric viruses was underestimated. Rotavirus ranked second, accounting for 5% of all HAIs. Studies limited to the pediatric population have identified viral agents as the most frequent healthcare-associated enteropathogens, with rotavirus being the agent most frequently identified *(14)*. In one study in a pediatric hospital, the following nosocomial enteropathogens were detected: rotavirus, 43%; calicivirus, 16%; astrovirus, 14%; minireovirus, 12%; adenovirus, 8%; *Salmonella* spp., 4%; and parvovirus/picornavirus, 3% *(22)*.

TABLE 50-1

Enteropathogens and Other Microorganisms Associated with Healthcare-Associated Gastroenteritis

Bacteria
Campylobacter jejuni
Clostridium difficile
Escherichia coli
Enteroaggregative (EAEC)
Enterohemorrhagic (EHEC)
Enteroinvasive (EIEC)
Enteropathogenic (EPEC)
Enterotoxigenic (ETEC)
Leuconostoc species
Salmonella species
Shigella species
Vibrio cholerae
Yersinia enterocolitica

Viral
Enteric adenovirus
Astrovirus
Human calicivirus including Noroviruses and Sapoviruses
Rotavirus
Human Parechoviruses

Parasites
Cryptosporidium parvum
Cyclospora cayetanensis
Entamoeba histolytica
Giardia lamblia
Strongyloides stercoralis

Other
Candida species
Agents possibly associated with necrotizing enterocolitis

Potential healthcare-associated gastrointestinal tract pathogens
Aeromonas species
Klebsiella species
Pantoea agglomerans
Plesiomonas shigelloides
Pseudomonas aeruginosa

Known gastrointestinal tract pathogens (that are potential healthcare-associated pathogens)
Campylobacter upsaliensis
Vibrio parahaemolyticus
Isospora belli
Encephalitozoon intestinalis
Enterocytozoon bieneusi

Viral

Viruses are recognized as important healthcare-associated enteropathogens that spread via person-to-person transmission or point-source infection through food or water. Studies show that enteric viruses have caused 86% of healthcare-associated gastroenteritis in infants and children *(10,22–24)*.

Enteric Adenoviruses Enteric adenoviruses consist of two serotypes—40 and 41—which are members of group F adenoviruses *(25)*. These agents primarily infect children younger than 2 years and occur year-round *(26,27)*. Adenoviruses cause a spectrum of conditions ranging from asymptomatic infection in 40% of infected children to diarrhea and vomiting lasting for 7 to 10 days. The incubation period is 3 to 10 days. Illness is frequently associated with fever and respiratory tract symptoms *(28)*. Transmission occurs via the fecal–oral route and readily transfers from person to person *(26)*. Treatment is nonspecific, and fluid

replacement is dictated by the patient's condition. The frequency of dehydration and fever due to enteric adenovirus gastroenteritis appears to be similar to that of other enteric viruses *(29)*. In several reports, enteric adenovirus was the third most frequent cause of viral gastroenteritis in hospitalized infants and young children *(28–32)*. In one study, 54% of 127 enteric adenovirus infections were healthcare associated *(31)*. Adenovirus type F41 caused an outbreak in a pediatric bone marrow transplant unit and was shed in the stool for up to 64 days in these immunocompromised patients (33). These viruses have been shown to be a major cause of morbidity in hospitalized infants who have undergone ileostomy or colostomy procedures for necrotizing enterocolitis (NEC) *(34)*. The HAI rate in these patients was higher than other nursery patients, and infection resulted in a prolonged hospital stay. Diagnosis of enteric adenovirus-associated gastroenteritis can be made by an evaluation of stool specimens using either EM or a commercially available enzyme immunosorbent assay (EIA). Research methods use PCR and gene sequencing for detection, genotyping, and outbreak analysis (33).

Astrovirus Eight antigenic types of human astrovirus have been identified. Gastroenteritis due to astrovirus occurs worldwide and has been associated with outbreaks of mild diarrhea in schools *(35,36)*, childcare centers *(37,38)*, nursing homes *(39,40)*, and pediatric hospital wards *(41–43)*. Astroviruses are responsible for approximately 3% to 5% of hospital admissions for gastroenteritis. Illness occurs mainly in children younger than 2 years and frequently causes asymptomatic infection *(44)*. The illness lasts for 1 to 4 days following an incubation period of 24 to 36 hours. Gastrointestinal tract symptoms are nonspecific, consisting of vomiting, diarrhea, fever, and abdominal pain. The mode of transmission is person to person among children. Astrovirus has been reported to be responsible for 5% to 7% of nosocomial gastroenteritis in children's hospitals *(41,43,45–48)*. An attack rate of between 7% and 62% was reported during an outbreak of nosocomial infection in a children's ward *(43)*. Astrovirus caused a prolonged outbreak of diarrhea among immunocompromised patients in a pediatric bone marrow transplant unit *(49)*. Astrovirus-associated gastroenteritis is diagnosed by an examination of a stool specimen by EM, EIA, or RT-PCR *(37,49,50)*. Commercial EIAs for the detection of human astroviruses are not available in the United States but may be used in other countries.

