With tremendous gratitude to all of my colleagues and authors who have made the commitment and worked so hard to provide excellent chapters for the four editions of this book.

PREFACE FOR THE FOURTH EDITION

Once again, I appreciate the opportunity to edit the Fourth Edition of Hospital Epidemiology and Infection Control. The Fourth Edition has 104 chapters prepared by 184 authors. It has the most changes between editions compared to those between the First and Second Edition and those between the Second and Third Edition. Nineteen chapters from the Third Edition were retired, and ten new chapters were added to the Fourth Edition. The authors of the chapters on computer fundamentals and on the personal computer collaborated on a single chapter for the Fourth Edition entitled "Using the Personal Computer for Healthcare Epidemiology." A chapter on meta-analysis was added to Section I, and another new chapter in this section integrates the information from the other chapters in the section to provide the reader with a useful approach to study design and data analysis. This author cites other chapters in the section by page number.

Once again, my good friend and colleague, Dr. David Birnbaum, provided guidance and direction on revision of Section II on Healthcare Quality Improvement. I particularly appreciate his suggestion on adding a chapter on working with the media on public communication.

Other new chapters include mechanisms of biofilm formation in staphylococci, microbiologic sampling of the environment in healthcare facilities, antimicrobial stewardship, and elements of design in the built environment of the healthcare facility. Biofilms have been recognized to be of importance in infections related to inanimate materials and devices inserted into patients. The chapter on environmental cultures was included, because when culture of the environment is indicated, the best data can be obtained when appropriate techniques are used to obtain the samples. The chapter on elements of design of the built environment is intended to be a companion chapter to the chapter on prevention of infections related to construction. Inclusion of a chapter on antimicrobial stewardship relates to the increasing resistance of healthcare-associated microorganisms and the need for defined programs to prevent antimicrobial resistance. The first two chapters in Section XIII provide an excellent background for the chapter on antimicrobial stewardship.

Many chapters in this edition have new coauthors and several chapters have been revised or rewritten by an entirely new set of authors.

A new feature for the Fourth Edition is that only 15 to 20 key references are located at the end of the chapters in the printed book while all references cited in the chapters are online. The numbers for the references that are only online are italicized in the text whereas the numbers for the references printed at the end of the chapters are not italicized in the text.

As for all of the editions of this reference text, my goal has been, and is, to bring together many of our colleagues with particular areas of expertise in Healthcare Epidemiology and other experts in related fields to provide a comprehensive and up-to-date reference text that the reader will find useful in the daily practice of Healthcare Epidemiology.

CONTRIBUTORS

Joseph H. Abramson, BSc, MB, BCh
Emeritus Professor of Social Medicine
Hebrew University-Hadassah School of Public Health and Community Medicine
Jerusalem, Israel

Applied Epidemiology and Biostatistics in Healthcare Epidemiology and Infection Control

CHAPTER 1

Principles of Infectious Diseases Epidemiology

Lennox K. Archibald

Epidemiology is defined as the study of the factors determining the occurrence of diseases in human populations. It is an indispensable tool for characterizing infectious disease occurrences in medical institutions, communities, regions, or industry, and for determining the exposure–disease relationship in humans and the modes of acquisition and spread that are critical for treatment, control, and prevention of these infectious disease occurrences. Clinicians, microbiologists, and other personnel involved in the preventive and public health professions use epidemiologic methods for disease surveillance, outbreak investigations, infectious diseases outcome measurements, and observational studies to identify risk factors for various infectious diseases. Knowledge of these risk factors is essential for making decisions regarding further epidemiologic or microbiological investigations, directing research activities, implementing relevant prevention and control measures or interventions, and establishing public health policies. In the pharmaceutical and biomedical industries, the application of epidemiologic methods is integral to the investigation of intrinsic contamination of products, ascertainment and characterization of risk factors for contamination, and maintenance of quality assurance practices in the laboratory or manufacturing operations before distribution of products.

The use of epidemiology and the use of statistical methods to analyze epidemiologic data grew out of attempts to understand, predict, and control the great epidemics of our past; the diseases associated with those early epidemics were largely infectious. The study and implementation of infection control practices and interventions grew out of the need to understand and control the institutional epidemics of infectious diseases that complicate the care of the ill *(1,2)*. Thus, discussions of the principles of epidemiology begin with examples of methods that were first formalized in the study of transmissible microorganisms, many of which continue to cause problems today.

The term *hospital epidemiology* was a modern addition by workers in the United States *(3)*, as was the recognition of the potential use of epidemiologic methods in hospitals for the study and control of noninfectious diseases *(4)*. The term *nosocomial* infection has traditionally defined acute infections acquired in the hospital inpatient setting *(5)*. However, in the current era of managed care, healthcare systems in the United States have evolved from the traditional acute care hospital inpatient setting to a new integrated, extended care model that now encompasses hospitals, outpatient clinics, ambulatory centers, long-term care facilities, and the home. As expected, infections (and antimicrobial resistance among implicated pathogens) may be acquired at any of these levels of care. For this reason, the term *nosocomial infection* has been replaced by *healthcare-associated infection*. Except for the acute care hospitals, however, the relative importance of each of these levels of care as risk factors for the acquisition of healthcare-associated infections remains largely uncharacterized or unknown.

The terms *hospital epidemiology* and *infection control* remain synonymous in the minds of many, and both the terms and their associated programs have grown in definition and function over the past five decades. Interest in infection control has broadened from focused concerns

with puerperal sepsis and surgical site infection to full, scientifically tested programs of surveillance, prevention, and control of healthcare-associated infections acquired at other anatomic sites. Hospital epidemiology programs were among the earliest projects used to demonstrate the utility of the scientific method and statistics for characterizing and analyzing infectious diseases data and using the results of these analyses to improve the quality of care and patient outcomes. In the special environment of the acute care hospital, a natural repetition of earlier studies of population-based infectious diseases provided the basis for epidemiologic investigations.

Surveillance data generated from epidemiologic studies may be used to determine the need for clinical or public health action; assess the effectiveness of prevention, intervention, or control programs, or diagnostic algorithms; or set priorities for rational or appropriate use of limited microbiology resources, planning, and research. An understanding of epidemiology is important for quantifying and interpreting microbiology and pharmaceutical data, and for application of these data to clinical practice, quality assurance, hypothesis generation during investigation of outbreaks and other adverse events, rational prescribing policies, and public health.

Data from epidemiologic and microbiological studies can inform diagnostic and therapeutic practice and indicate areas for allocation of already scarce resources. For example, one of the perennial problems that clinicians and microbiologists face is how to differentiate between true bacteremia and blood culture contamination resulting from coagulase-negative staphylococci, which are the most frequently isolated microorganisms in blood cultures (6). Blood culture contamination can occur during venipuncture if the skin is not adequately cleaned, after the blood draw at the time of inoculation of blood into the culture bottle, or at some point during processing of blood culture bottles in the microbiology laboratory. To make an informed decision on true bacteremia versus contamination, clinicians and microbiologists need to be familiar with the epidemiology of bloodstream infections in different clinical settings and be able to integrate these data with the relevant clinical and microbiology information at hand so that a decision could be made whether or not to initiate antimicrobial therapy or request additional, supplemental investigations that might facilitate the decision-making process.

DEFINITIONS

In the application and discussion of epidemiologic principles, standard definitions and terminology have been widely accepted *(7,8)*. The definitions of some commonly used terms are outlined in this section:

Attack rate A ratio of the number of new infections divided by the number of exposed, susceptible individuals in a given period, usually expressed as a percentage. Other terms are the *incidence rate* and the *case rate*.

Attributable mortality indicates that an exposure was a contributory cause of or played an etiologic role leading to death.

Attributable risk The measure of impact of a causative factor. The attributable risk establishes how much of the disease or infection is attributable to exposure to a specific risk factor. It is a proportion where the numerator is the difference between the incidence in exposed and unexposed groups and the denominator is the incidence for the exposed group.

Bias The difference between a true value of an epidemiologic measure and that which is estimated in a study. Bias may be random or systematic. There are three types of bias: selection bias, information bias, and confounding. Selection bias is a distortion in the estimate of effect resulting from the manner in which parameters are selected for the study population. Information bias depends on the accuracy of the information collected. Confounding arises from unrecognized factors that may affect interpretation of epidemiologic data. Unrecognized, systematic bias presents the greatest danger in studies by suggesting relationships that are not valid (see also Chapter 2).

Carrier An individual (host) who harbors a microorganism (agent) without evidence of disease and, in some cases, without evidence of host immune response. This carriage may take place during the latent phase of the incubation period as a part of asymptomatic disease or may be chronic following recovery from illness. Carriers may shed microorganisms into the environment intermittently or continuously, and this shedding may lead to transmission. Shedding and potential transmission may be increased by other factors affecting the host, including infection by another agent.

Case An individual in a population or group recognized as having a particular disease or condition under investigation or study. This definition may not be the same as the clinical definition of a case.

Case–fatality rate A ratio of the number of deaths from a specific disease divided by the number of cases of disease, expressed as a percentage.

Cluster An aggregation of relatively uncommon events or diseases in time and/or space in numbers that are believed to be greater than are expected by chance alone.

Colonization The multiplication of a microorganism at a body site or sites without any overt clinical expression or detected immune reaction in the host at the time that the microorganism is isolated. Colonization may or may not be a precursor of infection. Colonization may be a form of carriage and is a potential source of transmission.

Communicability The characteristic of a human pathogen that enables it to be transmitted from one person to another under natural conditions. Infections may be communicable or noncommunicable. Communicable infections may be endemic, epidemic, or pandemic.

Communicable period The time in the natural history of an infection during which transmission to susceptible hosts may take place.

Confounding An illusory association between two factors when in fact there is no causal relationship between the two. The apparent association is caused by a third variable that is both a risk factor for the outcome or disease

and is associated with but not a result of the exposure in question.

Contact An exposed individual who might have been infected through transmission from another host or the environment.

Contagious Having the potential for transmission.

Contamination The presence of an agent (e.g., microorganism) on a surface or in a fluid or material—therefore, a potential source for transmission.

Cumulative incidence The proportion of at-risk persons who become diseased during a specified period of time.

Endemic The usual level or presence of an agent or disease in a defined population during a given period.

Epidemic An unusual, higher-than-expected level of infection or disease by an agent in a defined population in a given period. This definition assumes previous knowledge of the usual, or endemic, levels.

Epidemic curve A graphic representation of the distribution of defined cases by the time of onset of their disease.

Epidemic period The time period over which the excess cases occur.

Hyperendemic The level of an agent or disease that is consistently present at a high incidence and/or prevalence rate.

Immunity The resistance of a host to a specific agent, characterized by measurable and protective surface or humoral antibody and by cell-mediated immune responses. Immunity may be the result of specific previous experience with the agent (wild infection), from transplacental transmission to the fetus, or from active or passive immunization to the agent. Immunity is relative and governed through genetic control. Immunity to some agents remains throughout life, whereas for others, it is short-lived, allowing repeat infections by the same agent. Immunity may be reduced in extremes of age, through disease, or through immunosuppressive therapy.

Immunity: cell-mediated versus humoral Cell-mediated immune protection, largely related to specific T-lymphocytic activity, as opposed to humoral immunity, which is measured by the presence of specific immunoglobulins (antibodies) in surface body fluids or circulating in noncellular components of blood. Antibodies are produced by B lymphocytes, also now recognized to be under the influence of T-lymphocytic functions.

Immunogenicity An agent's (microorganism's) intrinsic ability to trigger specific immunity in a host. Certain agents escape host defense mechanisms by intrinsic characteristics that fail to elicit a host immune response. Other agents evoke an immune response that initiates a disease process in the host that increases cellular damage and morbidity beyond the direct actions of the microorganism itself. These disease processes may continue beyond the presence of living microorganisms in the host.

Incidence The ratio of the number of new infections or disease in a defined population in a given period to the number of individuals at risk in the population. "At risk" is frequently defined as the number of potentially exposed susceptible persons. Incidence is a measure of the transition from a nondiseased to a diseased state and is usually expressed as numbers of new cases per thousands (1,000, 10,000, or 100,000) per year.

Incidence rate or density Similar to the incidence but members of the at-risk population may be followed for different lengths of time. Thus, the denominator is the sum of each person's time at risk (i.e., total person-time of observation).

Incubation period The period between exposure to an agent and the first appearance of evidence of disease in a susceptible host. Incubation periods are typical for specific agents and may be helpful in the diagnosis of unknown illness. Incubation periods may be modified by extremes of dose or by variations in host immune function. The first portion of the incubation period following colonization and infection is frequently a silent period, called the *latent period*. During this time, there is no evidence of host response(s) and evidence of the presence of the infecting agent may not be measurable. However, transmission of the microorganism to other hosts, though reduced during this period, is a recognized risk (e.g., chicken pox, hepatitis B virus, human immunodeficiency virus [HIV]). Measurable early immune responses in the host may appear shortly before the first signs and symptoms of disease, marking the end of the latent period. Signs and symptoms of disease commonly appear shortly thereafter, marking the end of the incubation period.

Index case The first case to be recognized in a series of transmissions of an agent in a host population. In semiclosed populations, as typified by chronic disease hospitals, the index case may first introduce an agent not previously active in the population.

Infection The successful transmission of a microorganism to the host with subsequent multiplication, colonization, and invasion. Infection may be clinical or subclinical and may not produce identifiable disease. However, it is usually accompanied by measurable host response(s), either through the appearance of specific antibodies or through cell-mediated reaction(s) (e.g., positive tuberculin test results). An infectious disease may be caused by the intrinsic properties of the agent (invasion and cell destruction, release of toxins) or by associated immune response in the host (cell-mediated destruction of infected cells, immune responses to host antigens similar to antigens in the agent).

Infectivity The characteristic of the microorganism that indicates its ability to invade and multiply in the host. It is frequently expressed as the proportion of exposed patients who become infected.

Isolation The physical separation of an infected or colonized host, including the individual's contaminated body fluids and environmental materials, from the remainder of the at-risk population in an attempt to prevent transmission of the specific agent to the latter group. This is usually accomplished through individual environmentally controlled rooms or quarters, hand washing following contact with the infected host and environment, and the use of barrier protective devices, including gowns, gloves, and, in the case of airborne agents, an appropriate mask.

Morbidity rate The ratio of the number of persons infected with a new clinical disease to the number of persons at risk in the population during a defined period; an *incidence rate* of disease.

Mortality rate The ratio of those infected who have died in a given period to the number of individuals in the defined population. The rate may be *crude*, related to all causes, or *disease-specific*, related or *attributable* to a specific disease in a population at risk for the disease.

Odds The ratio of the probability of an event occurring to the probability of it not occurring.

Pandemic An epidemic that spreads over several countries or continents and affects many people.

Pathogenicity The ability of an agent to cause disease in a susceptible host. The pathogenicity of a specific agent may be increased in a host with reduced defense mechanisms. For some agent–host interactions, the resultant disease is due to the effects of exaggerated or prolonged action of defense mechanisms of the host.

Prevalence The ratio of the number of individuals measurably affected or diseased by an agent in a defined population at a particular point in time. The proportion of the population having the disease during a specified time period, without regard to when the process or disease began, defines the period prevalence.

Pseudo-outbreak Real clustering of false infections or artifactual clustering of real infections. Often it is identified when there is increased recovery of unusual microorganisms.

Rate An expression of the frequency with which an event occurs in a defined population. All rates are ratios. Some rates are proportions; that is, the numerator is a part of the denominator. A comparable rate is a rate that controls for variations in the distribution of major risk factors associated with an event.

Ratio An expression of the relationship between a numerator and a denominator where the two are usually distinct and separate quantities, neither being a part of the other.

Relative risk The ratio of the incidence rate of infection in the exposed group to the incidence rate in the unexposed group. Used to measure the strength of an association between exposures or risk factors and disease.

Reservoir Any animate or inanimate niche in the environment in which an infectious agent may survive and multiply to become a source of transmission to a susceptible host. Medical care workers and patients constitute the main animate reservoir for microorganisms associated with healthcare-associated infections; water-related sources are important inanimate reservoirs that have been implicated in outbreaks related to dialysis units and to air conditioning systems.

Secular trend Profile of the changes in measurable events or in the incidence rate of infection or disease over an extended period of time; also called a *temporal trend*.

Sensitivity For surveillance systems, the ratio of the number of patients reported to have an infection divided by the number of patients who actually had an infection.

Specificity For surveillance systems, the ratio of the number of patients who were reported not to have an infection divided by the number of patients who actually did not have an infection.

Sporadic Occurring irregularly and usually infrequently over a period of time.

Surveillance The ongoing systematic collection, analysis, and interpretation of healthcare data essential to the planning, implementation, and evaluation of public health practice, closely integrated with the timely dissemination of these data to those contributing data or to other interested groups who need to know. Surveillance was popularized by Langmuir and others at the Centers for Disease Control and Prevention (CDC) and has been the basic method in infection control programs in the United States since the 1960s.

Susceptibility A condition of the host that indicates absence of protection against infection by an agent. This is usually marked by the absence of specific antibodies or specific measures of cell-mediated immunity against the infecting microorganism.

Transmission The method by which any potentially infecting agent is spread to another host. Transmission may be direct or indirect. *Direct transmission* may take place by touching between hosts, by the projection of large droplets in coughing and sneezing onto another host, or by direct contact by a susceptible host with an environmental reservoir of the agent. *Indirect transmission* may be vehicle-borne, airborne, or vector-borne. In *vehicle-borne transmission*, contaminated environmental sources, including water, food, blood, and laundry, may act as an intermediate source of an infectious agent for introduction into a susceptible host. The agent may have multiplied or undergone biologic development in the vehicle. In *airborne transmission,* aerosols containing small (1–5 μm) particles may be suspended in air for long periods and inspired into the lower respiratory tract to become a site of infection in a host. These infectious particles may be generated by evaporation of larger particles produced in coughing and sneezing (*Mycobacterium tuberculosis*), by mechanical respiratory aerosolizers (*Legionella*), or by wind or air currents (fungal spores). In *vector-borne transmission,* arthropods or other invertebrates may carry or transmit microorganisms, usually through inoculation by biting or by contamination of food or other materials. The vector may be infected itself or act only as a mechanical carrier of the agent. If the vector is infected, the agent may have multiplied or undergone biologic development in the vector. This type of transmission has been of little importance for healthcare-associated infections in the United States.

Virulence The intrinsic capabilities of an agent to infect a host and produce disease and a measure of the severity of the disease produced. In the extreme, this is represented by the number of patients with clinical disease who develop severe illness or die—the case–fatality rate.

EPIDEMIOLOGIC METHODS APPLIED TO INFECTIOUS DISEASES

The classic epidemiologic methods are essential for the study, characterization, and understanding of the various infections that occur in healthcare settings, communi-

ties, or regions. Such methods are used to determine the exposure–disease relationship in humans; establish the modes of acquisition, mechanisms of transmission, and spread; identify risk factors associated with infection and disease; characterize and relate causal factors to an infectious disease; determine or select appropriate methods of prevention and control; or guide rational application and practice of clinical microbiology methods. These epidemiologic methods were developed in an attempt to control common errors in observations that occur when one studies the association of one event (a risk or causal factor) with another later event (the outcome or disease).

Epidemiologic study methods are grouped as either *observational* or *experimental*. Observational epidemiologic methods are further classified as either *descriptive* or *analytic. Observational studies* are conducted in natural, everyday community or clinical settings, where the investigators observe the appearance of an outcome but have no control over the environment or the exposure of people or product to a risk factor or suspected etiologic agent, a specific intervention or preventive measure, or a particular therapeutic regimen.

Descriptive Epidemiology

Observational descriptive studies establish the case definition of an infectious disease event by obtaining data for analysis from available primary (e.g., medical records) or secondary (e.g., infection control surveillance) sources. These data enable the characteristics of the population that has acquired the infection to be delineated according to (a) "person" (age, sex, race, marital status, personal habits, occupation, socioeconomic status, medical or surgical procedure or therapy, device use, underlying disease, or other exposures or events); (b) "place" (geographic occurrence of the health event or outbreak, medical or surgical service, place of acquisition of infection, or travel); and (c) "time" (preepidemic and postepidemic periods, seasonal variation, secular trends, or duration of stay in hospital). The information from descriptive studies might provide important clues regarding the risk factors associated with infection, and in each case it is hoped that an analysis of the collected data might be used to generate hypotheses regarding the occurrence and distribution of disease or infection in the population(s) being studied.

Analytic Epidemiology

Observational analytic studies are designed to test hypotheses raised by the findings in descriptive investigations. The objectives of these studies are (a) to establish the cause and effects of infection in a population and (b) determine why a population acquired a particular infection in the first place. The three most common types of observational analytic studies are cohort studies, case–control studies, and prevalence or cross-sectional studies.

Cohort Studies In cohort studies, hypotheses that have been generated from previous (descriptive) studies are tested in a new population. A population of individuals (a cohort) that is free of the infection or disease of interest is recruited for study. The presence or absence of the suspected (hypothesized) risk factors for the disease is recorded at the beginning of the study and throughout the observation period. All members of the cohort population (e.g., all premature infants admitted to a neonatal intensive care unit during a defined time period) are followed over time for evidence or appearance of the infection or disease and classified accordingly as exposed or unexposed to specific risk factors. If the observation period begins at the present time and continues into the future or until the appearance of disease, the study is called a *prospective cohort study*. If the population studied is one that in the past was apparently free of the markers of disease on examination of records or banked laboratory specimens, it may be chosen for study if data on exposure to the suspected risk factors for disease also are available. The population may be followed to the present or until the appearance of disease. This type of study, common in occupational epidemiology, is called a *historical* or *retrospective cohort study*.

A key requirement of a cohort study is that participants be reliably categorized into exposed and unexposed groups. *Relative risk*, that is, the ratio of the incidence of the outcome in the exposed group to the incidence in the unexposed group, is used to measure the strength of an association between exposures or risk factors and disease. Cohort studies have the advantage of enabling identification and direct measurement of risk factors associated with disease, determination of the incidence of infection and disease, and ascertainment of the temporal relationship between exposure and disease. In cohort studies, observational bias may be less of a limitation on the validity or results, since the information on the presence of risk factors is recorded before the outcome of disease is established. To ensure sufficient numbers for analysis, cohort studies require continual follow-up of large populations for long periods unless the disease under investigation is one of high incidence. Cohort studies are, in general, more expensive and time-consuming to conduct and are not suitable for the investigation of uncommon infections or conditions. However, they render the most convincing nonexperimental approach for establishing causation.

Case–Control Studies In a case–control study, individuals (cases) who are already infected, ill, or meet a given case definition are compared with a group of individuals (controls) who do not have the infection, disease, or other outcome of medical interest. In contrast to cohort studies, participants in a case–control study are selected by manifestation of symptoms and signs, laboratory parameters, or a specific condition, disease, or outcome. Thus, the search for exposure of case and control subjects to potential risk factors remains a retrospective one. For case–control studies, the measure of association between exposures or risk factors and health outcome is expressed as an odds ratio, that is, the ratio of the odds of an exposure, event, or outcome occurring in a population to the odds in a control group, where the odds of an event is the ratio of the probability of it occurring to the probability of it not occurring.

The presence of significant differences in the exposure to risk factors among case versus control subjects suggests an etiologic (causal) association between those factors and the infection or disease defined by cases. Case–control methods are useful for studying infections, events, or outcomes likely associated with multiple risk factors or

low incidence rates; for investigating situations in which there is a long lag-time between exposure and outcome of interest; and for establishing etiologic associations or causation of a disease, infection, or other outcome when there is no existing information about the cause or source. In an attempt to reduce bias, control subjects might be selected from individuals matched with cases for selected characteristics, such as age, gender, socioeconomic status, or other variables not suspected or under investigation as risk factors. Compared with cohort studies, case–control studies may be conducted in relatively shorter time, are relatively less expensive, or may require a smaller sample size to execute. Limitations of case–control studies include selection bias in choosing case and control subjects; recall bias in which study subjects might have difficulty in remembering possible exposures; incomplete information on specific exposures; or risk factor data may be difficult to find (or remember). Case–control studies are not used to measure incidence or prevalence rates and, generally, are not capable of establishing temporal relationships between an exposure and outcome.

Prevalence or Cross-Sectional Studies In prevalence studies, the presence of putative risk factors and the disease under investigation is recorded in a survey of a study population at a specific point in time or within a (short) time period. The rates of disease among those with and without the suspected risk factors are compared. Thus, cross-sectional studies can establish association but not causation for suspected risk factors. Prevalence studies are relatively inexpensive and can be carried out rapidly if well-planned. However, they do not allow the ascertainment of risk factors at the beginning of disease nor do they enable one to establish a temporal sequence of risk factors preceding the infection or other outcome of interest. Point prevalence, period prevalence, and seroprevalence surveys are examples of cross-sectional studies.

Experimental Epidemiology

In *experimental studies*, the investigator controls an exposure of individuals in a population to a suspected causal factor, a prevention measure, a therapeutic regimen, or some other specific intervention. These exposure modalities are *randomly* allocated to comparable groups, thereby minimizing confounding factors. Both the exposed and unexposed groups are monitored thereafter for specific outcomes (e.g., appearance of infection or disease, evidence of effective prevention or control of the disease, or cure). Experimental studies often are used to evaluate antimicrobial or vaccine treatment regimens and are generally expensive to conduct. Within healthcare settings, studies that examine restriction of certain antimicrobials or promotion of use of alternative antimicrobials for the control of antimicrobial resistance could be considered under the category of experimental. For ethical reasons, it is rarely possible to expose human populations to potential pathogens or to withhold a preventive measure that could potentially be beneficial to the patient. Unfortunately, animal hosts are not naturally susceptible to many agents of human disease. Thus, one has to be careful when extrapolating epidemiologic findings in animal experimental studies to the control of infections in human subjects.

Quasi-experimental studies: more recently, there has been an increase in the number of published papers describing results from these studies. This type of study shares the design characteristics of experimental studies but lacks random assignments of study subjects. Quasi-experimental studies are useful where randomization is impossible, impractical, or unethical. The main drawbacks of quasi-experimental studies are their inability to eliminate confounding bias or establish causal relationships.

EPIDEMIOLOGY OF INFECTION AND DISEASE

The epidemiology of infectious disease presents two processes for discussion: (a) the epidemiology of the determinants leading to infections in hosts and (b) the epidemiology of the appearance and extent of disease related to the infection in those hosts. It is common to discuss health and disease as the result of a series of complex interactions between an agent of change, the host that is the target of the agent's actions, and the mutual environment in which the host and agent are found. In studies of healthcare-associated infections, the agents are the microorganisms associated with the infections, the hosts are the patients under care or their healthcare workers, and the common environment is the acute care hospital, intensive care unit, outpatient, home, or other healthcare venues.

The interactions determining the probability of a microbiologic agent causing infection in a host may be simply presented by an equation of infection:

$$I_p = (D \times S \times T \times V)/H_d,$$

where I_p is the probability of infection, D is the dose (number of microorganisms) transmitted to the host, S is the receptive host site of contact with the agent, T is the time of contact (sufficient for attachment and multiplication or not), and V represents virulence, the intrinsic characteristics of the microorganism that allow it to infect. The denominator in the equation (H_d) represents the force of the combined host defenses attempting to prevent this infection.

Any reduction in host defenses (represented by the denominator) in such an equation allows infection to take place with a similar reduction in one or more of the agent factors in the numerator. Infection may take place with a smaller dose of microorganisms. Infection may take place at an unusual site. The contact time for a microorganism to fix to an appropriate surface may be briefer, or infection may take place with an agent of lesser virulence, one that does not cause infection in the normal host. These reductions in the host defense characteristics, represented by the denominator, and the reduction of requirements to infect for the agent are typical of the interactions that allow opportunistic infections in compromised hosts, represented by many patients under care in modern hospitals. In this model, equation of infection, the environment might be considered the background or playing field on which the agent–host interaction takes place. A number of additional models of the interaction of agent, host, and environment have been suggested to help understand these processes. The three models in Figure 1-1—the seesaw model, the

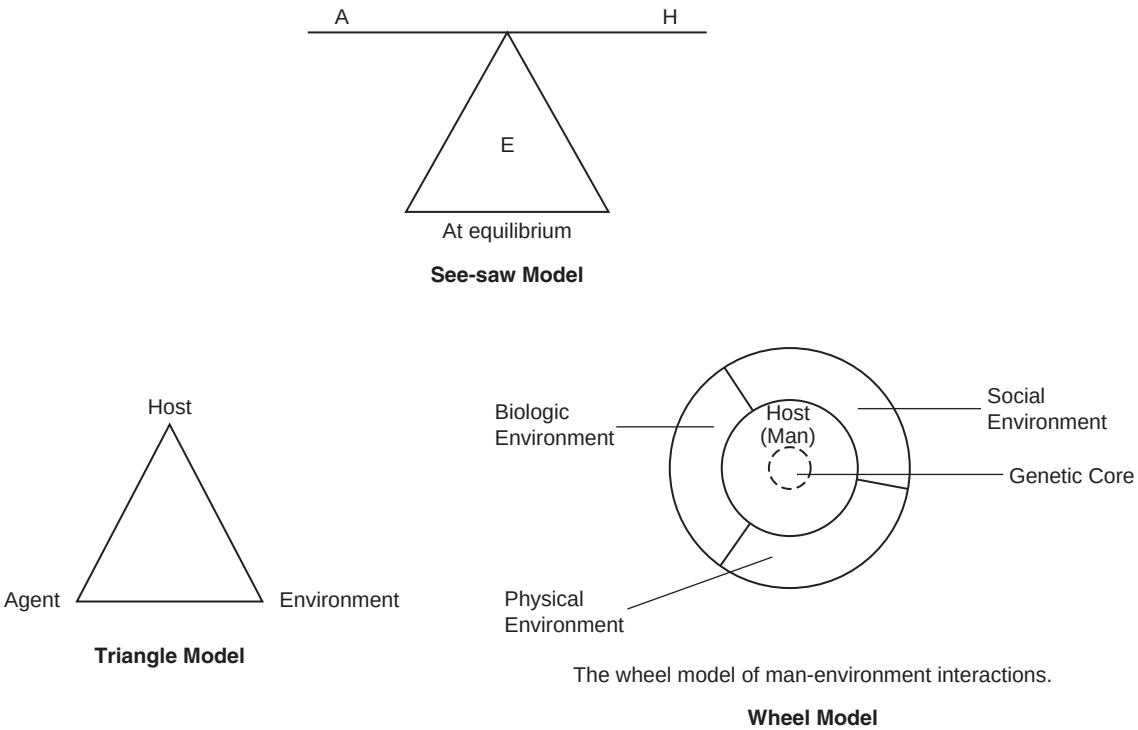

FIGURE 1-1 Models of interactions of agent, disease, and environment. (See-saw model from Fox JP, Elveback L, Gatewood L, et al. Herd immunity. *Am J Epidemiol* 1971;94:179–189, by permission of Oxford University Press. Triangle model and wheel model from Mausner JS, Kramer S, eds. *Mausner & Bahn epidemiology—an introductory text*. Philadelphia, PA: WB Saunders, 1985.)

triangle model, and the wheel model—have been frequently cited *(9,10)*. Each attempts to simply visualize the interplay between the three components.

INTERACTIONS OF AGENT, HOST, AND ENVIRONMENT

All outcome events (infection or disease) have multifactorial causes. For some infectious diseases, a single unique factor or agent is *necessary* and *sufficient* for the disease to appear. This is exemplified by measles or rabies. It is only *necessary* for the host to be exposed to and infected by an agent (the measles virus or the rabies virus) for that disease to develop. For other infectious diseases, the single factor of infectivity of the agent is *necessary* but not *sufficient* to cause disease in the host. *M. tuberculosis*, polio virus, hepatitis A, and many other agents *necessary* for specific disease in a human host infect without causing disease in a majority of cases. Within the hospital setting, exposure to a specific microorganism or colonization of an inpatient with an agent, such as vancomycin-resistant *enterococcus* (VRE) or *Staphylococcus aureus*, may be *necessary* but not *sufficient* to generate disease, which only develops through complex interactions between other contributory factors, such as age, state of debilitation, immune or nutritional status, device use, invasive procedures, antimicrobial usage, or susceptibility of the microorganism to available antimicrobials. The fact of the infection in these cases is not *sufficient* to produce disease in the host without the contribution of these latter elements in the host and the environment.

Agent

The agents causing healthcare-associated infectious diseases are microorganisms ranging in size and complexity from viruses and bacteria to protozoa and helminths. Bacteria, fungi, and certain viruses have been the agents most recognized and studied as causes of healthcare-associated infections *(11)*. For transmission to take place, the microorganism must remain viable in the environment until contact with the host has been sufficient to allow infection. Reservoirs that allow the agent to survive or multiply may be animate, as exemplified by healthcare worker carriage of staphylococci in the anterior nares or throat (12,*13–15*), or the inanimate environment, as demonstrated by *Pseudomonas* spp. colonization of sink areas, *Legionella* in hot or cold water supply systems *(16–19)*, *Clostridium difficile* spores on computer keyboards, or *Serratia marcescens* growing in contaminated soap or hand lotion preparations *(20–22)*.

Certain intrinsic and genetically determined properties of a microorganism are important for it to survive in the environment. These include the ability to resist the effects of heat, drying, ultraviolet light, or chemical agents, including antimicrobials; the ability to compete with other microorganisms; and the ability to independently multiply in the environment or to develop and multiply within another host or vector. Intrinsic agent factors important to the production of disease include infectivity, pathogenicity, virulence, the infecting dose, the agent's ability to produce toxins, its immunogenicity and ability to resist or overcome the human immune defense system, its ability to replicate only in certain types of cells, tissues, or hosts (vectors), its

ability to persist or cause chronic infection, and its interaction with other host mechanisms, including the ability to cause immunosuppression (e.g., HIV).

Once transferred to a host surface, the agent may multiply and colonize without invading or evoking a measurable host immune response *(23–25)*. The presence of an agent at surface sites in the host does not define the presence of an infection. Nonetheless, patients so colonized may act as the reservoir source of transmission to other patients *(26)*.

If infection takes place, a measurable immune response will develop in most hosts even if the infection is subclinical. The success of this process for the agent is increased in the nonimmune host and is most successful in the nonimmune, immunocompromised host. A microorganism's ability to infect another host vector (e.g., yellow fever virus in mosquitoes) or another nonhuman reservoir (e.g., yellow fever virus in the monkey) is important in the epidemiology of certain infectious diseases in world populations at large but plays little role in healthcare infection epidemiology.

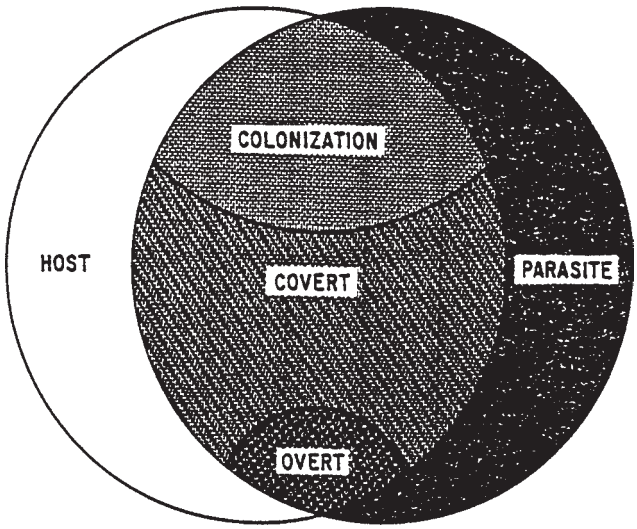

FIGURE 1-2 Venn diagram of agent–host interactions. An interaction between host and parasite may result in infection. Infection consists of colonization and an infectious disease. An infectious disease may be either covert (subclinical) or overt (symptomatic). (From Hoeprich PD, ed. *Infectious diseases*. Hagerstown, MD: Harper & Row, 1972:40.)

Host

Infection depends on exposure of a susceptible host to an infecting agent. Exposure of the susceptible host to such agents is influenced by age, behavior, family associations, occupation, socioeconomic level, travel, avocation, access to preventive healthcare, vaccination status, or hospitalization. Whether or not disease takes place in the infected host and the severity of disease when it appears depend not only on the intrinsic virulence factors of the agent but more importantly on the pathogenicity of the interactions between the agent and the host. The host immune defenses attempt to prevent infection. Thus, any reduction in host defenses may allow infection to take place with a smaller dose of microorganisms or at a body site that is not usually susceptible to infection. A combination of reductions in host defense characteristics and the requirements for an agent to cause infection are typical of the interactions that allow acquisition of opportunistic infections in immunocompromised patients. A commonly cited model indicating the potential interactions between agent and host and the relationships among colonization, infection, and clinical and subclinical disease is shown in Figure 1-2 *(27)*.

Host factors important to the development and severity of infection or disease may be categorized as intrinsic or extrinsic. Intrinsic factors include the age at infection; birth weight; sex; race; nutritional status *(28)*; comorbid conditions (including anatomic anomalies) and diseases; genetically determined immune status; immunosuppression associated with other infections, diseases, or therapy; vaccination or immunization status; previous experience with this or similar agents; and the psychological state of the host *(29)*. Colonization of the upper and lower respiratory tracts is more likely when the severity of illness increases in critically ill patients. This, along with other host impairments (e.g., reduced mucociliary clearance or changes in systemic pH), allows colonization to progress to invasive infection. Moreover, other clinical conditions may lead to an alteration in epithelial cell surface susceptibility to binding with bacteria, leading to enhanced colonization *(23–25)*. Extrinsic factors include invasive medical or surgical procedures; medical devices, such as intravenous catheters or mechanical ventilators; sexual practices and contraception; duration of antimicrobial therapy and hospitalization; and exposure to hospital personnel.

Environment

The environment provides the mutual background on which agent–host interactions take place and contains the factors that influence the spread of infection. Environmental factors include (a) physical factors such as climatic conditions of heat, cold, humidity, seasons, and surroundings (e.g., intensive care units, outpatient clinics, long-term care facilities, or water reservoirs); (b) biologic factors (e.g., intermediary hosts such as insect or snail vectors); and (c) social factors (e.g., socioeconomic status, sexual behavior, types of food and methods of preparation, and availability of adequate housing, potable water, adequate waste disposal and healthcare amenities). These environmental factors influence both the survival and the multiplication of infectious disease agents in their reservoirs and the behavior of the host in housing, occupation, and recreation that relate to exposure to pathogens. Food- and water-borne diseases flourish in warmer months because of better incubation temperatures for the multiplication of the agent and recreational exposures of the host, whereas respiratory agents appear to benefit from increased opportunities for airborne and droplet transmission in the closed and closer living environments of the winter. In US hospitals, the frequency of hospital-acquired *Acinetobacter* spp. infections is increasing in critical care units and has been shown to be seasonal in nature *(30)*. The seasonal variation in the incidence of this pathogen is thought to be due to changes in climate—summer weather increases the number of *Acinetobacter* spp. in the natural environment and transmission of this microorganism in the hospital environment during this season *(30)*.

Within healthcare settings, the components of the agent, host, and environment triad interact in a variety of ways to produce healthcare-associated infections. For example, the

intensive care unit is now considered the area of highest risk for the transmission of healthcare-associated pathogens in US hospitals (31). Moreover, methicillin-resistant *S. aureus* (MRSA), VRE, and ceftazidime-resistant *Pseudomonas aeruginosa* are endemic in many intensive care units in these hospitals (31). The emergence of vancomycin-resistant *S. aureus* in US institutions highlighted the unwelcome but inevitable reality that this pathogen may become endemic in acute care settings (32). A complex interaction of contributory factors, such as inadequate hand washing and infection control practices among healthcare workers, fluctuating staffing levels, an unexpected increase in patient census relative to staffing levels in the intensive care unit, or an unprecedented increase in the number of severely ill patients with multiple invasive devices, could all contribute to the acquisition of hospital infections caused by one of these endemic microorganisms *(33,34)*. Adding to the complexity of the process would be the unquantifiable mechanism of transmission of the agent from host to healthcare worker, healthcare worker to healthcare worker, and host to environment. Thus, acceptable measures for the prevention and control of healthcare-associated infection dictate that the healthcare epidemiologist looks at and analyzes the interrelationships among all components of the triad of agent, host, and environment (31).

It is well-known that the social environment is extremely significant in determining personal behavior that affects the direct transmission of agents, such as HIV via breast milk in regions of high HIV endemicity, gram-negative microorganisms via artificial nails worn by healthcare workers in US intensive care units *(35)*, and pathogens that cause sexually transmitted diseases. What must be understood to be equally relevant is the impact of other factors in the social environment, such as the distribution of and access to medical resources; the use of preventive services *(36–38)*; the enforcement of codes in food preparation, infection control practices, or occupational health practices; the extent of acceptance of breast-feeding for children *(39–41)*; and the acceptance of advice on the appropriate use of antimicrobials (*42–44*,45,*46*). Also, there must be an appreciation by patients, relatives, and healthcare workers alike that at-risk patients (e.g., those born very prematurely have severe congenital abnormalities, the very elderly, or those with premorbid end-stage cardiac or pulmonary disease), who have numerous indwelling medical invasive devices, or who have undergone multiple invasive procedures or surgical procedures would be particularly susceptible to healthcare-associated infections that are likely nonpreventable. There must be an informed and ethically sound willingness to reject the extraordinary application of medical technology, including the inappropriate or repeated use of resistance-inducing antimicrobials when clinical evidence and experience suggest that the condition of the sick patient is untreatable or irreversible.

Special Environments

Microenvironments, including military barracks, dormitories, day-care centers, chronic disease institutions, ambulatory surgery and dialysis centers, and acute care hospitals, provide special venues for agent–host interactions. Historically, epidemics in these institutional environments provided the experience that drove the development and acceptance of control measures, guidelines, and infection control programs. Acute care hospitals, especially those offering regional secondary and tertiary care, remain the dominant examples of these environments. Changing patterns of outpatient practice, home healthcare, and technical advances in medicine have resulted in increasingly severely diseased and injured populations being managed in acute care facilities. Data from CDC demonstrate that the changing healthcare environments in the United States are resulting in larger intensive care unit populations while there has been a general decrease in the number of general medical beds (31).

Special units for intensive medical or surgical care for extensive burns, trauma, transplantation, and cancer chemotherapy frequently house patients with increased susceptibility to infection (47). In these patients, reduced inocula of pathogens or commensals are required to cause infection, infection may take place at unusual sites, and usually nonpathogenic agents may cause serious disease and death. Frequent opportunistic infections in these patients require repeated, broad, and extended therapy with multiple antimicrobials, leading to increasingly resistant resident microbial populations (31,*46*).

The emergence or reemergence in this setting of pathogens resistant to all available antimicrobials is taking place, a situation that has not been present since the 1950s *(48)*. For example, in some institutions during the early 1990s, >80% of VRE isolates were documented as being resistant to all available antimicrobials *(49)*. Similarly, spiraling healthcare costs have been the major factor leading to the current shift toward managed care in the United States. The process has resulted in the downsizing of hospital workforces to cut costs and reduce patient charges. As a result, more severely ill patients are being managed or treated as outpatients or at home. For example, central venous catheters may be placed in the hospital, and kept *in situ* for long-term home infusion therapy. The trade-off is minimum exposure to the hospital environment with decreased costs to the patient. On the other hand, a patient with a central venous catheter in the home environment may be potentially at risk of bloodstream infections due to contamination of lines, dressing, and infusates in a care environment where infection control practices are not as well understood, practiced, or regulated.

INFECTION, COLONIZATION, AND SPECTRUM OF DISEASE

Infection is the successful transmission of a microorganism to a susceptible host, through a suitable portal of entry, with subsequent colonization, multiplication, and invasion. The source of a microorganism (the primary reservoir) may be animate (e.g., humans, mammals, reptiles, or arthropods) or inanimate (e.g., work surfaces, toys, false fingernails, toiletries, or soap). *Disease* is the overt damage done to a host as a result of its interaction with the infectious agent: it represents a clinically apparent response by or injury to the host after infection, with the affected person showing symptoms or physical signs that may be characteristic of infection with the invading pathogen. Thus, disease is the outcome of an infectious process, and

a *pathogen* is any microorganism with the capacity to cause disease in a specific host.

Unapparent or subclinical infection is a frequent occurrence where the infected person may not manifest any symptoms, signs, disability, or identifiable disease. For example, in patients who acquire *Salmonella typhi* infection (typhoid fever), a chronic infection of the gallbladder may develop with asymptomatic fecal excretion of the pathogen for years after the acute event. Patients in HIV-endemic countries may have *M. tuberculosis* bloodstream infections despite having normal chest radiographs and no symptoms or signs suggestive of underlying pulmonary disease *(50)*. Persons with subclinical infection are sometimes referred to as *carriers*. Subclinical infection may be recognized through laboratory testing of blood or other appropriate body material from the host. These tests may indicate evidence of an immune response to infection, the presence of antigens characteristic of the microorganism, abnormal cellular function in response to infection, or the presence of the microorganism itself.

Colonization is the presence of a microorganism in or on a host, with growth and multiplication, but without any overt clinical expression or detected immune reaction in the host at the time the microorganism is isolated. An infectious agent may establish itself as part of a patient's flora or may cause low-grade chronic disease after an acute infection. For example, 20% of healthy adults are persistent carriers of *S. aureus* in the anterior nares without any manifestation of clinical illness (*51*,52,*53*). However, under suitable conditions, patient populations colonized with *S. aureus* are at an increased risk of having infection and disease develop *(54–58)*. Once colonization or infection is established in a susceptible host, the agent may enter a silent or latent period during which there is no clinical or typical laboratory evidence of its presence. Thereafter, the host may manifest signs and symptoms of mild disease without disability, exhibit rapid or slow progression of disease, or progress to either temporary or chronic disability. Ultimately, the patient may die or have a complete recovery and return to health without sequelae.

The outcome of an infection is determined by the size of the *infecting dose*, the site of the infection, the vaccination status of the host, the speed and effectiveness of the host immune response, other intrinsic host factors (e.g., nutritional status), or promptness of instituting and effectiveness of the therapy. These factors together with intrinsic properties of a microorganism, such as its infectivity, pathogenicity, virulence, and incubation period, determine the course and progress of an infection, and manifestation of disease. *Infectivity* is the characteristic of the microorganism that indicates its ability to invade and multiply in a susceptible host to produce infection or disease; it is expressed as the proportion (i.e., the *attack rate*) of patients who become infected when exposed to an infectious agent. The basic measure of infectivity is the minimum number of infectious particles required to establish infection. Pathogens like polio or measles viruses have high infectivity.

The *pathogenicity* of an infectious agent is a measure of its ability to cause disease in a susceptible host. Thus, while the measles virus has a relatively high pathogenicity (i.e., few subclinical cases), the poliovirus has a low pathogenicity (i.e., most cases of polio are subclinical). The measure of pathogenicity is the proportion of infected persons with clinically apparent disease. The pathogenicity of an agent that is usually innocuous may be increased in a host with reduced defense mechanisms. For some agent–host interactions, the resultant disease is due to the effects of exaggerated or prolonged defense mechanisms of the host. The *virulence* of a microorganism is its intrinsic capability of infecting a host to produce disease. It follows that a pathogen might have varying degrees of virulence. Thus, although the nonencapsulated form of *Haemophilus influenzae* is a common inhabitant of the upper respiratory tract of healthy humans and causes localized infection without bacteremia (e.g., conjunctivitis or otitis media in children), the more virulent encapsulated type b form causes more invasive disease and is an important cause of meningitis or epiglottitis. If the disease is fatal, virulence can be measured with the case–fatality rate. For example, the rabies virus almost always produces fatal disease in humans and is therefore an extremely virulent agent.

The ability to diagnose an infection or disease depends on the degree to which typical symptoms and physical signs develop in patients, the appropriateness of diagnostic tests, and the sensitivity and specificity of these tests for the particular infecting agent. Whether an infecting agent produces clinical or subclinical infections depends on the agent and host factors, for example, age or immune status. Thus, *P. aeruginosa,* a ubiquitous pathogen that thrives in aquatic environments and vegetation, seldom causes disease in healthy humans. However, in debilitated, hospitalized patients, such as those with burns, critical care patients with multiple *in situ* invasive medical devices, or those who are on prolonged mechanical ventilation, this pathogen remains an important cause of ventilator-associated pneumonia in US hospitals *(59)*.

Certain agents may be associated with a variety of different syndromes that depend on age and vaccination status of the host, previous infection with the agent, and agent-related mechanisms that remain unclear. Thus, *Strongyloides* spp., a nematode that is endemic in many parts of the world, including Southeast Asia and some parts in the southeastern United States, can cause asymptomatic infection or be associated with several syndromes ranging from mild epigastric discomfort and chronic skin rashes to life-threatening hyperinfection that results in gram-negative bacteremia, pneumonia, and multisystem disease in immunosuppressed patients, including solid organ transplant recipients or patients with chronic airways disease who are steroid-dependent *(60–63)*. These differences in host–agent interactions underscore the difficulty in establishing causation and the importance of confirmatory laboratory evidence to precisely identify the causal agent associated with syndromes of infectious disease.

Once colonization or infection is established in a susceptible host, the agent may enter a silent or latent period during which there is no clinical or usual laboratory evidence of its presence. Thereafter, the host may manifest signs and symptoms of mild disease without disability, may have a rapid or slow progression of disease, or may progress to either temporary or chronic disability, or, ultimately, death. Alternatively, the patient may have a complete recovery and return to health without sequelae. In other instances, the entire process may be inapparent

or subclinical without evidence of disability or disease. Subclinical cases may be recognized through laboratory testing of blood or other body fluids of the host. These tests may indicate evidence of abnormal cellular function (abnormal liver function tests), the presence of an immune response to infection (antibody to hepatitis B virus core antigen), the presence of antigens characteristic of the microorganism (positive test for hepatitis B virus surface antigen), or the presence of the microorganism itself.

The ability to diagnose an infection or disease is obviously easier in clinical cases and much easier in severe clinical cases wherein the typical signs and symptoms of the disease are apparent and routine tests are diagnostic of the agent. The ratio of clinical to subclinical infections varies widely by agent and is influenced by certain host factors, such as age and immune status. Certain agents may be associated with a variety of different syndromes that depend on age and vaccination status of the host, previous infection with the agent, and agent-related mechanisms that remain unclear. Poliovirus is less likely to appear as a paralytic syndrome in children, and Coxsackie virus B infections may appear as myocarditis one year and more prominently as meningoencephalitis the next. Respiratory syncytial virus infections may appear as bronchiolitis in infants and as a common cold syndrome in their older caregivers. Since the ability to diagnose an infection or disease caused by a specific pathogen depends partly on the degree to which typical symptoms and physical signs develop in patients, variation in the clinical manifestation of disease underscores the difficulty in establishing causation, the importance of clinical awareness of syndromic variations of certain infections, and the importance of confirmatory laboratory evidence to precisely identify the causal agent associated with syndromes of disease outbreaks. Evans provides a detailed and excellent review of the principles and issues in establishing causation in infection and disease *(64)*.

MECHANISM OF SPREAD

Transmission

For infection to take place, microorganisms must be transferred from a reservoir to an acceptable entry site on a susceptible host in sufficient numbers (the infecting dose) for multiplication to occur. The infecting dose of a microorganism may depend in varying degrees on infectivity, pathogenicity, or virulence of the microorganism itself. The entire transmission process constitutes the *chain of infection*. Within the healthcare setting, the reservoir of an agent may include patients themselves, healthcare workers (e.g., nares or fingernails), tap water, soap dispensers, hand lotions, mechanical ventilators, intravascular devices, infusates, multidose vials, or various other seemingly innocuous elements in the environment.

Direct transmission from another host (healthy or ill) or from an environmental reservoir or surface by direct contact or direct large-droplet spread of infectious secretions is the simplest route of agent spread. Examples of direct-contact transmission routes include kissing (infectious mononucleosis), shaking hands (common cold [rhinovirus]), or other skin contact (e.g., contamination of a wound with staphylococci or *Enterococcus* spp. during trauma, surgical procedures, or dressing changes). Transmission of *Neisseria meningitidis*, group A streptococcus, or the respiratory syncytial virus (an important cause of respiratory infection in young children worldwide) by large respiratory droplets that travel only a few feet is regarded as a special case of direct-contact transmission.

Vertical transmission of infection from mother to fetus is another form of direct-contact transmission that may occur through the placenta during pregnancy (e.g., HIV, rubella virus, hepatitis B virus, or parvovirus), by direct contact of the infant with the birth canal during childbirth (group B streptococci), or via breast milk (HIV).

Indirect-contact transmission may occur via the hands of people, contaminated inanimate objects (fomites), various work surfaces, food, biological fluids (e.g., respiratory, salivary, gastrointestinal, or genital secretions, blood, urine, stool), invasive or shared medical devices, or through arthropod or animal vectors. Indirect-contact transmission is the most common mechanism of transfer of the microorganisms that cause healthcare-associated infections and commonly occurs via the hands of healthcare workers, their clothing, or instruments like stethoscopes or thermometers. Rapid dissemination of agents, such as respiratory syncytial virus or the influenza virus, may occur in day-care centers through salivary contamination of shared toys and games. *C. difficile* is an important diarrheal agent transmitted from patient to patient in acute care hospitals. Its transmission is abetted by its spore-forming ability to survive in the environment, and its selection and promotion in patients by the repeated and prolonged use of certain antimicrobials (65). Medical devices contaminated with blood-borne pathogens, including hepatitis B and C viruses, cytomegalovirus, and HIV, are sources of infection for both patients and medical care personnel in healthcare institutions *(66,67)*. Some viruses can remain viable for extended periods under suitable conditions. For example, Hepatitis B virus is relatively stable in the environment and remains viable in dried form for at least 7 days to 2 weeks on normal working surfaces at room temperature *(68)* This property has led to Hepatitis B virus transmission among dialysis patients through indirect contact via dialysis personnel or work surfaces in the dialysis unit *(69,70)*. Examples of other sources of healthcare-associated infections that occur through indirect contact include bacterial or viral contamination of musculoskeletal allograft tissues, intrinsic contamination of infusates or injectable medications, liquid soap, or contaminated medications prepared in the hospital pharmacy (*20*,*71*,72,*73–75*). The continuing presence of *Pseudomonas* spp. and other gram-negative rods in potable water supplies acts as an important reservoir for these agents and a readily available source for hand transmission to patients, especially the severely ill *(19,76)*.

Airborne transmission is another mechanism of indirect transfer of pathogens. Microorganisms transmitted by this method include droplet nuclei (1–10 μm) that remain suspended in air for long periods, spores, and shed microorganisms. The airborne transfer of droplet nuclei is the principal route of transmission of *M. tuberculosis*, varicella, or measles. The transmission of *Legionella* spp. through the

air in droplet nuclei from cooling tower emissions, and from environmental water sites, such as air-conditioning systems, central humidifiers, and respiratory humidification devices, is another important example of this type of spread (*77–79*,80,*81*). *C. difficile*–associated disease, the most common cause of healthcare-associated gastrointestinal infection in the United States, is frequently acquired through the transmission of spores via hospital work surfaces and the hands of healthcare workers (65,82). In fact, *C. difficile* may become endemic if its spores are propagated by air currents throughout an institution. Fungal spores can be an important cause of healthcare-associated infections. Spores of invasive fungi, such as *Aspergillus* spp., may be carried over long distances in hospitals to cause severe infections in immunosuppressed patients. The risk of spore contamination was highlighted by an outbreak of *Curvularia lunata* (a black fungus) among silicone breast implant recipients, who had undergone the breast augmentation procedures in an operating room that was erroneously maintained at negative pressure resulting in high spore counts in the operating room environment (operating rooms are supposed to be maintained at net positive pressures relative to adjacent areas). The surgeons had not implemented a closed system for inflating the breast prostheses with saline; instead, they had inflated the silicone prostheses using syringes filled with saline drawn up from a sterile bowl exposed to the ambient operating room environment. The end result was contamination of sterile saline in the open bowl with *C. lunata* spores, which were then injected inadvertently into the breast prostheses *(83)*. In some settings (e.g., burn units), staphylococci have been thought to spread on skin squamous cells that have been shed from patients or healthcare personnel. The importance of this mode of transmission, however, is not thought to be of great significance in other care settings. More recent data suggest that *S. aureus* is a common isolate in oropharyngeal cultures *(13)*. Although the epidemiologic implications of this finding remain uncharacterized, the ramification for infection control in healthcare facilities would be enormous if indeed the chain of infection for *S. aureus* includes oropharyngeal secretions or droplet nuclei. More recently, the emergence of extensively drug-resistant (XDR) strains of *M. tuberculosis* (i.e., strains resistant to practically all second-line agents) has again highlighted the importance of airborne transmission and the fact that the underlying reason for XDR emergence stems from poor general tuberculosis control and the subsequent development of multi-drug resistant (MDR)-tuberculosis (84,*85*).

Vector-borne transmission by arthropods or other insects is a form of indirect transmission, and may be mechanical or biologic. In mechanical vector-borne transmission, the agent does not multiply or undergo physiologic changes in the vector; in biologic vector-borne transmission, the agent is modified within the host before being transmitted. Although the potential for microorganism carriage by arthropods or other insect vectors has been described *(86,87)*, this type of transmission has not played any substantial role in the transmission of healthcare-associated infections in the United States. In tropical countries with endemic dengue, yellow fever, or malaria, vector-borne transmission is relatively more important, requiring screening of patients or other interventions, and preventive measures not ordinarily required for patients in colder climates.

Reservoirs

Humans are the primary reservoir for *Neisseria gonorrhoeae*, *S. typhi*, HIV, Hepatitis B and C viruses, or *Shigella* spp. Animals (zoonoses) harbor the rabies virus, *Yersinia pestis, Leptospira* spp., or *Brucella* spp. Environmental reservoirs include the soil (*Histoplasma capsulatum, Clostridium tetani*, and *Bacillus anthracis*) and water (*Legionella* spp., *P. aeruginosa, Serratia* spp., and *Cryptosporidium* spp.). In critical care units, reservoirs in ventilation circuits often harbor gram-negative pathogens, such as *P. aeruginosa, Serratia* spp., or *Acinetobacter* spp. For some infections, the interaction between host, agent, and environment might include an extrinsic life cycle of the agent outside of the human host. The interplay of such factors can add significant layers of epidemiological complexity in properly understanding the cause of an outbreak or in characterizing the chain of infection.

INCUBATION PERIOD AND COMMUNICABILITY

The *incubation period* is the time between exposure to an infectious agent and the first appearance of evidence of disease in a susceptible host. The incubation period of a pathogen usually is typical for that class of microorganisms and may be helpful in diagnosing unknown illness or making a decision regarding further diagnostic testing. The first portion of the incubation period after colonization and infection of a person is frequently a silent period, called the *latent period*. During this time, there is no obvious host response, and evidence of the presence of the infecting agent may not be measurable or discernible. Measurable early immune responses in the host may appear shortly before the first signs and symptoms of disease, marking the end of the latent period. Incubation periods for a microorganism may vary by route of pathogen inoculation, and the infecting dose. For example, brucellosis may be contracted through direct contact with blood or infected organic material, ingestion of raw dairy products, or through airborne transmission in a laboratory or abattoir; these various modes of transmission result in an incubation period for brucellosis that is highly variable, ranging from 5 days to several months. Incubation periods for other common microorganisms are as follows: 1 to 4 days for the rhinovirus (the common cold) or influenza virus; 5 to 7 days for herpes simplex virus; 7 to 14 days for polio virus; 6 to 21 days for measles virus; 10 to 21 days for chickenpox virus; 20 to 50 days for hepatitis A virus and the rabies virus; and 80 to 100 days for hepatitis B virus.

The *communicable period* is the time in the natural history of an infection during which transmission may take place. Generally, microorganisms that multiply rapidly and produce local infections are associated with short incubation periods. For example, enterotoxin-producing *S. aureus* undergoes such rapid multiplication in unrefrigerated food that symptoms of food poisoning may become manifest within 1 to 6 hours of ingestion of the contaminated meal. Microorganisms that cause disease that depend on

hematogenous spread or multiplication in distant organs tend to have longer incubation periods. HIV antibodies are generally detectable 1 to 3 months after the initial exposure, whereas the HIV-infected person might remain asymptomatic for years. Cytomegalovirus, a blood-borne pathogen that frequently causes posttransplant or post-transfusion infection, generally causes illness 3 to 8 weeks after initial exposure.

OUTBREAKS, EPIDEMICS, AND EPIDEMIC INVESTIGATION

An infectious disease outbreak or epidemic is defined as an increase in the occurrence of infection or disease above the baseline or background rate, in a given area in a specific patient population. Epidemics may originate from a common source or be propagated from person to person. Common source epidemics appear when susceptible persons have mutual exposure to the same agent in the same time period. If the exposure to an infectious agent happens at a single event at a single time and place, such as at a church dinner, it is called a *point source epidemic*. When this happens, the affected (exposed) patients usually have a similar incubation period, and the average time from the onset of first symptoms back to the initial, common exposure event is the natural incubation period of the agent. If the agent is known, its identified incubation period helps to define the time of the common event. For example, onset of symptoms of food poisoning caused by *S. aureus* usually occurs within 1 to 6 hours; symptoms due to *Shigella* spp. usually occur within 24 to 48 hours. If exposure to an infecting agent is continuous, as in a hospital room with an air-conditioner contaminated with *Legionella* spp., episodes of *Legionella* pneumonia among hospital inpatients may appear sequentially. Sewage from a treatment plant seeping into a water supply is another example of continuous source exposure in which a persistent increase above an expected level extends beyond a single incubation period.

Propagated epidemics occur when serial direct or indirect transmission of a microorganism occurs from susceptible host to susceptible host (e.g., person-to-person spread of *Malassezia pachydermatis*, a microorganism with a short incubation *(88)*), or it may occur at a more leisurely pace as in transmission of an agent from a carrier to a susceptible individual (e.g., transmission of *Nocardia farcinica* from the hands of a colonized healthcare worker to a surgical site *(89)*). Thus, investigation of an epidemic requires a prioritized and systematic approach to the gathering and analysis of data with careful attention to epidemiologic and clinical detail and correct interpretation of microbiological and other laboratory information.

Investigating an Epidemic

The first and most critical step in an outbreak investigation is ascertaining that an epidemic does indeed exist. This step assumes some previous information on the usual or endemic rate of occurrence of the infection or disease under study. When there is a perceived increase in the occurrence of an infection without reference to a baseline level, the aggregation of case-patients is classified as a *cluster*. Many clinical microbiology laboratories that serve large teaching hospitals or other healthcare institutions maintain computerized, retrospective line listings of infection or colonization caused by pathogens that are endemic in the institution. Such line listings are readily available on request and enable documentation of endemic infection rates.

The first hint of an outbreak or an unusual cluster of infections may be the appearance of a microorganism from epidemiologically related sources noticed by the clinician, infection control team, pharmacy, or laboratory personnel. The microbiology laboratory has been likened to an early warning, laboratory-based surveillance system for the detection of outbreaks *(11,90)*. For example, laboratory technologists might be the first to suspect the presence of an outbreak of healthcare-associated infections by being alert and noting in a line listing the existence of an unusual cluster of isolates of a particular morphology, species, or antimicrobial susceptibility profile. End-of-the-day scrutiny of routine line listings of microorganisms growing in cultures by a staff microbiologist might herald the presence of a cluster of infections or antimicrobial-resistant microorganisms in a specific hospital inpatient service that would have otherwise been overlooked or missed by the clinician or healthcare epidemiologist. Or perception by an astute pharmacist of overprescribing of antimicrobials for infections caused by an unusual microorganism could be a lead to ascertainment of a putative cluster or outbreak.

Computerized laboratory records, line listings, and culture reports that have been retrospectively archived constitute an invaluable source of site-specific, baseline data on endemic infection rates with which to compare current perceived increases in infection rates for various patient populations in a facility. If a comparison of epidemic and preepidemic infection rates suggests the presence of an outbreak, the clinical microbiology personnel on the team conducting the outbreak investigation must then ensure that all isolates and relevant specimens from patients associated with the putative outbreak are saved for culture or other analyses that might become necessary later on in the investigation. Thus, the initial investigation and characterization of outbreaks or clusters of infection must necessarily involve the laboratory *(91)*.

To determine the existence of an outbreak, one must understand the etiology of the infection or disease. If the syndrome is unrecognized, a consensus case definition or criteria for the condition must be formed. This case definition must be fulfilled for each event that is judged to be associated with the epidemic. The case definition may include a medical sign or symptom; a syndrome; an abnormal laboratory test (e.g., a raised white blood cell count); the isolation of an etiological agent (e.g., positive blood cultures for bacteremia); or one of the serologic tests, such as those for serum immunoglobulin levels (e.g., immunoglobulin M group), that suggest acute or recent infection. The case definition for epidemics of unknown etiology might include combinations of clinical and laboratory parameters. Depending on the data available at the onset of an investigation, a case definition may include classification of the ill as (a) definite cases, (b) probable cases, or (c) possible cases.

Case definitions of healthcare-associated infections usually involve clinical, epidemiologic, and laboratory parameters and delineate the patients (*person*) who have specific symptoms or syndromic features, the period (*time*) during which the symptoms began or were recognized, the location (*place*) of the problem, and the infecting agent and anatomic site of infection (*what*). If the case definition is microorganism-based, a careful review of the existing microbiology records usually is all that is needed to identify case-patients and determine numerator and denominator data for the calculation of comparable rates. After a case definition has been formulated, the outbreak investigators must identify and ascertain case-patients. This step may be accomplished by calling hospitals, clinics, health departments, physicians' offices, schools, or workplaces, or careful examination of patients' medical, surgical, or laboratory records, patient census listings, administrative staffing records, death certificates, or existing surveillance data, such as frequency of medical device or antimicrobial use. Laboratory records play a vital role in this undertaking by providing confirmatory data on pathogen identification, site of infection, antimicrobial susceptibility testing profiles (antibiograms), or microorganism biochemical profiles (biotype number).

In industry, annual product reviews analyze the assorted quality parameters that intersect with a given product, such as reviewing the number of laboratory deviations, the number of confirmed batch failures, or the number of manufacturing/testing changes. If available, such data are helpful in investigations of national or international outbreaks, such as those associated with widespread distribution of an intrinsically contaminated drug, device, or other product. Within healthcare systems, comparable quality systems are found largely in clinical laboratories. For example, in the microbiology laboratory, quality reviews similar to those performed in the pharmaceutical industry include systematic analyses of batch failures of reagents; monitoring culture media quality and variability of set incubation temperatures for incubators; quality assurance checks of antimicrobial-impregnated disks and adherence to standards set by the Clinical and Laboratory Standards Institute for antimicrobial susceptibility testing; regular assessments of the ability of microbiology personnel to accurately identify or characterize "unknown" isolates from the American Type Culture Collection; or weekly checks of the optical density cutoff points for spectrophotometers used in serological testing. Data from these reviews are indispensable for outbreak investigations, especially when an outbreak is linked epidemiologically to practices and procedures in the laboratory (see Chapter 9).

When an infection outbreak is recognized only by the presence of a cluster of patients with a specific syndrome, idiosyncratic clinical features, or pyrogenic reactions, and the case definition contains only clinical or epidemiologic parameters, initial cultures of relevant body sites may be negative. In these instances, it is vital that the laboratory be involved in all subsequent decision making in the outbreak investigation, particularly regarding the types of cultures, specimens, serologic tests, or assays that should be considered to assist in determining the source or cause of the outbreak. Such additional investigations may include testing large volumes of dialysis fluid or water for endotoxin, performing specialized serologic tests for *Salmonella* spp., or molecular genotyping. These indispensable roles of the laboratory underscore the interdependency of epidemiology and laboratory disciplines during the investigation of an outbreak where the suspected pathogen is absent or not initially apparent, and the direction of the subsequent investigation may require specialized laboratory tests or assays that become obvious only after an epidemiologic evaluation (see Chapter 95).

After case ascertainment, the next steps are to prepare a line listing of the patients who meet the case definition and construct an *epidemic curve* by plotting the number of cases (*y*-axis) over time (*x*-axis), and identify on a geographic map the location of the cases. The line listing should contain the basic demographic data and characteristics that are relevant to the outbreak, and should include the features of the outbreak in terms of person, place, and time that were established by the case definition.

Critical variables in an outbreak investigation include the following: (a) When did the exposure take place? (b) When did the disease begin? (c) What was the incubation period for the disease? If any two of these are known, the third can be calculated. The epidemic curve can graphically suggest the temporal relationship between acquisition of infection or disease and index case, the existence of a common source, the incubation period of an infectious agent, or the mode of transmission. In addition, the epidemic curve can be used to determine the probable period of exposure to a source: first look-up the average, median, and range of the relevant incubation period of the suspected infection in question. This information can be obtained from a recognized reference source (e.g., the *Control of Communicable Diseases Manual (7)*. The median incubation period is the time when 50% of case-patients would have acquired the infection. A rapid assessment would be to count back the average incubation period from the median case-patient and the minimum incubation period from the earliest case-patient. There are limitations in extrapolating inferences from an epidemic curve. For example, the curve might not have a "classic" shape, especially if the outbreak is small. Moreover, an observed shape may be consistent with more than one interpretation; intermittent exposures to a common source may look like person-to-person exposure, or the incubation period may remain unknown.

With an initial count of the cases completed, one can determine the rates of infection and illness in the population by age group, birth weight, gender, ethnic origin, religious affiliation, socioeconomic status, water supply, food ingestion, device use, treatment regimens, or other factors that appear to be historically associated with the individuals infected. On the basis of this preliminary analysis, a hypothesis is generated to identify the high-risk population. One may consider conducting a case–control epidemiologic study to compare ill persons (case-patients) with randomly selected persons who have remained well (control group) to identify exposures significantly associated with cases. The contrast between cases and controls is then determined by calculation of the odds ratios and

confidence intervals for each exposure. Alternatively, one may conduct a cohort study in which attack rates are compared through calculation of relative risks and confidence intervals for persons exposed and not exposed to a specific risk factor. Not all case-patients can be expected to fit the hypothesis because a background rate of endemic infections or disease must be assumed for many infectious agents (e.g., *Enterococcus* spp. in healthcare facilities). Using the hypothesis, one searches for additional case-patients, both to increase the numbers for statistical study and to include persons with mild or subclinical disease, who might otherwise escape evaluation.

With the additional findings, the data are analyzed and an interpretation of the events is prepared. If the hypothesis is supported, it is confirmed in a final report; if not, the data are reviewed for alternative hypotheses, and another round of testing and analyses is begun. On the basis of the analyses and the supported hypothesis, intervention and follow-up programs are outlined, including both short-term and long-term control measures. Finally, the findings are reported formally to local and regional authorities, public health agencies, and medical and public groups, indicating the nature of the outbreak and recommendations for future prevention and control.

The Role of Epidemiology and Microbiology in the Investigation of Outbreaks

Traditionally, the most important function of the microbiology laboratory during outbreak investigations has been to accurately identify outbreak pathogens, to conduct relevant antimicrobial susceptibility testing, and to determine the clonality (similarity) of outbreak pathogens based on whatever phenotypic or genotypic typing methods are available to the laboratory. These functions now encompass all stages of outbreak investigations. There are two different approaches to an investigation of infectious disease outbreaks: (i) to conduct extensive culture surveys to identify the source of the outbreak (*laboratory-based investigation*) or (ii) to conduct an epidemiologic investigation with subsequent epidemiology-directed environmental or personnel cultures or assays (epidemiologic investigation with laboratory confirmation). Experience from CDC suggests that the former "shot-gunning" approach creates much superfluous work and may be counterproductive, because risk factors or environmental reservoirs that are epidemiologically relevant could potentially be missed altogether, or the wrong source identified *(92)*. Initial culture surveys of the environment or personnel without a prior epidemiologic investigation may appear to identify or "implicate" the causal agent or person, but also may represent secondary contamination or colonization rather than the true source. This may result in erroneous recommendations or interventions, or inappropriate actions against staff members who are not in any way epidemiologically associated with disease transmission. Other published data from CDC suggest that an epidemiology-directed approach is generally more accurate and less costly for identifying the source and mode of transmission of outbreak pathogens *(93,94)*.

In many CDC outbreak investigations, subsequent laboratory studies have indeed confirmed the epidemiologic findings *(93–95)*; moreover, there have been occasions when the investigators of an outbreak have had to draw conclusions solely on the epidemiologic findings without laboratory confirmation, because relevant microbiological specimens often are discarded before the decision to conduct a formal investigation is made *(74,75)*. Random culture surveys of personnel, products, or the environment without a prior epidemiologic investigation may be misdirected, expensive, unsustainable, or costly in terms of human and laboratory resources and should not be performed before comparative epidemiologic studies are completed.

Epidemiologic principles are particularly important when addressing the issue of intrinsic microbial contamination of a product within an industrial plant. Intrinsic contamination of a normally sterile product may be detected in-house through quality assurance surveillance, such as end-product sampling, or it may manifest as a common-source outbreak of local, national, or international proportions *(73)*. If a pharmaceutical product is suspected to be associated with an infectious disease outbreak, integration of epidemiology and microbiology remains vital to conducting a successful outbreak investigation (the principles have been described earlier). Such an approach has been used to successfully investigate a nationwide outbreak of sterile peritonitis due to intrinsic endotoxin contamination of peritoneal dialysis solution from a single manufacturer, infections among recipients of contaminated allograft tissues, and fungal infection of saline-filled silicone breast implants *(83,96)*.

Epidemiologic methods are used to investigate and relate causal factors to an outbreak and are essential for understanding the mechanisms of infection acquisition and transmission, determining risk factors, and directing the application and practice of clinical microbiology methods. The information from epidemiologic and descriptive studies may provide important clues regarding the causes of or risk factors associated with infections, and may be used to generate causal hypotheses.

To test a hypothesis, one may attempt to identify the high-risk population and design appropriate microbiologic studies and culture surveys. Thus, the laboratory service must be able and prepared to collect relevant specimens through liaison with the epidemiologist, culture or process these specimens using reproducible, quality-controlled methods, and disseminate the information back to other outbreak coinvestigators in a timely manner.

In summary, the following issues must be considered when interpreting environmental culture data: (a) surfaces by themselves do not transmit disease; transmission from surfaces is more likely mediated by personnel who might not have maintained scrupulous aseptic conditions resulting in cross contamination of patient care items; (b) for environmental sampling, there are no benchmarks or standards to compare data generated from different culture methods; and (c) epidemiology is essential for interpreting environmental cultures—just because a pathogen is isolated from an environmental culture does not necessarily mean that there is a problem. The classic steps in the recommended investigation of an epidemic are outlined in Table 1-1.

TABLE 1-1

Steps in Investigating an Epidemic

- Confirm the existence of an epidemic
- Establish a case definition that reflects time, place, and person
- Ascertain cases and create a line listing
- Create an epidemic curve
- Determine the extent and characteristics of cases by rapid survey
- Formulate a working hypothesis
- Test the hypothesis through epidemiologic studies
- Initiate appropriate microbiology or other laboratory studies that are directed by the epidemiologic data
- Analyze all cases for interpretation
- Reassess hypothesis if not proven and initiate additional studies where warranted
- Draw conclusions and inferences from investigation
- Communicate with relevant personnel and recommend appropriate control and preventive measures (exit interviews and preliminary report)
- Continue postoutbreak surveillance for new cases
- Reevaluate control measures
- Prepare a formal written report and disseminate findings in a published manuscript

PREVENTION AND CONTROL

Measures for the prevention and control of communicable diseases are directed at various links in the *chain of infection*. These include interventions to (a) eliminate or contain the reservoirs of infectious agents or curtail the persistence (endemicity) of a microorganism in a specific setting; (b) interrupt the transmission of infectious agents; or (c) protect the host against infection and disease. This approach calls for a detailed knowledge of the epidemiology of infectious diseases in a variety of settings or environments.

Modifying Environmental Reservoirs

Interventions chosen to modify a reservoir depend on whether the reservoir is *animate* or *inanimate*. *Quarantine*, the restriction of movement of individuals who have been exposed to a potentially transmissible agent for the entire incubation period of the infection, is now rarely used to control human disease in healthcare settings and has been replaced, largely, by active surveillance of exposed individuals in acute care hospitals or long-term care facilities. Animate reservoirs (i.e., carriers) include healthcare personnel who are colonized with potential pathogens in their nares or hands, relatives (or pets) who visit patients in intensive care units, or patients known to be colonized or infected with a particular healthcare pathogen and are moved from one unit to another within a given institution, or are transferred from one hospital to another. Since disease is often subclinical, it may be difficult to recognize and separate silent carriers from susceptible persons.

Treatment of humans to eradicate their carriage of transmissible pathogens that are typically found in healthcare settings has had variable success. For example, treatment to eradicate VRE often yields mixed results *(97–99)*; whereas, there has been limited success in the eradication of MRSA among hospital inpatients (100,*101–103*) and in the community (*104*). There are no compelling data that show an association between eradication of gram-negative carriage among patients or healthcare personnel and reduced rates of transmission. Thus, removal of an individual healthcare worker, known to be a reservoir for a potentially transmissible pathogen, from a healthcare setting (e.g., bone marrow unit or surgical intensive care unit) with susceptible patients might be the only control or preventive option. Human carriers of transmissible pathogens may be isolated from susceptible individuals, who are not colonized or infected, for the duration of their stay at the institution or for as long as they harbor the microorganism (*105*,106). Finally, ethical issues arise when the decision is made to expose asymptomatic carriers or colonized but well persons to medical therapy that might have serious side effects, or render them susceptible to adverse events, such as healthcare-associated infections, disease, or undue morbidity.

In healthcare settings, reservoirs of a transmissible pathogen might be limited solely to the inanimate environment. Thus, appropriate control measures might include removing contaminated fruit, flowers, intravenous infusates, hand lotions, toys, white coats, stethoscopes, or other objects deemed to be potential reservoirs; appropriate handling of sewage and medical waste per published guidelines; ensuring that scrupulous aseptic techniques are maintained during invasive procedures or line insertion; or destroying the agent in the environmental niche (e.g., work surfaces in an intensive care unit, medicine preparation areas, or moisture reservoirs in mechanical ventilators) by chemical or physical means. In some healthcare settings, such as medical or intensive care units, microorganisms, such as VRE or *C. difficile*, may remain endemic or persistent despite identification and appropriate treatment or elimination of reservoirs. Such persistence may require periodic enhanced environmental cleaning of the concerned unit to curtail the endemicity of the pathogen (107). The importance of modifying environmental reservoirs for the control and prevention of infectious disease is sustained by the fact that much of the reduction in disease and death from infectious diseases in the industrialized world during the 20th century has been attributed to purification of potable water by filtration and chlorination, improvements in the cooking, processing, and inspection of food, and advancements in housing, nutrition, and sanitary disposal of human waste (*108*).

Interrupting Transmission

Many of the features of interventions necessary for interrupting the transmission of infection are identical to those included in the interventions necessary for modifying inanimate environmental reservoirs discussed above. The most important addition to these has been in the behavioral changes necessary to support improvements in the area of personal hygiene, specifically in the washing of hands between tasks in the preparation of food, caring for children, and caring for the sick (*109,110,*111). In the control of healthcare-associated infections, the use of appropri-

ate barriers, including the use of gloves, gowns, and eye protection, has been emphasized to prevent the transmission of blood-borne pathogens (e.g., HIV and hepatitis B) between patients and healthcare workers, as has the use of high-filtration masks for protection from respiratory transmission of influenza or tuberculosis (*105*,106). Although one of the key measures for the prevention and control of healthcare-associated infections remains the routine washing of hands before, between, and after patient contacts in healthcare settings, compliance or adherence to hand washing protocols among healthcare professionals—a behavioral attribute—remains wanting *(112)*; this is not surprising since as far back as 1996, Goldmann et al. found that National Guidelines seldom are studied thoroughly by physicians, and, if they are read, they rarely are incorporated into everyday practice *(46)*. Compounding the problem is the growing body of evidence that hand hygiene is but one factor in the complex interplay of host, agent, and the environment that facilitates transmission.

For a microorganism like VRE, transmission is enabled by one or more of the following factors: (a) the degree of hand hygiene among healthcare personnel; (b) the inherent properties of the microorganism that enable it to remain viable *days to weeks* on dry, inert environmental surfaces, coats, or ties; (c) the proportion of patients in the unit of concern who are colonized with VRE; (d) the proportion of patients who are inherently susceptible to infection; (e) selective pressure of vancomycin use in the unit; and (f) adherence to prevention efforts among healthcare personnel. Given the above, it follows that complete adherence to a strict hand hygiene policy alone will not necessarily preclude intrahospital transmission of VRE.

One method commonly used to interrupt transmission of pathogens in healthcare settings is the isolation of patients known to be colonized or infected with a particular pathogen in a separate area so as to reduce the probability of transmission of infection to other patients. This method may include allocation of these cohorted patients to specific healthcare workers to avoid transmission of the pathogen by the healthcare workers themselves.

Protecting the Host

The risk of acquisition and transmission of infectious diseases among patient populations in healthcare settings is better characterized if the patients' immune status or immune response is known. Immunization is the most effective method of individual and community protection against epidemic diseases, and can be active or passive. Through active immunization, smallpox, one of the major global communicable diseases, was eradicated *(113–115)*. Although polio has been eliminated from large areas, including all of the Americas (80), and indigenous transmission of wild poliovirus types 1 and 3 infection has been interrupted in all but four countries worldwide (Afghanistan, India, Nigeria, and Pakistan), there were still 1,655 cases reported in 2008 *(116)*. The occurrences of other childhood diseases have been substantially reduced, including diphtheria, pertussis, tetanus, measles, mumps, rubella, and infections of *H. influenzae* type B *(36,117,118)*. Since one of the main goals of epidemiology is to identify subgroups in the patient population that are at high risk for infection and disease, a knowledge of the vaccination status of patients is essential for the prevention of infection or disease. Institutional immunization programs have been recommended as part of the occupational health services of healthcare facilities for some time, but compliance for all healthcare workers has only recently come under mandate. Evaluation of patients for immunization during hospital admission is another program widely recommended but incompletely implemented. The residual endemic problems and periodic outbreaks of these vaccine-preventable diseases in both populations at large and in healthcare institutions have been largely the result of failure of the delivery programs for the vaccines. These have been due to poor funding, poor prioritization of the programs, the lack of political will, and the lack of organization of the vaccine effort—not to failure of the vaccine to immunize *(38)*.

Passive immunization with hyperimmune or standard immunoglobulins is another intervention valuable in a small group of diseases, including certain genetic and acquired immunodeficiency diseases, primary antibody-deficiency disorders, hypogammaglobulinemia in chronic lymphocytic leukemia, measles, hepatitis A, varicella-zoster, hepatitis B, and HIV infections in children *(36)*. Hyperimmune globulin preparations are obtained from blood plasma donor pools preselected for high antibody content against a specific antigen (e.g., hepatitis B immune globulin, varicella-zoster immune globulin, cytomegalovirus immune globulin, and respiratory syncytial virus immune globulin). Although active searches have been carried out for other kinds of immunomodulating agents (e.g., interferons and cytokines) and biologics that heighten host immune function and protect the host from infection or disease, there are no data that indicate such treatment modalities play any significant role in the prevention and control of healthcare-associated infections.

Administering antimicrobials to ensure the presence of an anti-infective agent at the site of a potential infection is a more recent addition to the control programs protecting the host. The use of a single dose or short course of preoperative antimicrobials to reduce the probability of infection with agents commonly seen following certain procedures has become a standard part of surgical practice *(119)*.

Profound cellular and humoral immunosuppression may ensue in patients following chemotherapy or radiotherapy of certain malignancies, or may be a consequence of the primary disease process. Therapy-related immunosuppression occurs during or following bone marrow transplantation or may be a sequelae of therapeutic regimens used to prevent rejection of transplanted organs. The use of local and systemic anti-infectives in these patients has either prevented infection or mitigated the duration and severity of infection, leading to reduced morbidity and mortality, and improved outcomes *(120–123)*. The use of preprocedure (e.g., surgery or dental) antimicrobial prophylaxis in individuals with a history of rheumatic heart disease is also a standard recommendation to prevent bacterial endocarditis *(124–126)*. Unfortunately, one of the side effects of repeated short courses of antimicrobials has been the appearance of significant resistance to these agents among pathogens associated with healthcare-associated infections (31,*127*,*128*). This problem has been aggravated by overprescribing of antimicrobials for nonbacterial infection by some practitioners, over-the-counter

sale of antimicrobials in many parts of the world, and the use of subtherapeutic doses of growth promoters in animal husbandry in the United States and other countries (*129–131*,132).

HEALTHCARE-ASSOCIATED INFECTIONS AND INFECTIOUS DISEASES

Inherent in the measures for the prevention and control of healthcare-associated infections is the ongoing education of healthcare workers in infection control practices and procedures through guidelines published by CDC *(133,134)*, and the implementation of surveillance measures to detect changes in the incidence or prevalence rates of infections caused by microorganisms commonly associated with healthcare-associated infections. The acute care hospital (inpatient, outpatient, and intensive care unit) settings and long-term care and home healthcare facilities provide special settings for the interaction of the agents of infection and patients and healthcare workers. The ongoing study of the basic epidemiologic features of agent–host interactions in these environments has led to recommendations for wide application of, and extensive testing of, surveillance, prevention, and control programs, which have proven highly successful. Descriptions of the special features of the investigations and interventions of these programs are the topics of the chapters to follow.

Despite falls in overall rates of healthcare-associated infections involving the bloodstream, respiratory tract, surgical wounds, and urinary tract, rates of infections caused by *antimicrobial-resistant* pathogens have been increasing across the United States. Thus, control of antimicrobial resistance in the 2000s remains inextricably linked to the control of transmission of healthcare-associated, *antimicrobial-resistant* pathogens and the infections they cause. The seriousness of the problem was underscored in an editorial by Muto, who made the point that "for as long as CDC has measured the prevalence of hospital-acquired infections caused by multidrug-resistant microorganisms, it has been increasing" *(135)*. The myriad of articles in the medical literature has in effect helped explain this failure since much of the data originated in facilities that had implemented untried control programs or had already instituted considerably ineffective programs.

Acute care hospital (inpatient, outpatient, and intensive care unit) settings, free standing medical and surgical centers, long-term care facilities, and the home provide special settings for the interaction of the agents of infection and hosts (i.e., patients, relatives, and healthcare workers alike). The ongoing study of the basic epidemiologic features of agent–host interactions in these environments has led to evidence-based recommendations for healthcare-associated infections surveillance, and prevention and control programs, which have proved highly successful. For example, the Society for Healthcare Epidemiology of America (SHEA) has established evidence-based guidelines to control the spread of MRSA and VRE in acute care settings (136). The tenets of the SHEA guidelines are based on identification and containment of spread through (a) active surveillance cultures to identify the reservoir for spread; (b) routine hand hygiene; (c) barrier precautions for patients known or suspected to be colonized or infected with epidemiologically important antimicrobial-resistant pathogens, such as MRSA or VRE; (d) implementation of an antimicrobial stewardship program; and (e) decolonization or suppression of colonized patients (136). Numerous reports presented at the SHEA annual meetings over the past 5 years have repeatedly shown control of endemic or epidemic MRSA and VRE infections through implementation of the SHEA guidelines. There is now growing evidence that active surveillance cultures do indeed reduce the incidence rates of MRSA and VRE infections and that programs described in the SHEA guidelines are effective and cost-beneficial (137,*138*,*139*). Many other studies have since established that identification of patients colonized with MRSA or VRE on admission to hospital for critical care may enhance implementation of interventions to decrease infection (*140*).

Despite all of the resources put into surveillance activities for healthcare-associated infections in facilities throughout the nation, there remain several obstacles that hinder progress in the control of these infections. These include (a) substantial variation in surveillance activities from one medical center to another and in the collection, aggregation, and use of surveillance data; (b) lack of designated staff healthcare epidemiologists to proactively aggregate, manage, and analyze surveillance data, and apply the results effectively; (c) failure of healthcare facilities to use effective control measures or inconsistent implementation of such measures (e.g., surveillance cultures not being performed as recommended); (d) lack of commitment and prescience among healthcare providers and administrative personnel alike in appreciating the fact that the initial outlay of financial resources that is necessary for employing healthcare epidemiologists and infection preventionists and executing surveillance activities and preventive measures could actually result in improved patient outcomes and substantial savings.

In conclusion, epidemiologic methods can enhance and strengthen evidence-based infection prevention and control through the design and conduct of studies to ascertain risk factors for infection and disease, establish the appropriateness of laboratory testing (e.g., the clinical significance of positive blood cultures), or determine best outcome correlates. In addition, familiarity with infectious diseases epidemiology enables characterization of community or healthcare-associated infections, the pathogens that cause these infections and their respective antimicrobial susceptibility profiles, and risk factors that cause (or are associated with) infection. Such data allow cost-effective patient care in hospitals with adequate resources, and enable development of logical, evidence-based preventive policies that could be applied to hospitals without sophisticated epidemiologic or laboratory support. Finally, the integration of epidemiologic and microbiologic principles is necessary for the development of robust surveillance systems for tracking emerging infections and antimicrobial resistance, for the effective conduct of infection control activities and outbreak investigations, and for informed clinical and public health decision making, research, and management practices.

CHAPTER 2

Modern Quantitative Epidemiology in the Healthcare Setting

Jerome I. Tokars[1]

I often say that when you can measure what you are speaking about, and express it in numbers, you know something about it; but when you cannot express it in numbers, your knowledge is of a meager and unsatisfactory kind; it may be the beginning of knowledge, but you have scarcely, in your thoughts, advanced to the stage of Science, whatever the matter may be. *Lord Kelvin*

The job of the hospital epidemiologist is an intensely political one, into which we can occasionally interject some science. *Jonathan Freeman*

This chapter is about quantitative epidemiology, a term without a formal definition. However, epidemiology can be defined as "the study of the distribution and determinants of health-related states or events in specified populations, and the application of this study to control of health problems" *(1)*. "Distribution" refers to rates of disease overall and in various subgroups; for example, what percent of patients having cardiac surgery develop a surgical site infection? Assembling such rates requires an important series of steps, including determining which diseases are important, how they should be defined, and by what practical means they can be measured. "Study of … determinants of health-related states," or risk factors for disease, is the part of the definition closest to quantitative epidemiology. For example, what determines whether one patient gets a surgical site infection while another does not, or why the infection rate is higher at one hospital than at another? "Application of this study to control of health problems" is the all-important final step, requiring wisdom, judgment, and political savvy. Given the difficulty of this final step, we should at least be sure that we have done the best possible job at quantitative epidemiology, that is, of analyzing and presenting the data needed for decision making.

In one sense, epidemiology is merely "quantified common sense." For example, the simple observation that "our infection rate is higher than theirs because our patients are sicker than theirs" describes what epidemiologists call confounding. Confounding bedevils a variety of activities in healthcare epidemiology, including the comparisons of disease rates among hospitals that underlie interhospital comparisons (benchmarking) and quality assurance programs. Simply comparing crude infection or death rates among hospitals, without accounting for factors such as severity of illness, leads to obviously incorrect conclusions. While the concept of confounding may be intuitive, there is considerable complexity in application of the methods of quantitative epidemiology to deal with confounding.

It is difficult to determine the boundary between quantitative epidemiology and a related discipline, statistics. Many healthcare epidemiologists have taken introductory statistics courses, but such entry-level courses are becoming less and less adequate with each passing year. A study of articles in a prominent medical journal showed substantial increases in the use of advanced methods such as multiple regression (from 5% of articles in 1978–1979 to 51% of articles in 2004–2005), survival methods (from 11% to 61%), and power analyses (from 3% to 39%) *(2)*. In 2004 to 2005, 79% of the articles used methods beyond the scope of introductory statistics courses. Greater knowledge of quantitative epidemiology/statistics is needed both to interpret the infection control literature and to practice healthcare epidemiology.

HISTORY OF EPIDEMIOLOGY

A famous early example of applied epidemiology is the work of Dr. John Snow, a physician in London during the cholera epidemic of 1855 (3). At that time, the germ theory of disease had not been accepted and the pathogen causing cholera, Vibrio cholerae, was unknown. Whereas the prevailing view during this period was that disease was caused by a miasm or cloud, Snow inferred from epidemiologic evidence that cholera was a water-borne illness. He constructed a spot map of cholera cases and noted a cluster of cases near a water pump on London's Broad Street, the so-called Broad Street pump. This early use of a spot map to find the putative cause of an outbreak is an example of descriptive epidemiology. He also

[1]The findings and conclusions in this report are those of the author and do not necessarily represent the official position of the Centers for Disease Control and Prevention.

performed several analytic studies, noting that the rate of cholera was higher for people who obtained water from more polluted areas of the Thames. His well-known intervention was to remove the handle from the Broad Street pump, thereby preventing the use of this contaminated water, after which cases of cholera in the vicinity were said to have decreased. This example illustrates that epidemiologists can define the mechanism of disease spread and institute control measures before the agent causing disease is discovered. More recent examples of this power of epidemiology include Legionnaires' disease and human immunodeficiency virus disease; for both diseases, the mechanism of spread and means of prevention were inferred by epidemiologists before the microbe was discovered in the laboratory.

DESCRIPTIVE VERSUS ANALYTIC EPIDEMIOLOGY

In descriptive epidemiology, we describe characteristics of the cases and generate hypotheses. The line list of cases, case series, epidemic curves, and spot maps are examples. In analytic epidemiology, we use comparison groups, calculate statistics, and test hypotheses. Many outbreaks and other problems in healthcare epidemiology can be solved by thoughtful examination of descriptive data without the use of analytic epidemiology. However, the increasingly complex nature of healthcare and associated illness demands that we have a firm grounding in analytic or quantitative epidemiology, which is the main focus of this chapter.

MEASURES OF FREQUENCY

Proportions (synonyms are *probability*, *risk*, and *percentage*) are the simplest way to represent how often something occurs. A proportion is the ratio of a part to the whole; that is, the numerator of the ratio is included in the denominator. The proportion with disease is the number of people who get the disease divided by the total number at risk for the disease; that is, proportion ill = number ill/(number ill + number well). The probability of pulling an ace from a deck of cards is 4/52 = 7.7%. Proportions can be represented by a fraction (e.g., 0.077) or a percentage (e.g., 7.7%) and can range from 0 to 1.0 or from 0% to 100%. Proportions cannot be >1.0 or 100% since, using proportions, each entry in the denominator can have at most one entry in the numerator. A proportion is unitless, because the numerator and denominator have the same units. The proportion is the measure of frequency used in cohort studies and to calculate the relative risk.

Odds represent the ratio of a part to the remainder or the probability that an event will occur divided by the probability that it will not occur. Unlike in proportions, the numerator of the ratio is not included in the denominator. The odds of a disease occurring equal the number of people with the disease divided by the number without the disease; that is, odds of illness = number ill/number well. The odds of pulling an ace from a deck of cards are 4/48 = 8.3%. Note that the odds of illness are always higher than a corresponding proportion ill, because the denominator is smaller for odds. Odds are unitless and have bounds of zero to infinity. Odds are used in case–control studies and to calculate the odds ratio.

A rate, in contrast to proportions and odds, has different units of measure in the numerator and denominator, as in 55 miles/hour or 20 healthcare-associated infections/1,000 observed patient-days. A rate can have any value from zero to infinity. Rates are used in incidence density analyses.

Common Usage

The proportion ill, especially in outbreaks, is often called an "attack rate," although strictly speaking it is a misnomer to refer to a proportion as a rate. This chapter follows common usage in using the following terms interchangeably with proportion ill: percent ill, attack rate, and rate of illness.