Caliciviruses Four genera of the family *Caliciviridae* have been described including Noroviruses (formerly known as Norwalk-like viruses) and Sapoviruses (formerly known as Sapporo-like viruses) *(51)*. Human calicivirus infections occur year-round, although some studies suggest a seasonal predominance. The incubation period is 12 hours to 4 days, and the clinical symptoms include vomiting and diarrhea, which last for 1 to 4 days. The severity of symptoms caused by caliciviruses is indistinguishable from that of symptoms caused by other enteric viruses *(52,53)*. Persistent excretion may occur in immunocompromised hosts. Caliciviruses have been identified in stools for up to 2 weeks after the onset of symptoms *(54)*. Calicivirus is transmitted by the fecal–oral route through food-borne and waterborne transmission *(55)*. Calicivirus can be detected in stool specimens of 0.2% to 6% of children hospitalized for gastroenteritis. When calicivirus was detected in hospitalized children, it was healthcare-associated in approximately 40% of cases *(46,53,56)*. Caliciviruses have tremendous antigenic and genetic diversity that make detection assays insensitive. Multiple strains have been detected in pediatric hospitals *(57)*. It is apparent that most studies have certainly underreported the significance of calicivirus infections because of these insensitive assays. Caliciviruses can be detected in stool specimens by EM, immune EM, RT-PCR, or EIA, but these tests are available only in research laboratories *(25)*.

Two of these genera—the Noroviruses and Sapoviruses—infect humans. Many of the Noroviruses are known only from a single outbreak and have been named after the sites at which the outbreaks occurred. They include Norwalk; Hawaii; Snow Mountain, MX (Mexico); and Lordsdale *(51,58,59)* Norwalk virus is the best-studied member of the genus. Norwalk virus illness follows an incubation period of 18 to 48 hours and is characterized by vomiting, diarrhea, abdominal pain, and low-grade fever lasting 1 to 2 days *(60)*. Epidemics of Noroviruses have been reported in nursing homes, schools, recreational areas, cruise ships, and hospitals *(61–67)*. Waterborne *(55)*, food-borne *(68,69)*, and person-to-person transmission have all been implicated in epidemics *(58,70,71)*, and the results of volunteer studies suggest the possibility of fecal–oral transmission. There is evidence of the survival of noroviruses in environmental reservoirs (72). Aerosolization of vomitus has also been implicated as a mode of transmission. In one hospital outbreak, 55% of elderly patients and 61% of the healthcare workers on one floor became ill *(73)*. The healthcare workers most likely spread the infection from patient to patient. Another reported outbreak affected 57 patients and 69 staff members over a 26-day period. The index case was a patient hospitalized with acute abdominal pain and diarrhea 2 days prior to the outbreak. The epidemic curve indicated person-to-person transmission *(74)*. In another report of an outbreak in a children's ward, 15 children had the Norwalk virus in stool specimens, and the ward had to be closed to control the outbreak *(61)*.

Norovirus infections in enclosed settings were studied for the effectiveness of control measures. One review identified norovirus outbreaks as the most common cause to result in the closure of a medical department (75). The median outbreak duration was 16 days. Other studies have not shown interventions that successfully shortened the outbreaks *(76)*.

The Sapoviruses have also been associated with sporadic outbreaks and have been named after the location of the outbreak. They include Sapporo, Houston, London, Manchester, and Parkville *(77–79)*. Illness due to Sapoviruses is similar to that associated with the Noroviruses.

Rotavirus Rotavirus is the most thoroughly investigated and described etiology of healthcare-associated viral gastroenteritis and is one of the most important enteric pathogens worldwide. There are six distinct rotavirus groups, three of which infect humans. Group A rotavirus is the most common cause of diarrhea in infants and children throughout the world, including the United States. Groups B and C cause human disease in the Far East *(25,27,80)*.

Rotavirus has an incubation period of 1 to 3 days. Excretion of rotavirus in stool can precede the onset of illness by several days and can persist for 8 to 10 days after symptoms of illness have abated *(81)*. The illness usually has an abrupt onset characterized by explosive, watery diarrhea and is often associated with vomiting either before or after the onset of diarrhea. Dehydration occurs in 40% to 80% of patients and is usually mild, but severe dehydration and death have been reported in children and adults *(82)*. Rotaviruses are transmitted principally by the fecal–oral route. They are found in nearly 50% of stool specimens from children admitted to the hospital with gastroenteritis. The majority of patients with rotavirus infection are between 6 and 24 months old *(83)*. In North America, the annual rotavirus season begins in late fall in Mexico and moves across the continental United States from the southwest to the northeast, resulting in a peak of rotavirus activity in March and April in eastern Canada and the northeastern United States *(84)*.

A 5-year retrospective study of 577 children with confirmed rotavirus gastroenteritis revealed that 121 (20%) were healthcare associated. The incidence was 4.2 cases per 10,000 patient days. The median age was 11 months. All healthcare-associated rotaviruses were type G1 with four different PCR subtypes described. The long-term and intensive care units had a considerably higher proportion of nosocomial infection than the more acute care medical beds where the majority of community-acquired rotavirus infections were treated (85).