Cumulative Incidence Versus Incidence Density

In a cumulative incidence study, time at risk is not taken into account; the denominator is the total number of persons at risk, and the proportion with disease (or proportion with potential risk factors for disease) is calculated. The cohort and case–control studies presented in the following section are examples of cumulative incidence. In an incidence density study, time at risk is accounted for; the denominator is person-time at risk and a rate of illness (e.g., infections per 1,000 patient-days) is calculated. This type of study is considered later in this chapter.

BASIC STUDY DESIGN

There are three types of analytic study: cohort, case–control, and cross-sectional. The goal of analytic epidemiologic studies is to discover a statistical association between cases of disease and possible causes of disease, called *exposures*. A first step in any such study is the careful definition of terms used, especially defining what clinical and laboratory characteristics are required to indicate a case of disease.

The Cohort Study and Relative Risk

Prospective Cohort Study There are several subtypes of cohort study, but all have certain common features and are analyzed the same way. In the prospective cohort study, we identify a group of subjects (e.g., persons or patients) who do not have the disease of interest. Then, we determine which subjects have some potential risk factor (exposure) for disease. We follow the subjects forward in time to see which subjects develop disease. The purpose is to determine whether disease is more common in those with the exposure ("exposed") than in those without the exposure ("nonexposed"). Those who develop disease are called "cases," and those who do not develop disease are "noncases" or "controls."

A classic example of a prospective cohort study is the Framingham study of cardiovascular disease, which began in 1948 (3). Framingham is a city about 20 miles from Boston with a population of about 300,000, which was considered to be representative of the US population. A random sample of 5,127 men and women, age 30 to 60 years and without evidence of cardiovascular disease, was enrolled in 1948. At each subject's enrollment, researchers recorded gender and the presence or absence of many exposures, including smoking, obesity, high blood pressure, high cholesterol, low level of physical activity, and family history of cardiovascular disease. This cohort was then followed forward in time by examining the subjects every 2 years and daily checking of the only local hospital for admissions for cardiovascular disease.

Note several features of this study. The study was truly prospective in that it was started before the subjects developed disease. Subjects were followed over many years and monitored to determine if disease occurred, that is, if they became "cases." This is an incidence study, in which only new cases of disease were counted (because persons with cardiovascular disease in 1948 were not eligible for enrollment). In an incidence study, it is necessary to specify the study period, that is, how long the subjects were allowed to be at risk before we looked to see whether they had developed disease.

The Framingham study allowed investigators to determine risk factors for a number of cardiovascular disease outcomes, such as anginal chest pain, myocardial infarction (heart attack), death due to myocardial infarction, and stroke. One finding of this study was that smokers had a higher rate of myocardial infarction than nonsmokers. An advantage of this study design is that it is very flexible, in that the effect of many different exposures on many different outcome variables can be determined. The disadvantages are the time, effort, and cost required.

Relative Risk Performing hospital surveillance for surgical site infections (SSIs) is an example of a prospective cohort study. Assume that during one year at hospital X, 100 patients had a certain operative procedure. Of these, 40 were wound class 2 to 3 and 60 were class 0 to 1. Note that wound class was determined before it was known which patients were going to develop SSI; this makes it a prospective cohort study. A subgroup or sample of patients was not selected; that is, the entire group was studied. When the patients were followed forward in time, the following was found: of 40 patients with class 2 to 3 procedures, 10 developed SSI; of 60 patients with class 0 to 1 procedures, 3 developed SSI.

Cohort study data are commonly presented in a 2×2 table format. The general form of the 2×2 table is shown in Table 2-1, and the 2×2 table for this SSI example is shown below. Notice that the columns denote whether disease (SSI) was present and the rows whether exposure (wound class 2–3) was present. In this example, exposed means being class 2 to 3 and nonexposed means being class 0 to 1. In the 2×2 table below, the total number of cases is 13, total noncases is 87, total exposed is 40, total nonexposed is 60, and total patients is 100.

TABLE 2-1

The 2 × 2 Table and Associated Formulas

Exposure	Disease: Yes	Disease: No	
Yes	a	b	$a + b = h_1$
No	c	d	$c + d = h_2$
	$a + c = v_1$	$b + d = v_2$	N

Exposed cases = a
Exposed noncases = b
Nonexposed cases = c
Nonexposed noncases = d
Total cases = $a + c = v_1$
Total noncases = $b + d = v_2$
Total exposed = $a + b = h_1$
Total nonexposed = $c + d = h_2$
Total subjects = $a + b + c + d = n$

$$\text{Relative risk} = \frac{\%\text{ ill exposed}}{\%\text{ ill nonexposed}} = \frac{a/(a+b)}{c/(c+d)}$$

$$\text{Odds ratio} = \frac{ad}{bc}$$

Expected values (where "ea" denotes "the expected value of cell a")
ea = $h_1 v_1 / n$
eb = $h_1 v_2 / n$
ec = $h_2 v_1 / n$
ed = $h_2 v_2 / n$

$$\text{chi-square} = \frac{(a-\text{ea})^2}{\text{ea}} + \frac{(b-\text{eb})^2}{\text{eb}} + \frac{(c-\text{ec})^2}{\text{ec}} + \frac{(d-\text{ed}^2)}{\text{ed}}$$

Alternate "calculator" formula: chi-square = $(ad - bc)^2(n - 1)/(a + b)(c + d)(a + c)(b + d)$

Disease: Surgical Site Infection

Exposure	Yes	No	
Class 2–3	10	30	40
Class 0–1	3	57	60
	13	87	100

In the exposed group, the proportion ill = 10/40 = 0.25 or 25%. In the nonexposed group, the proportion ill = 3/60 = 0.05 or 5%. We compare the frequency of disease in the exposed versus nonexposed groups by calculating the relative risk (often called risk ratio). The relative risk of 5.0 means that patients in wound class 2 to 3 were five times more likely to develop SSI than were patients in wound class 0 to 1.

$$\text{Relative risk} = \frac{\%\text{ ill exposed}}{\%\text{ ill nonexposed}} = \frac{\%\text{ ill class } 2-3}{\%\text{ ill class } 0-1} = \frac{a/(a+b)}{c/(c+d)} = \frac{25}{5} = 5.0$$

Retrospective Cohort Study A retrospective cohort study is started after disease has developed. A study period

(start date and stop date) is decided upon. Using patient records, we look back in time to identify a group (cohort) of subjects that did not have the disease at the start time. We then use patient records to determine whether each cohort member had a certain exposure. Again using patient records, we determine which cohort members developed disease during the study period. Finally, we calculate the percent with disease in those with the exposure and those without the exposure and compare the two.

The following is an example of a retrospective cohort study based on the SSI example above. Hospital X noted that the overall SSI rate of 13% was higher than in previous years. We want to determine whether a new surgeon (surgeon A) was responsible for the increase. The prospective surveillance system did not routinely record the surgeon performing each procedure, so we pull the records from each procedure and record whether or not surgeon A was involved. We find that surgeon A operated on 20 patients,3 of whom later developed SSI. Among the 80 other patients, 10 developed SSI. The percent ill in the exposed group (surgeon A) = 3/20 = 15%. The percent ill for other surgeons (nonexposed) = 10/80 = 12.5%. The relative risk = 15%/12.5% = 1.2.

The interpretation is that patients operated on by surgeon A were 1.2 times (or 20%) more likely to develop disease than patients operated on by other surgeons. Factors to consider in deciding whether surgeon A is truly a cause of the problem are presented below (see Interpretation of Data, Including Statistical Significance and Causal Inference).

To review, this was a retrospective cohort study, since data on the exposure were collected from patient records after we knew which patients had developed SSI. The retrospective nature of data collection is sometimes irrelevant and sometimes a problem. For certain types of data, such as length of hospital stay or death, retrospective data collection will be as good as prospective. However, determining other factors, such as which ancillary personnel treated a given patient, may be difficult to do after the fact, and retrospective studies using such data may be less valid.

Observational Versus Experimental Studies Epidemiologic studies are generally observational; that is, the investigator collects data but does not intervene in patient care. Patients, physicians, nurses, and random processes all play a part in determining exposures in the hospital. The goal of observational studies is to simulate the results of an experimental study (see Quasi-Experimental Studies)

In an experimental study, a group (cohort) of subjects is identified and the investigator assigns some of them to receive treatment A (exposed) and the remainder to receive an alternate treatment B (nonexposed). The patients are followed forward in time, the cases of disease are recorded, and the rates of illness and relative risk are calculated as usual. The experimental study is a special type of a prospective cohort study where the two exposure groups are assigned by the investigator.

Cohort Studies With Subjects Selected Based on Exposure In this type of cohort study, subjects are selected based on exposure. We select two subgroups: one that is exposed and one that is nonexposed. Both groups are followed forward in time to see how many develop disease. Consider the SSI example and surgeon A above. We study all 20 patients operated on by surgeon A (exposed); of the 80 patients operated on by other surgeons, we randomly select 40 (nonexposed). Thus, only 60 patients of the original group of 100 are included in this study.

Note that this is a type of cohort study, not a case–control study. In a case–control study, the subjects are chosen based on whether or not they have disease. In this study, subjects were chosen based on whether or not they had exposure.

The disadvantage of this type of cohort study, where the subjects are selected based on exposure, is that only one exposure (i.e., the exposure that you selected subjects on) can be studied. However, this type of study is very useful for studying an uncommon exposure. In the SSI surveillance example used above, consider the situation if there had been 500 surgical procedures, and surgeon A had performed only 20 of them. If you performed a cohort study of the entire group, you would have to review 500 charts, which would waste time and effort. Instead, you could perform a cohort study of the 20 procedures performed by surgeon A (exposed), and 40 randomly selected procedures performed by other surgeons (nonexposed). The second alternative would be much more efficient.

Cohort Studies—Summary Cohort studies can be prospective or retrospective, observational or experimental. They usually include a whole group of subjects, but studying two subgroups selected based on exposure is also possible. The 2×2 table layout and calculations are the same for all types of cohort studies. All have in common that subjects are chosen without regard to whether they develop disease.

The Case–Control Study and Odds Ratio

In a case–control study, we choose subjects for study based on whether they have disease. Since we have to know which subjects developed disease before we select them, case–control studies are always retrospective. We usually study those with disease (cases) and choose a sample of those without disease (controls). We usually study one to four controls per case. The more controls, the greater the chance of finding statistically significant results. However, there is little additional benefit from studying more than four controls per case. Controls are usually randomly selected from subjects present during the study period who did not have disease.

Example: Case–Control Study of Surgical Site Infections This is the same example presented in the section on cohort study and relative risk. At hospital X, 100 patients had a certain operative procedure, 40 class 2 to 3 (exposed) and 60 class 0 to 1 (nonexposed), and 13 developed SSI. To perform a case–control study, we select the 13 patients with SSI (cases) and also study 26 patients who had surgical procedures but did not have SSI (controls). We studied two controls per case, but could have studied fewer or more controls. The controls were randomly chosen from all patients who had the surgical procedure under study but did not develop SSI. From their

medical records, we find which of the subjects had class 2 to 3 procedures and which had class 0 to 1 procedures. Our data showed that, of 13 cases, 10 had class 2 to 3 procedures. Of 26 noncases, 9 had class 2 to 3 procedures. The 2×2 table for this example is as follows:

Disease: Surgical Site Infection

		Yes	No	
Exposure	Class 2–3	10	9	
	Class 0–1	3	15	
		13	26	39

In a case–control study, we cannot determine the percent ill in the exposed or nonexposed groups, or the relative risk. In this example, note that the percent ill among class 2 to 3 is NOT = 10/(10 + 9) = 52.6%. However, we can validly calculate the percent of cases that were exposed, 10/13=76.9%, and the percent of noncases that were exposed, 9/26 = 34.6%. Note that the cases were much more likely to have the exposure than were the controls. Most importantly, we can calculate the odds ratio (also called the relative odds; Table 2-1) as follows:

$$\text{Odds ratio} = \frac{ad}{bc} = \frac{10 \times 15}{9 \times 3} = \frac{150}{27} = 5.6$$

We can interpret the odds ratio as an estimate of the relative risk. Using the case–control method, we estimated that patients in class 2 to 3 were 5.6 times more likely to develop SSI than were patients in class 0 to 1. Note that the odds ratio is similar to, but slightly higher than, the relative risk (5.0) we calculated previously. If the frequency of disease is not too high, that is, is less than approximately 10%, the odds ratio is a good approximation of the relative risk.

The meanings of the letters (i.e., *a*, *b*, *c*, and *d*) used to represent the 2×2 table cells are different in cohort versus case–control studies (Table 2-1). For example, in a cohort study, *a* denotes the number of cases of disease among exposed persons; in a case–control study, *a* denotes the number exposed among a group of cases. Although this distinction may not be clear to the novice, it will suffice to keep in mind that in a case–control study, it is not valid to calculate percent ill or relative risk, but it is valid to calculate an odds ratio.

A more in-depth explanation of the odds ratio is as follows. In a case–control study, we actually measure the odds of exposure among those with disease and the odds of exposure among those without disease. The ratio of these two odds is the exposure odds ratio; if equal to 2.0, this would be interpreted as "the odds of exposure are twice as high in those with disease versus those without disease." However, the exposure odds ratio is not a very useful quantity. Fortunately, it can be proven mathematically that the exposure odds ratio equals the disease odds ratio. Therefore, using our example of 2.0, we can say that the odds of disease are twice as high in those exposed versus those not exposed, which is closer to being useful. Finally, we use the odds ratio as an approximation of the relative risk (where the frequency of disease is not too high) and say simply that those with exposure are twice as likely to get disease.

Selection of Controls Selection of controls is the critical design issue for a case–control study. Controls should represent the source population from which the cases came; represent persons who, if they had developed disease, would have been a case in the study; and be selected independently of exposure *(4)*. It is always appropriate to seek advice when selecting controls, and may be worthwhile to select two control groups to compare the results obtained with each.

An example of incorrect selection of controls is provided by a case–control study of coffee and pancreatic cancer (3,5). The cases were patients with pancreatic cancer, and controls were selected from other inpatients admitted by the cases' physicians but without pancreatic cancer. The finding was that cases were more likely to have had the exposure (coffee drinking) than the controls, which translated into a significant association between coffee drinking and pancreatic cancer. The problem was that the controls were not selected from the source population of the cases (cases did not arise from hospital inpatients) and thus were not representative of noncases. The physicians admitting patients with cancer of the pancreas were likely to admit other patients with gastrointestinal illness; these control patients were less likely to be coffee drinkers than the general population, possibly because they had diseases that prompted them to avoid coffee. A better control group might have been healthy persons of similar age group to the cases.

More contemporary examples of problematic control selection are studies of the association between vancomycin receipt and vancomycin resistance (6). Cases are often hospitalized patients who are culture positive for vancomycin-resistant enterococci. Controls have often been selected from patients who were culture positive for vancomycin-sensitive enterococci. Using this control group, case-patients will be more likely to have received vancomycin than the controls, resulting in a significant association and elevated odds ratio. The problem is that controls were not representative of the source population and were less likely to have received vancomycin than other patients, since vancomycin would have suppressed or eliminated vancomycin-sensitive microorganisms. Better control groups would be hospital patients similar in age and severity of illness to the cases.

A potential problem is that hospital patients without a positive culture may include some patients who had the microorganism but were not cultured. Inclusion of these patients as controls would bias the odds ratio to 1.0 (null result). An alternative method is to limit controls to those with at least one clinical culture performed. However, this may not be preferable since it results in selection of sicker controls ("severity of illness bias") and also biases the odds ratio toward 1.0 *(7)*. Another way to look at this issue of potential "contamination" of the control group with unrecognized cases is as follows: in a study design called the case-cohort study, cases are compared with subjects chosen from all patients (i.e., from both cases and noncases); then, the *ad*/*bc* statistic equals the relative risk rather than the odds ratio; therefore, inadvertent inclusion of noncases in the control group when performing a case–control study may "bias" the odds ratio toward the relative risk and thus be advantageous.

Comparison of Cohort Versus Case–Control Studies

Cohort studies may be prospective or retrospective, but case–control studies are always retrospective. A major advantage of cohort studies is that we can calculate the percent ill and the relative risk. Cohort studies are less subject to bias than case–control studies. The potential disadvantages of cohort studies are that they are more time-consuming and expensive and may require study of a large group to collect information on a small number of cases.

Prospective cohort studies are the premier type of observational study. They provide the strongest evidence; are less subject to bias in collecting exposure data, since exposure is recorded before the subjects develop disease; and are flexible in that it is possible to study many exposures and diseases. The disadvantage is that it may be necessary to follow subjects over a long period of time to determine whether they develop disease.

The advantages of the case–control study are that we can determine risk factors while studying a relatively small group of patients; we can study as many risk factors as desired; and case–control studies are usually quicker, easier, and cheaper than cohort studies. The disadvantages are that the percent ill and relative risk are not determined; only one disease can be studied at a time; and the selection of controls can be subtle and introduces the chance of error. Deciding which is the most appropriate control group for a particular study is a matter of opinion about which even well-trained epidemiologists may disagree.

Cross-Sectional or Prevalence Study

A third type of study (besides cohort and case–control) includes only subjects who are present in a locality at one point in time. Exposure and disease are ascertained at the same time. Depending on the way the subjects were selected, a cross-sectional study may be analyzed as a cohort study or a case–control study.

A cross-sectional study is clearly not an incidence study, which would include as cases only those free of disease at the start of the study and who develop disease during the study period. However, if an entire group present at one point in time is studied, the results can be analyzed in a 2×2 table similar to that used for cohort studies. The formula used to calculate a relative risk in a cohort study would yield a prevalence ratio in a cross-sectional study. If the group present at one point in time is sampled as in a case–control study (i.e., the cases and a random selection of noncases are studied), then the odds ratio formula could be used to calculate a prevalence odds ratio.

Incidence Versus Prevalence

Incidence includes only new cases of disease with onset during a study period; the denominator is the number of subjects without disease at the beginning of the study period. Incidence measures the rate at which people without the disease develop the disease during a specified period of time; it is used to study disease etiology (risk).

Prevalence includes both new and old cases that are present at one time and place, measuring the proportion of people who are ill. The commonest measure of prevalence is point prevalence, which is the proportion of individuals who are ill at one point in time. Point prevalence is a unitless proportion. A different measure of prevalence, period prevalence, is the proportion of persons present during a time period with disease. Period prevalence has been criticized as an undefined mixture of both prevalent and incident cases without quantitative use, but is occasionally seen.

Prevalence studies are the ideal way to measure disease burden and plan for needed resources. For example, if we wanted to know how many isolation rooms would be needed for patients with resistant microorganisms, we would want to know average prevalence, that is, the total number of patients with recognized drug-resistant microorganisms of either new or old onset in the hospital at any given time.

Prevalence can also be used as a simple, quick, and dirty way to measure disease frequency and risk factors, but such estimates may be biased by length of stay. It is often said that prevalence equals incidence *times* duration. That is, prevalence is higher if either incidence is higher or if the duration of the illness is longer. In hospital studies, prevalence is greatly influenced by length of stay and mortality. For example, assuming that ascertainment of vancomycin-resistant enterococci is stable, the prevalence of vancomycin-resistant enterococci in a hospital may decrease because of an effective prevention program, or because patients with this microorganism are being discharged sooner or dying more commonly than had been the case previously.

Point prevalence and incidence density are mathematically linked; in a steady-state or dynamic population, one can be derived from the other. Prevalence can be derived from incidence density and distributions of durations of disease, and incidence density may be derived from prevalence and distributions of durations to date of disease *(8–11)*.

INTERPRETATION OF DATA, INCLUDING STATISTICAL SIGNIFICANCE AND CAUSAL INFERENCE

Measures of Size of Effect and their Interpretation

The relative risk and the odds ratio measure the size of effect, that is, the magnitude of the association between an exposure and a disease. A relative risk of 1.3 shows a modest association, whereas a value of 20 shows a large association. In general, odds ratios are interpreted in the same manner as relative risks.

Because the relative risk = percent ill exposed/percent ill nonexposed, the relative risk can fall into three categories. First, if the two percents are approximately equal, the relative risk is approximately 1.0; this is a null result showing no association between exposure and disease. Second, if the percent ill is higher in the exposed group, the relative risk is >1.0; exposure is apparently associated with disease, is a risk factor for disease, and may be a cause of disease. Third, if the percent ill is higher in those without exposure,

the relative risk is <1.0; exposure is again apparently associated with disease, but in this instance the exposure prevents disease. An example of a preventive exposure is vaccine use; persons who are "exposed" to the vaccine have a lower rate of disease than those not exposed, leading to a relative risk <1.0. Interpretation of odds ratios as equal to, greater than, or less than 1.0 is similar. To intelligently interpret relative risks and odds ratios, we must in addition understand statistical significance and the distinction between association and causation (presented below).

Relative risks can be interpreted as a percent increase or decrease. For example, a relative risk of 1.5 could be interpreted in two ways: disease is 1.5 times more likely in exposed than in nonexposed, or disease is 50% more likely in exposed than in nonexposed. Similarly, a protective relative risk of 0.6 could be interpreted in two ways: illness was 0.6 times as likely in exposed than in nonexposed, or illness was 40% less likely in the exposed group.

Statistical Significance and *p* Values

For a given group and time period, an association between exposure and disease might occur due to chance alone. For example, suppose that over many years the rate of SSI at hospital A is the same as that of other hospitals. However, during a given quarter, the rate at hospital A may be higher or lower than average by chance alone. To tell us the probability that the SSI rate at hospital A differed from the rate at other hospitals due to chance alone, we commonly use two measures of statistical significance, the *p* value and the confidence interval.

The *p* value measures the probability that a given result, or one more extreme, could have happened by chance alone if there was no association between exposure and diseases. Because computer packages calculate *p* values automatically, it is more important to know how to interpret than to calculate them. *P* values range from >0 to 1.0. By convention, a *p* value ≤.05 indicates statistical significance. This means that there is a ≤5% or ≤1/20 chance that the result we found (or one more extreme) could have occurred by chance alone; exposure is associated with disease. Another way of stating this is that we are 95% certain that this observed difference did not arise by chance alone. If the *p* value is >.05, the result is not considered statistically significant and could well have happened by chance alone; we do not have evidence that exposure is associated with disease.

The .05 cutoff was not chosen for any particular reason but now is very commonly used. There is not a meaningful difference between *p* values of .04 and .06; although the latter would not usually be considered statistically significant, in fact there is only a 6% chance that such a result could have occurred by chance alone. The adoption of the arbitrary .05 standard has its unfortunate aspects and is subject to interpretation after considering all of the sources of bias described below. Some published manuscripts describe interesting or important studies where the *p* value did not reach .05, thus allowing readers to make their own determinations of biologic importance.

Small epidemics, or epidemics that are stopped before there are sufficient cases to demonstrate statistical significance at the .05 level, may be biologically very important, so epidemiologists who work with observational data in hospitals should not consider statistical *p* values to be of primary interest. Biologic importance and size of effect are much more compelling than *p* values in the face of an ongoing problem in a hospital.

In biostatistical terms, significance testing can be viewed as follows. We assume the null hypothesis that there is no true difference in rate of illness between the exposed and nonexposed groups. We then compute the *p* value, that is, probability of the results (or results more extreme) under the null hypothesis. If the *p* value is low, then apparently the null hypothesis was wrong, and we reject the null hypothesis and embrace the alternative hypothesis, namely, that there is a true difference between exposed and nonexposed (see Chapter 3).

Type I Versus Type II Error The *p* value required for statistical significance is commonly called the chance of type I error. This means that if we conclude that hospital A has a high (or low) rate of illness based on a *p* value of .05, there is a 5% chance that we are drawing this conclusion in error. The type I error then indicates the chance of concluding that a difference in rates exists when in fact there is no true difference. Type II error measures the opposite problem—that there really is a difference between the two rates but we erroneously conclude that they are the same. The power of a study (discussed below) = 1—the probability of type II error.

Methods of Calculating p Values *P* values for 2×2 tables may be calculated by the chi-square or Fisher exact methods. The chi-square *p* value is valid when an expected value (Table 2-1) is not <5; if an expected value is <5, the Fisher exact results should be used. Computer packages commonly calculate expected values and print out a suggestion to use the Fisher exact *p* value if appropriate. In addition to a simple or uncorrected chi-square value, computer packages may compute a continuity corrected (or Yates corrected) value. The formula for continuity correction involves subtracting 0.5 from each cell in the 2×2 table. There are usually not great differences among these chi-square values, and many authorities suggest using the simple or uncorrected value.

The calculation of chi-square value does not differ depending on whether data are from a cohort, case–control, or cross-sectional study. However, the computation of chi-square value is different for incidence density data. Calculation of chi-square value is shown in Table 2-1 and Question 3 in Appendix 1 at the end of this chapter. Later in this chapter we suggest some shareware programs that perform these calculations. When one has the value for chi-square, one can determine the *p* value by looking it up in a table or by using a statistical program. In Excel, the CHIDIST function calculates the *p* value for a given chi-square value and number of degrees of freedom.

P values may be one-tailed or two-tailed. Two-tailed *p* values are usually twice as great as one-tailed values. A two-tailed *p* value assumes that the rate in the exposed group could have been either higher or lower than in the unexposed group due to chance alone. A one-tailed value recognizes only one of these two possibilities. For example, suppose that a study showed rates of illness significantly lower among those exposed to a putative toxin

than among those not exposed; if the intent had been to conclude that the "toxin" might actually be protective, we should use a two-tailed test; however, if the intent had been to consider such a finding to be spurious and probably due to chance alone and conclude that the toxin has no effect, then we should use a one-tailed test. Although there is no uniform agreement as to whether one- or two-tailed results should be used, the majority of authors use two-tailed *p* values. This suggests that, for uniformity and ease of comparison among studies, two-tailed *p* values should be the standard.

One-tailed tests are standard for noninferiority studies, which are becoming more common in the literature. An example is a trial of whether hepatitis A vaccine is inferior to the standard method, immune globulin, for postexposure prophylaxis *(12)*. Hepatitis rates were 4.4% among those vaccinated and 3.3% among those receiving immune globulin (relative risk = 1.35, two-tailed confidence interval = 0.7–2.67, one-tailed upper confidence limit = 2.40). Since the one-tailed upper confidence limit did not overlap a predetermined relative risk of 3.0, the authors concluded that the vaccine was noninferior. If the rate of hepatitis A had been lower among those receiving vaccine than immune globulin, the authors would have dismissed the finding and not concluded that the vaccine was better. Given this intent, a one-tailed test was appropriate for this study, as it is for other noninferiority trials.

Confidence Intervals

The second way to judge statistical significance is the confidence interval for a relative risk or odds ratio. The confidence interval combines the concepts of size of effect (relative risk) and strength of association (*p* value). A 95% confidence interval means that, roughly speaking, we are 95% sure that the true relative risk lies between the upper and lower confidence interval limits. For example, assume that a study showed a relative risk of 5.0 with a 95% confidence interval of 1.47 to 17.05. Our best guess is that the relative risk is 5.0, which seems quite high, but we are 95% sure that it lies between 1.47 and 17.05. This is much more informative than simply reporting the probability of our results under the null hypothesis (*p* value). An additional benefit of the confidence interval is humility; a wide interval points out the uncertainty in our results.

If a 95% confidence interval does not cross 1.0, the result is statistically significant at the .05 level. Remembering the formula for the relative risk, a relative risk >1.0 with a 95% confidence interval excluding 1.0 means that we are 95% sure that the rate of illness in the exposed group is greater than the rate of illness in the nonexposed group.

Causal Inference: Association Versus Causation

A statistical association between an exposure and a disease does not necessarily mean that the exposure caused the disease. Sir Bradford Hill first described a set of logical criteria by which associations could be judged for potential causality. Fulfillment of Hill's criteria does not guarantee that an association is causal, but failure to meet these criteria generally excludes the possibility of causality. These criteria have changed somewhat over time, but here is a version appropriate for healthcare epidemiology:

1. Size of effect can be estimated by the relative risk. Large effects are more likely to be causal than small effects. The magnitude of a credible relative risk must depend on the magnitude of the potential sources of bias. Generally, a relative risk >2.0 or <0.5 in a well-done study is difficult to ignore.
2. Strength of association can be measured by the *p* value. A relatively weak association can more easily be the result of random or systematic error. A *p* value near .05 would be considered a weak association. The same information is better presented by the statement that a relative risk 95% confidence bound near 1.0 would be evidence of a weak association.
3. Consistency: A particular effect should be reproducible in different populations and settings.
4. Temporality: The cause must precede the effect.
5. Biologic gradient: There should be a dose–response effect. More exposure should lead to more outcome.
6. Plausibility of the biologic model: There should be a reasonable biologic model to explain the apparent association. This includes Hill's criteria of coherence, experimental evidence, and analogy.

ERRORS IN EPIDEMIOLOGIC STUDIES

Epidemiologic studies, even observational studies, involve people and are usually expensive. Therefore, the practical goal is to design a study that requires the least resources yet will provide a good-enough answer to a question. Since the perfect epidemiologic study will never be done, every epidemiologist has to be an expert on sources of error in measurement. For every question or every study, one must review the potential sources of error, estimate their likely direction and magnitude, and then decide what overall effect these distortions might have on the result of the study.

It is worthwhile to distinguish random variation, random error, and systematic error. Random variation is the statistical phenomenon of variability due to chance alone, and is sometimes called background or noise. If we were measuring SSIs, the true underlying SSI rate would vary each month according to many factors, including the mix of surgeons and patients involved; assuming hypothetically that these factors could be held stable, the SSI rate would still vary each month because of chance alone (i.e., random variation). On the other hand, random and systematic *errors* are produced by inaccuracies in finding or recording data. Random error would occur if we incorrectly measure the SSI rate to be higher than it actually is during some months and lower than it actually is in other months; over many months, these random errors in measurement balance each other and the average value would be correct. Systematic error would occur if we consistently measured the SSI rate as higher or lower than the true rate, and an average over many months would be wrong; systematic error is also called *bias*. We define validity as getting the right answer, or alternately as a lack of bias.

A related concept is *precision,* which may be functionally defined as the width of the confidence interval. A narrow

confidence interval indicates high precision; that is, we are confident that the true value is within a narrow range. A confidence interval is narrower when both random variation and random error are low and vice versa. A larger sample size leads to a narrower confidence interval and greater precision. Precision may also be improved by modifying the study design to increase the statistical efficiency by which information is obtained from a given number of study subjects.

Selection Bias or Berkson's Bias

Selection bias occurs when inappropriate subjects are chosen for a study. An example is a study of mortality rates in patients with versus without bacteremia. The problem is that blood cultures are selectively obtained from patients who appear septic, and thus mildly ill patients who may have unrecognized bacteremia are not included as cases. Therefore, cases are not representative of all patients with bacteremia. Including only the sicker cases leads to an overestimate of the mortality associated with bacteremia. Other examples of selection bias are given in the section on selection of controls for case–control study. Selection bias cannot be corrected by data analysis techniques. In traditional surveillance, however, where no selection of subjects occurs, selection bias is not usually a problem.

Misclassification or Information Bias

After subjects are chosen, errors in classification of exposure or outcome are called *misclassification*. For example, suppose that one is comparing postsurgical infections between thoracic and general surgeons. In this hypothetical hospital, the thoracic surgeons do routine urine cultures for all patients with urinary catheters, sputum cultures for all intubated patients, and vascular catheter tip cultures when catheters are removed. However, the general surgeons obtain cultures only when they feel it is necessary. A comparison of infection rates shows higher infection rates for the thoracic surgeons when all that has really happened is that infection status has been misclassified.

Misclassification may be differential or nondifferential. Differential misclassification means that, in a case–control study, exposure is incorrectly determined to a differing extent among those with versus without disease or, in a cohort study, that disease is incorrectly determined to a differing extent among those with versus without exposure. Differential misclassification may bias the calculated relative risk away from the null value of 1.0, making the relative risk either falsely high (for risk factors with relative risk >1.0) or falsely low (for protective factors with relative risk <1.0). Conversely, nondifferential misclassification would mean that exposure was recorded incorrectly to a similar extent for those with and without disease, or disease was recorded incorrectly to a similar extent in those with and without exposure. This type of misclassification biases the relative risk toward the null value of 1.0.

Note that mere low sensitivity does not mean that data are not useful. The reliability of data primarily depends on how consistent the sensitivity remains in the data collection. National data on sexually transmitted diseases and food-borne illnesses such as salmonella gastroenteritis have a consistent sensitivity of around 0.01 or 1%, but these data remain useful because the sensitivity has been relatively constant at that level over time, so that secular increases or decreases are evident. Data with higher levels of sensitivity but greater variability are actually less reliable in making valid comparisons. Benchmarking comparisons among facilities should be attempted only when a practitioner has some measure of the comparative sensitivities of data from different populations.

A Broader View of Bias

Bias can be more generally defined as a systematic deviation from the truth: any trend in the collection, analysis, interpretation, publication, or review of data that can lead to conclusions that are systematically different from the truth *(13)*. In the analysis phase of a study, if one has a strong preconceived idea of what the answer should be, then a biased analysis and interpretation of the data may result. If one keeps analyzing and reanalyzing data with a view to finding something statistically significant to publish, eventually a satisfactory result will be found. This has been expressed as "If you torture data enough, it will confess to anything." Publication bias results when studies that show a statistically significant difference between study groups are published, whereas other studies of the same topic that did not show such a difference remain unpublished.

Inaccuracy of Hospital Surveillance

Errors in routine hospital surveillance for healthcare-associated infections could result in either reporting of spurious episodes of infection or lack of reporting of true infections. In practice, the latter problem is much more common. Patients with true healthcare-associated infections escape detection because (a) not all relevant data are present in the medical record or laboratory reports; (b) the data collector may overlook relevant data; and (c) the physician did not order appropriate tests to detect the infection. Estimates of the loss of sensitivity due to (a) and (b) above are shown in Table 2-2. In this table, all sensitivities are related to a composite standard, including data from multiple independent surveys of the medical record, bedside examination, and microbiology laboratory records.

The effect of point (c) above was measured in the Study of the Efficacy of Nosocomial Infection Control (SENIC) (14,*15*). The overall culturing rate, which was the proportion of patients with signs or symptoms of any infection that had at least one appropriate culture done, was 32% in 1970 and 40% in 1975 to 1976 (14). The proportion of febrile patients from whom at least one appropriate culture was obtained was 28% in 1970 and 45% in 1975 (14). These measures varied substantially from 5% to 95% by hospital type and region of the country. Patients in academic hospitals in the northeast United States had the highest likelihood of being appropriately cultured. It follows that patients in such hospitals were more likely to have a healthcare-associated infection documented. For urinary tract infections, pneumonias, and bacteremias, the lack of availability of objective data was a major determinant of observed rates of infection *(15)*.

The National Nosocomial Infections Surveillance (NNIS) system, now replaced by the National Healthcare Safety Network (NHSN), conducted a study of the accuracy of reporting healthcare-associated infection rates in intensive care unit patients (16). The sensitivity in this study was greatly improved over that found in the SENIC

TABLE 2-2

Sensitivities of Methods of Case-Finding for Healthcare-Associated Infections Quantifying Only Omissions from Limited Data Sources and Errors by Surveyors

Method	*Study (Reference)*	*Sensitivity*
Reference standard: Duplicate surveys + Record review + Bedside examination + Laboratory tests		
	UVA, BCH, CDC (23)[a]	1.00
Single survey: Record review + Bedside examination + Laboratory tests		
	BCH	0.98
Physician self-reports	CHIP (23)[a]	0.14–0.34
Micro laboratory reports	CHIP (23)[a]	0.33–0.65
Micro laboratory reports	UK *(82)*	0.71
Kardex clues (50% sample)	UVA (23)[a]	0.69–0.85
Record review (100% sample)	UVA (23)[a]	0.90
Kardex clues	UK *(82)*	0.49
Ward Ilaison	UK *(82)*	0.58
ICD-9 coded dx	BCH (22)	0.02–0.35
ICD-9 coded dx	Yale *(83)*	0.57
SENIC pilot record review	CDC *(84)*	0.66–0.80
SENIC project record review	CDC *(85)*	0.05–0.95
NNIS	CDC (16)	0.30–0.85

Note: The effects of failure of physicians to evaluate patients with suspicious clinical episodes were not included in these measures. These data do not include losses from unresolved clinical episodes.
[a]Some of these results have previously been summarized in Freeman and McGowan (23).
UVA, University of Virginia; BCH, Boston City Hospital; CDC, Centers for Disease Control and Prevention; CHIP, Community Hospital Infection Protocol; UK, United Kingdom; Yale, Yale University; NNIS, National Nosocomial Infections Surveillance; SENIC, Study of the Efficacy of Nosocomial Infection Control.
(Adapted from Freeman J, McGowan JE Jr. Methodologic issues in hospital epidemiology. I. Rates, case finding, and interpretation. *Rev Infect Dis* 1981;3:658–667.)

project, as the NNIS hospitals correctly reported the majority of infections that occurred. Still of concern, however, was the continuing wide range in the sensitivity that varied from 30% to 85%, depending on the site of infection. In this study, substantial numbers of healthcare-associated infections were missed by prospective monitoring and a different large group was missed by retrospective chart review.

The implications of these findings for benchmarking rates among hospitals are obvious. There is a disincentive for physicians and hospitals to self-report healthcare-associated infections, and this leads to the paradox that hospitals that do the worst job of collecting data and documenting infections report the lowest rates.

External Validity (Generalizability)

The sections above on bias and errors concern internal validity; that is, are we measuring correctly within the population we selected? External validity or generalizability asks the question, are our results applicable in other settings? Generalizability is always a matter of opinion. A lack of bias does not guarantee generalizability. A perfectly done epidemiologic study may or may not be generalizable to a larger population.

Epidemiologists frequently choose to study unrepresentative samples of subjects in order to answer a scientific question cleanly, cheaply, practically, or safely. Although not widely generalizable, a study result may be scientifically sound for the population on which the study was performed. In a randomized trial, for example, potential study subjects and their physicians must determine that it is safe for the study subjects to accept any of the study treatments before they can be randomized. Patients who have a contraindication to one of the treatments cannot be included in the study on the chance that they might be randomized to the contraindicated treatment. Thus, many treatable patients must ordinarily be excluded from randomized trials, rendering the sample of patients on whom the trial is actually performed highly unrepresentative of the population as a whole *(17)*. This lack of representativeness does not indicate that the study is epidemiologically biased, but it may limit the generalizability of the study result to a larger population.

The Collaborative Antibiotic Prophylaxis Efficacy Research Study (CAPERS) of antibiotic prophylaxis for clean (herniorrhaphy and breast) surgery used both experimental and observational components *(18,19)*. In the experimental component, 1,218 patients were randomized to receive or not receive prophylaxis; patients were not included in this study if they or their physicians did not provide consent. In the observational component, 3,202 other patients received prophylaxis at the discretion of their surgeons. Both components showed that about half of the SSIs were prevented by antibiotic prophylaxis. In this particular instance, the result of the randomized trial turned out to be generalizable to the larger group, but this need not have been so.

ACCOUNTING FOR TIME AT RISK

Because many healthcare-associated infections are related to time at risk, and because average lengths of hospital stay are decreasing, state-of-the-art studies must use methods that account for time at risk. Studies of mortality present a similar challenge: we all have one death per lifetime, and that is unavoidable, but it matters very much just when that death occurs. Methods used to account for time at risk include incidence density methods and survival analysis.

Incidence Density

Incidence density studies are a type of cohort study where the denominator is the total person-time at risk for all subjects, rather than the number of subjects. Commonly used denominators in healthcare-related incidence density studies are patient-days (vascular or urinary), catheter-days, and ventilator-days. Of the four most commonly studied healthcare-associated infections, three are device-related and are best studied using incidence density methods: catheter-associated bloodstream infections (BSIs), ventilator-associated pneumonias, and catheter-associated urinary tract infections (20).

Only one of the four (SSI) is best studied using cumulative incidence methods; that is, the denominator is the number of surgical procedures.

If the event being studied is an infection, then incidence density is the number of infections in a specified quantity of person-time in the population at risk. The population at risk is composed of all those who have not yet suffered an infection. After a patient acquires an infection, that patient would be withdrawn from the population at risk. All hospital days for each patient who never acquired an infection would be included in the pool of days at risk, but for a patient who became infected only those hospital-days before the onset of the infection would be included.

Incidence density is the instantaneous rate of change or what used to be called the force of morbidity. For convenience in healthcare epidemiology, healthcare-associated infection rates are usually expressed as the number of events in 1,000 hospital-days, because this usually produces a small single- or double-digit number, but we could have used seconds or years.

The basic value of this measure can be seen when comparing healthcare-associated infection rates in two groups with large differences in time at risk, for example, in short-stay patients versus long-stay patients, or infection rates with peripheral venous catheters versus implanted ports. By contrast, if one looks at events that come from a point source, such as eating vanilla ice cream at a church supper, or events that are not time related, like acquiring tuberculosis during bronchoscopy with a contaminated bronchoscope, the attack rate or cumulative incidence is an excellent measure of incidence. SSIs are usually thought of as having a point source—the operation; therefore, cumulative incidence methods are adequate for studies of SSI.

An incidence density rate = total events/total time at risk for an event. If we have an exposed and nonexposed group, then we define the rate ratio = rate ill in exposed/rate ill in nonexposed. The rate ratio is a measure of the size of effect analogous to the relative risk used in cumulative incidence studies. Rate ratios are sometimes called incidence density ratios, relative risks, or risk ratios. Rate ratios are interpreted in a similar manner to relative risks; a rate ratio of 2 means that disease incidence was twice as great in the exposed group than in the nonexposed group. Note that the units for the denominators of incidence density divide out, so that you will find the same incidence density ratio no matter whether you use time units of seconds or millennia. *P* values for the rate ratio may be calculated by a chi-square or binomial exact method.

Multiple Events in a Single Patient

Standard statistical tests assume that each observation in a data set is independent, having no linkage with other observations. A corollary is that each subject in a study should contribute at most one event to a data set; that is, we should study only first events in an individual. If this rule is not followed, the calculated confidence intervals and *p* values may not be valid. However, it is well-known that a subset of patients will have multiple episodes of infection and other adverse outcomes. Also, patients with a first event are more likely to suffer a second (*21*,*22*,23,24,*25*). For quantitative analyses, these nonindependent events cannot simply be summed. The biologic and statistical import of 5 infections per 100 discharges would be entirely different depending on whether it represented five sequential infections in a single patient or five first infections in 5 different patients.

Furthermore, a first healthcare-associated infection becomes a risk factor for a second, and risk factors for multiple infections are different from the risk factors for a first infection. The simplest way to cope with multiple incident events in the same individual is to restrict quantitative analyses to first events. A second method is to stratify by number of previous infections, for example, study the effect of exposures on risk of first infection, then on risk of second infection, and so on. These individual strata would then be combined into a summary relative risk. However, this method also violates the independence rule for conventional data analyses. A third alternative is to use statistical methods designed for longitudinal or correlated data. This type of analysis is technically complex (see Longitudinal Analysis and Repeated Measures, below).

Survival Analysis

Survival analysis is a second method for accounting for time at risk (3). Survival analysis usually consists of the familiar Kaplan–Meier plot, where at time zero survival begins at 1.0 or 100% and gradually falls off as subjects are followed forward in time. Survival can literally mean not dying, or it can mean remaining free of infection or whatever outcome variable is being studied. The opposite of survival is termed "failure," which again may either mean death or onset of another adverse event. An extremely useful feature of survival analysis is that it can make use of subjects who are lost to follow-up or die of a disease other than that of interest; these subjects are called "censored" since we don't know if they would have failed if we had been able to follow them for a longer period of time.

Statistical packages automatically plot survival curves for two or more groups and calculate a *p* value for the difference between the two groups. Median survival (the follow-up time when the probability of survival is 0.5 or 50%) is often reported. The Kaplan–Meier plot represents a univariable analysis. Multivariable survival analysis is accomplished via regression models, the most common of which is the Cox model (discussed below).

CONFOUNDING AND EFFECT MODIFICATION

Confounding

Confounding can be defined as "a situation in which a measure of the effect of an exposure on risk is distorted because of the association of the exposure with other factor(s) that influence the outcome under study" *(1)*. An intuitive example given in the chapter introduction was "our infection rate is higher than theirs because our patients are sicker than theirs." We can set up an experimental study to measure the effect of only one exposure at a time, but in observational studies where several exposures may act jointly to produce disease, we often need to use statistical techniques to tease out the independent effect of any one exposure.

TABLE 2-3

Sample Data: Simple and Stratified Analyses

a. Numbers of Patients Total and Infected, Hospitals A vs. B

	High-Risk Patients		*Low-Risk Patients*		
Hospital	*Total*	*Number Infected*	*Total*	*Number Infected*	*Overall Infection Rate*
A	900	90	100	1	91/1,000 = 9.1%
B	100	10	900	9	19/1,000 = 1.9%

b. Simple (Crude) Analysis: Effect of Hospital

Hospital (Exposure$_1$)	*Total Patients*	*No. (%) Infections*	*Relative Risk*
A	1,000	91 (9.1)	4.8
B	1,000	19 (1.9)	—

c. Stratified Analysis: Effect of Hospital Stratified by Patient Risk

Patient Risk (Exposure$_2$)	*Hospital (Exposure$_1$)*	*Total Patients*	*No. (%) Infections*	*Relative Risk*
High	A	900	90 (10)	$RR_1 = 1.0$
High	B	100	10 (10)	—
Low	A	100	1 (1)	$RR_2 = 1.0$
Low	B	900	9 (1)	—

Note: Mantel–Haenszel summary relative risk (RR_{MH}) = 1.0.

Example of Confounding by Severity of Illness Let's hypothetically assume that we were studying healthcare-associated infections at two hospitals, A and B. In our simplified example, there are two types of patients: high-risk patients who have a 10% risk of disease per hospitalization and low-risk patients who have a 1% risk. During a time period, hospitals A and B both admit 1,000 patients, but hospital A admits 900 high-risk and 100 low-risk patients, whereas hospital B admits 100 high-risk and 900 low-risk patients. Using hospital A as the exposed group, the relative risk is 9.1/1.9 = 4.8; that is, the risk of infection after admission to hospital A was 4.8 times higher than after admission to hospital B (Table 2-3).

This is an example of confounding. We are primarily interested in the relationship between one exposure (hospital A, which we shall denote as exposure$_1$) and disease. However, the effect of a second exposure (high- vs. low-risk patient, denoted by exposure$_2$) confuses or confounds our ability to measure the effect of exposure$_1$. This occurs because of an unequal mix of exposure$_2$ among the exposure$_1$ groups (high-risk patients comprise 90% of hospital A admissions but only 10% of hospital B admissions).

Stratified Analysis Stratification is an important method to detect and control for confounding. First, we compute a simple or crude relative risk by our usual 2 × 2 table methods (Table 2-3b). Second, we perform a stratified analysis: we calculate two relative risks (RRs), designated RR_1 and RR_2. In the above example of hospitals A and B, RR_1 measures the effect of hospital A among high-risk patients and RR_2 the effect of hospital A among low-risk patients (Table 2-3c). In this example, both RR_1 and RR_2 are equal to 1.0. Third, with the help of a statistical program, we compute a Mantel–Haenszel summary relative risk (RR_{MH}), which is a weighted average of RR_1 and RR_2. In this example, the RR_{MH} was also 1.0 (i.e., null result), indicating that there was no association between hospital and infection after adjusting for patient risk.

There was an obvious case-mix difference between hospitals A and B. The RR_{MH} is our prediction of what the crude relative risk would have been if there had not been a case-mix difference between the hospitals. Calculating an RR_{MH} is a way of adjusting for a potential confounding exposure, and thus the RR_{MH} is a type of adjusted relative risk. Other methods of calculating an adjusted relative risk include indirect standardization and regression modeling (these methods are presented later in this chapter).

Calculation of Mantel–Haenszel Relative Risk and Odds Ratio If there are i strata, the four cells of the 2 × 2 table are designated a_i, b_i, c_i, and d_i; the total number of subjects in each stratum is $n_i = a_i + b_i + c_i + d_i$; and $\sum$ indicates the sum over all i strata:

$$\text{Mantel–Haenszel summary relative risk} = \frac{\sum a_i(c_i + d_i)/n_i}{\sum c_i(a_i + b_i)/n_i}$$

$$\text{Mantel–Haenszel summary odds ratio} = \frac{\sum (a_i d_i)/n_i}{\sum (b_i c_i)/n_i}$$

Recognizing Confounding The following is a simple functional definition of confounding: if the adjusted relative risk differs to a meaningful extent from the crude relative risk, then confounding is present. There is no statistical test or firm guide for how great the difference must be.

In the hospital A versus B example above, the RR_{MH} of 1.0 differed substantially from the crude relative risk of 4.9, so confounding was obviously present. We say that the effect of $exposure_1$ (hospital A vs. B) was confounded by the effect of $exposure_2$ (high- vs. low-risk patients). In order for confounding to occur, both of the following are required: $exposure_2$ must be associated with disease and $exposure_1$ must be associated with $exposure_2$.

Additional Examples of Confounding Older age, female gender, and instrumentation of the urinary tract are risk factors for urinary tract infections. If we want to measure the effect of instrumentation alone, a simple 2×2 table analysis will be confounded by the effects of the other two variables. However, confounding can be adjusted for if one has data on the confounders (age and gender) and uses an appropriate statistical method.

Investigators in the SENIC project reported a relative risk of 0.94 for healthcare-associated infections in hospitals with infection surveillance and control programs compared with those lacking such programs, or a preventive effect of 6%. One could argue that this small apparent preventive effect could have been due to confounding factors that were imperfectly measured and adjusted for. Measurement of such small differences may be beyond the capabilities of statistical methods applied to observational data.

Quality assurance (26–28) is an area of healthcare epidemiology beset with difficulties posed by confounding variables. The degree to which the unalterable characteristics of the individual patient determine the inherent susceptibility to infection and probability of death are only partially defined, yet must be controlled for to make interhospital quality assurance comparisons meaningful *(29)*. After adjustment for severity of illness, using objective comparisons, it is often difficult to detect differences in hospital care that led to excess mortality *(30)*.

Methods to Deal with Confounding We can prevent confounding in the design phase of a study by doing a randomized trial or by doing a matched case–control study. We can adjust for the effects of confounding in the analysis phase by stratification, by standardization, or by performing regression analyses.

Randomization Randomized trials are rarely used because of their expense and difficulty, but are an effective way to avoid confounding. The magic of randomization is that it produces groups that are similar with respect to both known and unknown confounders. The previously mentioned CAPERS contained both a randomized component, which produced an unconfounded result, and an observation component, which required logistic regression to adjust for multiple confounding variables *(18,19)*.

Matched Case–Control Studies In a simple case–control study, the controls are usually a random sample of all noncases. In a matched case–control study, controls are selected by matching one or more noncases with each case according to some potentially confounding variable. For example, if we wanted to study the effects of an exposure on risk of vancomycin-resistant enterococcus, we would want to control for some well-known risk factors for vancomycin-resistant enterococcus. Therefore, for each case we could select some controls that were closest to the case in a measure of severity of illness such as Apache II score and antimicrobial receipt. To analyze the matched data, we do not do a simple 2×2 table analysis. Instead, we would perform a stratified analysis, where each case and its associated controls form one stratum. The Mantel–Haenszel summary odds ratio is then used rather than the simple odds ratio.

A matched design makes sense only if the potential confounders are well known and one has no need to study them further. In the matched study, one cannot calculate an odds ratio or *p* value for the variables that were used to match the controls (Apache II score and antimicrobial receipt, in the example above). To produce an unbiased odds ratio, we must analyze the data using the stratified method outlined above, thus reducing flexibility in the analysis phase. Also, the *p* value calculated in a matched study will be higher than that from a conventional 2×2 table, reducing the chance of finding a statistically significant result. Rather than matching, well-trained epidemiologists usually prefer to select a random sample of noncases and adjust the data using a multivariable method. However, matching clearly makes sense if an important confounding variable is common in cases and rare in noncases; under such conditions, if random sampling is done, only a few of the controls will have the confounding variable, and much effort will be expended to collect data on controls that have little relevance.

Standardization There are two methods of standardization, direct and indirect. Direct standardization is rarely used in healthcare epidemiology and is not presented here. However, indirect standardization is commonly used in healthcare surveillance. This method is typically used when stratum-specific event rates are available from a large reference population (e.g., a large number of facilities) and we want to compare a smaller group (e.g., a single facility) to this reference population. Any outcome event can be studied by indirect standardization. When applied to infections, indirect standardization produces a standardized infection ratio (SIR) and when applied to deaths a standardized mortality ratio is produced.

The following example of indirect standardization (Table 2-4) uses the incidence density approach to calculate rates and rate ratios *(31)*. We want to compare the BSI rate at a single dialysis center, center X, with the average rate of a large reference group. At center X, we observed 101 BSIs during 3,395 patient-months of follow-up, for a BSI rate of 2.97 per 100 patient-months. The crude rate ratio comparing center X to all centers was 1.67, indicating that the risk of BSI was 1.67 times higher (or 67% higher) at center X.

Vascular access type is a potential confounding variable. Rates of BSI from the reference group vary widely from 0.25 to 8.73 BSIs per 100 patient-months among four vascular access types (Table 2-4). If center X treats more patients with high-risk vascular access (e.g., tunneled or nontunneled catheters) than other centers, we would

TABLE 2-4

Example of Indirect Standardization to Calculate a Standardized Infection Ratio

Vascular Access Type	*BSI Rate[a] All Centers*	*Patient-Months, Center X*	*Expected BSI, Center X*
Fistula	0.25	1,709	4.27
Graft	0.53	528	2.80
Tunneled catheter	4.84	958	46.37
Nontunneled catheter	8.73	200	17.46
Total	—	3,395	70.9

Note: Crude rate ratio = rate at Center X/rate at all centers = 2.97/1.78 = 1.67.
Standardized infection ratio = actual BSI/expected BSI = 101/70.9 = 1.42.
[a]Rate per 100 patient-months. BSI rate for all centers from reference (31).
BSI, bloodstream infection.

expect more BSI at center X. We want to determine the intrinsic risk of BSI at center X if the mix of vascular access types at center X were the same as that at all centers.

To calculate an SIR, we first determine the expected numbers of BSI at center X for each access type by multiplying the all-center rates by the center X denominators (e.g., for nontunneled catheters, $0.0873 \times 200 = 17.46$). Second, we sum the expected values for the four access types to get total expected BSIs = 70.9. If the BSI rates at center X were the same as the all-centers rates, we would have expected 70.9 BSIs at center X. Finally, the SIR is calculated as the ratio of the actual to expected BSIs. The SIR is interpreted as an adjusted rate ratio; that is, after adjusting for vascular access type, the rate of BSI at center X is 1.42 times higher than that at other centers. Notice that the SIR or adjusted rate ratio (1.42) was lower than the crude value (1.67), indicating a minimal degree of confounding by vascular access type.

Effect Modification (Interaction)

Using the terminology of exposure$_1$, exposure$_2$, and outcome, we say that effect modification is present when the effect of exposure$_1$ and exposure$_2$ together is different from what would have been predicted by their independent effects. Cigarette smoking and asbestos exposure as joint causes of lung cancer are a familiar example. Each of these is a risk factor for lung cancer individually, but when both are present, the risk of cancer is particularly high; that is, the relative risk when both are present is even higher than would be predicted from the sum or product of the two individual relative risks. The carcinogenic potential of asbestos fibers is thought to result from their unusual size, which allows them to migrate easily through the lung tissue. In smokers, these fibers become coated with the carcinogenic materials in cigarette smoke, and thus asbestos fibers become a uniquely efficient system for the delivery of powerful carcinogens from cigarettes into lung tissue. Thus, there is biologic plausibility to the epidemiologic finding of effect modification.

Recall that in the example of confounding involving hospitals A and B presented earlier (see Example of Confounding by Severity of Illness, above), the stratum-specific relative risks were equal (i.e., $RR_1 = RR_2$, Table 2-3). In contrast, effect modification would have been present if RR_1 and RR_2 were found to differ. Unlike the situation with confounding, statistical tests may be used to determine whether effect modification is present (see Chapter 3, Breslow–Day test). An example of effect modification is presented below (see Example of Confounding and Effect Modification, and Example of Logistic Regression Model: Healthcare-Associated Infection and Neonatal Mortality, and Tables 2-7 and 2-11).

Although a single RR_{MH} can be calculated when effect modification is present, this is not recommended; instead, report RR_1 and RR_2 separately. The value of identifying effect modification and reporting separate relative risks is to identify subgroups where a certain exposure is a greater or lesser problem, or in which certain treatments may be more or less effective.

Examples of Stratified Analyses

Stratification is a powerful tool to investigate confounding and effect modification. Stratification is simple, intuitive, and accessible, because the data remain visible in tables, and the origin and validity of surprising results can be investigated immediately by reference to the tables containing the data.

Example of Confounding Without Effect Modification In the following example, the effect of healthcare-associated infections (exposure) on mortality (disease) was studied in the neonatal intensive care unit at the Utah Medical Center (32). Note that in this instance healthcare-associated infection, which we usually consider to be the disease or outcome, was instead considered the exposure. The crude relative risk was 2.46, indicating an association between infection and death (Table 2-5). However, if low birth weight is also a cause of death acting jointly with healthcare-associated infection, and infection occurs preferentially in low-birth-weight infants, then the crude relative risk is incorrect, having been confounded by birth weight. To investigate this possibility, we can stratify by birth weight and see how the answers change (Table 2-6). Note that, for simplicity, we have left out several lines from each table.

Adjusting for birth weight produced an adjusted relative risk of 1.89, which represents a substantial change from the crude value of 2.46 (Table 2-5 vs. Table 2-6 and Fig. 2-1). Thus, low birth weight was a substantial cause of mortality in this data set and confounded the original relative risk. The crude estimate of the relative risk of mortality with healthcare-associated infection of 2.46 was 30% too high—it represented the added effect of low birth weight that was mixed in with the effect of healthcare-associated infection in causing death (Fig. 2-1). After adjustment to remove the confounding effect of low birth weight, the relative risk was lower, the *p* value was larger, and the lower bound for the relative risk was closer to 1.0

There might also have been a slight trend of increasing relative risks (from 1.44 to 2.65) as birth weight category increased. If the relative risk were significantly

different in the different strata, this would represent effect modification. However, statistical testing did not show that the relative risk differed significantly among the strata, and instead the relative risks from the various strata appear to represent random variation from a true underlying relative risk. Therefore, effect modification was not present and the reporting of the RR_{MH} was appropriate.

Example of Confounding and Effect Modification In another study of mortality with healthcare-associated infections from a different neonatal intensive care unit, data were available on underlying disease as well as birth weight *(25)*. Infants in neonatal intensive care units have only a few different diagnoses, and of these underlying diseases, only the persistence of a patent ductus arteriosus (PDA) appeared to have any influence on the outcome

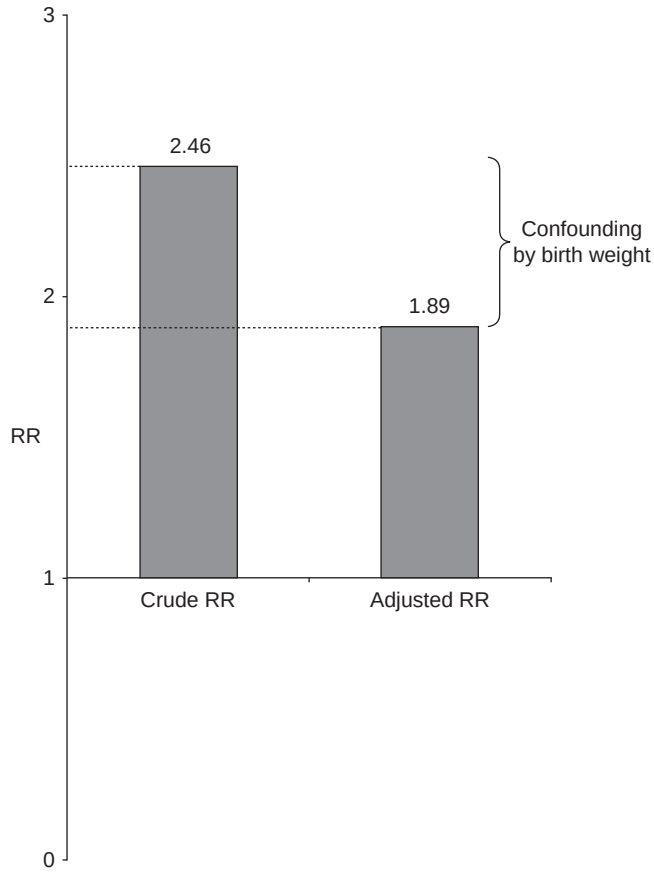

FIGURE 2-1 Crude and adjusted risk ratios for the association of healthcare-associated infection with death in neonates in Utah for Table 2-6, showing the effect of confounding by birth weight.

(survived vs. died). The data, stratified on birth weight and PDA, are presented in Table 2-7. Again, the interest is in the effect of healthcare-associated infection (exposure) as a cause of mortality (outcome), but here we can also consider effect modification and confounding by the two extraneous variables, birth weight and the presence of a PDA. If we combine all of the data from this study into a single table (Table 2-7) and look at the crude effect of healthcare-associated infection on mortality, without stratifying by birth weight or PDA, this crude relative risk is 3.20. If we adjust for birth weight, the relative risk is 2.16, indicating confounding.

We can now investigate whether PDA modified the effect of healthcare-associated infection as a cause of death among these neonates. The relative risk of healthcare-associated infection on mortality was 0.88 for infants with PDA versus 5.01 for those without PDA (Table 2-7). This heterogeneity of the effect of infection on mortality according to PDA status was highly significant (chi-square value = 7.3, $p = .007$), indicating that effect modification was present. Because the effect of healthcare-associated infection is so obviously different for neonates with and without PDA, it makes no biologic or statistical sense to combine these two groups. Thus, the crude and adjusted relative risks of mortality with healthcare-associated infection are presented separately for those with and without PDA. The crude and adjusted relative risks and the effect modification by

PDA, patent ductus arteriosus.
Crude relative risk[a] = 3.20.
Relative risk adjusted for birth weight[b] = 2.16.
Stratified by PDA:
With PDA, relative risk = 0.88.
Without PDA, relative risk = 5.01.
Breslow-Day test for effect modification, chi-square = 7.3, $p = .007$.
Stratified by PDA and adjusted for birth weight:
With PDA, relative risk[b] = 0.90.
Without PDA, relative risk[b] = 3.42.
[a]All relative risks are the relative risk of death (outcome) for infants with nosocomial infection (exposure).
[b]Mantel–Haenszel relative risk.

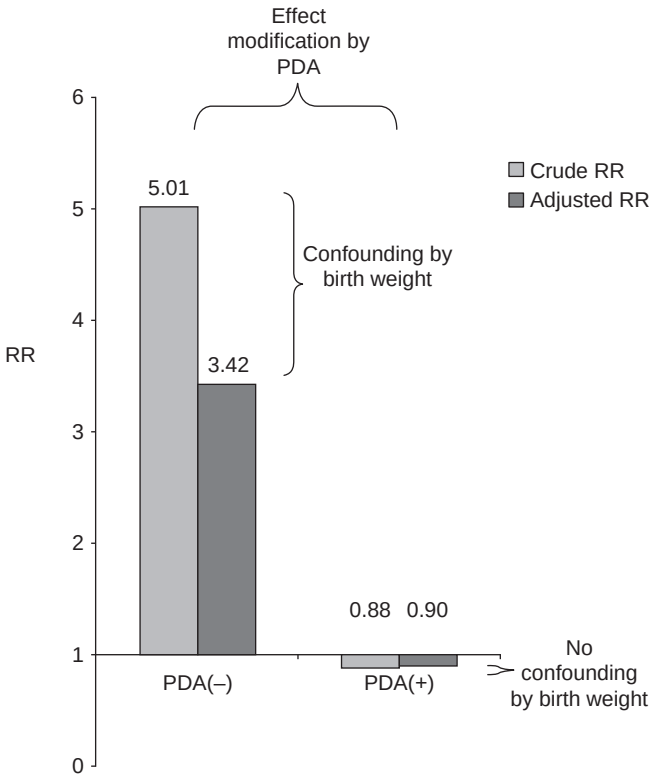

FIGURE 2-2 Crude and adjusted risk ratios for the association of healthcare-associated infection with death in neonates for Table 2-7, showing the effects of confounding by birth weight and effect modification by patent ductus arteriosus (PDA) status.

PDA are presented visually in Figure 2-2. Investigation of effect modification provides more biologic information concerning which patients (those without PDA) will be affected and also shows how much greater the effect will be for that group.

Finally, we both stratify by PDA and adjust for birth weight. Birth weight was not a confounder among those with PDA (crude relative risk = 0.88, $RH_{MH} = 0.90$; Table 2-7), but was a strong confounder among those without PDA (crude relative risk = 5.01, $RH_{MH} = 3.42$). Similar results are obtained when these data are analyzed by logistic regression later in this chapter (see Example of Logistic Regression Model: Healthcare-Associated Infection and Neonatal Mortality, below, and Table 2-12).

Example of Confounding When Incidence Density Is the Outcome Measure One frequently needs to correct for differing durations of exposure while investigating the effect of a specific exposure on an outcome. Incidence density data taken from an investigation of an apparent outbreak of healthcare-associated bacteremia with coagulase-negative staphylococci in a neonatal intensive care unit are presented in Table 2-8 (32). Neonatologists were convinced that an epidemic of bacteremia had occurred in 1982, so the number of individuals with first positive blood cultures for coagulase-negative staphylococci were enumerated for that year and for 1975. The numbers of patient-days at risk for a first positive blood culture were also accumulated for these neonates. On a simple level, the neonatologists were

TABLE 2-8

Longitudinal Comparison of Incidence Densities of Blood Cultures Positive for Coagulase-Negative Staphylococci in a Neonatal Intensive Care Unit

	Positive Cultures/Days at Risk		
Birth Weight (g)	*1982*	*1975*	*Incidence Density Ratio*
500–749	3/535	0/10	Unbounded
750–999	8/1,034	2/358	1.4
1,000–1,249	1/424	2/821	1.0
1,250–1,499	1/213	1/567	2.7
1,500–1,749	0/179	1/233	0.0
1,750–1,999	0/455	0/351	Undetermined
2,000+	3/1,880	2/1,289	1.0
Totals	16/4,720	8/3,629	

Ratio of numbers of cases 2.0.
Risk ratio crude for birth weight = 1.54, indicating an apparent 54% increase in 1982.
Mantel–Haenszel adjusted risk ratio = 1.13 (95% confidence interval 0.44–2.86).
There was no significant heterogeneity by birth weight, $p > .05$.
(Adapted from Freeman J, Goldmann DA, McGowan JE Jr. Methodologic issues in hospital epidemiology. IV. Risk ratios, confounding, effect modification, and the analysis of multiple variables. *Rev Infect Dis* 1988;10:1118–1141.)

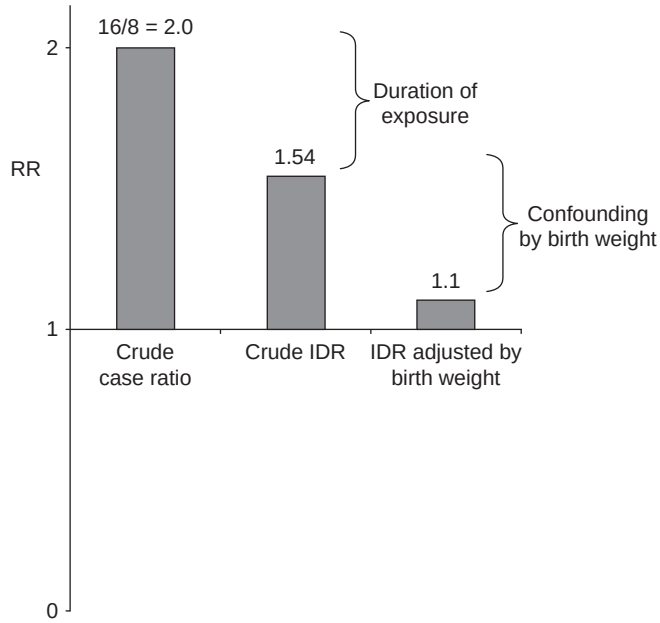

FIGURE 2-3 Crude, partially adjusted, and completely adjusted incidence density ratios for the longitudinal comparison of bacteremias in neonates in Table 2-8, showing the confounding effects of time at risk and of birth weight.

correct, because the number of bacteremias had doubled from 8 to 16, a relative risk of 2.0. Accounting for patient-days at risk led to a crude incidence density ratio of 1.54 (16/4,720 vs. 8/3,629). This incidence density ratio corrects for the much longer exposures to hospital experienced by the smallest neonates in 1982, and reduces the apparent relative risk from 2.0 to 1.54. This example used patient days for the incidence density denominator, whereas central or umbilical line-days are typically used for surveillance (20).

Finally, we can also adjust for birth weight in this analysis, and the adjusted incidence density ratio is approximately 1.1, indicating no real change in the bacteremia rate (Fig. 2-3). Note that different statistical programs and methods may produce slightly different results. In the original article, the authors combined the two strata containing infants with birth weights from 1,500 to 1,999 g to avoid a table with a zero marginal total, and calculated an adjusted relative risk of 1.13. Using OpenEpi, the Mantel–Haenszel adjusted relative risk is 1.16 if all seven strata are used and 1.14 if the 1,500 to 1,999 g birth weights are combined.

Inspection of the data shows many more patient days contributed by the lowest birth weight infants (those under 1,000 g) during 1982 than in 1975. What occurred was not an epidemic of bacteremia but *an epidemic of survival among the smallest neonates*. Important insights are thus gained through simple inspection of the stratified data.

Summary: Confounding and Effect Modification

To reiterate, several factors or determinants, acting jointly, are almost invariably responsible for a single outcome in healthcare epidemiology. Confounding is the case-mix–induced distortion of the relative risk for one exposure by the effects of other exposures. Effect modification is the biologic interaction of two exposures to produce an unexpectedly high or low relative risk. Confounding and effect modification are compared in Table 2-9. A general scheme for collection and analysis of data for epidemiologic comparisons is presented in Table 2-10.

To detect confounding and effect modification, first calculate a crude relative risk; then perform a stratified analysis, calculating RR_1 and RR_2 separately and an RR_{MH}. If the crude relative risk and the RR_{MH} differ to a meaningful extent, then confounding is present; report the RR_{MH}. If RR_1 and RR_2 are statistically significantly different, effect modification is present; report RR_1 and RR_2 separately and do not report the RR_{MH}.

CONTINUOUS VARIABLES

Epidemiologists most commonly deal with dichotomous (e.g., exposed yes or no, infected yes or no) categorical variables. However, continuous variables that can take on an infinite number of values, such as age, height, and weight, are also seen. Continuous variables can be plotted to form a frequency distribution. These data may be approached differently depending on whether they form a normal (bell-shaped) distribution. If the data are not normally distributed, transforming the data, as by taking the logarithm, may result in a normal distribution.

If data are normally distributed, the central tendency is described by the mean and the spread (how closely the values cluster around the mean) by the standard deviation; parametric methods (i.e., *t*-test, analysis of variance) are used to calculate *p* values that test whether the mean values in two or more groups are significantly different. If data are not normally distributed, the central tendency is best

TABLE 2-9

Comparison of Confounding and Effect Modification by a Third, Extraneous Variable, Which is Neither the Exposure nor the Outcome Under Study, in a Specific Epidemiologic Comparison[a]

	Confounding	*Effect Modification*
Comparison of attributes		
Effect on comparison	Always distorting: distorting effect may be positive or negative; not itself informative (see Tables 2.5–2.8)	Not distorting (unless also a confounder); provides additional information (see Table 2.7)
Source and generalizability	One specific data set; not a feature of biology; will differ among data sets containing same comparison	Biology/the real world; likely to be similar in most data sets containing same comparison; probably a real attribute of the biology of a disease
Analytic strategies:		
Observe effect in analysis by	Comparison of crude and adjusted measures	Comparison of effect across strata
Determine quantitative importance in analysis by	Subjective observation of magnitude of distorting effect in context of a specific study (see Tables 2.5–2.8)	Objective tests for heterogeneity of effect across strata of effect modifier: subjective inspection for effects in opposite directions

Note: In an epidemiologic comparison, a single extraneous variable may be a confounder, an effect modifier, neither, or both.
[a]Suggested methods refer to epidemiologic comparisons with discrete outcomes and utilize stratification as the primary analytic strategy. Reference is made to one or more of the studies reanalyzed in this chapter by table number.
(Adapted from Freeman J, Goldmann DA, McGowan JE Jr. Methodologic issues in hospital epidemiology. IV. Risk ratios, confounding, effect modification, and the analysis of multiple variables. *Rev infect Dis* 1988;10:1118–1141.)

described by the median and spread by the interquartile range (the 25th–75th percentile); nonparametric methods (i.e., Mann–Whitney *U* test, Wilcoxon test) are used to calculate *p* values for differences among groups.

In the following example, we determine whether maternal age was significantly related to disease in a neonatal intensive care unit outbreak. There were nine cases and 173 noncases. The simplest approach is to dichotomize age at its median (26.5 years) and analyze the data in the familiar 2×2 table. This yields a relative risk = 3.5 and *p* value = .17.

		Disease		
		Yes	No	
Exposure	Age ≤26.5	7	84	91
	Age >26.5	2	89	91
		9	173	182

To analyze age as a continuous variable, we used the freeware program EpiInfo. The mean ± standard deviation maternal age was 21.9 ± 5.3 years for cases versus 26.95 ± 6.2 for noncases. EpiInfo produces two *p* values, one parametric *p* value = .018 and a nonparametric *p* value = .0226. In this package, parametric *p* values are calculated assuming the variances are equal in the two groups; other statistical packages compute an additional parametric *p* value that assumes the variances are different in the two groups. Parametric *p* values are based on calculating the variances and are valid only if the data are normally distributed, whereas nonparametric *p* values are valid regardless of the distribution. For simplicity, nonparametric *p* values are often used in epidemiology. As in this instance, the nonparametric *p* value is usually marginally higher, that is, less likely to be statistically significant, than the parametric value. Note that the *p* values obtained by treating maternal age as a continuous variable ($p = .02$) are lower than the value obtained in the 2×2 table above after converting to a dichotomous variable ($p = .17$).

The above example was for analysis of unpaired continuous variable data. Alternate methods are used for analyzing paired values, for example, scores on a test before versus after an educational program. Rather than just averaging the mean of all scores before and comparing it with the mean of all scores after, we can take advantage of some additional available information, that is, that we know each score before corresponds to a score after. In brief, the method is to compute the difference between the before versus after scores for each subject, so that one value per subject is obtained, and then to statistically test the null hypothesis that the difference equals zero. This provides a more precise answer and can be done by either parametric or nonparametric methods.

ADDITIONAL TOPICS IN HEALTHCARE EPIDEMIOLOGY

Hypothesis-Generating Versus Hypothesis-Testing Studies

The classic hypothesis testing approach is to state a hypothesis, for example, postulate an association between one or a few exposure(s) and disease(s), and then deliberately collect data to verify or refute the hypothesis. Most explanations of how to conduct and analyze epidemiologic studies refer to this approach, that is, focusing on an exposure of primary interest and checking for confounding or effect modification from secondary exposure variables. However, in practice many modern epidemiologic studies take an alternate approach, namely, to evaluate a number of exposure variables and report whether any are significantly associated with disease. Using this approach, which is one type of

TABLE 2-10

General Approach to the Collection and Analysis of Data for Epidemiologic Comparisons With Discrete Outcomes[a]

Action	*Details of Method*
Collection and preliminary inspection of data	
Anticipate confounding and effect modification	Collect data on multiple variables associated with exposure or outcome; include data on severity of underlying illness and indications for therapy (if therapy was used)
Preliminary stratification for inspection of data	Stratify data repeatedly over a number of extraneous variables that might confound comparisons or modify the effect of an exposure on an outcome; experiment with alternative categorizations; determine workable sizes for strata
Preliminary inspection for presence of confounding variables	Compare crude risk ratios with risk ratios adjusted for various extraneous variables; identify and retain variables for which adjustment alters the risk ratio in an epidemiologically meaningful way
Preliminary inspection for presence of effect modification	Compute stratum-specific risk ratios for different categories of various extraneous variables; identify and retain variables for which the risk ratio appears to vary across strata: if different categories produce risk ratios in opposite directions, then any summary estimate will be misleading (see Table 2.7): plan to report stratum-specific values
Test for effect modification	If different categories produce risk ratios of varying magnitude in same direction, formally test for heterogeneity of effect over strata: if no significant heterogeneity is present, plan to use Mantel-Haenszel summary risk ratio (see Tables 2.6, 2.7, 2.8); if significant heterogeneity is present, look for pattern to heterogeneity; also, plan to use standardized summary risk ratio
Final analysis and presentation of data	
Select variables for inclusion in final analysis	Retain confounding variables and variables that modified the effect of the exposure on the outcome as stratification variables in the final analysis
Select categories for stratification of confounders and effect modifiers	Choose most efficient and informative categories for stratification; use multiway stratification if necessary to include multiple variables simultaneously (see Table 2.7)
Present data in stratified format so readers can observe confounding and effect modification	Give summary risk ratios with confidence intervals if appropriate; compute Mantel–Haenszel estimates if there is no significant effect modification; compute standardized estimates if effect modification is present and stratum-specific risk ratios in same directions; give standard and reason for choice

[a]Suggested methods utilize stratification over levels of variables that may confound a comparison and/or modify the effect of the exposure on the outcome under study.
(Adapted from Freeman J, Goldmann DA, McGowan JE Jr. Methodologic issues in hospital epidemiology. IV. Risk ratios, confounding, effect modification, and the analysis of multiple variables. *Rev Infect Dis* 1988;10:1118–1141.)

hypothesis-generating study, there is no exposure of primary interest—all are created equal.

Repetition of data analyses with varying assumptions or methods until a statistically significant result is obtained have been called "data dredging" or "data torturing." Any complex data set will contain many apparent associations. Some of these are real and causal, whereas others are the result of random processes and represent no true association. Therefore, associations are less likely to be valid and reproducible if found in a hypothesis-generating study and should be interpreted with the caveats regarding performance of multiple testing and attention to Hill's criteria for causality.

A valid approach is to use one data set for hypothesis generation and a second independent data set for hypothesis testing. If only one data set is available, this can be divided into two, with the first for hypothesis generation and the second for hypothesis testing.

Multiple Comparisons

Strictly speaking, our use of the *p* value assumes that only one potential exposure is being evaluated. If the variable is statistically significant at the .05 level, there is a 5% chance that this association occurred due to chance alone. We are willing to accept this chance of error. However, if a large number of potential exposure variables are evaluated, the probability that one or more will be significant by chance alone rises. To compensate, it has been proposed that the required level of significance be set to approximately .05 divided by the number of variables tested (Bonferroni correction). For example, if 10 variables were tested, then we would require a *p* value of approximately .005 for statistical significance. This approach or other more sophisticated methods to account for multiple hypothesis testing is increasingly used in the literature. However, many epidemiologists prefer not to use rigid formulae such as these, but to interpret findings by considering Hill's criteria for causation as well as the *p* value and the number of variables considered. For example, if 15 independent statistical tests are performed, we can calculate that there is a 54% chance, that is, $1 - (1 - 0.05)^{15}$, that at least one would be statistically significant at the .05 level *(33)* and interpret any statistically significant findings accordingly.

Subgroup Analyses

Classically, studies specify a primary hypothesis, for example, that a given exposure is a risk factor for disease. It is common to additionally report the results of the exposure in subgroups; for example, the exposure may be a significant risk factor in men but not in women or in older but not in younger subjects. Testing in a large number of subgroups is a form of "data-dredging" that will often produce at least one statistically significant result. Therefore, subgroup analysis should be supported by statistical tests for interaction and generally considered to be hypothesis generating rather than hypothesis testing. Other guidelines for reporting subgroup analysis include presentation of a subgroup analysis in the published abstract only if it was a primary study hypothesis, indication of the number of prespecified subgroup analysis performed and reported, indication of the number of post hoc subgroup analyses performed and reported, and indication of the potential effect of multiple testing on type I error *(34)*.

Stratifying Continuous Variables and Analyzing Multilevel Tables

In data analysis, it is often necessary to construct appropriate groups from a continuous variable. An example is the grouping of neonates by birth weight. The cutoff values used to divide the groups can be chosen by allocating the same number of subjects in each group (e.g., quartiles with 1/4 of the subjects in each group), dividing the group at even numbers (e.g., 750–1,000 g), or using cut points that are widely used and accepted. The method used should be nonbiased (i.e., the cutoff values should not be manipulated to produce a predetermined result), include an adequate number of subjects in each stratum, and include subjects with a similar risk of the outcome in individual strata. Multilevel categorical variables result from this grouping.

To analyze multilevel categorical variables, we use a variation of the 2×2 table methods previously presented for dichotomous or binary exposure variables. In an example of the effect of birth weight on neonatal mortality, the continuous exposure variable birth weight has been divided into four groups to form a categorical multilevel variable (Table 2-11). Note that as the birth weight increases, the percent of neonates who died decreases from 22.2% to 5.7%; this is an example of a dose–response relationship as mentioned in Hill's criteria for causality. These data are analyzed by forming multiple 2×2 tables with the lowest rate stratum (≥2,000 g) acting as the nonexposed group in each (Table 2-11a–c). The number of 2×2 tables will be one less than the number of strata of the multilevel variable. Compared with the reference category, birth weight ≥2,000 g, which is assigned relative risk = 1.0, the risk of death was 1.44 times higher for 1,500 to 1,999 g, 2.31 times higher for 1,000 to 1,499 g, and 3.87 times higher for <1,000 g. Individual *p* values for each 2×2 table may be reported along with the individual relative risks. However, it is well to also calculate a test for heterogeneity among the four categories; this tests the null hypothesis that the rates are the same in the four birth weights. In this example, the chi-square value of 24.8 with three degrees of freedom indicates a highly significant difference in mortality among the birth weight groups.

Epidemic versus Endemic Disease

The approach to data collection and analysis may differ for epidemic versus endemic diseases. An epidemic is simply an increase in the frequency of occurrence of events above the usual level, often due to a high relative risk operating over a short period of time. Simpler cumulative incidence methods may be adequate for investigation of epidemics, but incidence density methods are generally preferable for measuring more subtle effects in surveillance of endemic disease. Of note, up to 90% of healthcare-associated infections and other adverse events are endemic rather than epidemic (35).

The approach to data interpretation may also differ during an epidemic. An epidemiologist should be more concerned with the biologic import of observed events, the size of the effect, and potential future events than with statistical significance. Hospital epidemics tend to involve small numbers and an epidemiologist may have to act before a sample size large enough for a contrast to reach statistical significance can be collected. A single unexpected fatality should trigger the same investigation as do multiple, less serious events *(36)*.

Systematic Reviews and Meta-Analyses

A systematic review is a "review of a clearly formulated question that uses systematic and explicit methods to identify, select, and critically appraise relevant research, and to collect and analyze data from the studies that are included in the review" *(37)*. Meta-analysis refers to the use of statistical techniques in a systematic review to integrate the results of included studies *(37)*. Using meta-analysis, the results (e.g., estimates of the relative risk) of multiple studies may be pooled to produce a single estimate that may be more informative and precise than any of the individual estimates. Meta-analyses may resolve uncertainty when reports disagree and produce more objective summaries of the literature than might be possible with unaided intellectual interpretation. In addition, meta-analyses may answer new questions not posed at the start of individual trials.

Originally, *meta-analysis* had meaning only in terms of randomized trials *(38)*, but it is now commonly used for observational studies as well. The results of randomized trials are, on average, unconfounded because of the randomization process. A summary of unconfounded study results will itself be unconfounded. On the other hand, meta-analysis of confounded observational studies will produce a confounded summary result.

The simplest statistical method to perform meta-analysis is to perform a stratified analysis where each separate study forms one strata and an RR_{MH} is calculated. As in conventional stratified analyses, we would not want to calculate and report an RR_{MH} if the relative risks differed significantly among the strata, that is, if there was heterogeneity of the relative risks. This amounts to a form of effect modification where the variable causing the effect modification is the study itself. Probably the most important epidemiologic issue confronted in a meta-analysis is the determination of whether there is heterogeneity among studies *(4,38–43)*. This is the same heterogeneity issue described in Table 2-7.

TABLE 2-11

Analysis of a Multilevel Variable Created by Categorization of a Continuous Variable

				Indicator Variables[b]		
Birth Weight (g)	***Died, n(%)***	***Survived (n)***	***Relative Risk***[a]	***BW1***	***BW2***	***BW3***
<1,000	14 (22.2)	49	3.87	1	0	0
1,000–1,499	20 (13.2)	131	2.31	0	1	0
1,500–1,999	13 (8.3)	144	1.44	0	0	1
≥2,000	31 (5.7)	509	1.0	0	0	0

Note: Data collated from Table 2-7.
Test for heterogeneity, chi-square = 24.8, three degrees of freedom, $p < .001$.
[a]See Table 2-11 a–c for calculation of the relative risks.
[b]For use in logistic regression model (Table 2-12).

TABLE 2-11A

		Died		
		Yes	*No*	
Exposure	<1,000	14	49	63
	≥2,000	31	509	540

Relative risk = (14/63)/(31/540) = 3.87, $p < .0001$.

TABLE 2-11B

		Died		
		Yes	*No*	
Exposure	1,000–1,499	20	131	151
	≥2,000	31	509	540

Relative risk = (20/151)/(31/540) = 2.31, $p = .004$.

TABLE 2-11C

		Died		
		Yes	*No*	
Exposure	1,500–1,999	13	144	157
	≥2,000	31	509	540

Relative risk = (13/157)/(31/540) = 1.44, $p = .3$.

There are two additional threats to the validity of a meta-analysis. First, publication bias may mean that studies with a statistically significant effect were more likely to be published and therefore to be included in the meta-analysis. Publication bias can be assessed with a funnel plot, that is, a scatterplot with one dot for each study, sample size plotted on the vertical axis, and effect size on the horizontal axis. If there is no publication bias, the scatterplot will be symmetric; if publication bias is present, there will be more small-sample studies with a large effect size than those with a small or negative effects (44). Second, variations in the quality (generally forms of misclassification or confounding) of studies included may bias the result. Criteria for the quality of studies included should be set, and a detailed checklist of items should be reported (*45*,46) (see also Chapter 7).

Quasi-Experimental Studies

The prefix "quasi" means "having some resemblance usually by possession of certain attributes." Here, we are referring to studies that have some resemblance to a randomized controlled study, for example, observational studies that aim to evaluate an intervention. Such pre–post intervention studies are very common, in part because of the difficulty and expense of performing formal randomized trials (47). A recent example is the successful use of a package of proven infection control measures to reduce catheter-associated bloodstream infections in Michigan hospitals *(48)*. These studies have a number of potential limitations: (a) confounding; that is, patients in the pregroups and postgroups may differ in severity of illness or other ways difficult to measure and control

for; (b) regression to the mean; that is, if infection rates in the preintervention period are higher than the historical mean, they will tend to decrease toward the historical mean in the postintervention period regardless of an intervention *(49)*; (c) preexisting temporal trends; that is, the infection rate may be increasing or decreasing independent of the intervention; and (d) seasonal trends in certain (especially outpatient respiratory) diseases, which may coincide with premeasurement or postmeasurement periods (47,*50*).

Quasi-experimental studies can be strengthened by using more sophisticated designs. For example, a simple study might have only one group with infection rates measured before and after an intervention (47). A more robust design might have two groups followed over time, only one of which receives the intervention. Another way to improve validity is to use more sophisticated data analysis methods that account for confounding variables, temporal trends, changes in temporal trends, and autocorrelation among infection rates measured several times both before and after an intervention *(51)*.

Propensity Scores

A related problem is the use of observational data, rather than a randomized study, to assess the effect of a treatment on disease. In this case, treatment is the exposure variable in an observational epidemiology study. Often the analysis is confounded by the fact that patients who receive a given treatment differ from those who do not. For example, treated patients may be sicker than those not treated. A standard approach to this problem would be to use a multivariable model with disease as the outcome variable and controlling for as many confounders as possible. However, if disease is uncommon, the number of confounders that can be adjusted for is limited. An alternate approach is to control for the propensity to receive treatment *(17,52)*.

The steps in using a propensity score are (a) construct a logistic model where the outcome variable is receipt of treatment and all available factors influencing receipt of treatment are included as explanatory variables; (b) based on the model, assign each patient a probability of being treated; (c) group the patients into categories (e.g., quintiles) with similar probabilities of being treated; and (d) measure the effect of treatment on disease while controlling for these propensity categories *(53)*. Thus, patients with a ¼ chance of receiving treatment are compared with other patients having a ¼ chance of receiving treatment, and so on, improving the reliability of the result. Propensity scores are useful when there are few patients with disease, many patients receiving the treatment, and many measured factors that are associated with receipt of treatment. However, unlike randomization, analyses adjusted for propensity score cannot control for the effects of unmeasured confounding variables.

One example of the use of propensity scores was to investigate whether intensive care unit mortality was lower for patients cared for by critical care specialists versus other physicians *(54)*. Patients cared for by critical care specialists had substantially higher severity of illness than other patients and would be expected to have higher mortality, and so an analysis that stratified for propensity to receive treatment from an intensivist was used. In a second example, the authors determined the effect of candidemia on hospital mortality, length of stay, and cost *(55)*. Propensity scores were used to compare patients with candidemia to patients without candidemia but who had the same propensity for exposure to *Candida*.

Sensitivity, Specificity, and Predictive Values

Suppose that we have a recognized laboratory method that we consider the "gold standard" (referred to as the "standard") and a proposed newer method (referred to as the "test") that may be cheaper, faster, or have some other advantage. We want to see how the newer test compares with the recognized standard. We run many specimens by both methods and arrange the data in the same format as the 2 × 2 table ("Yes" indicates a positive test, and "No" indicates a negative test). This same format can be used to compare two case definitions, two methods of collecting data, etc., as long as one can be considered the accepted standard.

		Standard: Yes	Standard: No	
Test	Yes	a	b	$a + b$
	No	c	d	$c + d$
		$a + c$	$b + d$	

We can then define four performance characteristics of the new test:

- Sensitivity = $a/(a + c)$: Of all true positives, what proportion were identified by the test?
- Specificity = $d/(b + d)$: Of all true negatives, what proportion were identified by the test?
- Positive predictive value = $a/(a + b)$: Of those positive by the test, what proportion are true positive?
- Negative predictive value = $d/(c + d)$: Of those negative by the test, what proportion are true negative?

Sensitivity and specificity are biologic characteristics and are not influenced by the frequency of disease in the population. On the other hand, the predictive values are influenced by the frequency of disease in the population. Thus, if the disease is rare in a population, the positive predictive value will tend to be low even if specificity is high. Stated another way, if the test is applied in a population where there are few true positives, then a large number of false positives (cell b in the 2 × 2 table) will be found, and most of those found to be positive will in fact be false positives (cell b will be higher than cell a).

There is a trade-off between sensitivity and specificity. A change that makes the test more sensitive (more able to detect true disease) will usually make it less specific (less able to exclude nondisease). This relationship can be depicted graphically as a receiver operating curve plotting sensitivity versus 1–specificity (56).

Sample Size and Power

Assume that there is a true difference in rates of disease in the exposed versus nonexposed populations that would be found if a very large number of subjects were studied.

However, by chance alone, a study of a limited sample of these subjects might or might not find a statistically significant difference. Power is the probability of finding a significant difference between the exposed and nonexposed in your *sample* of study subjects if there really is a difference in the rates in the *populations* from which the samples were taken. Power = 1—the probability of type II error, where type II error is the probability of not finding a significant difference when there really is a difference between the rates in the two populations.

Calculations of sample size and power involve specifying the following *(1)*:

- The rate of illness in the nonexposed group
- The rate of illness in the exposed group (or the relative risk)
- The *p* value required for statistical significance (usually .05) and whether a one- or two-tailed test will be performed
- The ratio of the number of exposed to nonexposed subjects

If the above four are specified, then one can additionally specify the power desired and calculate the sample size required. Alternately, one can specify the sample size and calculate the power that will be achieved. These calculations can be made easily by shareware programs such as EpiInfo, OpenEpi, and WINPEPI. For example, assume that the rate of SSI last year (nonexposed) was 4%, and one wanted to have 80% power to detect an SSI rate of 8% this year (exposed; relative risk = 2.0) with $p < .05$; entering these assumptions into the computer program, we would find that we would need 1,202 subjects, 601 exposed and 601 nonexposed. These types of calculations should probably be used more frequently in planning hospital surveillance, so that surveillance efforts can be continued for a sufficient period of time to detect a predetermined rate of illness.

In a prospectively planned study, it is desirable to have ≥80% power to detect a difference between exposure groups. A hypothesis-testing study with marginal power to detect a true difference generally will not be worth conducting. On the other hand, power calculations may not be crucial in pilot studies or hypothesis-generating studies. Power calculations are at best only a crude estimate that cannot anticipate all the intricacies of the final data set; for example, the need to control for confounders may increase the sample size needed. Additionally, planning for sufficient power may not be possible during an outbreak investigation, where, in the interests of protecting patients, one should usually proceed even though the number of subjects involved may be too small to yield a desirable degree of power.

For studies showing a statistically nonsignificant effect, calculations are sometimes performed to show that the sample size was inadequate to detect statistical significance given the measured rates of disease. However, such post hoc power calculations are misleading and should not be performed or relied upon *(57)*. For example, consider a study showing 2/20 (10%) ill in the exposed and 1/20 (5%) ill in the nonexposed, relative risk = 2.0, 95% confidence interval = 0.2–20.3 (nonsignificant). A post hoc calculation shows that if the true population relative risk were 2.0, the total sample size of 40 has only 9% power to find a significant difference. This low power is predictable given the nonsignificant result. If the relative risk of 2 encouraged us to do a larger study with 874 total subjects, which we calculate has 80% power to detect a population relative risk of 2.0, we might be disappointed to find the rates of disease to be similar, say 7.5% in both the exposed and unexposed groups. The problem with the post hoc power calculation stems from assuming, based on the results of the smaller study, that the true population relative risk is 2.0, when in fact we are only 95% sure it is between 0.2 and 20.3.

Shareware Programs for Epidemiologic Analyses

EpiInfo, available from the Centers for Disease Control and Prevention, was originally developed in DOS format in the 1980s. The current windows version allows the user to create data entry screens, enter and manage data, sort and print data, and perform bivariate and multivariate regression analyses *(58)*. A "Utilities" tab provides access to DOS versions of Statcalc, which permits quick entry of the four elements of a 2×2 table and calculation of the relative risk, odds ratio, *p* values, and confidence intervals; and a sample size and power calculator (see Chapter 15). OpenEpi is an online program developed by the creators of EpiInfo that performs many of the same functions but does not have data entry and management capabilities (59).

WINPEPE, a freeware program that performs a wide variety of epidemiologic and statistical calculations, can be downloaded from www.brixtonhealth.com *(60)*. This software does not have data entry and management capabilities, but some modules can import and analyze data sets created by other programs. Chapter 3 of this textbook contains a number of examples of the use of WINPEPE.

R is an increasingly popular statistical freeware program written in a language similar to S-plus that provides a platform for development of data analysis packages *(61)*. A strength is its sophisticated graphics, mapping, and spatial analytic tools. Currently, R is not the most convenient option for performing the typical analyses used by epidemiologists and is more appropriate for sophisticated analyses performed by mathematicians and statisticians. However, as its development continues and documentation improves, R may be an increasingly viable freeware option.

SaTScan is a DOS-based program for detection of disease clusters across both time and space *(62)*. It was first developed to scan for clustering of chronic diseases, more recently has been used for analysis of syndromic surveillance data *(63)*, and currently is being adapted for use in defining clusters of antimicrobial resistance *(64)*.

MULTIVARIABLE REGRESSION ANALYSIS

As noted in the introduction, regression modeling is used increasingly in the medical literature despite the lack of training of most healthcare epidemiology personnel in its use. Published articles using regression models show numerous omissions, such as lack of documentation of identification, coding, and selection of potential confounders and effect modifiers, and no investigation of potential nonlinearity of response (65). Multivariable models can be validly produced only by those well trained and experienced. This section is merely an introduction and overview. Essential reading is a paper by Sander Greenland (66), which is a literate description of the use of multivariable

models in epidemiologic research. For most epidemiologists, it is more important to understand how to interpret results of regression models than to actually fit them. However, some insight into the regression "black box" will benefit everyone who either collects or interprets data.

Regression models are used to identify confounding and effect modification, calculate adjusted relative risks and *p* values that are free of confounding and reflect the independent effects of variables, find which of several potential variables are independently associated with disease, and make predictions. Regression analysis makes it much easier to sift through a large number of variables to find the few that are significant predictors. Additionally, regression models produce a more precise result (narrower confidence interval) than other multivariable methods such as stratification. However, with these advantages come the potential for abuse: fitting models has become easy enough that well-meaning but inadequately trained individuals may easily and efficiently produce incorrect results.

Automated Algorithms for Modeling

Many statistical packages provide the capability for automated model building. This may occur by forward selection, starting with the single most highly statistically significant variable and adding one variable at a time to the model, or by backward elimination, starting with all variables in the model and removing nonsignificant variables one by one. The backward elimination method may produce poor results if too many variables are under consideration. Automated methods typically use *p* values for selecting variables; human judgment and intervention are required to consider biologic plausibility, confounding, effect modification, and nonlinearity of response. Automated methods may sometimes be used by experienced personnel as a first step in producing a model, but should never be relied on by inexperienced personnel to produce a final model.

Practical Aspects of Model Building

Model building requires skill and experience and cannot be reduced to a cookbook approach. It is not too difficult to fit a model involving cumulative incidence data and only a few dichotomous (e.g., yes or no) exposure variables. For this simple case, a model that controls for potential confounding can be produced. Complexity is introduced by the presence of a large number of potential exposure variables, a small number of cases, multilevel exposure variables (i.e., ≥3 levels), continuous (e.g., age, weight) exposure variables, colinearity among exposure variables, and effect modification. Additional complications include the need to account for time at risk (as in incidence density or survival analyses) and study designs with nonindependent records (see below).

Two variables are collinear if they measure nearly the same biologic property. An example would be two severity-of-illness scores that include many of the same components. It is advisable to identify colinearity by exploration before multivariable analysis. If collinear variables are introduced into a model, large changes in the regression coefficients and *p* values may occur. It may be obvious that only one of these variables can be in the model, but there is no statistical test to indicate which to choose.

All variables should be examined by univariable (e.g., 2×2 tables) methods first, and some should be further explored in stratified analyses. Continuous variables should be explored by plotting; for the model, they should be divided into categories (e.g., quartiles) and represented by indicator variables (Table 2-11).

Criteria for inclusion of a variable in a model include:

- The variable is statistically significant (usually $p < .05$) when in the model.
- The variable is an exposure of primary interest.
- The variable is a confounder of an exposure of primary interest. An informal rule of thumb would be that the variable produces a change of ≥10% in the regression coefficient of the variable of primary interest.
- The variable is of special biologic interest, for example, has been found in previous studies to be an important predictor.

Variables are introduced into the model one at a time and retained in the model if they meet one of the criteria for inclusion listed above. Continuous variables should be examined in several ways: as a simple continuous variable, as the continuous variable plus its square, as a transform (e.g., logarithm, reciprocal) of the continuous variable, and (most importantly) as a series of indicator variables coding (Table 2-11) for discrete categories. If the squared value of a continuous variable is statistically significant, this suggests a curvilinear relationship between the continuous variable and the outcome variable.

The pool of variables to try in the model includes those of special biologic interest and those with less than a certain *p* value in univariable analysis. It may be advisable to set this *p* value at a relatively high level, say .2, since some such variables may prove to have lower *p* values in the model or to be important confounders. Remember that it is necessary that a confounder be associated with the outcome, and a very weak association as indicated by $p > .20$ cannot result in much confounding effect *(67,68)*. Thus, if the available automatic algorithms employing *p* values are to be used for screening for potential confounders, the selection criterion should be set at some much larger value than .05, for instance, $p < .20$.

Effect Modification

After variables have been selected for the model, effect modification should be tested for. Interaction terms can be created by multiplying the main effect variables by one another, two at a time. These terms are then introduced into the model and checked for statistical significance. A problem is that there may be many interaction terms. A model with five main effect variables will have nine potential interaction terms, one or more of which may be significant by chance alone. If an interaction term is found to be statistically significant, one must decide whether to retain it in the final model on much the same basis as other variables, for example, by considering factors such as the *p* value, size of effect, biologic plausibility, and whether it substantially changes the main effects. It may be reasonable to report models with and without interaction terms.

Additional Considerations

In evaluating the validity of a fitted model, a variety of regression diagnostic tools, including analysis of residuals, are available (65,66,*67–74*). These diagnostics are extremely useful when multiple variables appear to carry the same

basic information (colinearity). When the results of fitting a multivariable model to estimate relative risk differ substantively from the results of stratified analysis on the same data, the results of the multivariable analysis are wrong. Remember, again, that no analytic scheme can correct selection bias or misclassification.

Recall that two conditions must be present for an exposure (i.e., $exposure_1$) to be confounded by a second exposure ($exposure_2$): $exposure_1$ must be associated with $exposure_2$ and $exposure_2$ must be associated with disease. Retaining $exposure_2$ in a model when it is not a confounder will, by definition, not change the estimated effect of $exposure_1$ and therefore will not produce a wrong answer. However, there will be a statistical penalty in the sense of an increased *p* value and wider confidence interval for $exposure_1$. Deciding whether to retain a confounding variable may be subjective, and in borderline cases models with and without the confounder may be reported *(68)*.

Multiple Regression Models Commonly Used in Epidemiology

Many types of regression models have been developed, but the following four are most commonly used: multiple linear regression, when the outcome variable is continuous; logistic regression, when the outcome variable is dichotomous; Poisson regression for incidence density data; and the Cox model for survival analysis data.

Linear Regression Linear regression or ordinary least squares regression is used for continuous outcome variables such as length of hospital stay or cost. The regression coefficients obtained in the model may be simply interpreted as in the following example where days of hospital stay is the outcome variable: if the regression coefficient for male gender was 2.0, then males on average had a length of stay 2 days longer than females, and if the coefficient for age ≥60 was 3.0, then patients ≥60 had an average stay 3 days longer than younger patients. The effects of the regression coefficients are combined by addition.

A number of statistical assumptions underlie this model, and one of the most important is that the outcome must be approximately normally distributed. If the outcome is not normally distributed, then the *p* values that arise from fitting a multiple linear regression model are uninterpretable *(69–71)*. Confidence intervals for regression coefficients are easily calculated from standard errors and the distribution of Student's *t*-test. Another very useful quantity that arises from multiple linear regression is the square of the multiple correlation coefficient or the multiple R^2. The multiple R^2 represents the proportion of variation of the outcome variable that is explained by the model. In contrast to other common types of regression models, the regression coefficients in a linear model can be calculated by an exact mathematical formula.

Logistic Regression Logistic regression, the most common type of model used in healthcare epidemiology, is used when the outcome variable is dichotomous (e.g., disease yes or no). The regression coefficient obtained for a variable is the natural logarithm of the odds ratios for that variable. Therefore, to obtain the odds ratio, the regression coefficient is exponentiated. Even in a cohort study, the relative risk cannot be directly determined using logistic regression, and therefore the odds ratio is used where logistic regression modeling is required. However, if data from a cohort study are analyzed using logistic regression, a simple formula can be used to estimate the adjusted relative risk from the adjusted odds ratio obtained from logistic regression *(75)*. The effects of the regression coefficients are combined by adding the regression coefficients or multiplying the odds ratios (see Example of Logistic Regression Model: Healthcare-Associated Infection and Neonatal Mortality, below).

Logistic regression requires less stringent biostatistical assumptions than linear regression but does not inherently adjust for differences in duration of exposure. There is no exact analog for multiple R^2 in logistic regression, but the area under receiver operating curves yields similar information. Unlike linear regression models, logistic regression models do not have exact algebraic solutions, and computers fit them with iterative approximation procedures. Not all models converge to a solution. Iterative fits were practically impossible before the general availability of the computer and still may be difficult for large and complex data sets (see Chapter 3).

Try study questions 8 and 9 in Appendix 1 at the end of the chapter.

Poisson Regression Poisson regression uses incidence density data, that is, the number of cases of disease during a certain person-time of follow-up. Like the incidence density approach, Poisson regression does not account for possible differences in disease incidence during early versus late follow-up. The regression coefficients obtained are the natural logarithm of the incidence density rate ratio. Poisson regression is a valid method to determine the rate ratio for a variable while accounting for time at risk and adjusting for potential confounding from other variables. However, Poisson regression is mainly used when data on individual subjects are not available; that is, Poisson regression is used if we know the total number of cases and the total person-time but do not know the person-time contributed by individual subjects or whether individual subjects were cases. If data on individual patients are known, then survival analysis (Kaplan–Meier plot or the Cox model) is used preferentially. Analogous to logistic regression, the effects of two or more exposures are predicted by adding the regression coefficients or multiplying the rate ratios.

Cox Proportional Hazards Models Cox models were created for survival analysis and are used when the outcome variable is dichotomous and when it is desirable to account for time at risk *(76,77)*. The terminology and methods for survival analysis were presented in an earlier section of this chapter. There are other survival analysis regression methods available, but these depend on modeling the shape of the survival curve. The Cox model represented a breakthrough, because it is not necessary to model the shape of the survival curve. The regression coefficients from Cox models are the natural logarithms of what are called hazard ratios; hazard ratios may be

interpreted as incidence density rate ratios or relative risks. The effects of two or more exposures are predicted in a manner similar to that used in logistic regression. As with logistic regression models, the Cox model can be fit only by iterative processes.

The Cox model assumes that the hazard ratio for a given exposure is constant over time; this is the proportional hazards assumption *(76,77)*. This means that if the hazard ratio for male gender is 2.0, then throughout all times of follow-up males have twice the risk of disease as females. If the hazard ratio for males were 2.0 during early follow-up but 1.0 (or anything other than 2.0) during late follow-up, this data set would not fit the proportional hazard assumption and the Cox model would not be appropriate. If the hazard ratio for a variable changes over the time of follow-up, essentially time is an effect modifier for the variable. The proportional hazards assumption can be investigated graphically or by creating a time-dependent covariate with the logarithm of time and the independent variable *(76)*. If the hazard ratio varies significantly over time, then the proportional hazards assumption is violated. In the previous investigation of the use of multivariate models in the medical literature, checking of the proportional hazards assumption was not reported in more than 80% of publications that used Cox models (65).

Cox Regression With Time-Dependent Covariates An important variant is the Cox model with time-dependent covariates. Although some exposure variables (e.g., gender) are inherent characteristics of the subject, others may vary over a time of follow-up (e.g., neutropenia, Apache II score). Most analysis methods would require some type of compromise for variables that change value; for example, neutropenia could be coded as never, sometimes, or always present. However, the Cox model with time-dependent covariates allows us to actually use different values for exposure variables at different times of follow-up. For example, a study of bloodstream infections in home infusion therapy patients allowed the value of several variables, such as catheter type, to vary as appropriate over time for each patient followed *(78)*.

Example of Logistic Regression Model: Healthcare-Associated Infection and Neonatal Mortality

The data for this exercise are from Table 2-7. The outcome variable was dichotomous (died or survived), and so logistic regression was used. Recall that in logistic regression we always produce odds ratios, even if the data are from a cohort study. We found in stratified analysis that healthcare-associated infection was a risk factor for death, birth weight was a confounder of this relationship, and PDA was an effect modifier.

Our logistic regression starts with model 1 (Table 2-12), which has only healthcare-associated infection (odds ratio = 3.9). We next add three indicator variables for birth weight groups (model 2); Table 2-11 shows how these indicator variables were coded. These indicator variables show the expected increase in mortality as birth weight decreases, and also that the effect of healthcare-associated infection decreases when we control for birth weight (odds ratio decreases from 3.9 to 2.6, suggesting confounding). We can do a statistical test for heterogeneity of the birth weight categories by taking the difference in –2 × log likelihood between models 1 and 2. This difference is 15.6, which can be evaluated as a chi-square with three degrees of freedom, since three variables were added to model 1 to produce model 2. The resulting *p* value for heterogeneity of the birth weight groups = .0014. Next, we add PDA to produce model 3; we note that PDA has a minimal effect on mortality (odds ratio = 1.2, $p = .6$). Finally, we create model 4 by adding the interaction term between healthcare-associated infection and PDA. This interaction term is not highly significant ($p = .03$) but has a substantial effect (odds ratio = 0.16).

TABLE 2-12

Logistic Regression Model: Confounding and Effect Modification in a Study of Neonatal Mortality

Model	*–2 × Log Likelihood*	*Variable*	*Regression Coefficient*	*Odds Ratio*	*Wald p Value*
1	522.4	HAI	1.37	3.9	.0004
2	506.8	HAI	0.97	2.6	.02
		BW1	1.41	4.1	.0001
		BW2	0.79	2.2	.01
		BW3	0.33	1.4	.3
3	506.4	HAI	0.91	2.5	.03
		PDA	0.20	1.2	.6
		BW1	1.36	3.9	.0003
		BW2	0.75	2.1	.02
		BW3	0.32	1.4	.4
4	501.7	HAI	1.65	5.2	.001
		PDA	0.58	1.8	.12
		BW1	1.26	3.5	.001
		BW2	0.71	2.0	.03
		BW3	0.26	1.3	.5
		HAI_PDA	–1.85	0.16	.03

Note: BW1–BW3 are indicator variables for age group (see Table 2-11), and HAI_PDA denotes interaction term between healthcare-associated infections and patent ductus arteriosus.
HAI, healthcare-associated infection; PDA, patent ductus arteriosus.

Model 3 (Table 2-12), without an interaction term, would indicate that the odds ratio was 1.0 (reference group) for infants with no PDA and no healthcare-associated infection, 1.2 for infants with PDA but no healthcare-associated infection, 2.5 for those with healthcare-associated infection but no PDA, and 3.0 (the latter calculated by 1.2 × 2.5 = 3.0) for those with both PDA and healthcare-associated infection. Model 4 indicates that the risks are 1.0, 1.8, 5.2, and 1.5 (the latter calculated by 5.2 × 1.8 × 0.16 = 1.5) for these four possibilities, respectively. The interaction term leads to a markedly different (in this case, lower) estimate of the risk in neonates with both PDA and healthcare-associated infection (3.0 in model 3 vs. 1.5 in model 4) than one would have predicted based on the separate effects of these two variables.

Longitudinal Analysis and Repeated Measures

Standard statistical techniques assume that all observations in a data set are independent. This assumption may be violated in various ways. First, since some patients are more prone to disease than others, most healthcare studies include patients with more than one episode of the illness. One approach to this problem is to study only the first infection for each individual, but this wastes data and does not represent the reality that patients often have multiple events. Second, longitudinal follow-up studies with repeated measurements on individual patients over time are sometimes necessary.

A third issue involves studies carried out at a limited number of medical centers. For example, consider a study done at five hospitals with 100 patients studied at each. Individual hospitals vary greatly in patient populations and style of practice. The 500 records from five hospitals are not independent as would be the case if a random sample of 500 patients from all US hospitals were studied. Methods for adjustment for center in multicenter studies, including the problems of nonindependence, confounding by center, and effect modification by center, have been reviewed (79).

To use all the data available without violating statistical assumptions, we can use methods that were developed specifically for longitudinal or repeated measures studies. The most popular method is the use of generalized estimating equations (GEEs) *(80)*. GEE models can be fit by various statistical packages including SAS; PROC GENMOD uses GEE to fit linear, Poisson, or logistic regression models *(81)*. Fitting these models is more complicated than fitting the other models discussed above. For example, it is necessary to specify the form of the matrix describing the correlations to be accounted for. It is worthwhile to compare the results obtained by standard models including all repeated events, standard models including only first events in a given patient, and the robust estimates from GEE models using various correlation assumptions. If these methods produce similar results, one can feel confident in drawing conclusions, and if they produce different results, more insight into the data is obtained. Fitting models using GEE must be done iteratively for both continuous and discrete data, and the fitting process will not always converge to a solution.

The author acknowledges the substantial contributions of Jonathan Freeman, who authored the original version of this chapter, and much of whose wisdom is retained in the current version.

APPENDIX 1: STUDY QUESTIONS

Question 1

Reliable information on patient admissions and discharges is usually available from the hospital administration. From a list of discharges during a 6-month period, a healthcare epidemiologist selected all cases that suffered at least one healthcare-associated urinary tract infection during hospitalization and an equal number of reference patients who did not acquire such infection during hospitalization. If the healthcare epidemiologist compared the cases of healthcare-associated urinary tract infection with the reference subjects for mortality during hospitalization, would this be a case–control study or a cohort study? (Hint: Carefully identify the exposure and the outcome.) Suppose the noncases were matched to the cases by primary underlying illness, operation, and age. Would this change your answer?

Question 2

Consider again the situation described in question 1. Using the same cases of healthcare-associated urinary tract infection and the same uninfected reference patients, the healthcare epidemiologist then compared the cases with the comparison subjects for events that occurred in the first week of hospitalization prior to the onset of the healthcare-associated infections. Specifically, the epidemiologist compared placement of indwelling bladder catheters among cases and reference patients. (Again, carefully identify the exposure and the outcome.) Would this be a case–control study or a cohort study?

Question 3

Among the discharges for a 6-month period, the healthcare epidemiologist in the questions above found 200 patients who suffered first healthcare-associated urinary tract infections. Of these infected patients, 30 died. The next sequential uninfected patient discharged after each of these infected patients was selected as a comparison subject, and the administrative records indicated that 10 of the 200 comparison patients died. Fill in the table below and calculate the relative risk of mortality with healthcare-associated urinary tract infection (refer to Table 2-1).

		Disease: Yes	Disease: No
Exposure	Yes		
	No		

$$\text{Relative risk} = \frac{\%\ \text{ill exposed}}{\%\ \text{ill nonexposed}} = \frac{a/(a+b)}{c/(c+d)}$$

Optional: If you are interested, compute the value of chi-square. For a single fourfold table, the value of chi-square may be computed as:

$$\text{chi-square} = \frac{(ad-bc)^2(n-1)}{(a+b)(c+d)(a+c)(b+d)}$$

Question 4

If the sampling fraction were changed and 10 times as many unexposed enrolled, with the same probability of infection, what would happen to the estimate of the relative risk? Optional: What would happen to the confidence intervals?

Question 5

Having decided that healthcare-associated urinary tract infections were a problem, the healthcare epidemiologist made a first inquiry into the possible causes of these

infections. The medical records of the above 400 patients were read, and the frequency of use of indwelling bladder catheters in the first week of hospitalization, prior to the onset of urinary tract infections, was determined. One hundred of the 200 infected patients had experienced prior bladder catheterization, but only 10 of the noninfected patients had been catheterized. Fill in the table below and calculate the odds ratio of exposure to bladder catheterization among infected and noninfected patients (see Table 2-1).

		Disease: Yes	Disease: No
Exposure	Yes		
	No		

$$\text{Odds ratio} = \frac{ad}{bc}$$

Question 6

Suppose the sampling fraction among the noncases, that is, those who were outcome-negative, was changed in question 5, and 10 times as many noncases were enrolled, but the odds of having a catheter remained the same in this larger group of noncases. How would this new larger sample affect the estimate of the odds ratio in question 5? Optional: How would it affect the confidence intervals?

Question 7

Suppose you erroneously calculated the relative risk instead of the exposure odds ratio for the data in question 5. What would happen to the relative risk if the new larger sample of noncases were used in this erroneous calculation?

Introduction to Questions 8 and 9

These questions were prepared to entice you to evaluate your own assumptions. As with many things in life, these questions have no unique correct answers.

Question 8

This is a question to help you discover how your brainstem is calibrated with respect to the additive or the multiplicative models in causal inference in epidemiology. Suppose there are two independent determinants of infection, and the first has a relative risk of 3.0 and the second has a relative risk of 5.0. If you use the conceptual framework of relative risks, this means that the relative risk of infection in the absence of either determinant of infection is defined as 1.0; the relative risk of infection with just the first determinant is 3.0; and the relative risk of infection with just the second determinant is 5.0. Now, in your view, what should be the relative risk of infection in the presence of both determinants of infection? Can you defend your choice of a relative risk of either 8.0 or 15.0 on a biologic basis? Remember that your selection of regression models makes this choice for you.

Question 9

After you have decided what the value of the relative risk should be in the presence of both determinants, consider the implications if the actual measured value of the relative risk in the presence of both determinants turns out to be less than the level you predicted (antagonism) or more than the level you predicted (synergy). Note that there are five different values for the relative risk (RR) in the presence of both determinants on which you should comment:

RR < 8.0
RR = 8.0
RR > 8.0 but <15.0
RR = 15.0
RR > 15.0

APPENDIX 2: ANSWERS TO STUDY QUESTIONS

Question 1

The question is whether this is a case–control study or a cohort study. Here the outcome is survival status at discharge (lived or died), and the exposure is healthcare-associated urinary tract infection (or not) prior to discharge. Although individuals who acquired healthcare-associated urinary tract infections were called cases, infection is the exposure. Because subjects were enrolled in this study on the basis of their exposure status (infected or not) and then compared for subsequent mortality, this is an exposure-selective cohort study with count data (numbers of persons). Matching may increase statistical efficiency but has nothing to do with whether this is a case–control or cohort study.

Question 2

In this example, the situation has been reversed, and healthcare-associated urinary tract infection is now the outcome with prior bladder catheterization the exposure. Because subjects were enrolled in this study by their outcome status (infected or not) and then compared for prior exposure to catheters, this is a case–control study.

Question 3

		Disease: Yes	Disease: No	
Exposure	Yes	30	170	200
	No	10	190	200

$$\text{Relative risk} = \frac{30/200}{10/200} = \frac{15\%}{5\%} = 3.0$$

RR = 3.0; chi-square = 11.08; $p < 10^{-3}$

Note: The combination of the relative risk and its 95% confidence interval, 3.00 (1.57–5.73), is much more

informative than just having the relative risk and the *p* value separately.

Question 4

If the sample of the unexposed is increased to 2,000 from 200 but the probability of the outcome remains the same, the relative risk will remain unchanged, but the value of chi-square will increase and the confidence intervals will shrink. The relative risk is 3.00 (2.06–4.37).

Question 5

		Disease: Yes	Disease: No
Exposure	Yes	100	10
	No	100	190
		200	200

$$\text{Odds ratio} = \frac{(100)(190)}{(100)(10)} = 19.0$$

chi-square = 101.3; $p < 10^{-8}$

Question 6

If the sample of noncases is increased 10 times from 200 to 2,000 but the odds of exposure remain the same, the odds ratio will remain unchanged, but chi-square will again increase and the confidence interval will shrink. The odds ratio is 19.0 (14.5–24.9).

Question 7

If one erroneously computes the relative risk from the above case–control study with the original sample size, relative risk = 2.64. If one then erroneously computes the relative risk with the larger sample size, relative risk = 1.82. The sampling fractions do not change the estimates of relative risks when they are calculated correctly.

Question 8

If one believes that independent effects are additive, then the relative risk in the presence of both determinants would be 3.0 + 5.0 = 8.0. If one believes that independent effects are multiplicative, then the relative risk in the presence of both determinants would be 3.0 × 5.0 = 15.0. Which is applicable depends on your point of view and the underlying biology.

Question 9

Any value less than your projected estimate would indicate antagonism between the two determinants, and any value greater than your projected estimate would indicate synergy between the two determinants. In either model, a relative risk of 7.0 in the presence of both determinants would indicate antagonism, and a relative risk of 16.0 would indicate synergy. However, if you believe in the additive model, then a relative risk of 10.0 would represent synergy, but if you believe in the multiplicative model, then the same relative risk of 10.0 would indicate antagonism. Effect modification is the epidemiologic term for synergy or antagonism.

CHAPTER 3

Biostatistics for Healthcare Epidemiology and Infection Control

Elizabeth A. Tolley

It is common knowledge that investigators face challenges during all phases of planning and implementing research protocols. Clinical and experimental researchers possess the necessary expertise for the medical and scientific aspects of their investigations. Moreover, researchers usually have some knowledge of elementary statistical methods. Some researchers find elementary statistics adequate for their purposes and need only an occasional consultation with a biostatistician. However, recent trends in clinical research, especially in healthcare epidemiology and infection control, indicate increasing complexity that demands a higher level of statistical expertise. These general trends are probably going to continue for the foreseeable future—a situation that may leave a researcher feeling somewhat overwhelmed by all of the tasks to be handled in addition to mastery of subject matter. This chapter discusses the challenges and dilemmas related to statistical issues faced by the researcher during the various phases of planning and implementing a research protocol.

Statistics is the science of collecting, analyzing, interpreting, and presenting data. Descriptive statistical methods involve data reduction and summarizing many observations in a few representative numbers. Biostatistics is the application of statistical methods to biologic, biomedical, or health science problems. Data are numeric observations or measurements that result from a random phenomenon or process *(1,2)*. A random process cannot be controlled, and the data collected can never be reproduced exactly. Data from a random process always contain some natural variation. To identify reasons for observed differences among groups of observations, the researcher must sort out the special causes that lead to systematic variation and separate these from the natural variation that is always present. Consequently, decisions will be uncertain. Before making a decision, the researcher uses statistical inference to objectively evaluate data and quantify the level of uncertainty. In addition, the researcher uses statistical models to represent data in terms of special causes and natural variation; these models aid the researcher in making inferences and decisions based on the data.

The numeric observations are in the form of variables, also called *random variables*. Certain statistical techniques apply to each type of random variable (*1*–4,5,*6*,*7*,8,*9*). Measurement variables may be continuous, if the number of values is very large, or discrete, if only few values (generally <10) are possible. Some measurement variables are actually computed variables, for example, Acute Physiology and Chronic Health Evaluation III (APACHE III) scores. A ranked variable is a measurement variable, the values of which have been placed in ascending or descending order and replaced by the ranks. Attributes must translate into numbers (e.g., frequencies of occurrence or number of infected patients). Attributes are sometimes called *categorical variables*. If an attribute can be only present or absent, the term *dichotomous variable* is frequently used.

In today's clinical studies, even the most focused research protocol can yield enormous amounts of information. The typical clinical setting contains a multitude of measuring devices that can provide exquisitely detailed measurements. Many measurements are collected because of availability rather than need. As a consequence, when a study is concluded, an investigator can be faced with the task of sorting through a huge amount of data. Certain measurements or variables are relevant to and necessary for carrying out the specific objectives of a study. An investigator determines what type of data to collect based primarily on specialized knowledge.

Two concepts have especially important implications for investigators. *Accuracy* is the closeness of the measure to the true value; lack of accuracy has to do with bias *(1–3,9,10)*. Before recommending a study or grant for approval and/or funding, most reviewers insist that an investigator show how the results will be unbiased. Thus, the investigator's responsibility includes demonstrating the experimental validity of the study. *Precision* is the closeness of repeated measurements to each other *(2,3,9)*. Importantly, precision has no bearing on closeness to the true value. In fact, precision without accuracy can be a problem when an investigator is trying to make statistical inferences.

Most clinical studies involve samples that are chosen from a population, instead of the entire population (*2–4*,8,11,*12*,*13*). The term *population* refers to the reference or study population. A random sample is a group chosen from a population such that each member of the sample has a nonzero probability of being chosen, independent of any other member being chosen. A simple random sample is the same as a random sample, except that each member of the population has the same nonzero probability of

being chosen. Parameters of the reference population are usually unknown and unknowable. The investigator uses statistics from samples to estimate the parameters of the reference population. Because the sample is smaller than the population, information obtained from the sample is partial, and the investigator uses this information to infer something about the population. Most statistics used in healthcare epidemiology and infection control require the investigator to make the assumptions that (a) the reference population is infinitely large and well defined and (b) the sample behaves like a simple random sample. In practice, the population may not be well defined or infinite. Likewise, the sample may not be random; for clinical studies, samples are often composed of those patients who have been admitted to a particular hospital over a specified period because of certain underlying diagnoses and who have undergone various medical and surgical procedures.

DESCRIPTIVE STATISTICS

In published reports, healthcare epidemiologists summarize patient characteristics with descriptive statistics (*1–4*,5,*6*,*7*,8,*9*,11,*12*,*13*). Typically, a list of patient characteristics includes measures of central tendency and dispersion for continuous variables.

During the research process, the clinical investigator may start exploratory data analysis by obtaining descriptive statistics of important variables. These descriptive statistics have a variety of other practical uses. For example, a potentially important determinant of disease, such as age, may vary only slightly for those patients included in the study; consequently, the clinical investigator may decide not to consider this variable as a potential risk factor in this study. In addition, the researcher may note which variables have highly skewed distributions and, thus, might yield spurious results during data analysis. Finally, unusually high or low values can be identified and verified, if necessary. The following sections describe descriptive statistics for continuous variables.

Measures of Location or Central Tendency

Location refers to where on an axis a particular group of data is located relative to a norm or another group. Measures of central tendency or central location are used to obtain a number that represents the middle of a group of data.

Mean Mean usually refers to the arithmetic mean or average. The mean is probably the most commonly used measure of location. However, the investigator should be aware that the mean is sensitive to extreme values—both very high and very low values. Other means exist but are used less frequently; the geometric mean is an example. An investigator computes a geometric mean by first taking the logarithm of a group of numbers, computing the mean of the transformed values, and then obtaining the antilog of the mean. Blood pH values are logarithms; however, in practice, after calculating the mean of pH values, no one takes the antilog to obtain the mean hydrogen ion concentration. The Greek letter μ is used to represent the population mean. The sample mean $\bar{X}$ is an unbiased estimator of μ regardless of the shape of the distribution. If the underlying distribution is normal, then the sample mean is the unbiased estimator with the smallest variance.

Median The median is the 50% point or 50th percentile and, as such, is insensitive to extreme values. If an odd number of observations is ranked from smallest to largest, the median is the middle observation. If an even number of observations is similarly ranked, the median is the average of the $n/2$ and $(n/2) + 1$ observations where n is the sample size. For example, if the sample size is 20, after ranking, the median is the average of the 10th and 11th observations. For symmetric distributions, the mean and the median coincide. There is no standard symbol for the median of a population or a sample; however, M can be used for connoting the population parameter or the sample statistic *(4)*.

Mode The mode, or the value with the highest frequency, is a measure of concentration. Distributions may have more than one mode. Distributions with two modes are called bimodal. Trimodal refers to distributions with three modes. For symmetric distributions, the mean, median, and mode have the same value. No standard symbol exists for the mode of a population or a sample.

Measures of Dispersion or Spread

Range The range is the distance between the highest (largest) and the lowest (smallest) value. In healthcare epidemiology, investigators often refer to the interquartile range, which is the distance between the 25th and 75th values. Researchers should report ranges with medians; in this way, information on both location and dispersion can be conveyed to others. For a sample, the range is symbolized by R.

Variance The variance is a measure of dispersion that is often used in calculations. Another name for the variance is the mean square. For populations, the variance is called sigma squared and symbolized with the Greek letter σ^2; for samples, the variance is represented by s^2. Because of the availability of inexpensive calculators and spreadsheets with statistical functions, only definitional formulas for the variance of a population and a sample are given, where n is the sample size from a population with N members, and N is much greater than n. For the population, the variance is computed as

$$\sigma_X^2 = \frac{\sum_{i=1}^{n}(X_i - \mu_X)^2}{N},$$

where X_i is the value of the random variable X, measured on each member of the population; i is a unique identifier of each member of the population; μ is the population mean for the variable X; Σ signifies summing the squared deviations of the individual values from the mean over all members; and N is the number of members in the population. For the sample, the variance is computed as

$$s^2 = \frac{\sum_{i=1}^{n}(X_i - \bar{X})^2}{n-1},$$

where X_i is the value of the random variable X, measured on each observation in the sample; i is a unique identifier of each observation in the sample; $\bar{X}$ is the sample mean for the variable X; $\sum$ signifies summing the squared deviations over all observations; and n is the number of observations in the sample.

Standard Deviation The standard deviation is the square root of the variance and is sometimes called the root mean square. The standard deviation is a measure of the average distance from the mean. If the standard deviation is small, the observations are crowded near the mean; if the standard deviation is large, there is substantial spread in the data. For populations, the standard deviation is symbolized with the Greek letter σ; for samples, the standard deviation is represented by s. Standard deviations correspond to means. Occasionally, an investigator must approximate the standard deviation of a future sample. The expected range (i.e., the largest value that one expects to record from a future sample minus the smallest value) divided by 4 provides an approximation when no other information is available.

Other Descriptive Measures

Measures of Skewness Measures of skewness and kurtosis may be computed to evaluate how a distribution deviates from a normal distribution. Most clinical investigators do not routinely need these measures. In practice, the investigator may plot the distribution of the data to evaluate the presence of outliers, those observations with values much larger or smaller than the rest of the sample. A distribution that has a few to a moderate number of high values and a mean that is greater than the median is generally referred to as right or positively skewed. Conversely, a distribution that has a few to a moderate number of low values and a mean that is smaller than the median is generally referred to as left or negatively skewed. In summary, the direction in which the tail of the distribution points characterizes the direction of skew.

Kurtosis Kurtosis refers to how flat or peaked the distribution is relative to the normal distribution. If a distribution is flatter than the normal distribution, it is called platykurtotic. On the other hand, if a distribution is more peaked than the normal distribution, it is called leptokurtotic. For kurtotic distributions, the mean and the median coincide, but the standard deviation is either larger or smaller, respectively, than it would have been if the observations were sampled from a normal distribution.

Coefficient of Variation The coefficient of variation allows the researcher to compare two or more standard deviations, because the standard deviation has been standardized by the mean. The population coefficient of variation is $(\sigma/\mu)100\%$, and the sample coefficient of variation is $(s/\bar{X})100\%$. For most biologic data, the standard deviation increases as the mean increases. Therefore, the coefficient of variation of a particular variable tends to be rather stable over a wide range of values. For experimental studies, the coefficient of variation is an indicator of the reproducibility of the observations. The clinical investigator may use the coefficient of variation to compare variables that may be potential confounders or effect modifiers. For one group of subjects, the spread of different variables may be compared using the coefficient of variation. For two or more groups of subjects, the coefficient of variation may be used to compare the groups with respect to the spread of a particular variable.

PROBABILITY

Many patient characteristics are dichotomous attributes, which are either present or absent, such as fever. Some characteristics have the form of categorical variables with only a few possible states. For example, the investigator may categorize patients according to the presence of a rapidly fatal disease, an ultimately fatal disease, or a nonfatal disease. In some statistical texts, authors apply the term *discrete variable* to a characteristic or attribute with two or more states. In published reports, healthcare epidemiologists summarize these types of patient characteristics by indicating the proportion of the total group with each characteristic of interest.

During the research process, the clinical investigator often begins exploratory data analysis by considering the relationships between pairs of categorical variables. The following sections contain important rules and definitions that the clinical investigator must master before undertaking a complex study. Dichotomous variables are emphasized, because many clinically important risk factors are dichotomous variables.

Definitions and Rules

Many problems in healthcare epidemiology and infection control involve analysis of frequencies for various attributes (e.g., numbers of patients with and without infections). When only two outcomes are possible, the variable is called a dichotomous variable. For this example, a patient either has an infection or does not and cannot be characterized as being in both states simultaneously. Thus, having an infection is a dichotomous variable that represents mutually exclusive states. The infected state is represented by I and the noninfected state by $\not{I}$ (i.e., I stricken through with a line connoting "not"). The probability that an infection is present is represented by p; the probability that an infection is not present is represented by $(1–p)$. Some authors of statistics texts represent $(1–p)$ as q. Mathematically, we express the probability that a patient has an infection by the expression, $\Pr(I) = p$. Because the states are mutually exclusive and only these two states can occur, p and q, or $(1–p)$, sum to 1.0.

Probability can be expressed as a fraction with a numerator and denominator, a decimal fraction or proportion, or a percentage. In this chapter, probability is always a proportion. Probabilities can have any value between 0 and 1.0, inclusive. For dichotomous variables, a probability of 0 implies that an event (i.e., one of the two possible states) cannot occur; a probability of 1.0 implies that the event will always occur.

Researchers in healthcare epidemiology need a basic understanding of some concepts related to probability. After mastering a few easily understood concepts (i.e., three rules and six definitions), the researcher can achieve

a deeper understanding of how and when important statistics, such as risk ratio (RR), are used.

Unconditional or Total Probability In healthcare epidemiology and infection control, researchers must assess total or unconditional probabilities (*1–4*,5,8,*12*,*13*). The definition of a total probability is illustrated in the following example. The probability that a patient chosen at random has an infection may be calculated as the relative frequency of patients with infections: the numerator is the number of patients with at least one infection, the denominator is the total number of patients in the study. If 15 of 45 patients in the medical intensive care unit (ICU) have at least one infection, the empirical probability of being infected is .33. This probability may be symbolized as $\Pr(I) = p = .33$. Thus, the total probability of an event occurring is the number of times the event occurs divided by the number of times that it could have occurred.

Empirical Versus Theoretical Probabilities A clinical investigator obtains empirical probabilities from the sample of patients in the particular study. A better method for estimating the true or theoretical probability of a future patient, π, having at least one infection would involve enumerating all infections in all the patients over a long period. The investigator could continue to expand the sample size by including other units and other hospitals and so on. Finally, after the investigator had gathered a very large group of patients from many locations, the empirical probability would approach the theoretical probability of an average hospitalized patient having an infection. Thus, the theoretical probability of infected patients is the relative frequency for cases of infection over an infinitely large sample. During an investigation of a possible outbreak of disease, infection control officers compare empirical probabilities, p, with theoretical probabilities, π.

Conditional Probability In healthcare epidemiology, researchers are also interested in conditional probabilities (*1*,*3*,*4*,5,8,*12*,*13*). An example of a conditional probability is the probability of pneumonia, given that the patient has been intubated. The condition states the circumstances restricting the type of patients of interest to the researcher. A researcher obtains a conditional probability of healthcare-associated pneumonia given intubation by (a) enumerating the number of patients with the two characteristics (i.e., intubated patients with pneumonia) and (b) dividing by the number of patients who are intubated (i.e., those at risk for ventilator-associated pneumonia). In this example, the conditional probability of having pneumonia given that the patient is intubated may be symbolized by $\Pr(P \mid V)$, where $\mid$ indicates given, P symbolizes a patient with pneumonia, and V symbolizes a patient who is intubated or on a ventilator. Therefore, if 25 patients are ventilated and have healthcare-associated pneumonia and 100 patients are ventilated, $\Pr(P \mid V) = 25/100 = .25$.

Joint Probability and the Product Rule The first rule of probability considered in this chapter is the product rule (*1*,*3*,*4*,5,8,*12*,*13*). The product rule states that for any two events A and B, the joint probability of events A and B occurring together is equal to the product of the conditional probability of A given B times the total probability of B. In this example, the probability of being intubated and having pneumonia is obtained by multiplying the conditional probability of having pneumonia given that the patient is intubated by the probability of the patient being intubated. In the ICU, the joint probability that a patient selected at random will be both intubated and have pneumonia may be symbolized mathematically by $\Pr(P \text{ and } V)$, where P indicates a patient with pneumonia and V indicates a patient who is intubated or on a ventilator. In this example, if $\Pr(V) = .40$ (i.e., 40% of the patients in the study are ventilated) and $\Pr(P \mid V) = .25$ (i.e., 25% of the intubated patients have pneumonia), then $\Pr(P \text{ and } V) = \Pr(P \mid V) \times \Pr(V) = .25 \times .40 = .10$. Thus, 10% of the patients in the study have both characteristics.

Independent and Dependent Events Often the healthcare epidemiologist will want to know if there is an association between two events (*1*,*3*,*4*,5,8,*12*). No causal relationship can be identified without substantially more evidence than that provided by one investigation. In this example, the researcher might be looking for an association between a patient being intubated and development of healthcare-associated pneumonia. Therefore, the epidemiologist wishes to know if the ventilated patients in the study are more likely to develop pneumonia than expected based on the theoretical probability of healthcare-associated pneumonia in the particular ICU. In making this decision, the epidemiologist determines the probability of an average patient developing pneumonia and being intubated under the assumption that these two events are independent (i.e., they have no association). Under independence, $\Pr(P \text{ and } V) = \Pr(P) \times \Pr(V)$. If 20% of the patients in the study have pneumonia, then $\Pr(P) = .20$. Thus, if there is no association between being on the ventilator and developing pneumonia, $\Pr(P \text{ and } V) = .20 \times .40 = .08$. This result implies that one would expect 8% of patients to be ventilated and to develop pneumonia if the assumption of independence is correct for this situation. Based on previous computations, the investigator knows that, in this study, 10% of the patients actually have both characteristics. Because the empirical probability is not the same as the theoretical probability, the conclusion is that there is evidence of an association between intubation and pneumonia. Determining whether this association is evidence of a special cause or merely a reflection of natural variability requires the researcher to use inferential statistics. Inferential methods appropriate for this example are presented in other sections.

In this example, the researcher could have reached the same conclusion by comparing total and conditional probabilities. Under independence, the probabilities are equal; therefore, $\Pr(P \mid V) = \Pr(P)$. For the healthcare epidemiologist, this statement implies that with respect to a patient developing pneumonia, the ventilator is neither a risk factor nor a protective factor; therefore, patients on the ventilator have the same risk of developing pneumonia as any other patient in the study. For this example, $\Pr(P \mid V)$ is .25, a value that is greater than $\Pr(P) = .20$. When these two probabilities are unequal, there is evidence of an association between the two variables of interest.

Addition or Total Probability Rule The second rule is called the addition or total probability rule (*1*,*3*,*4*,5,8,*13*). This rule states that for any two events A and B, the total probability of A equals the sum of the joint probability of A and B plus the joint probability of A and not B: $\Pr(A) = \Pr(A \text{ and } B) + \Pr(A \text{ and not } B)$. For convenience, these probabilities are often displayed in a 2×2 table. Accordingly, the term *marginal probability* is used interchangeably with *total probability*.

Before continuing the discussion of probability, the layout of a 2×2 table is considered. Statistically, no restriction exists that stipulates placement of exposure and disease on a particular margin or the order in which presence and absence are given on a particular margin. However, the interpretability of some measures of association, which specifically apply to epidemiology, depends on a particular arrangement. When an investigator devises a 2×2 table, the proportion of patients with the two attributes and those without the two attributes should be placed on the main diagonal (i.e., cells 1 and 4 of the following table). Epidemiologists have developed other conventions, the use of which has helped to standardize presentation of data. Furthermore, some statistical software products have specific requirements for placement of attributes.

	Exposed to Ventilator	*Not Exposed to Ventilator*	*Total or Marginal Probability of Disease*
Pneumonia present	p_1	p_2	$p_1 + p_2$
Pneumonia absent	p_3	p_4	$p_3 + p_4$
Total probability of exposure	$p_1 + p_3$	$p_2 + p_4$	

In the previous table, p_1, p_2, p_3, and p_4 are joint probabilities. For this example, p_1 is the joint probability of a patient having both exposure to the ventilator and pneumonia. Marginal probability of pneumonia can be calculated as the sum of the joint probabilities. In this example, the probability of having pneumonia, $\Pr(P)$, equals the sum of the joint probabilities, $\Pr(P \text{ and } V)$ and $\Pr(P \text{ and } \not V)$ (i.e., $p_1 + p_2$). The other total probabilities, $\Pr(\not P)$, $\Pr(V)$, and $\Pr(\not V)$, can be calculated by using the addition rule and are displayed in the following table.

	Exposed to Ventilator	*Not exposed to Ventilator*	*Total or Marginal Probability of Disease*
Pneumonia present	$\Pr(P \text{ and } V)$	$\Pr(P \text{ and } \not V)$	$\Pr(P)$
Pneumonia absent	$\Pr(\not P \text{ and } V)$	$\Pr(\not P \text{ and } \not V)$	$\Pr(\not P)$
Total probability of exposure	$\Pr(V)$	$\Pr(\not V)$	1.0

Alternatively, using the definition of joint probability, the healthcare epidemiologist can replace the joint probabilities p_1 and p_2 with the product of the conditional probability of disease multiplied by the respective probability of exposure. The same can be done with p_3 and p_4. Frequently, the healthcare epidemiologist uses this approach when the research question involves identifying risk factors. Typically, the healthcare epidemiologist asks that question before designing a prospective study.

	Exposed to Ventilator	*Not Exposed to Ventilator*	*Total or Marginal Probability of Disease*
Pneumonia present	$\Pr(V) \times \Pr(P \mid V)$	$\Pr(\not V) \times \Pr(P \mid \not V)$	$\Pr(P)$
Pneumonia absent	$\Pr(V) \times \Pr(\not P \mid V)$	$\Pr(\not V) \times \Pr(\not P \mid \not V)$	$\Pr(\not P)$
Probability of exposure	$\Pr(V)$	$\Pr(\not V)$	1.0

Finally, a healthcare epidemiologist may wish to study a particular exposure and describe the relationship of that exposure to the presence of a particular disease. In this example, the investigator would be interested in the probability of exposure to the ventilator given that a patient has pneumonia. Usually, the healthcare epidemiologist asks this question before designing a retrospective study, often a case–control study.

	Exposed to Ventilator	*Not Exposed to Ventilator*	*Total Probability of Disease*
Pneumonia present	$\Pr(P) \times \Pr(V \mid P)$	$\Pr(P) \times \Pr(\not V \mid P)$	$\Pr(P)$
Pneumonia absent	$\Pr(\not P) \times \Pr(V \mid \not P)$	$\Pr(\not P) \times \Pr(\not V \mid \not P)$	$\Pr(\not P)$
Probability of exposure	$\Pr(V)$	$\Pr(\not V)$	1.0

In the healthcare setting, patients are exposed simultaneously to several risk factors. By considering each exposure separately, the healthcare epidemiologist can use this approach to identify the most likely route of exposure given a particular disease.

In summary, when the healthcare epidemiologist investigates the relationship between two dichotomous events (e.g., exposure and disease), the 2×2 table provides a useful and flexible way of displaying the relative frequencies at which the four possible combinations of exposure and disease occur in the sample. Depending on the specific research question, the investigator chooses the most meaningful way to express p_1, p_2, p_3, and p_4.

Applications Relevant to Epidemiology

Epidemiologists measure morbidity in terms of prevalence and incidence. Several applications of probability to epidemiology require the investigator to recognize the distinction between these two measures. Prevalence is the proportion of individuals who have the disease. Stated another way, prevalence is the proportion of individuals who have the disease out of all individuals in the population

(i.e., those who are at risk for the disease). Prevalence can be defined as the probability that an individual has the disease regardless of the time elapsed since diagnosis. In contrast, incidence is the rate at which new cases occur among individuals who were disease free. Incidence is the number of new cases that have occurred over a specified time divided by the number of individuals who were disease free (i.e., at risk for the disease) at the beginning of the period. Therefore, incidence can be defined as the probability that a disease-free individual will develop the disease over a specified period.

Relative Risk or Risk Ratio RR is the ratio of the incidence of a disease among exposed persons to the incidence of a disease among unexposed persons (*1*,*3*,5,8,*12–14*, 15,*16*,17,*18*,*19*,20,*21*,22). Often, epidemiologists use the term *risk ratio* interchangeably with *relative risk*. Values for RR are positive and range theoretically from zero to infinity; however, in practice, the denominator probability (i.e., incidence of disease in the unexposed) determines the upper limit for RR. For example, if the incidence of disease in the unexposed is 0.4, then the upper limit for RR is 2.5. This restriction limits the direct comparability of RRs across locations or studies.

If the probability of disease is equally likely for those exposed and those not exposed, the RR equals 1.0. Whenever the RR equals 1.0, exposure and disease are independent. If the probability of disease is higher for those exposed than for those not exposed, RR is >1.0 and exposure is a risk factor. If the probability of disease is lower for those exposed than for those not exposed, RR is less than 1.0 and exposure is a protective factor. As the RR of disease increases or decreases from 1.0, there is evidence that the two events, exposure and disease, are associated or dependent. Using the information in a tabled display, the infection control officer can obtain two conditional probabilities: $\Pr(P|V) = .25$ and $\Pr(P|\not V) = .167$. Thus, the RR is 1.497. In this situation, the officer would conclude that according to these data, a patient on a ventilator is about 1.5 times as likely to develop pneumonia as a patient who is not on a ventilator.

Odds Ratio When incidence is not known, RR cannot be obtained. However, the RR can be approximated by the odds ratio (OR) (*1*,5,8,*12–14*,15,*16*,17,*19*,20,*21*,22). If the proportion of diseased persons (i.e., prevalence) is small (i.e., <0.1), then the OR is usually a reasonably good approximator of the RR. Therefore, the investigator is responsible for carefully evaluating the OR as an approximator of the RR. In making this evaluation, the investigator must consider whether the disease is chronic or acute. Approximation of the RR is biased when only prevalent cases are used in the analysis. When the duration is short (because of either rapid fatality or cure), the numbers of incident and prevalent cases are very nearly the same; very little bias in approximating RR based on prevalent cases is likely. However, when duration is long, bias can be a problem. For example, when serum cholesterol is used to predict death from heart disease, the OR from prevalent cases is lower than the RR from incident cases. This downward bias occurs, because the individuals with the highest cholesterol values are more likely to have a high fatality rate and thereby to escape detection as prevalent cases. In addition, the investigator should be aware that for a particular sample, the OR will have a more extreme value compared with the RR. If the estimates of the OR and RR based on the sample are >1.0, the estimated OR will be larger than the estimated RR. Conversely, if the estimates of the OR and RR based on the sample are <1.0, the estimated OR will have a value smaller than the estimated RR.

Both RRs and ORs are very useful statistics and have many applications for observational and quasi-experimental studies. Although the clinical investigator often makes the same inferences from an OR as from an RR, these statistics are not interchangeable. Therefore, investigators should be very strict in stipulating whether an estimate is an RR or an approximation based on an OR. Furthermore, it is incumbent on the investigator to demonstrate the validity of any implicit assumption that the approximation based on an OR is a good approximation of RR. Failure to do so can have dangerous consequences involving misinterpretation of published reports and erroneous clinical decisions about patient care.

From the first table, the RR may be computed as a ratio with $p_1/(p_1 + p_3)$ in the numerator and $p_2/(p_2 + p_4)$ in the denominator. If the number of patients with pneumonia is small, p_1 will contribute very little to the quantity $(p_1 + p_3)$; likewise, p_2 will contribute very little to the quantity $(p_2 + p_4)$. The OR equals a ratio with p_1/p_3 in the numerator and p_2/p_4 in the denominator. Statistically, the OR can always be used to approximate the RR. As p_1 and p_2 become smaller, the OR may become a better approximator of the RR. Like RR, the OR ranges theoretically from zero to infinity. However, the OR has a property that can make it a more useful statistic than the RR. The OR is independent of the denominator probability (i.e., an OR of 2.0 has the same meaning regardless of the population or sample on which it was based). The OR is considered the odds of having the disease with the factor present relative to the odds of having the disease with the factor absent. The OR may be calculated from a 2×2 table by calculating the ratio of cross-products (multiplying diagonally): $\text{OR} = (p_1p_4)/(p_2p_3)$.

Sensitivity, Specificity, and Predictive Value The healthcare epidemiologist can use joint, conditional, and total probabilities for quantifying commonly used laboratory tests (5,8,*12–14*,15,*16*,17,*18*,*19*,20,*21*,22,*23*,24,*25*,*26*). The total or marginal probability of disease may be represented as $\Pr(D)$; this probability is an estimate of disease state prevalence in a population. Prevalence can be thought of as the underlying probability of disease state in a particular population. Likewise, $\Pr(\not D)$ can be thought of as the underlying probability of not having the disease state; it is not necessarily the probability of wellness or health.

In terms of conditional probability, the probability of a positive test result given that a patient has the disease—that is, $\Pr(T|D)$—refers to test sensitivity. Similarly, the probability of a negative test result given that a patient does not have the disease—that is, $\Pr(\not T|\not D)$—refers to test specificity. The sensitivity and specificity of a test are independent of prevalence.

The healthcare epidemiologist can display the various possible combinations of disease states and test results in a 2×2 table.

	Positive Test Result	*Negative Test Result*	*Marginal Probability*
Disease present	$\Pr(D) \times \Pr(T \mid D)$	$\Pr(D) \times \Pr(\bar{T} \mid D)$	$\Pr(D)$
Disease absent	$\Pr(\bar{D}) \times \Pr(T \mid \bar{D})$	$\Pr(\bar{D}) \times \Pr(\bar{T} \mid \bar{D})$	$\Pr(\bar{D})$
Marginal probability	$\Pr(T)$	$\Pr(\bar{T})$	1.0

In contrast, the predictive values of a positive test result (PV+) and a negative test result (PV–) depend on prevalence. In terms of conditional probability, the probability of a patient having the disease given that the test result is positive—that is, $\Pr(D \mid T)$—refers to positive predictive value of the test (PV+). Similarly, the probability of a patient not having the disease given that the test result is negative—that is, $\Pr(\bar{D} \mid \bar{T})$—refers to negative predictive value of the test (PV–).

	Positive Test Result	*Negative Test Result*	*Marginal Probability*
Disease present	$\Pr(T) \times \Pr(D \mid T)$	$\Pr(\bar{T}) \times \Pr(D \mid \bar{T})$	$\Pr(D)$
Disease absent	$\Pr(T) \times \Pr(\bar{D} \mid T)$	$\Pr(\bar{T}) \times \Pr(\bar{D} \mid \bar{T})$	$\Pr(\bar{D})$
Marginal probability	$\Pr(T)$	$\Pr(\bar{T})$	1.0

Alternatively, the healthcare epidemiologist may interpret this table in terms of joint probabilities. From this perspective, the epidemiologist considers the probability of an average (or random) patient having a test result that is considered true positive (TP), true negative (TN), false positive (FP), or false negative (FN). Specifically, the probability of a TP test result is a joint probability—that is, $\Pr(T \text{ and } D)$. The other three outcomes may be expressed similarly as joint probabilities. The probability of obtaining a TN result is the joint probability of testing negative and not having the disease. The probability of obtaining an FP result is the probability that a patient selected at random will test positive but not have the disease. Finally, the probability of obtaining an FN result is the probability of a patient selected at random testing negative but having the disease. In practice, these probabilities are often expressed as percentages. These probabilities may be displayed as follows.

	Test Results		*Total Probability*
	Positive	*Negative*	
Disease present	$\Pr(TP) = \Pr(T \text{ and } D)$	$\Pr(FN) = \Pr(\bar{T} \text{ and } D)$	$\Pr(D)$
Disease absent	$\Pr(FP) = \Pr(T \text{ and } \bar{D})$	$\Pr(TN) = \Pr(\bar{T} \text{ and } \bar{D})$	$\Pr(\bar{D})$
Total probability	$\Pr(T)$	$\Pr(\bar{T})$	1.0

Prevalence is the sum of the probability of a TP result and the probability of an FN result. Similarly, the probability of testing positive is the sum of the probability of a TP result and the probability of an FP result. The other two marginal probabilities can be obtained in the same way.

Bayes' Theorem In more complex situations, the healthcare epidemiologist encounters more than two possible clinical signs or symptoms (symbolized as T_i, where i indicates the alternative clinical signs and symptoms) and more than two possible disease states (symbolized as D_j, where j indicates the alternative disease states). The 2×2 tables can be expanded into i columns and j rows, representing clinical findings and disease states, respectively. Bayes' theorem or rule allows the healthcare epidemiologist to obtain the conditional probability of a particular disease given a particular clinical finding (*1*,*3*,5,8,*12*,15,*16*,*18*,*25*). Bayes' theorem or rule states that the conditional probability of D_1 given T_1 equals the joint probability of T_1 and D_1 divided by the sum of the joint probabilities of T_1 and each D_j:

$$\Pr(D_1 \mid T_1) = \frac{\Pr(T_1 \text{ and } D_1)}{\sum_{j=1}^{k} \Pr(T_1 \text{ and } D_j)},$$

where (a) $\Pr(D_j)$ represents the known probabilities of disease states in a specified population and the sum of all $\Pr(D_j)$ values equals 1.0 and (b) the various D_j values are mutually exclusive (i.e., a patient cannot have more than one disease). When healthcare epidemiologists need to choose the most likely explanation for their clinical findings, they often use Bayes' rule to assess the conditional probabilities of several disease states in light of their particular clinical findings. In published literature, epidemiologists may use conditional probabilities to discuss the merits of several alternative explanations. Clinicians may use Bayes' rule to evaluate a number of diagnostic possibilities. They realize that although no test is absolutely accurate, positive test results do tend to increase the probability that a particular disease is present. The conditional probability of disease given certain clinical findings provides a number that quantifies the amount of confidence that can be placed in stating that a particular disease is present. Differential diagnosis, decision theory, and decision making involve applications of Bayes' rule.

HYPOTHESIS TESTING

Hypothesis testing does have a place in analysis of data related to healthcare epidemiology and infection control. One-sample tests can be used to determine whether the sample is different from the reference population. Clinical investigators often use two-sample tests during exploratory data analysis to identify potentially important risk factors. The following sections address general definitions and rules for hypothesis testing for one- and two-sample tests for categorical and continuous variables using parametric and nonparametric methods.

Definitions and Rules

The hypothesis is always formulated about parameters. H_0 designates the null hypothesis and H_1 the alternative hypothesis. Based on sample statistics, the healthcare epidemiologist chooses which is the true situation. For a

one-sample hypothesis test, the reasons for this choice are based on how likely it is that these data could have been obtained from a specified reference population. Similarly, for a two-sample hypothesis test, the reasons are based on how likely it is that the difference between the two groups obtained from these data could have occurred given that H_0 is true. In making this decision, the epidemiologist may make errors. Naturally, minimizing the probability of making an erroneous decision is a paramount concern of the epidemiologist, even though the truth remains unknown and unknowable. The decisions that an epidemiologist can make relative to the truth (*1*,*2*,*4*,5,8,*10*,*25*) are displayed in the following 2×2 table.

	Unknown But True State of Nature	
Decision in Favor of	***H_0 True***	***H_1 True***
H_0	Correct	Type II error
H_1	Type I error	Correct

Traditionally, scientific investigators have agreed on the principle of keeping the probability of a type I error as small as possible. Pr(type I error) is the conditional probability of rejecting H_0 when H_0 is correct. Stated another way, Pr(type I error) is the probability of rejecting H_0 given that H_0 is correct. Statisticians have symbolized Pr(type I error) as α. Another commonly used name for Pr(type I error) is the significance level. The interpretation of a p value is consistent with the definition of the probability of a type I error; a p value gives the probability of finding a result that is at least this extreme, assuming that the H_0 is true. Stated another way, the p value qualifies the rejection of H_0 with a level of significance. An investigator rejects H_0 when the p value is less than α. The p value tells others the statistical significance of the results. Statistical significance has absolutely nothing to do with the scientific or clinical importance of findings.

Another type of error is possible—type II error. Pr(type II error) is the conditional probability of not rejecting the H_0 when H_1 is true. Stated differently, Pr(type II error) is the probability of deciding in favor of H_0 given that H_1 is correct. Statisticians have symbolized Pr(type II error) as β. In practice, statisticians are more concerned with power, symbolized as $1-\beta$. Power is the probability of discriminating between H_0 and H_1, (a) given a specified sample size, a stipulated difference between the values of the parameter under H_0 and H_1, and a particular α; and (b) assuming H_1 is true. Thus, power is the probability of rejecting H_0 when H_1 is true. Power depends on α, H_0 and H_1, and sample size. As α decreases, β increases. As the difference between H_0 and H_1 decreases, power decreases. As sample size increases, power increases—power is very dependent on sample size. Investigators want power to be as large as practically possible, because power represents the probability of correctly rejecting H_0. Typical values for power are 0.80, 0.90, 0.95, and 0.99. Before recommending a clinical trial for approval and/or funding, most reviewers insist that the investigator show that the likelihood of getting conclusive results (i.e., statistical power) is high. In unplanned clinical studies, power may be as low as 0.20 or occasionally even lower. Sometimes, epidemiologists compute power after a study has been completed. Under these circumstances, power is the probability of discriminating between H_0 and H_1, given the findings of the study.

Hypothesis Tests for Categorical Data

A random variable is a numeric quantity that has different values, depending on natural variability. A discrete or categorical random variable is a variable for which there exists a discrete set of values, each having a nonzero probability. Many data from biologic and medical investigations have a common underlying structure.

Cumulative incidence and prevalence of a disease are distributed binomially (*1*,8,*12*). Variables that follow a binomial frequency distribution are characterized by the following criteria: (a) a sample is taken of n independent trials, (b) each trial may have two possible outcomes (e.g., success/failure, present/absent, alive/dead), and (c) the probabilities for the outcomes are a constant p for success and $(1-p) = q$ for each failure for every trial. Usually a healthcare epidemiologist is not concerned with the order in which the failures occurred; instead the epidemiologist is interested in the number of failures and the probability that a number as extreme or more extreme occurred given that H_0 is true.

Generally, an incidence density variable follows a binomial distribution. For variables such as incidence density, the Poisson distribution is often an accurate approximation of the binomial distribution. The Poisson distribution is a discrete frequency distribution of the number of occurrences of rare events (*1*,8,*12*). For the Poisson distribution, the theoretical number of trials is infinite and the number of possible events is also very large. Incidence density studies often involve one or more cohorts of disease-free individuals. A failure is defined as the occurrence of the disease of interest in a previously disease-free individual. The probability of k events (i.e., failures) occurring in a period of time T is defined for a Poisson random variable. Thus, the Poisson distribution depends on two parameters: the length of the interval, T, and the underlying λ, which represents the expected number of events per unit of time. Time may also be defined as a combination of time and level of exposure (e.g., pack-years of smoking or patient-days in the ICU). The mean and the variance of a Poisson distribution are the same. For variables that follow a binomial distribution, when n is large and p is small, the mean and variance will be similar; thus, the Poisson may be used as an approximation of the binomial.

The following two sections describe statistical methods for one- and two-sample tests on binomial proportions or rates (*1*,*3*,*4*,5,*6*,*7*,8,15,*18*,*25*,*27*). Throughout these sections, unless otherwise stated, the significance level is .05; power is 0.80; and all tests are two-sided. In power and sample size formulas, a z-score for the 97.5th percentile is used for a two-sided test with a significance level of .05: $z_{0.975}$ is 1.96. When power of 0.80 is used to determine sample size, a z-score for the 80th percentile is used: $z_{0.80}$ is 0.842.

These sections, describing one- and two-sample tests for binomial proportions or rates, are not designed as casual reading material; instead, they provide a concise reference of commonly used statistical methods. The only

formulas included are those for the test statistics. Most clinical investigators use statistical packages for obtaining sample size estimates or power calculations. For appropriate formulas, the reader is referred to various biostatistical textbooks, for example, Rosner (8) or Sokal and Rohlf *(2)*. For a binomial probability, π refers to the population parameter and p refers to the sample statistic, which approximates the parameter. Each section follows the same format, which is outlined in the following.

Step 1. Set up H_0 and H_1.

The investigator uses the research question to form H_0 and H_1. Generally, H_1 reflects the result that the investigator expects to find (i.e., that there is a special cause that differentiates the study group from the norm). For a one-sample hypothesis test, H_0 states that the proportion of events or rate of occurrence (π) in the study group is the same as some specified or norm value, π_0. The investigator obtains this value, π_0, from some source other than the current study. Typically, the investigator obtains π_0 from theoretically derived values or uses nationally or locally compiled values. In the one-sample situation, H_1 states that the proportion of events or rate of occurrence (π) in the group being studied differs from the specified value, π_0. The investigator estimates π from a sample as p. If the estimated value is sufficiently close to the specified value, π_0, the investigator decides in favor of H_0 (i.e., that the data are consistent with H_0 being true). If the data fail to support H_0, the conclusion is that the data are not consistent with H_0 being true; therefore, the investigator rejects the H_0, concluding that the rate or proportion must be some other value (i.e., higher or lower than π_0).

For a two-sample hypothesis test, H_0 states that the proportion of events or rate of occurrence (π_1) from the first group is the same as that (π_2) from the second group. For a clinical trial, the groups might reflect those receiving and not receiving the treatment. For an observational study, the groups might reflect those subjects with and without the attribute of interest. Interpretations of failing to reject and rejecting H_0 are similar to those described for the one-sample situation.

Step 2. Choose α, power, and the difference between π and π_0 (or π_1 and π_2) that is clinically meaningful. Another term for the difference between π and π_0 (or π_1 and π_2) is effect size. Frequently, investigators overlook this step. For example, the healthcare epidemiologist may not have the opportunity to conduct a formal power analysis before data collection begins. However, whenever the effect size estimated from the sample is clinically meaningful but the results are consistent with H_0, the investigator should determine power retrospectively. This analysis allows the investigator to determine how much larger the sample would have to be to reject H_0, given the results of the study. Even when statistical significance is achieved, a retrospective power analysis can indicate how cautiously the results should be interpreted.

Step 3. Using an available computer package, determine sample size, n. Sample size is extremely sensitive to the effect size chosen by the investigator.

Step 4. Obtain data.

Step 5. Compute test statistic in terms of parameters under H_0. Obtain the p value associated with the test statistic, assuming H_0 is correct. The interpretation of the p value is valid only in terms of H_0 and H_1. By choosing to make a hypothesis test, the investigator restates the research question and must decide between H_0 and H_1 based on how consistent or inconsistent the data are with H_0. The term *consistent* connotes having sufficient empirical support for the investigator to decide that the unknown true state of nature is likely to be H_0 instead of H_1. Conversely, the term *inconsistent* connotes having sufficient empirical support for the investigator to decide that the unknown true state of nature is likely not to be H_0 but rather H_1. Therefore, the p value is the probability of obtaining a result that is at least as extreme as this result, which the investigator has obtained from these data, given that H_0 is true. Stated another way, the investigator rejects H_0 when the results from the study could be called unusual if H_0 were correct. The consensus among statisticians and scientists is that, if the p value is .05 or smaller, the investigator should reject H_0 and decide that H_1 is correct. A p value of .05 indicates that this result would occur no more often than 1 in 20 times if H_0 were true.

Step 6. Decide whether to reject or fail to reject H_0. Compare the p value to α.

One-Sample Tests for a Binomial Proportion or Rate

Normal Approximation Method The normal approximation method based on a z-test was selected because the computation of this test statistic more closely parallels the estimation of confidence limits than any of the other methods. If the normal approximation to the binomial distribution is valid (i.e., $npq > 5$), a two-sided hypothesis test is conducted as follows:

Step 1. Set up H_0 and H_1.

$$H_0: \pi = \pi_0 \text{ versus } H_1: \pi = \pi_0$$

Step 2. Choose α, power, and the difference between π and π_0 that is clinically meaningful.

Step 3. Using an available computer package, determine sample size, n. Sample size is extremely sensitive to the difference between π and π_0 and to how close these are to 0 or 1.0. When no information is available, a pilot study can be conducted to get some idea of differences that can be obtained in a particular clinical situation.

Step 4. Obtain data.

Step 5. Compute test statistic z_s in terms of parameters under H_0, where z_s is a z-score from the standard normal distribution, and obtain the p value as twice the probability associated with the z_s assuming that H_0 is correct. If the significance level is .05, $z_{0.975}$ is 1.96. With the wide availability of computer-based packages that contain statistical functions, many clinical investigators can obtain the p value.

$$z_s = \frac{(p - \pi_0)}{\sqrt{[(\pi_0(1-\pi_0)/n)]}},$$

where p is the estimate from the sample of the parameter π_0. One should note that $z^2 = \chi^2_{[1]}$; the squared z-score, obtained from the data (i.e., z_s), equals a chi-square test statistic with 1 degree of freedom obtained from the same data (i.e., χ^2_s). Most computer packages report a chi-square test statistic with 1 degree of freedom (i.e., χ^2_s) along with the associated p value. If the significance level is .05, $\chi^2_{[0.95]}$ with 1 degree of freedom is 3.84,

which equals 1.96^2. If the normal approximation to the binomial is not valid, p values may be obtained by the exact method.

Step 6. Decide whether to reject or fail to reject H_0. Compare the p value to α.

One-Sided Hypothesis Tests If the hypothesis test is one-sided (i.e., $H_1: \pi > \pi_0$), calculate power and estimate sample size substituting $1-\alpha$ for $1-\alpha/2$ in the previous formulas (e.g., $z_{0.95}$ is 1.645). In addition, the p value is not multiplied by 2. It is always easier to reject a one-sided test than a similar two-sided test. In addition, an effectively larger α increases power by reducing β.

Two-Sample Tests for Binomial Proportions or Rates When the random variable under study is classified into discrete categories, hypothesis testing and methods of inference should reflect the data structure. For the two-sample situation, there are two typical study designs: independent and paired samples. Before formulating the hypothesis, the investigator must determine whether the samples are independent or not. Two samples are independent when the data points in one sample are unrelated to the data points in the second sample. Samples that are not independent are paired. Paired samples may represent two sets of measurements on the same individuals. Alternatively, paired samples may represent measurements on different individuals chosen or matched such that each member of the pair is very similar to the other. Statistical analysis of data from clinical studies is valid only in the context of the study design; inferences are only valid in the context of research questions.

When a healthcare epidemiologist investigates the relationship between two dichotomous variables, the observations are tabulated in 2×2 tables according to attributes. For example, suppose the epidemiologist classifies observations according to the following two attributes:

Attribute 1: A, $\not{A}$
Attribute 2: B, $\not{B}$

The results will be classified into four groups that include all possible combinations of attributes 1 and 2: (A and B), ($\not{A}$ and B), (A and $\not{B}$), and ($\not{A}$ and $\not{B}$). After tabulation, data can be presented in the following format, where a, b, c, and d are the frequencies at which the four groups occur in the sample.

	B	$\not{B}$	*Total*
A	a	b	$a+b$
$\not{A}$	c	d	$c+d$
Total	$a+c$	$b+d$	n

The results of studies with either independent or paired designs may be tabulated according to the frequencies into the same four groups. Thus, this table can be obtained in different ways.

Two-Sample Tests for Independent Samples Both the table and the test statistic are the same regardless of whether the data are obtained from an observational study or a clinical trial. However, the research questions, hypotheses, and statistical tests may be different depending on the type of study. Consequently, the analyses also depend on study design.

Step 1. Set up H_0 and H_1. In many observational studies, the investigator can only control the total number of subjects; the research question involves whether the two sets of attributes are independent of each other. The statistical test is called a test of independence or association. In observational studies, the concept of independent samples stems from the notion that for a given attribute, such as pneumonia, the patients with pneumonia are unrelated to those without pneumonia. The null and alternative hypotheses may be written as follows:

$$H_0: \pi = \pi_0 \text{ for all four groups versus } H_1: \pi \neq \pi_0 \text{ for at leasts one group,}$$

where the null and alternative hypotheses are stated in terms of joint probabilities, that is, the observed proportion equals the expected proportion. The general approach is discussed in the earlier section on probability. For example, the investigator may record the observed joint probabilities of (a) developing pneumonia and being on the ventilator, (b) not developing pneumonia and being on the ventilator, (c) developing pneumonia and not being on the ventilator, and (d) not developing pneumonia and not being on the ventilator. The expected joint probabilities are those that would have occurred under the assumption of independence. The statistical test for association involves determining the probability of finding the observed joint probabilities if the attributes were independent.

For clinical trials, the general research question for studies with independent samples is whether the proportion of B (and $\not{B}$) is the same for A and $\not{A}$ (i.e., the proportion of patients who die is the same for those with the drug [treated] as for those without the drug [control subjects]). Usually, the investigator determines not only the total number of subjects but also the number of subjects in each group. The statistical test is called a test of homogeneity of two proportions. For example, a clinical trial of a drug that may reduce the death rate associated with ventilator-associated pneumonia may be conducted. In this example, the investigator first estimates the observed conditional probabilities of death depending on whether the subject is in the treated or the control group. Next, the investigator estimates the observed marginal probabilities of death and survival using the addition rule. Using these observed marginal probabilities, the investigator then estimates the expected conditional probabilities of death independent of whether the subject is in the treated or the control group. These expected (or theoretical) conditional probabilities are based on the assumption that the death rate is the same in both groups (i.e., that H_0 is true). The statistical test involves determining the probability of finding the observed conditional probabilities if the probability of death were the same in both groups. The null and alternative hypotheses may be stated as follows:

$$H_0: \pi_{B|A} - \pi_{B|\not{A}} = 0 \text{ versus } H_1: \pi_{B|A} - \pi_{B|\not{A}} = 0,$$

Step 2. Choose α, power, and the difference between $\pi_{B|A}$ and $\pi_{B|\not{A}}$ that is clinically meaningful.

Step 3. For clinical trials using an available computer package, determine sample size for each group, n_1 and n_2. Sample size is very sensitive to the difference between $\pi_{B|A}$ and $\pi_{B|\bar{A}}$. This difference, also called the effect size, should be that difference which is biologically or clinically meaningful in the opinion of the researcher. When no information is available, a pilot study can be conducted to get some idea of differences that can be obtained in a particular clinical situation. Although the algebra is not difficult, the formula for determining the sample size is quite complex; the reader is referred to the formula in Sokal and Rohlf *(2)* or Fleiss et al. (15), which minimizes the chances of underestimating the sample size required to detect the absolute value of the difference of $|\pi_{B|A}-\pi_{B|\bar{A}}|$ at given levels of significance and power. The formula in Rosner (8) is used in most statistical packages and yields sample size estimates that are generally about 5% smaller than those based on the Sokal and Rohlf or Fleiss formula. Computation of sample size can be tedious. For step 3, the investigator may wish to consult a biostatistician. Computer software is available for making some computations; however, the investigator should review documentation to determine which formulas are used and choose a software package that does not typically underestimate sample size. This precaution is especially important if sample sizes are less than 50 per group.

Step 4. Obtain data.

Step 5. Compute test statistic in terms of parameters under H_0 and obtain the p value. If the sample size is larger than 20 and no more than 20% of the expected cell frequencies (i.e., the cell frequencies expected under the assumption of independence) are <5, using large sample theory and the normal approximation to the binomial distribution is valid. In this situation, the following test statistic is appropriate for both observational studies and clinical trials. The test statistic is z_s, where

$$z_s = \frac{(p_{B|A} - p_{B|\bar{A}})}{\sqrt{(p_B(1-p_B)/n_1 + p_B(1-p_B)/n_2)}},$$

where n_1 and n_2 are the numbers of observations in each group. The p value is twice the probability associated with the test statistic, z_s, assuming that H_0 is correct.

Step 6. Decide whether to reject or fail to reject H_0. Compare the p value to α. When the two attributes are not independent of each other, there exists some form of association between the attributes. Inspecting the data will reveal what the association might be. The investigator must look closely at each of the individual cell chi-square values before making inferential statements about the nature of the association. The investigator's interpretation is based on the fact that the cells with the largest chi-square values have contributed proportionately more to the total chi-square test statistic. Note that $z^2 = \chi^2$; the squared z-score, obtained from the data (i.e., z_s), equals a chi-square test statistic with 1 degree of freedom obtained from the same data (i.e., χ_s^2). Most computer packages report a chi-square test statistic with 1 degree of freedom (i.e., χ_s^2) along with the associated p value. If the significance level is .05, $\chi_{0.95}^2$ with 1 degree of freedom is 3.84, which equals 1.96^2.

Fisher's Exact Test If the normal approximation to the binomial is not valid, Fisher's exact test must be used to obtain the exact probability of obtaining a table with cells *a*, *b*, *c*, and *d*. This situation is described by the hypergeometric distribution. Fisher's exact test may be used to give the exact p value for any 2×2 table. Many computer packages for statistical analysis provide results based on Fisher's exact test. For a calculator-based method, the reader is referred to Rosner (8). The interpretation of the p value from Fisher's exact test is the probability of obtaining a table at least as extreme as the observed table, assuming the two attributes are independent.

Two-Sample Test for Paired Samples

Both the table and the test statistic are the same regardless of whether the data are obtained from an observational study or from a clinical trial. When matched pairs are the basic experimental unit for a clinical study, pairs are classified as to whether or not the treatment or placebo was effective for each member of the pair. Sometimes each subject is used as its own control, thereby yielding paired results. In observational studies, the pairs may be classified as to whether or not the outcome is the same for each member of the pair.

A matched pair in which the outcome is the same for both members of the pair is called a *concordant pair*—that is, (present, present) or (absent, absent). For example, one might consider a study in which the event of interest is death (as contrasted with survival). If both members of the pair die, this result might be symbolized as (Yes, Yes); conversely, if both members live, the result might be symbolized as (No, No). A matched pair in which the outcomes are different for the members of the pair is called a *discordant pair*—that is, (present, absent) or (absent, present). Rosner (8) describes a type A discordant pair is a pair in which the outcome for the member from the first group is the event and the outcome for the member from the second group is not. Using the previous example, a type A discordant pair would contain a member from the first group who died and a member from the second group who survived—that is, (present, absent). According to the same logic, Rosner describes a type B discordant pair as a pair in which the outcome for the member from the first group is not the event and the outcome of the member from the second group is. Again, using the previous example, a type B discordant pair would contain a member from the first group who survived and a member from the second group who died—that is, (absent, present). After tabulation, data can be presented in the following format, where *a*, *b*, *c*, and *d* are frequencies.

	Treatment or Group 2		
Treatment or Group 1	*Present*	*Absent*	*Total*
Present	*a*	*b*	*a* + *b*
Absent	*c*	*d*	*c* + *d*
Total	*a* + *c*	*b* + *d*	*n*

Step 1. Set up H_0 and H_1. The null and alternative hypotheses may be stated as follows:

$$H_0 : \pi_{\text{Present|Group 1}} = \pi_{\text{Present|Group 2}},$$

where the estimate of $\pi_{\text{Present|Group1}} = a/(a + b)$ and the estimate of $\pi_{\text{Present|Group2}} = a/(a + c)$. This test is called McNemar's test. The investigator tests whether the "present" proportions for the two treatments or groups are the same. Note that the only important differences between $p_{\text{Present|Group1}}$ and $p_{\text{Present|Group2}}$ are between b and c. Testing for differences between b and c is the same as testing that the "present" proportion for treatment or group 1 is the same as the "present" proportion for treatment or group 2. Thus, the null hypothesis could be restated as the frequency that the two types of discordant pairs are equal: H_0:$\pi_{\text{Present\&Absent}} = \pi_{\text{Absent\&Present}} = 0.5$ versus H_1: $\pi_{\text{Present\&Absent}} \neq \pi_{\text{Absent\&Present}} \neq 0.5$, where the estimated $\pi_{\text{Present\&Absent}}$ is $b/(b + c)$ and the estimated $\pi_{\text{Absent\&Present}}$ is $c/(b + c)$. If the investigator chooses to state H_0 in terms of either $\pi_{\text{Present\&Absent}}$ and $\pi_{\text{Absent\&Present}}$, this becomes a one-sample test with n equaling $(b + c)$, the total number of discordant pairs. For the remainder of the procedure (i.e., steps 2 through 6), the reader is referred to the normal approximation method for one-sample tests for a binomial rate or proportion.

Two-Sample Test for Incidence-Density Variables In many epidemiologic studies, the investigator follows subjects for varying lengths of time (e.g., length of stay in the ICU), and the outcome variable is dichotomous. For example, the variable of interest might be whether or not a healthcare-associated infection developed in a sample of patients. When a subject converts from a negative status to a positive status, the investigator records the time to failure. The term *failure* connotes the event, usually death or a disease state, that the investigator is studying. In the simplest situation, the subjects are divided into two groups according to a single exposure (e.g., receiving or not receiving parenteral nutritional support). For this simple situation, the investigator has a choice of several methods for analyzing this type of data. Three commonly used methods are presented in this chapter. Two methods are presented in the following, and the third is discussed later (see the section on survival analysis). If the situation is more complex, the investigator must use either survival analysis or stratified analysis.

Rosner (8) presents a method that is appropriate when the investigator wishes to compare the incidence density rates of two groups. The investigator must assume that the incidence remains constant over the assessment time. Although patients are followed for varying lengths of time, the investigator knows whether a particular patient has either failed or not failed. The investigator counts the number of failures in each group. Then, the investigator computes the total number of person-time units elapsed from enrollment to the assessment time. After tabulation, data can be presented in the following format.

	Exposed	*Not Exposed*	*Total*
Number of events	a	b	$a + b$
Person-time	t_E	$t_{\bar{E}}$	$t_E + t_{\bar{E}}$

Step 1. Set up H_0 and H_1. The investigator tests whether the incidence-density (ID) is the same for the two groups of subjects. Stated another way, the investigator is interested in whether the rates of healthcare-associated infection per patient-day in the ICU are the same in the two exposure groups. The null and alternative hypotheses may be stated as follows:

$$H_0 : \text{ID}_E = \text{ID}_{\bar{E}} \text{ versus } H_1 : \text{ID}_E \neq \text{ID}_{\bar{E}},$$

where E indicates the exposed group, $\bar{E}$ indicates the unexposed group, the estimated $\text{ID}_E = a/t_E$ and the estimated $\text{ID}_{\bar{E}} = b/t_{\bar{E}}$. The total number of events in the exposed group equals a. Similarly, the total number of events in the unexposed group equals b.

Step 2. Obtain data. Because most studies of incidence density are observational, power analyses and sample size computations are usually not completed.

Step 3. Compute test statistic in terms of parameters under H_0 and obtain the p value. If normal approximation of the binomial is valid (i.e., $V_E \geq 5$), the test statistic is a z-score:

$$z_s = \frac{a - ((a+b)t_E/(t_E + t_{\bar{E}}))}{\sqrt{[(a+b)t_E t_{\bar{E}}/(t_E + t_{\bar{E}})^2]}}$$

where the observed number of events in the exposed group is a; the expected number of events in the exposed group (given that H_0 is true) is $(a + b)t_E/(t_E + t_{\bar{E}})$; and the variance is $(a + b)t_E t_{\bar{E}}/(t_E + t_{\bar{E}})^2$. The p value is twice the probability associated with the test statistic z_s, assuming that H_0 is correct. If the normal approximation of the binomial is not valid, exact binomial probabilities must be obtained.

Step 4. Decide whether to reject or fail to reject H_0. Compare the p value to α.

The second method is probably the most commonly used test for comparing incidence rates. The Mantel–Haenszel test, also called the log rank test, does not require the assumption of a constant incidence rate over time. In this situation, the investigator may place as much importance on time to an event as on whether or not the event occurred. For example, suppose a healthcare epidemiologist has a statewide surveillance program designed to detect new cases of positive tuberculin test results among nursing personnel during their first year of employment.

Step 1. H_0 and H_1 are the same as those described for the first method.

Step 2. Obtain data.

Step 3. Divide the year into shorter periods (e.g., months). Construct a 2×2 table for each interval. Note that subjects who have not experienced an event during a preceding interval are at risk for experiencing an event during the current interval; therefore, only the number of subjects not having the event in the preceding interval will appear in a given 2×2 table. Once a subject has experienced an event during a given interval, data for that subject does not appear on any table representing a subsequent interval.

Using these rules, the healthcare epidemiologist constructs the table for the first time interval using the following format.

	Group		
Event	*1*	*2*	*Total$_1$*
Yes	a_1	b_1	$a_1 + b_1$
No	c_1	d_1	$c_1 + d_1$
	$a_1 + c_1$	$b_1 + d_1$	n_1

where a_1 is the number of subjects in the first group who experienced events in the first interval; c_1 is the number of subjects in the first group who did not experience events during the first interval; $(a_1 + c_1)$ is the total number of subjects in the first group; b_1 is the number of subjects in the second group who experienced events during the first interval; d_1 is the number of subjects in the second group who did not experience events during the first interval; $(b_1 + d_1)$ is the total number of subjects in the second group; and n_1 is the total number of subjects in the study. Next, the healthcare epidemiologist constructs the second table using the following format.

	Group		
Event	*1*	*2*	*Total$_2$*
Yes	a_2	b_2	$a_2 + b_2$
No	c_2	d_2	$c_2 + d_2$
	$a_2 + c_2$	$b_2 + d_2$	n_2

where a_2 is the number of subjects in the first group who experienced events during the second interval; c_2 is the number of subjects in the first group who did not experience events during the second interval; $(a_2 + c_2)$ equals c_1 and is the total number of subjects in the first group who were at risk during the second interval; b_2 is the number of subjects in the second group who experienced events during the second interval; d_2 is the number of subjects in the second group who did not experience events during the second interval; $(b_2 + d_2)$ equals d_1 and is the total number of subjects in the second group who were at risk during the second interval; and n_2 equals $(c_1 + d_1)$ and is the total number of subjects at risk during the second interval. Continue constructing tables using the same format.

Step 4. Compute the test statistic over all the 2×2 tables in terms of parameters under H_0 and obtain the p value. The test statistic is the Mantel–Haenszel statistic, which may be computed with the following formula:

$$\chi_s^2 = \frac{\left(\sum_{i=1}^{t} a_i - \sum_{i=1}^{t} (a_i + b_i)(a_i + c_i)/n_i\right)^2}{\sum_{i=1}^{t} (a_i + b_i)(c_i + d_i)(a_i + c_i)(b_i + d_i)/n_i^2(n_i - 1)},$$

where i indicates the individual 2×2 tables and the other values are defined in the discussion on construction of the various tables. Under H_0, the Mantel–Haenszel statistic χ^2_{MH} follows a chi-square distribution with 1 degree of freedom. Therefore, for a test of significance at the .05 significance level, H_0 is rejected if χ^2_{MH} is greater than 3.84. The p value is the probability associated with χ^2_{MH} assuming that the null hypothesis is true.

Hypothesis Tests for Continuous Data

Distribution of Sample Means The central limit theorem states that, for a large sample size regardless of the underlying distribution of the individual observations, the sample mean, $\bar{X}$, follows a normal distribution with mean μ and variance σ^2/n (*1–4*,5,8,*9*,*16*). The mean of sample means is the same as the mean of the original population of individual values. The variance of sample means is needed to indicate dispersion or spread among $\bar{X}$ values. The standard error is the standard deviation associated with the population of means (i.e., the standard deviation of the mean): $\sigma_{\bar{X}} = \sigma / \sqrt{n}$. If the sample size n gets very large, the standard error approaches zero. What about the estimate from the one sample an epidemiologist actually collects? The estimated standard error (usually called simply the standard error) is $s/\sqrt{n}$, which is the standard deviation of $\bar{X}$, regardless of whether original data follow a normal distribution.

Clinical researchers often find that hypothesis testing for continuous variables is helpful. One-sample tests can be used to determine whether the sample differs from the reference population with respect to continuous variables such as APACHE III scores. Clinical investigators often use two-sample tests during exploratory data analysis to identify potentially important continuous risk factors such as age and temperature at admission.

The following two sections describe statistical methods for one- and two-sample tests for continuous variables (*1–4*,5,*7*,8,*9*,*16*). These sections are not designed as casual reading material; instead, they provide a concise reference of commonly used statistical methods. Each section follows the same format as has been described for hypothesis tests for categorical variables.

One-Sample Tests for a Continuous Variable

One-Sample Test for a Mean Provided that the sample size is adequate (e.g., 20 or more) and the distribution is approximately normal, a two-sided hypothesis test is conducted as follows.

Step 1. Set up H_0 and H_1.

$$H_0: \mu = \mu_0 \text{ versus } H_1: \mu \neq \mu_0,$$

where μ is the mean of the population from which the sample is obtained and μ_0 is the mean of the norm group.

Step 2. Choose α, power, and the difference between μ and μ_0 that is clinically meaningful.

Step 3. Using an available computer package, determine sample size n. Sample size is very sensitive to the difference between means, μ–μ_0, where μ is the mean of the population from which the sample is obtained and μ_0 is the mean of the norm group. This difference, also called the effect size, should be the difference that is biologically or clinically meaningful in the opinion of the researcher. When no information is available, a pilot study can be conducted to get some idea of the difference that can be obtained in a particular clinical situation.

Computer packages provide easily used algorithms for obtaining sample size estimates. If the estimated sample size n is relatively small (i.e., less than 30), that value should be adjusted by multiplying by the correction

factor $(t_{[0.975,n-1]}/z_{0.975})^2$, where $t_{[0.975,n-1]}$ is the *t*-score from a *t* distribution with $(n-1)$ degrees of freedom and *n* is the estimated sample size obtained from a computer package.

Step 4. Obtain data.

Step 5. Compute test statistic in terms of parameters under H_0, which follows a *t* distribution with $(n-1)$ degrees of freedom, and obtain the *p* value as twice the probability associated with the t_s, assuming that H_0 is correct. Like the standard normal distribution, the *t* distribution is symmetric; however, for each different degree of freedom, there is a different distribution. If the sample size is 100 or more, the *t* distribution resembles the standard normal distribution.

$$t_s = \frac{(\bar{X} - \mu_0)}{s/\sqrt{n}},$$

where $\bar{X}$ is the estimate of the mean obtained from the sample; μ_0 is the mean if H_0 is true; and $s/\sqrt{n}$ is the standard deviation of the mean estimated from the sample. The *p* value is twice the probability associated with the test statistic t_s with $(n-1)$ degrees of freedom, assuming that H_0 is correct.

Step 6. Decide whether to reject or fail to reject H_0. Compare the *p* value to α.

If the hypothesis test is one-sided (e.g., $H_1: \mu > \mu_0$), calculate power and estimate sample size substituting α for $\alpha/2$ in the previous formulas. In addition, the *p* value is not multiplied by 2. It is always easier to reject a one-sided test than a similar two-sided test. Furthermore, an effectively larger α increases power by reducing β.

One-Sample Test for a Variance or Standard Deviation The most frequently used hypothesis test for variances or standard deviations is the two-sided test, which is conducted as follows.

Step 1. Set up H_0 and H_1 in terms of σ^2 and σ_0^2.

$$H_0: \sigma^2 = \sigma_0^2 \text{ versus } H_1: \sigma^2 \neq \sigma_0^2,$$

where σ^2 is the variance of the population from which the sample was chosen and σ_0^2 is the variance of the norm group.

Step 2. Compute test statistic in terms of parameters under H_0, which follows a χ^2 distribution with $(n-1)$ degrees of freedom, and obtain the *p* value as twice the probability associated with the χ_s^2, assuming that H_0 is correct. Unlike the standard normal distribution, the χ^2 distribution is not symmetric. For each different degree of freedom, there is a different distribution. If the sample size is 100 or more, the χ^2 distribution resembles the standard normal distribution.

$$\chi^2 = \frac{(n-1)s^2}{\sigma_0^2},$$

where s^2 is the sample variance for the variable of interest; *n* is the sample size; and σ_0^2 is the variance if H_0 is true. The *p* value is twice the probability associated with the test statistic χ_s^2 with $(n-1)$ degrees of freedom, assuming that H_0 is correct.

Step 3. Decide whether to reject or fail to reject H_0. Compare the *p* value to α.

If the hypothesis test is one-sided (e.g., $H_1: \sigma^2 > \sigma_0^2$), the *p* value is not multiplied by 2. Sample size and power are based on the ratio of the standard deviations that the healthcare epidemiologist chooses as clinically important.

Two-Sample Tests for a Continuous Variable When the random variable under study is a continuous variable, hypothesis testing and methods of inference should reflect the data structure. Before formulating the hypothesis, the investigator must determine whether the samples are independent or not.

Two-Sample Paired Test for Means Paired samples are frequently encountered in biologic and health science research. For paired samples, a paired *t*-test is used. In follow-up or longitudinal studies, paired samples may represent two sets of measurements on the same individuals. Alternatively, paired samples may represent measurements on different individuals, matched such that each member of the pair is very similar to the other. In analyzing data from paired samples, the clinical investigator assumes that for the variable of interest, the mean difference, Δ, between paired observations is the same for all pairs.

Step 1. Set up H_0 and H_1.

$$H_0: \Delta = 0 \text{ versus } H_1: \Delta \neq 0$$

Step 2. Choose α, power, and the difference, Δ, that is clinically meaningful.

Step 3. Using one of the available computer packages, determine sample size *n*. Sample size is very sensitive to the mean difference. This difference, also called the effect size, should be that difference which is biologically or clinically meaningful in the opinion of the researcher. When no information is available, a pilot study can be conducted to get some idea of the mean difference that can be obtained in a particular clinical situation.

Step 4. Obtain data.

Step 5. Compute test statistic in terms of parameters under H_0, which follows a *t* distribution with $(n-1)$ degrees of freedom where *n* is the number of pairs, and obtain the *p* value as twice the probability associated with the t_s.

$$t_s = \frac{(\bar{X}_D)}{s_D/\sqrt{n}},$$

where $\bar{X}_D$ is the mean of the differences between pairs in the sample; s_D is the standard deviation of the difference between pairs in the sample; and *n* is the number of pairs. The *p* value is twice the probability associated with the test statistic t_s (assuming that H_0 is correct) with $(n-1)$ degrees of freedom where *n* is the number of pairs.

Step 6. Decide whether to reject or fail to reject H_0. Compare the *p* value to α.

If the hypothesis test is one-sided (i.e., $H_1: \Delta > 0$), calculate power and estimate sample size substituting α for $\alpha/2$ in the previous formulas. In addition, the *p* value is not multiplied by 2. It is always easier to reject a one-sided test than a similar two-sided test. Furthermore, an effectively larger α increases power by reducing β.

Two-Sample (Independent) Test for Means Independent samples are frequently encountered in biologic and health

science research. For independent samples, a *t*-test for independent samples is used. Continuous variables from cross-sectional studies involving two groups are often analyzed with independent *t*-tests.

Step 1. Set up H_0 and H_1.

$$H_0 : \mu_1 = \mu_2 \text{ versus } H_1 : \mu_1 \neq \mu_2 \quad \text{and}$$
$$H_0' : \sigma_1^2 = \sigma_2^2 \text{ versus } H_1' : \sigma_1^2 \neq \sigma_2^2$$

where μ_1 and σ_1^2 are the mean and variance of the population from which the first sample was chosen and μ_2 and σ_2^2 are the mean and variance of the population from which the second sample was chosen.

Step 2. Choose α, power, and the difference between μ_1 and μ_2 that is clinically meaningful.

Step 3. Using an appropriate computer package, determine sample size for each group, n_1 and n_2. Sample size is very sensitive to the difference between group means. This difference, also called the effect size, should be that difference which is biologically or clinically meaningful in the opinion of the researcher. When no information is available, a pilot study can be conducted to get some idea of differences between μ_1 and μ_2 that can be obtained in a particular clinical situation.

If the variances in the two groups are the same, the smallest total sample size involves equal sample sizes in each group. Sometimes it is not possible or practical to have equal sample sizes and the clinical investigator will specify different numbers of subjects in each group, usually in multiples of the smaller group size.

Step 4. Obtain data.

Step 5a. Compute test statistic in terms of parameters under H_0'. If the assumption about equal variances for the two samples is doubted, the investigator can use an *F*-test, commonly called *F'*, to determine the validity of this assumption. Under $H_0', F_s' = s_1^2 / s_2^2$ where s_1^2 is the variance estimated from the first sample and s_2^2 is the variance estimated from the second sample; F_s' follows an *F*-distribution with $\upsilon_1 = (n_1 - 1)$ and $\upsilon_2 = (n_2 - 1)$ degrees of freedom. For practical purposes, most textbooks recommend the following: label the populations (and hence the samples) such that $s_1^2 > s_2^2$ (i.e., $F_s' > 1.0$). Then, reject H_0' if $F_s' > F_{0.95}$ with υ_1 and υ_2 degrees of freedom, or $F_{0.95[\upsilon 1, \upsilon 2]}$. This is still a test at the α level of significance, but the upper tail value is used in determining the *p* value. If $p < .05$, the investigator rejects the assumption of equal variances and uses the Behrens–Fisher *t*-test, also called Satterthwaite's method. If $p > .05$, the investigator maintains the assumption of equal variances and uses Student's *t*-test. With general use of computers, restricting F_s' to be larger than 1.0 is no longer necessary. Therefore, the α level of significance for a comparable two-sided test is 0.10. Computer packages vary in reporting one- or two-sided *p* values; the investigator should check documentation to verify the nature of the *p* values.

Step 5b. For Student's *t*-test, compute test statistic in terms of parameters under H_0.

$$t_s = \frac{(\bar{X}_1 - \bar{X}_2)}{s_p \times \sqrt{(1/n_1 + 1/n_2)}},$$

where $\bar{X}_1$ is the sample mean obtained from the first sample; $\bar{X}_2$ is the sample mean obtained from the second sample; and s_p is the pooled sample standard deviation. The investigator obtains s_p by taking the square root and of the pooled sample variance, s_p^2.

The difference between two means follows a *t* distribution with $(n_1 + n_2 - 2)$ degrees of freedom. The *p* value is twice the probability associated with the test statistic t_s with $(n_1 + n_2 - 2)$ degrees of freedom, assuming that H_0 is correct.

For the Behrens–Fisher *t*-test

$$t_s = \frac{\bar{X}_1 - \bar{X}_2}{\sqrt{(s_1/n_1 + s_2/n_2)}},$$

where $\bar{X}_1$ is the sample mean obtained from the first sample; $\bar{X}_2$ is the sample mean obtained from the second sample; s_1^2 is the sample variance from the first sample; s_2^2 is the sample variance from the second sample; n_1 is the number of observations in the first sample; and n_2 is the number of observations in the second sample. The appropriate degrees of freedom (d') must now be calculated based on s_1^2, s_2^2, n_1, and n_2.

The *p* value is twice the probability associated with the test statistic t_s (assuming that H_0 is correct) with (d') degrees of freedom.

Step 6. Decide whether to reject or fail to reject H_0. Compare the *p* value to α.

If the hypothesis test is one-sided (i.e., H_1: $\mu_1 > \mu_2$ or $\mu_1 < \mu_2$), calculate power and estimate sample size substituting α for $\alpha/2$ in the previous formulas. In addition, the *p* value is not multiplied by 2. It is always easier to reject a one-sided test than a similar two-sided test. Furthermore, an effectively larger α increases power by reducing β.

Hypothesis Tests for Ranked Data

If the central limit theorem is not applicable, the clinical investigator must use nonparametric statistical methods to analyze data and make inferences (*1–4*,5,7,8,*12*). A more descriptive term for these methods is *distribution-free methods*. In general, nonparametric methods are more flexible than parametric methods, because nonparametric methods require fewer or no assumptions about the shape of the underlying distribution.

Distribution-free methods are required when the data are ordinal. Ordinal data are data that can be ordered but do not have specific numeric values. Measurement data are data that lie on a scale wherein common arithmetic is meaningful. In contrast, ordinal variables cannot be given a numerical scale that makes sense biologically or clinically. Essentially, the ranks are arbitrarily assigned; these could be reversed and still retain the same meaning for the researcher. Therefore, computation of means and standard deviations is absurd, because there would be no universally accepted meaning (outside of a researcher's laboratory or clinic). Medians and ranges are used instead.

A clinical investigator can apply nonparametric tests to any measurement data. This application may be particularly appropriate when the assumption of normality appears to be grossly violated. If the actual underlying distribution is in fact normal, the clinical investigator will pay a penalty, because in this situation the nonparametric counterpart for a parametric test statistic has less power.

Often, data are not normally distributed, even though a reasonable assumption has been made that the underlying (i.e., theoretical) distribution is normal. Parametric methods are often robust enough to withstand certain departures from normality. Some statisticians recommend that investigators analyze continuous data by both parametric and nonparametric methods. If the results of both analyses are consistent, the researcher is assured that the result reported from the parametric test is probably not biased. However, results from these analyses may not be consistent (i.e., the result from one analysis may be significant and the result from the other be very far from significance). In this event, the result from the parametric test is probably biased. After reviewing the data carefully, the researcher should (a) consider options for transforming the data so that the parametric test is valid or (b) report the result from the nonparametric test. Whenever it is appropriate to use nonparametric methods, these are usually more powerful than their parametric counterparts, and the results of tests are unbiased.

The following section describes nonparametric statistical methods for two-sample tests on ordinal (i.e., ranked) and continuous variables (*1–4*,5,*7*,8,*12*). These sections are not designed as casual reading material; instead, they provide a concise reference of commonly used statistical methods.

Sign Test This test was named because it depends only on the sign of the differences in responses between matched subjects in the treatment and control groups (or, alternatively, exposed and unexposed; survivors and nonsurvivors) and not on the magnitude of the actual differences, Δ. This test can also be used for paired observations on the same individual (e.g., before and after treatment). Under some conditions, we cannot observe an actual difference, D, between two treatments but can only observe if the differences are negative or worse (i.e., $D < 0$), positive or better (i.e., $D > 0$), or not apparent or discernible (i.e., $D = 0$). The sign test is based on the number of positive (i.e., $D > 0$) differences out of the total number of nonzero differences; all differences with a zero outcome are excluded from analysis. The sign test is a two-sided test. If the number of nonzero responses is greater than or equal to 20, the normal approximation to the binomial applies and the sign test is the same as McNemar's test (see the section on two-sample test for paired samples). If the number of nonzero responses is <20, exact binomial probabilities must be obtained.

Wilcoxon Signed Rank Test The Wilcoxon sign rank test may be applied to ordinal or measurement data. This test is the nonparametric counterpart for the paired *t*-test. This test is based on the ranks of the observations rather than on their actual values. It is more powerful than the sign test, because both the sign and the magnitude of the differences, based on rank, are used in computing the test statistic. If the distribution is normal, this test has less power than the paired *t*-test; otherwise, it is the more powerful test. This test should be used only when the number of nonzero differences is ≥16. For computation of the test statistic, see Rosner (8).

Wilcoxon Rank Sum Test and the Mann–Whitney U-Test The Wilcoxon rank sum test was developed for ranked or ordinal data; the Mann–Whitney *U*-Test was developed for comparisons that come from underlying distributions that are continuous. These tests are the nonparametric counterparts of the *t*-test for two independent samples. These tests, based on the ranks of the individual observations rather than on the actual values, should be used only when n_1 and n_2 are both ≥10. For computation of the test statistic, see Rosner (8).

POINT AND INTERVAL ESTIMATION

In the epidemiologic literature, interval estimation is more common than hypothesis testing. Confidence intervals from a single sample can be used to determine estimated upper and lower limits for a parameter from the reference population. Often, clinical investigators divide the sample into two or more groups according to certain characteristics and estimate confidence intervals (CIs) for each group. Using the previous example, the epidemiologist may be comparing the incidence of healthcare-associated pneumonia among patients who were ventilated to the incidence of healthcare-associated pneumonia among patients who were not ventilated. The following sections address general definitions and rules for estimating CIs, one- and two-sided CIs for categorical and continuous variables, and CIs for statistics with special application to epidemiology (*1–4*,5,8,*9*,*12*,15,*16*,20).

Definition and Rules

First, an epidemiologist estimates parameters according to data obtained from the sample. These estimates are called *point estimates*. For estimating the CI, the epidemiologist uses the point estimate from the sample and the standard deviation of that point estimate to compute a lower confidence limit, L_L, and an upper confidence limit, L_U. The confidence limits are affected by the level of confidence that the epidemiologist wishes to place in the statement. Typically, epidemiologists report 95% CIs; 95%, called the coefficient of confidence, equals $(1-\alpha)100\%$. Other traditional levels of confidence are 90% and 99%. It is crucial that the investigator state what level of confidence has been chosen. Often, the clinical investigator has a conflicting problem between having a high level of confidence and a CI that is not too large. For a specified level of confidence, increasing the sample size is the only option available to the epidemiologist for reducing the length of a CI. If the sample size must remain reasonably small, the epidemiologist may have to choose a lower level of confidence (e.g., 90%). The meaning of a CI is as follows: with repeated experiments, for each sample a different lower limit, L_L, and an upper limit, L_U, will be computed, because both the point estimate and standard deviation of that point estimate will be different for each sample; $(1-\alpha)100\%$ of the CIs will include the parameter and $\alpha 100\%$ will not. Thus, an investigator can state with $(1-\alpha)100\%$ confidence that the interval based on the sample contains the parameter. How does an epidemiologist obtain confidence limits, L_L and L_U?

Point and Interval Estimation for a Continuous Variable

Point and Interval Estimation for Means The point estimate for μ is $\bar{X}$. A more informative way of writing this point estimate is $\bar{X} \pm s_{\bar{X}}$ where $ss_{\bar{X}} = s/\sqrt{n}$. The second expression tells something about the precision of the estimate of the mean—the standard error or standard deviation of $\bar{X}$. Thus, it is not sufficient to give only $\bar{X}$. A two-sided 95% CI for μ is calculated as follows:

$$\bar{X} \pm \left(t_{[.975,n-1]} s_{\bar{X}}\right)$$

μ is fixed; L_L and L_U are variable so that $(1-\alpha)100\%$ of the intervals will contain μ. $\bar{X}$ and s both change with each new sample—thus, both location and length of the CI will change from one sample to the next. Because the t distribution is symmetric, $t_{0.025[n-1]}$ equals $-t_{0.975[n-1]}$.

Because the length of the CI depends on the sample through s, the healthcare epidemiologist must know something about s before making any decisions about sample size. The length of a two-sided $(1-\alpha)\%$ CI, L, is $2 \times t_{1-\alpha/2[n-1]} \times s/\sqrt{n}$. If the future value of σ can be estimated, sample size can be determined using an appropriate statistical package as

$$n' = [2 \times t_{1-\alpha/2[n-1]} \times s/L]^2$$

This number, n', underestimates the required sample size, because $t_{0.975[n-1]}$ is always larger than $z_{0.975}$. Thus, by multiplying n' by the squared ratio of the t-score with $(n'-1)$ degrees of freedom to the z-score, the adjusted sample, n_{adj}, can be obtained.

For observational studies, sample size determination relies heavily on how well the actual sample reflects the assumptions used to obtain sample size. Although there are no guarantees, sample size determination gives the clinical investigator some general idea of how large a sample may be needed.

Point and Interval Estimation for Variances and Standard Deviations The unbiased estimator of σ^2 is the sample variance, s^2. If the underlying distribution of the variable is normal, reliable estimates of CIs can be obtained. If the underlying distribution of the variable is not normal, the following methods may not be reliable. Variances do not follow a symmetric distribution. The ratio of s^2 to σ^2 follows a chi-square distribution with $(n-1)$ degrees of freedom, $\chi^2_{[n-1]}$. Note that the χ^2 distribution is not symmetric; thus, a CI for a variance or a standard deviation is not symmetric. A CI for a variance can be estimated using the following formula:

$$L_L = \frac{(n-1)s^2}{\chi^2_{[0.975,n-1]}} \quad \text{and} \quad L_U = \frac{(n-1)s^2}{\chi^2_{[0.025,n-1]}},$$

where L_L and L_U are always positive. A CI for σ is obtained by taking the square root of L_L and L_U. As the confidence increases, the length will increase. Reducing the length requires a reduction in confidence or an increase in sample size. As the sample size increases, the CI will become less skewed. These limits are independent of the estimated mean.

Point and Interval Estimation for a Binomial Proportion or Rate

The point estimate of π is p, estimated from the sample. When there is only one group with two outcome possibilities (i.e., survival and nonsurvival), the unbiased estimator of p is the proportion of the sample with the characteristic. The standard deviation of p is estimated by $\sqrt{pq/n}$. For a large sample, p is distributed normally with mean p and variance pq/n. Generally, the assumption of normality is valid when npq is >5.

Under the assumption of normality, approximate CIs for π can be obtained as follows:

$$p \pm \left(z_{1-\alpha/2} \times \sqrt{pq/n}\right)$$

The length of a two-sided $(1-\alpha)\%$ CI, L, is $2 \times z_{1-\alpha/2} \times \sqrt{pq/n}$. Sample size can be determined as follows: $n = [(2 \times 1.96pq)/L]^2$. Because the standard normal distribution is symmetric, $z_{0.025}$ equals $-z_{0.975}$. There are many other formulas for computing CIs for proportions and rates; the reader is referred to Rosner (8) and Fleiss et al. (15).

Point and Interval Estimation for Risk Ratios and Odds Ratios

For independent samples, a clinical investigator uses data displayed in 2 × 2 tables to estimate the RR or the OR. Whether the data reflect incidence or prevalence determines which statistic is estimated. Throughout this section, it is assumed that the clinical investigator has displayed the data such that exposure to the ventilator is the first column and presence of pneumonia is the first row.

When incidence of disease for the sample is known, the epidemiologist is interested in estimating the RR of disease, which is the ratio of two conditional probabilities. In the previous example, the RR of pneumonia is $\Pr(P|V)/\Pr(P|\not V)$.

	Exposed to Ventilator	*Not Exposed to Ventilator*	*Total or Marginal Probability of Disease*
Pneumonia present	$\Pr(V) \times \Pr(P\|V)$	$\Pr(\not V) \times \Pr(P\|\not V)$	$\Pr(P)$
Pneumonia absent	$\Pr(V) \times \Pr(\not P\|V)$	$\Pr(\not V) \times \Pr(\not P\|\not V)$	$\Pr(\not P)$
Probability of exposure	$\Pr(V)$	$\Pr(\not V)$	1.0

Conditional probabilities may be obtained as column probabilities by dividing the joint probability in each cell by the respective total probability of exposure. For the a-cell, $\Pr(V) \times \Pr(P|V)/\Pr(V) = \Pr(P|V)$.

After completing the process for each of the four cells, the clinical investigator obtains the following 2 × 2 table containing only conditional probabilities, that is, probabilities conditioned on exposure:

	Exposed to Ventilator	*Not Exposed to Ventilator*
Pneumonia present	$\Pr(P \mid V)$	$\Pr(P \mid \not V)$
Pneumonia absent	$\Pr(\not P \mid V)$	$\Pr(\not P \mid \not V)$
Probability of exposure	1.0	1.0

From this table, the RR can easily be obtained by dividing the conditional probability of developing pneumonia for those exposed to the ventilator by the conditional probability of developing pneumonia of those who were not so exposed: $\Pr(P \mid V)/\Pr(P \mid \not V)$. If $\Pr(P \mid V) = 0.25$ and $\Pr(P \mid \not V) = .167$, RR equals 1.497. The interpretation of the RR is as follows: patients who are ventilated are 1.497 times as likely to have pneumonia as those who are not ventilated.

Under the assumption of normality, approximate CIs for RR can be obtained as follows:

$$L_L = \mathrm{RR}(\exp[-z_{0.975}/s_{\mathrm{RR}}])$$
$$L_U = \mathrm{RR}(\exp[z_{0.975}/s_{\mathrm{RR}}])$$

where RR is estimated from the sample; $z_{0.975} = 1.96$; $\exp(x) = e^x$; and

$$s_{\mathrm{RR}} = \sqrt{[(1-\Pr(P \mid V))/n_{11} + (1-\Pr(P \mid \not V))/n_{12}]},$$

where n_{11} is the number of patients with pneumonia and exposure to the ventilator and n_{12} is the number of patients with pneumonia and no exposure to the ventilator.

When prevalence of disease for the sample is known, the epidemiologist estimates the odds in favor of disease based on joint probabilities. In the following table, p_1, p_2, p_3, and p_4 are joint probabilities. For example, p_1 is the joint probability of a patient having both exposure to the ventilator and presence of pneumonia. The OR equals a ratio with p_1/p_3 in the numerator and p_2/p_4 in the denominator. This expression can be simplified as follows: $\mathrm{OR} = (p_1p_4)/(p_2p_3)$.

	Exposed to Ventilator	*Not Exposed to Ventilator*	*Total or Marginal Probability of Disease*
Pneumonia present	p_1	p_2	$p_1 + p_2$
Pneumonia absent	p_3	p_4	$p_3 + p_4$
Total or marginal probability of exposure	$p_1 + p_3$	$p_2 + p_4$	1.0

Under the assumption of normality, approximate CIs for OR can be obtained as follows:

$$L_L = \mathrm{OR}[\exp(-z_{0.975}/s_{\mathrm{OR}})]$$
$$L_U = \mathrm{OR}[\exp(z_{0.975}/s_{\mathrm{OR}})]$$

where OR is the OR estimated from the sample; $z_{0.975}$ is 1.96; $\exp(x) = e^x$; and

$$s_{\mathrm{OR}} = \sqrt{[(1/n_{11} + 1/n_{12} + 1/n_{21} + 1/n_{22})]},$$

where n_{11} is the number of patients with pneumonia and with exposure to the ventilator; n_{12} is the number of patients with pneumonia and without exposure to the ventilator; n_{21} is the number of patients without pneumonia and with exposure to the ventilator; and n_{22} is the number of patients without pneumonia and without exposure to the ventilator.

For matched pairs, the clinical investigator can estimate RRs and ORs from stratified analyses. Methods for point and interval estimation are covered in that section.

Relationship Between CIs and Hypothesis Testing

CIs give a range of values within which the parameter (e.g., μ, σ, σ^2, π, RR, or OR) is likely to fall. When reporting CIs, the clinical investigator does not use a *p* value; however, the parameter estimate, the level of confidence, and the standard deviation of the estimate (i.e., the standard error) are reported. Conversely, when a hypothesis has been tested, the investigator should report the *p* value, the parameter estimate, and the standard deviation of the estimate (i.e., standard error). Sample size is as important for estimation of CIs as it is for testing hypotheses. In general, if H_0 is rejected, the corresponding CI does not contain the parameter under H_0. The one-to-one relationship between a CI and the corresponding hypothesis test is easiest to represent with the two-sided case. For completeness, it is a good practice for clinical investigators to provide enough information that both CIs and *p* values are obvious to anyone reading the report. In practice, editorial policies of various journals may restrict an investigator's report to either CIs or *p* values.

REGRESSION AND CORRELATION COEFFICIENTS

A clinical investigator uses regression or correlation analysis when the objective of the study is determining the functional relationship between two or more variables measured on the same individual. There are comparable regression and correlation methods for continuous and discrete variables.

Uses of Regression Analysis

Regression analysis has several applications that are relevant to epidemiologic studies (*1*,*2*,28). The first application is the study of causation. When looking for causal relationships, an epidemiologist must be aware that, although a cause-and-effect relationship may exist between two variables of interest, regression analysis cannot establish that the relationship is actually causal. Often, the study of causation will involve the second application of regression analysis for health science research—prediction. Nomograms, widely used in the clinical setting, have usually been developed from regression analysis. Third, the epidemiologist can use regression analysis to identify easily measured variables that can be substituted reliably for

others that may be difficult, expensive, or hazardous to collect. Substituting one variable for another does require a previous experimental study to establish the relationship between the variable of interest and the surrogate variable. A fourth commonly used application is controlling for one or more extraneous or confounding variables. After controlling statistically for a variable that cannot be controlled by experimental design, the clinical investigator can make more precise inferences about the relationship between the two variables of primary interest, usually exposure and outcome (or disease). Age, sex, weight, severity of illness, and type of infection are examples of common confounding variables. In a purely experimental setting, confounding variables can often be controlled or eliminated. However, in a naturalistic setting, the investigator must rely on statistical control. Finally, inverse regression or calibration is used for obtaining many assay results.

Regression Coefficients

In the simplest situation, the clinical investigator wishes to quantify the relationship between two variables, X and Y. For regression analysis, the convention is to call X the independent variable and Y the dependent variable. Another term for X is *explanatory variable*. Clinical investigators often call Y the *response variable*. Generally, the investigator is trying to predict Y from X (i.e., $Y|X$, read Y given X).

In regression analysis, the clinical investigator must describe the functional relationship between X and Y in terms of an ideal mathematical relationship or model, symbolized as $Y = F(X)$, which states that Y is a function (i.e., F) of X. The experienced investigator understands that the relationship between X and Y can take many forms. If the relationship is linear, the functional relationship can be symbolized as $F(X) = \alpha + \beta X$. Some relationships are curvilinear, requiring the addition of a quadratic term to the mathematical model: $F(X) = \alpha + \beta X + \gamma X^2$. Some curvilinear relationships vary episodically over a day or month and can be described reasonably well with sinusoidal functions: $F(X) = \alpha + \beta \sin X$. Some relationships are not linear; two examples are $F(X) = \alpha + \beta\sqrt{X}$ and $F(X) = \alpha + \beta/X$.

For the models presented in the preceding paragraph, the investigator can make these relationships linear by using transformations of X, Y, or both. Therefore, statisticians call these relationships intrinsically linear. The term *intrinsically linear* means that the parameters, such as α and β, are linearly related to X and Y. Some relationships are intrinsically nonlinear, meaning that the relationship of X and Y to the parameters is not linear: $F(X) = \alpha + \beta e^{-\gamma X}$. Special methods are needed for estimating regression coefficients when the relationship has a nonlinear functional form.

In nature, the observed relationship is never exact; because of natural variability, there is always some deviation from the ideal mathematical relationship or model. Thus, the clinical investigator describes the functional relationship in terms of a statistical relationship: $Y = F(X) + \varepsilon$, where ε is distributed normally with mean 0 and variance σ_ε^2. Conceptually, ε is an error term and σ_ε^2 represents the variance of Y for a given X. The investigator assumes that X is measured or controlled perfectly, thereby not contributing to the natural variability of Y. Collectively, the error terms are called the residuals, which are random deviations in Y from the ideal relationship. Thus, ε is a random variable that measures the deviation of each individual observation, Y_i, from $\mu_{Y|X}$ (i.e., the expected value of Y_i on the regression line). Furthermore, σ_ε^2 is independent of X. For example, σ_ε^2 is the same for both small and large values of X. The clinical investigator uses the residuals to determine if there is a linear relationship based on the data.

Simple Linear Regression Coefficients

Simple linear regression is the term for linear regression with only one independent variable (*1–4*,5,*6*,*7*,8,*9*,*10*,*12*,*16*, 28,*29*,30,*31*). For a simple linear regression, $Y = \alpha + \beta X + \varepsilon$, the parameters α and β are unknown and must be estimated from the data with statistics. The line $Y = \alpha + \beta X$ is defined as the regression line, where α is the intercept (i.e., the value on the Y-axis that corresponds to $X = 0$), and β is the slope. The regression line describes the regression of Y on X. The slope may be positive, indicating that as X increases, the expected value of Y increases. Similarly, the slope may be negative, indicating that as X increases, the expected value of Y decreases. Finally, the slope may be zero, depicting a horizontal line and indicating that there is no relationship between X and Y. By accounting for the systematic relationship between X and Y, the investigator reduces the total variability of Y. Even if a linear relationship exists, all observations could be displayed on one axis (i.e., the Y-axis) only; however, the variation in Y would be much larger (s_Y^2) , because no attempt has been made to account or adjust for the variability in the X values that contributes to the variability of Y.

Estimating the Intercept and Slope Plotting the data is an important step, because the graph is useful for suggesting whether there is a linear relationship. The difference between Y_i, the actual observation, and the corresponding expected value on the line, $\mu_{Y|X}$, reflects ε_i, the deviation for the particular observation. Some of these differences are positive and others are negative. The sum of the deviations (vertical deviations) is zero (i.e., $\sum_{i=1}^{n} \varepsilon_i = 0$). The investigator uses the method of least squares to minimize the squared deviation between the line and the observations.

Estimate of the Slope The investigator estimates β from the data, using the following formula:

$$b = \frac{s_{XY}}{s_X^2},$$

where the numerator is the sample covariance between X and Y, and the denominator is the sample variance of X. The covariance can be either negative or positive; the variance is always positive. One should note that a small value of β does not necessarily imply that the relationship is not strong between X and Y. By itself, b (as an estimate of β) does not tell whether there is any relationship between X and Y. An experienced investigator realizes that a change of units usually makes the size of the regression coefficient change. To determine whether the relationship is strong, the investigator has to know b relative to s_ε^2, the estimated variance of the residuals.

Estimate of the Intercept The estimate of α is a function of b: $\hat{\alpha} = \bar{Y} - b\bar{X}$, where $\bar{Y}$ is the estimated mean of Y and $\bar{X}$ is the estimated mean of X. Estimation of α is based on the premise that two points are necessary to determine a line. Thus, every regression line goes through the point $(\bar{X}, \bar{Y})$ and the Y-intercept. If the point $(\bar{X}, \bar{Y})$ and the estimated slope b are known, then the estimate of α is based on simple algebra.

Simple Linear Regression Analysis

Interpreting Residuals The assumptions on which linear regression is based are that the residuals are independently and identically distributed normally with mean 0 and variance σ_ε^2. One or more of these assumptions may be violated. In practice, a clinical investigator detects any violation of these assumptions by plotting the residuals and conducting certain hypothesis tests (*1*,*2*,28,*29*,30,*31*,32). The investigator applies diagnostic procedures to various plots of residuals and determines how the assumptions may be violated. Generally, lack of randomness in the residuals has some implications about possible violations. First, randomness or lack of randomness can be determined by examining a graph of the residuals plotted against the values of X. For example, plotting the residuals may reveal evidence of heteroscedasticity, which means unequal variances. In the clinical setting, heteroscedasticity is often characterized by increasing residuals as X increases. Second, systematic differences or deviations from the regression line are often revealed in a graph with actual values plotted on the X and Y axes and the predicted values superimposed on the same graph. Systematic deviations of the actual values from predicted values may indicate that a straight-line relationship is not the best fit. Third, plotting of actual values may reveal one or more points that are outliers and, as such, are influential points. Influential points often cause spurious results by drastically changing the estimated slope and intercept from what would have been expected had the influential points not been included in the analysis. Finally, the investigator chooses appropriate ways of dealing with the problem or problems. Typically, the investigator can make transformations or adjust the data in other appropriate ways so that the residuals will meet these assumptions. After the investigator has taken remedial action, the resulting graphs should reveal that the residuals meet the assumptions.

Prediction or Estimation of $\mu_{Y|X} = a + bX$ For a given value of X, $\hat{Y}$ is the estimation of $\mu_{Y|X}$ and is the corresponding point on the estimated regression line. Thus, the estimated regression line is composed of $\hat{Y}$s or expected values of Y across all values of X included in the study. Hence, $\hat{Y}$ is the estimate of the average response for a given X and is regarded as the predicted value of Y for a particular value of X. Interpolation within the range of the data is acceptable. Extrapolation is dangerous. Caution is needed when we are using any prediction equation outside the range covered by the X values in the study. Beyond these values, the relationship may no longer be linear.

Method of Least Squares The numerator of the sample variance for Y is $\sum_{i=1}^{n}(Y_i - \bar{Y})^2$. Another name for this expression is the total corrected sum of squares where *corrected* refers to the deviation of each observation from the mean (i.e., corrected for the mean). In some statistics texts, the total corrected sum of squares is abbreviated as CSS. Frequently, clinical investigators use the method of least squares to partition the total CSS for Y into two parts: (a) the sum of squares due to regression (i.e., regression SS or model SS) and (b) the residual or error sum of squares (i.e., residual SS or error SS).

As stated previously, the point $(\bar{X}, \bar{Y})$ always lies on the regression line. For any sample point, the total vertical deviation of each point (X_i, Y_i) from $(\bar{X}, \bar{Y})$ is the vertical distance that Y_i lies from the mean $\bar{Y}$; thus, measured on the Y-axis, the total deviation is $(Y_i - \bar{Y})$ (Fig. 3-1). The regression component of that point (X_i, Y_i) is the vertical distance from $(\bar{X}, \bar{Y})$ to the predicted value on the regression line $(X_i, \hat{Y}_i)$ measured on the Y-axis; thus, on the Y-axis, the regression component is the quantity $(\hat{Y}_i - \bar{Y})$ (Fig. 3-1). Now, for any sample point, the residual component

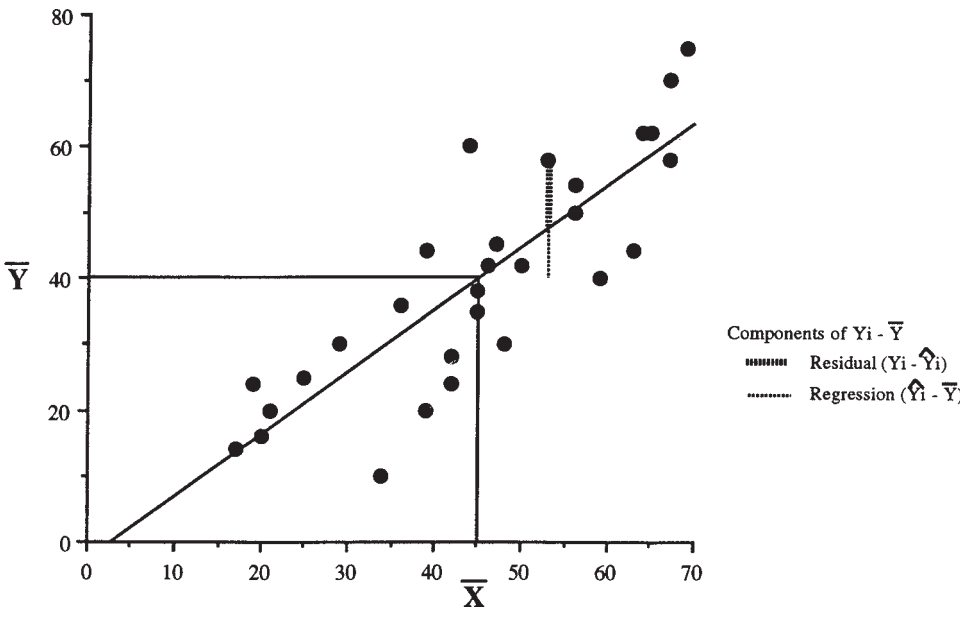

FIGURE 3-1 The total vertical deviation of each sample point (X_i, Y_i) from $(\bar{X}, \bar{Y})$ is divided into two components: the residual component $(Y_i - \hat{Y}_i)$ and the regression component $(\hat{Y}_i - \bar{Y})$. All three distances are measured on the Y-axis.

(i.e., residual) of that point about the regression line is the vertical distance from the actual observation (X_i, Y_i) to the predicted value on the regression line $(X_i, \hat{Y}_i)$; thus, on the *Y*-axis, the residual component is the quantity $(Y_i - \hat{Y}_i)$ (Fig. 3-1). Therefore, the total deviation $(Y_i - \bar{Y})$ of each point from the regression line can be separated into residual and regression components.

In using the least squares method, the investigator squares and sums the total deviations, the regression components, and the residuals: $\sum(Y_i - \bar{Y})^2 = \sum(\hat{Y}_i - \bar{Y})^2 + \sum(Y_i - \hat{Y}_i)^2$. The residual sum of squares (SS) tells the investigator how well the regression line fits the data. However, the investigator needs a formal goodness-of-fit test to assess whether this value is large or small. Partitioning the total corrected SS allows the investigator to construct an analysis of variance (ANOVA) table. The total deviations, the regression components, and the residuals correspond to three sources of variation. These sources of variation are similarly named: regression (also called model), error (also called residual), and total. The degrees of freedom for the total variation is the denominator of the sample variance of *Y*: $(n-1)$. The regression SS has 1 degree of freedom for each regression coefficient estimated; for simple linear regression, the degree of freedom is 1. The residual degrees of freedom are obtained by subtracting the regression degrees of freedom from the total degrees of freedom: for simple linear regression, $(n-1)-1 = (n-2)$. The mean squares (MSs) are the values of SS divided by the respective degrees of freedom. The regression MS has a special interpretation as the variance attributable to linear regression, $s^2_{\hat{Y}}$; conceptually, the regression MS is the explained variation of *Y* attributable to variation in *X*. The residual MS also has a special interpretation as the variance attributable to *Y* after adjusting for *X*, $s^2_{Y|X}$; conceptually, the residual MS is the unexplained variation of *Y*.

The formal goodness-of-fit test is an *F*-test with the model MS in the numerator and the error MS in the denominator: $MS_{Model}/MS_{Error} = F_s$. F_s follows an *F* distribution with numerator degrees of freedom equaling 1 and denominator degrees of freedom equaling $(n-2)$. The *p* value is the probability of obtaining a result this extreme, or more so, assuming that only natural or unexplained variability in *Y* exists. If the *p* value is <0.05, the investigator concludes that, according to these data, the model does account for a sufficient amount of the variation in *Y* to say that the model has adequate goodness of fit. Conversely, if the *p* value is >0.05, the investigator concludes that, according to these data, the evidence is insufficient to say that the model has adequate goodness of fit.

ANOVA TABLE

Source of variation	*Degrees of freedom*	*SS*	*MS*	F_s
Regression (or model)	1	$\sum(\hat{Y}_i - \bar{Y})^2$	$\sum(\hat{Y}_i - \bar{Y})^2$	MS_{Model}/MS_{Error}
Residual (or error)	$n-2$	$\sum(Y_i - \hat{Y}_i)^2$	$\sum(Y_i - \hat{Y}_i)^2/(n-2)$	
Total	$n-1$	$\sum(Y_i - \bar{Y})^2$		

Tests of Hypotheses The clinical investigator may wish to determine if there is a linear relationship between *X* and *Y*. If the slope β equals zero, there is no relationship between *X* and *Y*. Note that the magnitude of β does not tell the investigator whether the slope is different from zero. Therefore, the investigator forms the null hypothesis as H_0: $\beta = 0$ and the alternative hypothesis as H_1: $\beta \neq 0$. Single-sided alternative hypotheses (i.e., $\beta > 0$; $\beta < 0$) are allowed if there is previous knowledge that the relationship can only be either positive or negative or if a biologic phenomenon, such as growth, excludes one direction. Statistically, a one-sided test is superior to a two-sided test, because the probability of rejecting the null hypothesis is greater at the same level of significance.

Because the assumptions for regression analysis state that the residuals are normally distributed, the estimate of β (i.e., *b*) is also normally distributed with mean β and variance σ_b^2. The clinical investigator estimates the variance of *b*, s_b^2, from the data. The numerator of s_b^2 is the variation around the regression line (s_ε^2), and the denominator is the total variation of *X*.

One should note that the numerator, the variation around the regression line (s_ε^2), is interpreted as the amount of variation in *Y* remaining after taking into account or adjusting for the variation in *X*. Then, to test H_0: $\beta = 0$, the investigator computes the test statistic:

$$t_s = \frac{b}{s_b},$$

which follows a *t* distribution with $(n-2)$ degrees of freedom. Like all *t* statistics, the degrees of freedom for this test statistic are the degrees of freedom associated with the denominator, in this situation s_b^2. Because s_ε^2 is contained in s_b^2, the degrees of freedom equal the degrees of freedom for the residual SS, that is, $(n-2)$. The *p* value is twice the probability associated with t_s, assuming that the null hypothesis is true. For one-sided tests, the investigator uses the same t_s but does not multiply the probability associated with t_s by 2. Rejecting H_0 implies that the data show evidence of a linear relationship between *X* and *Y*. If the investigator does not reject H_0, this conclusion implies that the data show no linear relationship between *X* and *Y*.

Confidence Intervals for β The $(1-\alpha)100\%$ CI for β is computed in the usual way:

$$b \pm t_{[0.975,n-2]}s_b.$$

Conceptually, this CI is the same as the CI for μ. Whenever the CI does not include zero, the investigator rejects H_0. If the $(1-\alpha)100\%$ CI includes the hypothesized value, the results of the study, according to these data, are consistent with H_0. The interpretation of the CI is the following: the estimate of β is a random variable; for each sample, there will be a different estimate β and a different s_b. The slope can fluctuate within these bounds with 95% confidence that the true slope lies there.

R^2 for Simple Linear Regression R^2 measures the proportion of the variance or variation of *Y* that can be explained by the variance or variation in *X*. Stated another way, R^2 is the proportion of the total variation in *Y* explained

by regression. Mathematically, R^2 equals the regression SS divided by the total corrected SS: $R^2 = SS_{Reg}/CSS$. Therefore, R^2 is a summary measure of goodness of fit for simple linear regression.

For simple linear regression, the proportion of explained variance is usually expressed as r^2, instead of R^2. If the amount of explained variance is small, r^2 is small and a large proportion of the variation is unexplained by regression. Conversely, if the amount of explained variance is large, r^2 is large and a small proportion of the variation in Y is unexplained by regression. For this reason, r^2 is referred to as the coefficient of determination. Similarly, $(1–r^2)$ is called the coefficient of nondetermination.

This concept of r^2 extends to multiple linear regression, except that r^2 is replaced by R^2, which is called the sample multiple correlation coefficient. This concept can be easily demonstrated if multiple regression is addressed from the path coefficient perspective. For an excellent explanation, see Sokal and Rohlf *(2)*. No single quantity is the counterpart of r^2 or R^2 when the healthcare epidemiologist uses logistic regression analysis or survival analysis.

Correlation Coefficients

A correlation coefficient measures the degree (in terms of both closeness and direction) of association (or relationship) between two random variables that vary together. Usually, both variables are measured on the same subject. Unlike a regression coefficient, no distinction is made between the independent and the dependent variables; generally, any distinction would be arbitrary or meaningless. Furthermore, the correlation coefficient does quantify how strong the linear relationship is between the two variables of interest. Thus, a clinical investigator reports a correlation coefficient when there is no obvious outcome or response variable. Typically, the investigator intends to describe and quantify the relationship but does not wish to use one variable to predict another.

The correlation coefficient is a dimensionless value that ranges between –1.0 and +1.0, inclusive. Therefore, the investigator may compare correlation coefficients obtained from different studies. Unlike the regression coefficient, the correlation coefficient is unaffected by changes in scale.

If the correlation coefficient is –1.0, there is a perfect negative correlation between the two variables; all the points lie on a straight line. If the correlation coefficient is +1.0, there is a perfect positive correlation between the two variables; all the points lie on a straight line. A correlation coefficient between zero and –1.0 implies that there is a negative relationship; as one variable increases, the other decreases. Similarly, a correlation coefficient between zero and +1.0 implies that there is a positive relationship between the two variables; as one variable increases, the other also increases. Finally, if the correlation coefficient is zero, there is no relationship between the two variables; a graph of the data reveals that the points are randomly distributed within a circle or a horizontal rectangle.

Linear Correlation Coefficient

Estimate of ρ The linear correlation coefficient, ρ, is also called the Pearson product moment correlation coefficient (*1–4*,5,*7*,8,*9*,*12*,*16*). The sample Pearson correlation coefficient is used to estimate ρ when both variables are continuous variables that are both normally distributed. The investigator estimates ρ from the data using the following formula:

$$r = \frac{s_{Y1Y2}}{s_{Y1}s_{Y2}},$$

where the numerator is the covariance between the two random variables Y_1 and Y_2, and the denominator is the square root of the product of the variances of Y_1 and Y_2. The covariance can be either positive or negative. In the clinical setting, many more than two variables are measured on each patient. If more than one correlation coefficient is estimated, the clinical investigator should indicate which one is being discussed.

Because the assumptions for correlation analysis state that both variables are normally distributed, the estimate of ρ (i.e., r) follows a t distribution with $(n–2)$ degrees of freedom with mean ρ and variance σ^2_r. Therefore, the clinical investigator estimates the variance of r from the data: $s^2_r = (1–r^2)/(n–2)$.

Hypothesis Tests Most often, the clinical epidemiologist is interested in the question of whether or not Y_1 and Y_2 are correlated (*1–4*,5,8,*9*). Therefore, depending on how much information is known in advance, the epidemiologist forms the following hypotheses:

$$H_0: \rho = 0 \text{ versus } H_1: \rho \neq 0.$$

One-sided alternative hypotheses are allowed if there is previous knowledge that the relationship can only be either positive or negative or if a biologic phenomenon, such as growth, excludes one direction. Testing these hypotheses requires the assumption that both variables are continuous and distributed normally. The epidemiologist tests H_0 according to the following test statistic:

$$t_s = \frac{r}{s_r},$$

where s_r is $\sqrt{(1-r^2)/(n-2)}$. The test statistic follows a t distribution with $(n–2)$ degrees of freedom. The p value is twice the probability associated with the test statistic, assuming that H_0 is true. For one-sided hypothesis tests, the probability is not multiplied by 2.

Confidence Intervals for ρ The healthcare epidemiologist cannot use r directly for estimating CIs (*1–4*,5,8,*9*). First, r is transformed with Fisher's z-transformation. Then, the $(1–\alpha)100\%$ CI for z_F .is computed in the usual way. Finally, the epidemiologist transforms L_L and L_U back to the original correlation scale. Conceptually, this CI is the same as the CI for μ. Whenever the CI does not include zero, the investigator rejects H_0. If the $(1–\alpha)100\%$ CI includes the hypothesized value, the results of the study according to these data are consistent with H_0. The CI is interpreted as follows: the estimate of ρ is a random variable; for each sample, there will be a different estimate r and a different s_r. The linear correlation coefficient can fluctuate within these bounds with 95% confidence that the true value lies there.

Relationship Between the Linear Regression Coefficient and the Linear Correlation Coefficient For simple linear regression, there is a relationship among the regression coefficient, the correlation coefficient, and R^2. These relationships do not hold for multiple linear regression or other forms of regression. Conceptually, two simple linear regression coefficients exist. Usually, the investigator regresses Y on X: $Y = \alpha + \beta_{Y|X} X + \varepsilon$. However, the investigator could regress X on Y: $X = \alpha' + \beta'_{X|Y} Y + \varepsilon'$. The two estimated regression coefficients, $b_{Y|X}$ and $b'_{X|Y}$, always have the same sign. The estimated Pearson product moment correlation coefficient, r_{XY}, is the square root of R^2; the correlation coefficient also equals the geometric mean of two estimated regression coefficients (i.e., the square root of the product of slope from the regression of X on Y and the slope from the regression of Y on X), where the sign of the covariance between X and Y determines the sign of r. Thus, there is a relationship between correlation and regression. The closer the data points lie to a straight line, the stronger the relationship becomes and the larger the correlation coefficient is. The slope of the line has no bearing on the correlation. However, whenever there is a significant correlation, there will be a significant regression and vice versa. The clinical investigator can depict this relationship graphically by plotting the two estimated regression lines (i.e., $Y = a + b_{Y|X}X$ and $X = a' + b'_{X|Y}Y$) on one set of axes; the correlation coefficient is a measure of the angle between the two regression lines. As the angle becomes larger, the correlation coefficient decreases toward zero. When the angle is 90 degrees, the lines are perpendicular, the correlation coefficient is zero, and the scatter of data is circular or rectangular. As the angle between the regression lines becomes smaller, the correlation coefficient increases toward −1.0 or +1.0. When the angle is 0 degrees, the lines coincide, the correlation coefficient is either −1.0 or + 1.0, and the scatter of the data is a perfectly straight line.

The regression coefficient can also be interpreted as a rescaled version of the correlation coefficient where the scale factor is the ratio of the standard deviation of Y to that of X:

$$r = \frac{b_{Y|X}}{(s_Y / s_X)}.$$

Thus, the correlation coefficient can be regarded as a standardized regression coefficient (2). The standardized regression coefficient is a dimensionless value that represents the predicted change in Y, expressed in the number of standard deviation units that would be expected for each change in X by one standard deviation unit. The clinical investigator can use standardized regression coefficients to compare regression coefficients obtained from several studies on a variety of patient groups.

Nonparametric Correlation Coefficients The primary assumption for estimating linear correlation coefficients is that both variables are distributed normally. Sometimes the healthcare epidemiologist finds that one or more of the variables of interest is not distributed normally. In this circumstance, the epidemiologist can choose to estimate a nonparametric correlation coefficient (*1–4*,5,*7*,8,*9*,15,*16*,*33*).

Rank Correlation The Kendall coefficient of rank correlation, the Greek letter tau (τ), and the Spearman rank correlation coefficient, ρ_s, are nonparametric coefficients. When these are reported, the clinical investigator makes no assumptions about the distributions of the variables.

Spearman's rank correlation coefficient (also called Spearman's rho) is a sample correlation coefficient based on ranks. First, the investigator ranks the values of each variable from largest to smallest (or vice versa) and then estimates ρ_s using the Pearson product moment formula, substituting ranks for the actual values. The rationale for this estimator is that if there were a perfect correlation between the two variables, the ranks for each subject on each variable would be the same. Thus, the change in rank (i.e., the rank of the first variable minus the rank of the second variable) would be zero for every subject. Spearman's rank correlation coefficient can also be used for estimating the correlation between ordinal (i.e., rank) variables.

Kendall's τ provides a measure of reranking. Estimation of Kendall's τ is slightly more difficult than estimation of Spearman's rank correlation coefficient. For the method, see Sokal and Rohlf *(2)*. Usually, if both Kendall's τ and Spearman's rank correlation coefficient are estimated from the same data, the estimate of Kendall's τ is smaller than that of Spearman's rank correlation coefficient. However, the p values are usually very close to the same value. When an investigator estimates Kendall's τ, the Greek letter is used for the statistic. Kendall's τ is one of few examples of Greek letters being used for both the parameter and the statistic.

Point Biserial Correlation Coefficient The point biserial correlation coefficient, ρ_{pb}, is used when one random variable is dichotomous and the other is continuous. Asymptotically, the point biserial correlation coefficient is the same as a Pearson product moment correlation coefficient estimated for one dichotomous variable and one continuous variable.

Biserial Correlation Coefficient The biserial correlation coefficient, ρ_b, is used when one random variable has been forced to be dichotomous (e.g., by dividing a measurement into upper and lower halves) and the other random variable is continuous. Asymptotically, the biserial correlation coefficient is the same as a Pearson product moment correlation coefficient estimated for one dichotomous variable and one continuous variable.

Phi Fourfold Coefficient The phi (φ) fourfold coefficient is the special name given to the measure of concordance for 2×2 tables (*7*,15). Asymptotically, the phi coefficient is the same as a Pearson product moment correlation coefficient estimated for two dichotomous variables. Thus, this statistic gives a measure of correlation or concordance for dichotomous variables. When an investigator estimates φ, the Greek letter is used for the statistic; φ is another one of few examples of Greek letters being used for both the parameter and the statistic.

Contingency Coefficient The contingency coefficient is used to measure concordance between categorical variables depicted in $r \times c$ tables (i.e., tables in which

the numbers of rows and columns are not necessarily the same) *(7,33)*. Thus, when one or both of the categorical variables has three or more levels, the investigator would choose the contingency coefficient (*C*) as an estimate of the correlation coefficient.

The Kappa Statistic

The kappa statistic, κ, is used to measure concordance for 2×2 and square $r \times c$ tables (i.e., tables in which the numbers of rows and columns are the same) (8,*33*). Often, these tables reflect paired data. When an investigator estimates κ, the Greek letter is used for the statistic; κ is another one of few examples of Greek letters being used for both the parameter and the statistic.

The healthcare epidemiologist may find many uses for the kappa statistic. For example, two radiologists may read radiographs of patients in a particular ICU. On a given day, which radiologist reviews radiographs often depends on a staffing schedule. In actuality, each radiograph is reviewed by only one radiologist. Therefore, one radiologist may review the radiographs for a particular patient taken on admission. The next radiograph taken on the same patient 3 days later may be read by the other radiologist. Naturally, the healthcare epidemiologist would like to know whether the radiologists are likely to give the same diagnosis to the same patient based on the same radiograph. Analyzing data from patients in this ICU may require the epidemiologist to make the assumption that the diagnoses from the two radiologists are the same. Rather than making this assumption, the epidemiologist can design a study to measure the agreement (or concordance) between the two radiologists when they review the same radiographs. In a hypothetical study, one might suppose that the various diagnoses available to the radiologists are (a) definitely not interstitial disease, (b) probably not interstitial disease, (c) possibly not interstitial disease, (d) possibly interstitial disease, (e) probably interstitial disease, and (f) definitely interstitial disease. Therefore, the epidemiologist needs a measure of concordance. The epidemiologist forms the hypotheses for the kappa statistic:

$$H_0 : \kappa = 0 \text{ versus } H_1 : \kappa \neq 0.$$

First, the epidemiologist asks the radiologists each to review a number of radiographs. For this particular study, the epidemiologist is not as concerned about the radiologists agreeing with a gold standard as with their agreement with each other. After collecting the data, the epidemiologist tabulates the results in a 6×6 table.

Concordance is measured by the proportion of observations in the cells along the main diagonal. The healthcare epidemiologist compares the observed concordance rate with that which would be expected if there were no concordance among the two radiologists. The epidemiologist estimates κ and the variance of κ; for specific formulas, the reader should see Rosner (8). Then, to test H_0, the epidemiologist computes the test statistic, which is a *z*-score and follows the standard normal distribution. The *p* value is the probability associated with z_s, assuming that the null hypothesis is true. Rejecting H_0 implies that the data show evidence of concordance between the two radiologists. Finally, the epidemiologist uses the following guidelines for evaluation of the estimated κ statistic: (a) an estimated $\kappa > 0.75$ denotes excellent reproducibility; (b) an estimated κ between 0.40 and 0.75, inclusive, denotes good reproducibility; and (c) an estimated $\kappa < 0.40$ denotes marginal reproducibility (8).

The $(1-\alpha)100\%$ CI for κ is computed in the usual way. Conceptually, this CI is the same as the CI for μ. Whenever the CI does not include zero, the investigator rejects H_0. If the $(1-\alpha)100\%$ CI includes the hypothesized value, the results of the study, according to these data, are consistent with H_0. The CI is interpreted as follows: the estimate of κ is a random variable; for each sample, there will be a different estimate κ and a different s_κ. The concordance can fluctuate within these bounds with 95% confidence that the true concordance lies there.

MULTIVARIABLE ANALYSIS

Most epidemiologic investigations involve more than one or two variables of interest. Therefore, clinically based studies of disease determinants often yield data sets that require complicated analytic methods. Generally, the healthcare epidemiologist identifies an outcome variable (e.g., death, infection, or time to an event). In addition, there are other selected variables, including the particular exposure, that are relevant to the investigation. The primary focus of the study is the relationship between the particular exposure and the specified outcome; complexities arise, because the epidemiologist must sort out interrelationships among other variables that affect (confound) the relationship between the outcome and exposure (see Chapter 2).

Although the epidemiologist has specialized knowledge about the disease process under investigation, usually a complete theoretical framework describing the true relationship between the exposure and the outcome variables is lacking. Furthermore, the epidemiologist cannot control or manipulate through experiments the process linking exposure to outcome in ways that may reveal the true relationship. Fortunately, statisticians have developed a variety of multivariable analytic methods that address many problems encountered in clinically based research.

What does the term *multivariable analysis* mean? Many investigators refer to the statistical analysis of one dependent variable and several descriptive or explanatory variables (i.e., several independent variables) as multivariate analysis. However, this practice reflects a misuse of a statistical term that refers to the analysis of more than one dependent variable. For this reason, I have chosen to use the term *multivariable analysis* to encompass the following statistical methods: stratified analysis, multiple linear regression, multiple logistic regression, and survival analysis.

Model Selection Process

General Problems Dealing with more than one explanatory variable is a challenge for many clinical investigators. Kleinbaum et al. (28) suggest the following four ways in which multivariable analysis is more difficult than simple univariate analysis (i.e., one explanatory variable). First, usually more than one statistical model can be developed

for the same data set to adequately describe the relationship between the exposure and outcome variable. Choice of which model is the best is generally somewhat subjective and often sample dependent. Second, on any one graph, an investigator can depict at most three dimensions. Usually, an investigator considers more than three variables. In this situation, the investigator must limit each graphic depiction to two or three variables. Third, when the model includes more than one or two explanatory variables, most clinical investigators have difficulty translating the statistical model into a clinically meaningful explanation. Finally, analysis requires the investigator to use a computer software package for statistical analysis. When the number of independent variables is large, the model selection process can be very time-consuming. Many computer algorithms do not have built-in limits for the number of dependent or independent variables; the investigator has the responsibility of setting reasonable limits. The following discussion suggests some reasonable limits. Thus, in addition to specialized knowledge about the disease process, the epidemiologist must develop some expertise in multivariable analysis and acquire related computer skills.

Model Selection Whenever the research problem involves determining which explanatory variables should be included in the analysis, a clinical investigator needs a model selection strategy. Because some relationships among variables are specific to a particular sample (i.e., they are sample dependent), many investigators find that adhering to a formal strategy is especially helpful during exploratory data analysis. In a very real sense, each data set has new information that can provide the investigator with insight into the exposure–disease relationship. If some of the intricacies of this relationship, especially those that are unique to the current study, can be dissected early in the model selection process, the investigator is more likely to understand the clinical implications of the final model.

The goal of the model selection process is to identify a statistical model that reflects important aspects of the exposure–disease relationship. Therefore, before the process begins, the investigator must perceive a theoretical framework firmly based on considerations of subject matter. The statistical methods are the mathematical tools that the investigator uses to derive empirical support for the framework and discover new aspects of the relationship that can be used to modify the framework. Both biostatisticians and epidemiologists warn against relying exclusively on any statistical package to determine the best model for a data set. Except for pharmacokinetic, pharmacodynamic, and growth models, almost all statistical models commonly used in healthcare epidemiology are empirical rather than mechanistic. This distinction implies that even though a functional relationship may exist between the exposure and disease, limited information is available on the role that other variables have in influencing how the exposure–disease process is manifested in a given patient sample. Both biostatisticians and epidemiologists also caution investigators about literally interpreting the model as an accurate reflection of the true exposure–disease process. Finally, they are adamant in stating that any type of model selection technique can be abused.

After gaining experience with multivariable analysis, a clinical investigator may develop a unique style of model selection. However, until that experience has been gained, the cautious investigator should strictly adhere to guidelines provided by a biostatistician or epidemiologist who has extensive experience in model selection. Draper and Smith *(29)* have summarized, in a very readable chapter, the process of planning, developing, and validating a statistical model. In their text, Rothman et al. (34) devoted several chapters to the modeling process. Other authors have discussed the process and provided the reader with annotated examples: Kleinbaum et al. (20,28), Myers (30), and Myers and Milton *(31)*.

The Planning Stage The model selection process actually begins with the statement of the problem and identification of the research question. During the planning stage, the clinical investigator selects the response variable. If there is more than one response variable of interest, the investigator should limit the number to a few—no more than five is best. For each response variable, the clinical investigator lists all variables that could possibly be related to the outcome. This list is usually very long and may include almost every variable on a patient's chart. From this extensive list, the investigator identifies those variables that can be collected and groups these collectible variables into broad categories. For example, one category might contain all demographics, another could include severity of illness indices or perhaps comorbidities, and so on. Finally, by the end of the planning stage, the investigator should have a reasonable list of variables that merit inclusion in the study.

Are there resources available that can help the investigator in selecting variables for serious consideration? Resources include (a) reports of similar investigations published in the peer-reviewed literature and (b) discussions with experts in the disease of interest. During the initial planning stages, the clinical investigator bases decisions on subject matter expertise not statistics! However, some statistical considerations become important near the end of the planning stage.

Toward the end of the planning stage, the investigator studies the feasibility of the project. Specific items that require the attention of the investigator include the number of patients required to address the problem, the number of patients available, the time needed to accrue the minimum number of patients necessary for the investigation, the costs for data collection, other budget-related issues, and the availability of skilled ancillary personnel to ensure collection of high-quality data.

Data Collection and Quality Control Once the investigator has decided that the project is feasible, patient enrollment and data collection begin. Quality control of the data is vital to the success of the entire project. Remarkably, this is a step that some investigators overlook completely. Planning what quality control measures are needed for a clinical investigation may require advice from a biostatistician or epidemiologist. Unfortunately, despite precautions and the highest level of quality control, most data sets will contain some errors that escape detection. Reasonable goals for quality control include eliminating systematic errors,

especially misclassification, and minimizing the impact of random data entry errors. Therefore, the safeguards are directed at detecting influential errors, those errors that can bias results and threaten the validity of statistical inferences. Remember that a single error, such as a 50-lb newborn human infant, can have a disastrous impact on the findings of a study.

Model Selection—Univariate Analyses The first exploratory step in actual model selection involves obtaining descriptive statistics for the variables of interest. For continuous variables, testing for goodness of fit to the normal distribution may be important. In addition, for continuous explanatory variables, the range (or some other measure of variability) is usually an important consideration. For example, if the ages of the patients are very similar, age is not likely to influence the relationship between exposure and disease regardless of whether other studies have found that age is an important determinant of the disease of interest. Including variables with limited variability can compromise the model because of overparameterization.

The next steps in actual model selection are (a) plotting relationships between continuous variables, (b) using 2×2 and $r \times c$ tables to study relationships between discrete variables (i.e., attributes), and (c) estimation of Pearson and Spearman correlation coefficients for all pairs of variables. During this phase, the investigator is gaining an appreciation of which variables are associated with other variables and to what degree. The investigator should be careful about including explanatory variables in the multivariable model that are more highly correlated with each other than with the response variable. Including highly correlated independent variables in a model can lead to problems of multicollinearity. Other terms for the same phenomenon are collinearity and multiple collinearity. Multicollinearity in a statistical model occurs when two or more independent variables are strongly correlated with each other. When the explanatory variables are highly correlated with each other, the estimated coefficients are also highly correlated, thereby yielding unreasonable regression coefficients and an implausible and unusable statistical model.

At the end of the exploratory step, the investigator should have narrowed the list of potential explanatory variables to about 20 or fewer. Final models with more than five or six explanatory variables are difficult to explain. In narrowing the list, the investigator should be aware of the following rule: no fewer than 5 to 10 observations are needed for each potentially important explanatory variable that will be included in the final model. Having at least 30 observations for each variable included in the final model is a reasonable target.

Model Selection—Multivariable Analyses Style and philosophy influence the investigator's choice of which analytic procedures to use in developing multivariable models. Every procedure has strengths and weaknesses; all can be abused. Initially, most biostatisticians recommend using a rather liberal entrance or deletion criterion for variable selection (e.g., $p < .20$ or $p < .25$). As the final model emerges, traditional levels of significance for selected explanatory variables can be imposed. Regardless of what statistical procedure was used for model selection, most biostatisticians recommend that the investigator use appropriate diagnostic procedures to assess various aspects of the emerging statistical models and subject the results to the scrutiny of other clinical specialists with expertise in the exposure–disease process of interest. Regression diagnostics include examining the residuals and checking for systematic lack of fit.

Because more than one statistical model can provide a valid representation of the exposure–disease relationship, the investigator should select the best model and several competing models. Assessing the best model in light of competing models is a type of sensitivity analysis. The objective of this sensitivity analysis is to reveal which variables are stable in the model, reflecting the average patient, and which are seemingly sample specific (i.e., sample sensitive), reflecting small groups of patients with distinct characteristics.

Problems with Confounding Epidemiologists apply the term *confounder variables* to variables that are partially related to both the exposure and the outcome variables (20,34). In the statistical sense, a confounder is only partially confounded (i.e., associated or correlated) with both the exposure and the outcome variables; if a confounder were completely confounded with either variable, the confounder would be completely inseparable from that variable.

Confounders create problems for the investigator. The investigator's objective is to show whether a particular exposure and the outcome are related. If the investigator ignores an important and influential confounder, the estimates of RRs, ORs, or regression coefficients are biased. Consequently, the investigator does not know whether the relationship (or lack of one) is attributable to the confounder or to the exposure (see Chapter 2).

Indications of Multicollinearity Sometimes an explanatory variable will seem to have an important effect on a response when the variable is considered by itself with simple linear regression or correlation analysis. However, after adjusting for another explanatory variable, no significant relationship may remain. This apparent contradiction is an indication of multicollinearity. Inclusion of both variables in the statistical model may or may not be appropriate. There are rules for inclusion and exclusion, but their interpretation is subjective. Thus, the investigator must carefully assess any problems related to multicollinearity.

An investigator can learn to recognize some indications of multicollinearity. As variables are selected for inclusion or exclusion from the model, coefficients affected by multicollinearity will appear to be unstable in that their values will change dramatically. Sometimes multicollinearity can be severe enough to change the sign of an estimate. Another concomitant indication of multicollinearity is that affected coefficient estimates will often have large standard errors; sometimes the standard errors are several times larger than the estimates. Statisticians have developed several methods for detecting multicollinearity (*29*,30,*31*,32,35,36). Condition indices, variance inflation factors, and tolerance values can be used to determine which variables in the current model are affecting the estimates of regression

coefficients. Whenever multicollinearity appears to be an important problem, the clinical investigator should seek advice from a biostatistician experienced with model selection.

Indications of an Overparameterized Model Including explanatory variables that are not statistically significant can be considered overparameterizing the model. Subjective interpretation plays a role in the distinction between overparameterization and appropriate inclusion of a variable that is not statistically significant at traditional levels. Overparameterization and multicollinearity often occur simultaneously. One serious problem with highly correlated explanatory variables is that the model becomes very difficult to interpret in terms of actual clinical applications. After all, one of the reasons for using multiple linear regression is to allow the investigator to identify which explanatory variables have a significant relationship with the response after adjusting for other significant explanatory variables. Therefore, the investigator has to carefully evaluate problems associated with overparameterizing the model.

Detection of Influential Observations An influential observation is one that has an unusually large influence on the estimate of one or more regression coefficients. In general, influential observations are unique to a specific sample. By carefully examining the plots of each explanatory variable against the response, the investigator can identify many influential observations during exploratory analysis. However, in most large data sets, a few influential observations may emerge during model selection. In addition to examining plots of residuals, statisticians have developed several other methods for detecting influential observations (*18*,*29*,30,*31*,32,35,36). An investigator uses influence diagnostics for revealing which observations reflect the average patient and which are seemingly from patients with distinct characteristics. If possible, the investigator should determine why an observation has been identified as influential. Often, this process of examining influential observations reveals biologically and clinically important reasons for exclusion. After one or more influential observations have been identified, biostatisticians usually advise fitting the model after leaving out the suspect influential observations. Alternatively, inclusion of a dummy variable in the model (to designate the main group, $X = 0$, and set of influential observations, $X = 1$) may allow for including all observations in the final model.

Stratified Analysis

As discussed previously, cumulative incidence and prevalence of a disease are distributed binomially. An important assumption is that the probabilities for the outcomes are a constant p for success and $(1–p) = q$ for each failure for every trial. Often, in clinical studies, data from samples of patients fail to meet this assumption; other variables in addition to exposure influence the probability of the outcomes. One of the statistical methods for addressing confounders is stratified analysis (*1*,5,*6*,8,15,20,*21*,34). The investigator uses stratified analysis for controlling or adjusting for the confounder and estimates an adjusted RR or OR.

Mantel–Haenszel Test Two-way tables can be extended to multiway tables to accommodate several attributes. Typically, the Mantel–Haenszel test is used for situations in which (a) both the exposure and the outcome are dichotomous variables and (b) one or more other attributes are partially confounded with the relationship between exposure and outcome. The investigator forms a number of strata based on levels of one or more confounding variables; the confounding variables must be categorical, discrete, or continuous variables that have been forced to be categorical (e.g., by dividing into quintiles). The strata are chosen so that the data within each stratum are as homogeneous as possible. Typically, strata reflect patient characteristics (e.g., age category) or institutional characteristics (e.g., medical and surgical ICUs). The investigator assumes that the strata are independent. The Mantel–Haenszel test requires a reasonably large total sample size; however, this test was developed to accommodate sparse data within strata. The Mantel–Haenszel test for 2×2 tables can be generalized to $r \times c$ tables, but that application is beyond the scope of this chapter.

Within each stratum, the investigator constructs a 2×2 table relating the exposure and outcome variables. The test statistic does not depend on a particular arrangement of the 2×2 tables as long as the arrangement is the same for all strata. Choice of which variable is designated as the rows and which is designated as the columns is arbitrary. Similarly, the order in which the data for the rows and columns are coded is arbitrary. However, certain statistical software packages may require a particular arrangement, particularly when the investigator is estimating ORs or RRs.

H_0 states that there is no association between exposure and outcome after controlling for variables that create strata; H_1 states that there is an association after controlling for the strata. Under H_0, the Mantel–Haenszel statistic, χ^2_{MH}, follows a chi-square distribution with 1 degree of freedom. Thus, for a test of significance at the .05 significance level, H_0 is rejected if χ^2_{MH} is >3.84. The p value is the probability associated with χ^2_{MH}, assuming that the null hypothesis is true.

The investigator should report results based on the Mantel–Haenszel test only when there is no evidence of statistical interaction involving the strata. The Mantel–Haenszel test is still valid statistically; however, the interpretability of the results may be in question. Therefore, the investigator should not rely exclusively on the p value associated with the test statistic but should carefully study the patterns of association displayed in the various strata with a particular interest in detecting evidence of a statistical interaction involving the strata or test for homogeneity of strata using the Breslow–Day test. For example, if the Mantel– Haenszel test statistic is not significant, (a) there may be no association between the exposure and the outcome (i.e., H_0 is correct) or (b) there may be opposing or inconsistent patterns among the strata. An obvious interaction is present when the pattern exhibited by some strata is in the opposite direction from the pattern of other strata. In contrast, even without the presence of opposing patterns, interaction may be present when Fisher's exact test indicates significance for some strata and lack of significance for others; in this situation, determining what constitutes

an interaction is somewhat subjective. Finally, even if the Mantel–Haenszel test statistic reaches significance, there may be evidence of an interaction. In this circumstance, the issue of interpretability is addressed subjectively, according to subject matter considerations. For example, significance could be attributable to one or more dominant strata that have a strong pattern of association in one direction and overwhelm the lack of association or an opposing pattern in the remaining strata. Regardless of the significance of the test statistic, evidence of an interaction indicates that analysis of data over all strata may be inappropriate. If an investigator encounters evidence of an interaction involving the strata, he or she should seek the advice of an experienced biostatistician or epidemiologist (see also Chapter 2).

Estimates of Adjusted ORs and RRs The Mantel–Haenszel method can be used to estimate strata-adjusted ORs and RRs along with respective 95% CIs. The reader should review the previous discussion of unadjusted ORs and RRs estimated from 2×2 tables. Unlike the RR, the OR is not constrained by the denominator. This property is particularly advantageous when estimated ORs are combined over strata.

Strata-adjusted estimation is based on the assumption that the parameter is the same for each stratum and that the values of estimates differ because of sampling. When estimating adjusted measures of association, the investigator should carefully study the pattern of association displayed by the various strata. The same problems of interpretability discussed for the Mantel–Haenszel test apply to estimation. However, unlike the test statistic, estimates are not valid unless the assumption of homogeneity is met. Criteria for what constitutes a violation of this assumption are somewhat subjective.

Either test-based or precision-based CIs can be estimated. For a discussion of the advantages and disadvantages of these intervals, the reader is referred to Kleinbaum et al. (20). Sometimes, extreme estimates or confidence limits are obtained because of very small observed frequencies in some cells (often as few as only one or two events).

A Special Case—Matched Pairs For matched pairs, the clinical investigator can estimate RRs and ORs from stratified analyses with the strata representing the pairs. Methods for point and interval estimates are the same as those described previously. Usually, the investigator does not study the pattern of association for the various strata.

Breslow–Day Test The Breslow–Day test for homogeneity tests the null hypothesis that the ORs for all strata are equal versus the alternative that the OR for at least one of the strata is different *(37)*. The test statistic is valid only when every stratum has a large number of observations (generally more than 20). Under H_0, the test statistic follows a chi-square distribution with degrees of freedom equal to one less than the number of strata included in the test statistic. Strata with a zero column or row total are excluded from computation of the test statistic. Regardless of whether the investigator uses the Breslow–Day test, it is incumbent on the investigator to carefully study the pattern of association displayed by the various strata. When the estimates of ORs have opposing patterns, there is usually no question about the inequality of ORs over strata. However, evidence of other patterns of interaction is more subjectively determined.

Multiple Linear Regression

Multiple Linear Regression Analysis A clinical investigator uses multiple linear regression analysis when the objective involves studying the relationship between more than two variables at the same time (*1*,*2*,4, 5,*6*,*7*,8,*9*,*18*,*21*,28,*29*,30,*31*). There is a single continuous dependent or response variable, but there are several independent, descriptive, or explanatory variables. The explanatory variables may be continuous or dichotomous; in addition, categorical explanatory variables can be recoded for inclusion in a multiple regression model.

The statistical model is $Y_i = \alpha + \beta_1 X_{1i} + \beta_2 X_{2i} + \ldots + \beta_k X_{ki} + \varepsilon_i$, where i is the indicator for each subject and ranges from 1 to n. The data set contains n sets of $(k + 1)$ measurements where n indicates the number of subjects in the sample; a complete set of measurements is taken on every patient. Of these measurements, k values are X values, and one is a Y value. The β values are partial regression coefficients with the intercept, α, corresponding to the intercept in simple linear regression. A partial regression coefficient quantifies the relationship between a particular explanatory variable and the response after adjusting or controlling for all other effects in the model.

The same assumptions that were necessary for simple linear regression also apply to multiple linear regression. Multiple linear regression merely reflects an expansion of the simple case to p-dimensions, each representing a different independent variable. Regardless of form, the explanatory variables are assumed to function independently. Most often, the independent variables have the form of main or direct effects (e.g., age, days on mechanical ventilation, or APACHE III score). However, some of the independent variables may represent interactions of two other independent variables, X_1X_2. As a standard practice, the investigator should include the direct effects of X_1 and X_2 in a model in which the interaction is included. An example of an interaction is the joint effect of age and APACHE III score on a particular response variable. Independent variables may represent higher powers of other independent variables, X_1^2 or X_1^3. Generally, when higher powers, such as X_1^3, are included in the model, the lower powers (X_1 and X_1^2) are also included. For example, the relationship between the response and age may not be completely linear but may increase at an increasing rate, thereby requiring the inclusion of age and age-squared.

An investigator should always be conservative in interpreting a multiple regression model. Other variables, not included in the model, may actually be the cause of differences in the response.

Polynomial or Curvilinear Regression Models Polynomial regression is a special case of multiple linear regression for one independent variable, X, and one continuous dependent variable, Y. The highest degree polynomial that may be fit to the data is one less than the number of observations. For most biologic phenomena, biostatisticians

recommend limiting the model to a cubic regression. The general rule for using polynomial regression analysis is that the investigator use as simple a model as possible but one that explains as much of the variation of Y as possible. The investigator should be aware that as the degree of the polynomial becomes higher, the interpretation of the curve becomes more difficult. The model for a quadratic regression is

$$Y_i = \alpha + \beta X_i + \gamma X_i^2 + \varepsilon_i$$

where i is the indicator for each subject and ranges from 1 to n. Both β and γ are partial regression coefficients.

Tests of Hypotheses Methods for regression analysis and hypothesis testing are similar to those described for simple linear regression. The same principle of least squares is used to estimate the regression coefficients by minimizing the residual sum of squares over all data points. The clinical investigator tests the overall null hypothesis that all β values equal zero versus the alternative hypothesis that at least one β value does not equal zero. Under the null hypothesis, the F_s, which is the ratio of the model or regression MS divided by the residual or error MS, follows an F distribution with p and (n–k–1) degrees of freedom. The p value is the probability associated with F_s, assuming that the null hypothesis is true.

The overall F-test will not identify which specific explanatory variables are associated with the response. The clinical investigator must perform t-tests to investigate the specific association of each independent variable with the response. For one- or two-sided t-tests on individual partial regression coefficients, the investigator uses a t statistic with (n–k–1) degrees of freedom. The p value is twice the probability associated with t_s, assuming that the null hypothesis is true.

Interval Estimation Generally, the investigator wishes to estimate partial regression coefficients. The printed results from most computer software packages include estimates and standard deviations of the estimates. The standard deviations of the estimates may be called standard errors. The clinical investigator obtains the 95% CIs for each partial regression coefficient in the usual way:

$$b \pm t_{[0.975,n-k-2]} s_b$$

Conceptually, this CI is the same as the CI for μ. Whenever the CI does not include zero, the investigator rejects H_0. If the (1–α)100% CI includes the hypothesized value, the results of the study according to these data are consistent with H_0. The CI is interpreted as follows: the estimate of β is a random variable; for each sample, there will be a different estimate b and a different s_b. As the variable X changes by one unit, the expected response changes by b units after controlling for all other variables in the model. Controlling for all other variables implies that the value of each of the other explanatory variables in the model has been set to the respective mean value. An investigator should always be conservative in interpreting a multiple regression coefficient. Other variables, not included in the model, may actually cause the variability of response.

Standardized Partial Regression Coefficients The concept of standardized regression coefficients can be extended to multiple linear regression; these are called standardized partial regression coefficients. By using standardized partial regression coefficients, the clinical investigator can express relative changes that are independent of any units of measurement. In addition, the investigator can use standardized partial regression coefficients for ranking the effects of the explanatory variables in order of importance.

Partial regression coefficients are standardized by dividing the estimated partial regression coefficient by the ratio of the standard deviation of the response variable to the standard deviation of the respective explanatory variable:

Thus, the standardized regression coefficient is a dimensionless value that represents the predicted change in Y, expressed in standard deviation units that would be expected for each change in X of one standard deviation unit after adjusting for all other variables in the model.

Partial Correlation Coefficients The healthcare epidemiologist obtains estimates of partial correlation coefficients following analyzing data by multiple regression methods. Partial correlation coefficients provide an estimate of the remaining correlation after one or more other variables are held constant (i.e., after adjusting for the other variables) *(2,4,9)*. Partial correlation coefficients are used when there are correlations among the explanatory variables. In practice, the epidemiologist examines both the total (or unadjusted) correlation coefficients and the partial (adjusted) correlation coefficients.

Multiple Logistic Regression

A clinical investigator uses multiple logistic regression analysis when the outcome or response variable follows a binomial distribution (*1*,5,*6*,8,*18*,20,*21*,34). Generally, the objective is similar to that for multiple linear regression and involves studying the relationship between more than two variables at the same time. There is a single dichotomous dependent or response variable and several independent or explanatory variables. Typically, the investigator refers to any explanatory variables, other than the specified exposure, as confounding variables. The investigator wishes to examine the relationship between the exposure and the outcome after controlling for the confounding variables. These confounding variables may be continuous, dichotomous, or categorical variables. When the strata used in stratified analysis and the confounding variables used in logistic regression are defined similarly, the results from the two methods are identical. By permitting continuous variables and interactions to be included in the model as explanatory variables, logistic regression is more flexible than stratified analysis. However, logistic regression does have one potentially serious limitation—only ORs can be estimated from logistic regression. However, these ORs can be used as approximators of RRs if the study design permits.

In logistic regression, the response variable is expressed as p and is the probability that the response, Y, is an event—that is, $p = \Pr(Y = 1)$. For logistic regression analysis, the presence of the event is almost always coded as one. Given

that a subject has certain values for X_1 to X_k, the expected or average probability of an event is $p = \Pr(Y = 1)$. The event or outcome of interest may be a particular disease or death. For this discussion, the event is disease.

The statistical model is

$$p_i = \frac{e^{\alpha+\beta_1 X_{1i}+\beta_2 X_{2i}+\cdots+\beta_k X_{ki}+\varepsilon_i}}{(1+e^{\alpha+\beta_1 X_{1i}+\beta_2 X_{2i}+\cdots+\beta_k X_{ki}+\varepsilon_i})},$$

where i is the indicator for each subject and ranges from 1 to n; $\exp(x) = e^x$;

Using the logit transformation, this model becomes

$$\ln(p_i / (1 - p_i) = \alpha + \beta_1 X_{1i} + \beta_2 X_{2i} + \cdots + \beta_k X_{ki} + \varepsilon_i.$$

Note that the logit transformation yields a model that is linear in its parameters, thus incorporating certain properties of multiple linear regression. The data set contains sets of $(k + 1)$ measurements on each subject. Of these measurements, k values are X values, and one is the event, Y. The β values are partial regression coefficients with the intercept, α, corresponding to the intercept in simple linear regression. In a logistic regression model, the explanatory variables are related multiplicatively to each other rather than additively as they would be in a linear model. Unlike the errors from the multiple linear regression model that are distributed normally, the errors of the multiple logistic model are distributed according to a binomial distribution. Furthermore, the expected value of Y for a given X lies between zero and 1.0. Because of complexities that involve fitting the parameters of this model, clinical investigators rely on a computer-based iterative algorithm.

Throughout this discussion, note that the natural logarithm of the odds of disease is $\ln[p/(1–p)]$. The intercept, α, represents the natural logarithm of the baseline odds of disease (i.e., the event). The baseline odds correspond to the odds of disease among the unexposed—that is, when all X values are set to zero. The partial regression coefficients quantify the relationships between a particular explanatory variable and the response after adjusting or controlling for all other effects in the model. When a partial regression coefficient quantifies the relationship between a dichotomous variable and the response, β represents the natural logarithm of the additional odds of disease among those with the attribute after controlling for all other variables in the model. For a categorical or continuous variable, the multiplicative relationship between the explanatory and outcome variables becomes apparent. β represents the change in the natural logarithm of additional odds of disease per unit change in X. Controlling for all other variables in the model implies that all other attributes occur at equal frequencies. The reader is referred to Rothman et al. (34), Kleinbaum et al. (20), and Hosmer and Lemeshow (35) for additional information on implications for epidemiologic models.

The same assumptions that were necessary for analysis of data in 2×2 tables and stratified analysis also apply to multiple logistic regression. In addition, logistic regression shares many similarities with multiple linear regression. Multiple logistic regression reflects k-dimensions, each representing a different independent variable. Regardless of form, the independent variables are assumed to function independently. Independent variables usually have the form of main or direct effects (e.g., presence of a healthcare-associated infection, age, days on mechanical ventilation, or APACHE III score). However, some independent variables may represent interactions of two other independent variables that should also be included in the model as direct effects, X_1 and X_2.

An investigator should always be conservative in interpreting a multiple logistic regression model. Other variables, not included in the model, may actually be the cause of differences in the probability of an event.

Tests of Hypotheses Tests of hypotheses, interval estimation, and interpretation of the results are counterparts of those for multiple linear regression.

Generally, the clinical investigator does not test an overall null hypothesis that all of the explanatory variables in the model are zero. However, this test is usually available. If competing models for the same data are being compared, there are test statistics available for assessing the joint or combined significance of all explanatory variables included in the model. The Score, Akaike Information Criterion, and the Schwartz Criterion statistics are used for this purpose.

The clinical investigator can perform z-tests to investigate the specific association of each independent variable with the response. Alternatively, for two-sided hypothesis tests on individual partial regression coefficients, the investigator can use a Wald chi-square statistic, which follows a chi-square distribution with 1 degree of freedom under the null hypothesis. The p value is the probability associated with χ^2_s, assuming that the null hypothesis is true. For more information on hypothesis testing, see Lawless (36).

Interval Estimation Generally, the investigator wishes to estimate partial regression coefficients and adjusted ORs. The printed results from most computer software packages include estimates and standard deviations of the estimates. The estimates of regression parameters are maximum likelihood estimates. Standard deviations of these estimates may be called standard errors. Sometimes the printed results also contain estimated adjusted ORs and asymptotic 95% CIs. The clinical investigator obtains the asymptotic 95% CIs for each partial regression coefficient in the usual way.

Whenever the CI does not include zero, the investigator rejects H_0. If the asymptotic $(1–\alpha)100\%$ CI includes the hypothesized value, the results of the study, according to these data, are consistent with H_0. The CI is interpreted as follows: the estimate of β is a random variable; for each sample, there will be a different estimate b and a different s_b. As the variable X changes by one unit, the expected natural logarithm of additional odds of disease changes by b units after controlling for all other variables in the model.

The interpretation of the OR is illustrated in the following example: after controlling for all other variables in the model, patients who are ventilated are 1.497 times as likely to have pneumonia as those who are not ventilated. Controlling for all other variables implies that the value of each of the continuous explanatory variables in the model has been set to the respective mean value and that each of the dichotomous variables occurs at equal frequencies. An investigator should always be conservative in interpreting

an OR estimated from multiple logistic regression analysis. Other variables, not included in the model, may actually cause the variability of response.

Matched Case–Control Studies For matched case–control studies, the investigator can use conditional logistic regression to study the effects of confounders (20). The reason for matching is that the investigator knows that certain factors are partially confounded with the relationship between exposure and outcome. However, there may be other potential confounders that the investigator wishes to consider in a multiple regression model. Because of complexities involved in fitting the parameters of this model, clinical investigators rely on a computer-based iterative algorithm.

Survival Analysis

A clinical investigator uses survival analysis when the outcome or response variable is time to an event (*1*,*3*,5,*6*, 8,*18*,20,*25*,34,38,*39*,*40*). The event is often considered a failure. Survival analysis is a form of conditional logistic regression analysis that allows for censored observations. Some survival analysis is based on parametric models that allow for left-, right-, or interval-censored observations. In clinical investigations, the most commonly used models for survival analysis are nonparametric models that allow for right-censored observations. In the clinical setting, a common feature of lifetime or survival data is the presence of right-censored observations; censoring arises from either withdrawal of subjects or termination of the study. For censored observations, the lifetime is known to have exceeded the recorded value, but the exact lifetime remains unknown. Survival data should not be analyzed by ignoring the censored observations. Among other considerations, the longer lived units are generally more likely to be censored. Therefore, the analysis must correctly use the censored observations and the uncensored observations.

The investigator regresses the survival time variable on one or more independent variables. The survival curve gives the probability of survival up to time t for each time. The hazard function is the instantaneous probability of having an event at time t given that the subject has survived up to time t. Under Cox's proportional hazards model, the hazard is modeled as $H(t) = h_0(t)e^{(\beta_1 X_1 + \cdots + \beta_k X_k)}$, where X values are independent variables and $h_0(t)$ is the baseline hazard at time t. Cox's proportional hazards model has become the method of choice for multivariable analysis of incidence density variables. By taking logarithmic transformations, the investigator can interpret the regression coefficients in a way similar to multiple logistic regression. The investigator uses similar methods for hypothesis tests and point and interval estimation of regression coefficients and conditional RR approximations of RRs. Cox's proportional hazards model can be generalized to accommodate both time-dependent and constant explanatory variables. Because of complexities involved in fitting the parameters of survival models, clinical investigators rely on statistical software.

Usually, a first step in survival analysis is the estimation of the distribution of the failure times. The survival distribution function (SDF) is used to describe the lifetimes of the population of interest. The SDF evaluated at time t is the probability that a subject sampled from the population will have a lifetime exceeding t—that is, $S(t) = \Pr(T > t)$ where $S(t)$ denotes the survival function and t is the lifetime of a randomly selected subject. A likelihood ratio test may be used to test for equality of SDF between the strata. Estimates of some other functions closely related to the SDF may also be obtained. These related functions include the cumulative distribution function, the probability density function, and the hazard function. The hazard function indicates when the likelihood of failure is greatest.

Clinical investigators may select other variables for defining strata. Survival estimates within the strata can be computed and displayed using Kaplan–Meier plots for visual comparison of the results. The median survival time corresponds to that time when half the subjects have failed and half still survive. The investigator may also be interested in the times when 25% and 75% of the subjects in the sample have failed. In addition, rank tests for homogeneity can be used to indicate whether there are significant differences between strata at shorter and/or longer survival times. The Wilcoxon test places more weight on early (shorter) survival times. The log rank test places more weight on larger (longer) survival times.

Often there are additional variables, called covariates, that may be related to the failure time. These variables can be used to construct statistics that test for association between the covariate and the survival time. Two commonly used tests are the Wilcoxon and log rank tests. These tests on covariates are computed by pooling over any defined strata, thereby adjusting for the strata variables. These two tests are similar to those used to test for homogeneity.

Model Selection Techniques for Regression Analysis

Having selected a set of potential explanatory variables, the clinical investigator wishes to know which of these should be included in the final model. If there are only a few explanatory variables, the investigator can consider assessing all possible regression equations. With any more than three or four explanatory variables, the investigator should consider another technique. Statisticians have developed several techniques based on objective criteria for model selection. Before choosing one of these methods, a clinical investigator should review the section on model selection and consider consulting an experienced biostatistician or epidemiologist.

A forward inclusion procedure begins with no explanatory variables in the model. For each potential explanatory variable, the algorithm computes each variable's contribution to the model as if it alone were included in the model. Generally, for each potential explanatory variable, the p value associated with the test statistic is compared to a specified level of significance. That variable, which contributes the greatest amount of information and has a p value less than the specified value, is entered into the model. In the second step, the algorithm computes the contribution to the model (now containing one explanatory variable) for each remaining potential explanatory variable. That variable, which contributes the greatest amount of information and has a p value less than the specified value, is entered

into the model. If there is none that meets the entrance criteria, the process stops. If a variable does enter the model, this process continues until there are no variables remaining that meet the criteria for entrance. Once a variable has entered the model, it stays. Models selected with a forward selection technique should be scrutinized for multicollinearity and overparameterization.

A backward elimination procedure begins with a model that includes all potential explanatory variables in the model. For each variable included in the model, the algorithm computes the amount of information contributed by that variable and the *p* value associated with the test statistic. The variable that contributes the least amount of information and has a *p* value greater than a specified value is eliminated from the model. This process continues until all variables remaining in the model yield test statistics with associated *p* values that are smaller than the specified value. Once a variable has been eliminated, it is gone. Although this model selection was designed to address issues of multicollinearity and overparameterization, models selected with a backward elimination technique should be scrutinized for underparameterization.

A stepwise algorithm combines the techniques of forward inclusion and backward elimination. As with forward inclusion, potential explanatory variables are added one by one to the model. The technique begins with no variables in the model. The algorithm computes each potentially explanatory variable's contribution to the model as if it alone were included in the model. Generally, for each potential explanatory variable, the *p* value associated with the test statistic is compared to a specified level of significance. The variable that contributes the greatest amount of information and has a *p* value less than the specified value is entered into the model. However, a stepwise algorithm differs in that variables that are already in the model do not necessarily remain there. For each variable included in the model, the algorithm computes the amount of information contributed by that variable and the *p* value associated with the test statistic. The variable that contributes the least amount of information and has a *p* value greater than a specified value is eliminated from the model. This process continues until there are no variables remaining that meet the criteria for entrance or deletion. Even though this model selection technique was developed to minimize problems related to multicollinearity and overparameterization, models selected with a stepwise algorithm should be scrutinized.

ROLE OF A CONSULTING BIOSTATISTICIAN IN CLINICAL RESEARCH

In some situations, the statistical aspects of a study become so involved that consulting with a biostatistician is essential. Throughout this chapter, I have indicated when, in my opinion, an investigator with a moderate level of both research experience and analytic skills should consider seeking the assistance of a biostatistician. Those with a lower level of either experience or skills should seek advice earlier in the research process. For some projects, a healthcare epidemiologist should consider involving the biostatistician as a member of the research team. Ideally, this arrangement requires a high level of commitment on the parts of both the healthcare epidemiologist and the biostatistician. Most researchers lack the time and mathematical background required to master complex statistical issues and methods (e.g., multivariable model selection). Thus, a progressively more common practice is to include a biostatistician (or a scientist with specialized training in statistics) on research teams.

The research goals and objectives of a consulting biostatistician are similar to those of researchers in other scientific disciplines: to develop and disseminate high-quality science through research. However, the biostatistician focuses on the statistical aspects of research questions. These aspects include experimental design, statistical analysis, interpretation of results, and dissemination of results through publication. As a member of a research team, a biostatistician should be capable of serving all statistical needs of the project. Occasionally, a research project presents some unique feature that has not yet been considered in the field of applied statistics. Many biostatisticians will recognize that this feature provides a research topic in biostatistics and the opportunity for developing a new statistical technique.

Qualifications, abilities, and available time will limit a biostatistician's role on a research project. Obviously, technical skills and knowledge of statistical methods are essential. Most biostatisticians have a general knowledge of many statistical methodologies. However, like most professionals, biostatisticians have special interests and, thereby, acquire practical experience in specific types of analytic methods. For example, if the study involves complex multivariable model development and selection, the investigator should attempt to seek assistance from a biostatistician who has an interest in those analytic methods and is experienced in multivariable models and model selection.

Most research questions can be addressed several ways. Constraints that are independent of the question usually make one design more desirable than another. In addition to having the necessary practical experience, possessing problem-solving abilities allows a biostatistician to appreciate practical issues and to choose efficient experimental designs and appropriate statistical methods.

Good interpersonal skills are necessary for the biostatistician to communicate effectively with the principal investigator. If the biostatistician becomes a team member, these skills are needed for communication with coinvestigators, technicians, and other ancillary staff members. Oral and written communication abilities are important team traits. Tactfulness is an interpersonal skill that is especially needed by biostatisticians who interact with individuals who may feel uncomfortable and vulnerable when they discuss statistical issues.

Typically, biostatisticians work as consultants on a large number of projects. The demand for biostatisticians exceeds the supply. Therefore, researchers will need to make compromises with biostatisticians regarding their level of involvement as members of research teams. From the biostatistician's perspective, being a member of a research team represents a long-term investment of

time and effort. The biostatistician needs time to learn enough about the health science of the problem so that he or she can assist the investigator with the interpretation of results. The biostatistician needs time to complete the analyses. Because computers complete computations extremely quickly, investigators can forget that programming and exploratory data analyses can be extremely time-consuming for the biostatistician.

CHAPTER 4

Principles of Healthcare Epidemiology

Mary D. Nettleman, Robin L. Roach, and Richard P. Wenzel

Epidemiology is the study of the distribution and determinants of health and disease in populations. Healthcare epidemiology is the application of epidemiologic principles to the inpatient, long-term care, and outpatient environments. Healthcare epidemiology has its roots in infection control, and this activity remains central to most healthcare epidemiology programs. In the past two decades, however, the scope of the field has expanded to encompass control and prevention of both infectious and noninfectious adverse events. Concurrently, the reach of healthcare epidemiology has expanded to include events that are a result of hospital exposures that do not become evident until after discharge. The term *healthcare-associated* has come into common usage to encompass all healthcare-related events and is gradually replacing the more narrow term, *nosocomial*. This chapter examines the background and rationale for healthcare epidemiology and reviews the characteristics of an effective healthcare epidemiology program in the hospital.

HOSPITALS IN THE UNITED STATES

The hospital environment is highly complex and continuously presents new challenges to the epidemiology team. There are currently 5,815 hospitals in the United States, and this number has been relatively stable over the past decade *(1)*. Among hospitals, 86% are community based (including university hospitals), 8% are nonfederal psychiatric hospitals, and 4% are run by the federal government. US hospitals have 951,045 staffed beds and handle more than 37 million admissions each year. In 2006, there were 119 million visits to hospital emergency rooms and 102 million visits to hospital outpatient departments *(2)*.

Patients move through the hospital environment rapidly. In 2006, the average length of stay per inpatient was only 4.8 days, compared to 5.4 days in 1995 and 6.5 days in 1985 *(2)*. With this rapid turnover, it is easy for a patient to acquire an infection in the hospital and be discharged before the infection is diagnosed or becomes manifest. This creates a problem in case finding and thus affects the accuracy of attack rates.

Overall, 7.3% of the US population was hospitalized at least once in 2006, which is slightly less than the 7.7% figure for 1997. Although the major discharge diagnoses have remained relatively static over the past decade, the severity of illness has increased in many centers. In part, this is a reflection of advances in the outpatient environment, which can now handle mild or moderate illnesses without hospitalization. Third-party payers have also restricted or eliminated inpatient reimbursement for patients deemed to have milder illnesses, causing hospitals to try to limit admissions in this group. In addition, the inpatient population is influenced by population demographics. For example, as Americans have become more obese, type 2 diabetes has become more prevalent in the inpatient and outpatient settings *(3)*. Diabetes may increase the severity of many comorbid illnesses and the susceptibility to healthcare-acquired infections or surgical complications. Thus, although fewer patients are hospitalized and length of stay has decreased, severity of illness has increased in the inpatient population. The result is an increased susceptibility to adverse events and increased difficulty in detecting and preventing such events.

Healthcare is a major part of the US economy, and hospitals contribute a significant proportion of this cost. The total expenses for US hospitals exceed $690 billion per year *(1)*, accounting for 31% of all national health expenditures and rising steadily in the new millennium *(2)*. To the extent that adverse events are preventable, they represent an opportunity to reduce cost and improve quality.

The hospital environment includes healthcare workers as well as patients, and both groups have a right to be protected from harm. Almost six million workers are employed by hospitals in the United States *(2)*, and many of the nation's 1.7 million physicians work at least partially in an inpatient setting. Hospitals also provide a training site for the country's 71,000 medical students *(4)*, 145,000 nursing students in entry-level baccalaureate programs *(5)*, and 109,000 house staff *(6)*.

RATIONALE FOR HEALTHCARE EPIDEMIOLOGY

The practice and study of healthcare epidemiology is founded on the principle of nonmaleficence, as expressed in the phrase *primum non nocere*: "first do no harm." Unfortunately, the hospital environment has great potential to do harm. In the year 2000, the Institute of Medicine published

their seminal report *To Err is Human* (7), demonstrating that medical errors were a leading cause of death and injury in the United States. Based on data from previous studies, the report estimated that 44,000 to 98,000 Americans die annually in hospitals as a result of potentially preventable medical errors. As a result, medical errors have become at least the eighth most common cause of death in this country. In this context, medical errors are defined as potentially preventable adverse events, including medication errors *(8)*, accidental injuries, misdiagnoses, healthcare-associated infections, and others. Importantly, the goal of healthcare epidemiology is to improve patient outcomes and not all errors result in adverse outcomes.

Although the overarching goal of healthcare epidemiology is to improve health outcomes by reducing adverse events, an effective program can also save money for the hospital. Preventable adverse events are extremely costly. For example, one recent review estimated that ventilator-associated pneumonias cost approximately $23,000 per case, catheter-associated bloodstream infections cost over $18,000, and wound infections from coronary bypass surgery cost approximately $18,000 (9). Another study showed that wound infections from orthopedic infections cost approximately $18,000 per case *(10)*. Because there are large numbers of healthcare-associated infections, these costs add up rapidly. It has been estimated that more than 1.7 million healthcare-associated infections occur each year: 290,000 surgical site infections, 250,000 pneumonias, 250,000 bloodstream infections, and 561,000 urinary tract infections (11). Overall, the direct cost of healthcare-associated infections ranges from $28 billion to $45 billion each year (12). This total does not include the indirect costs of lost productivity.

Among noninfectious adverse events, medication errors and misdiagnoses are among the most common and serious events, respectively *(13)*. Medication errors include using the wrong dose, providing illegible prescription orders, using ambiguous abbreviations, giving the medication to the wrong patient, not paying attention to drug interactions or allergies, and using the wrong medication. It has been estimated that each hospital patient experiences approximately one medication error per day *(8)*. Most of these errors do not result in apparent harm, but some are serious. It is estimated that medication errors cause 1.5 million adverse outcomes and 7,000 deaths each year in the United States *(8)*.

Misdiagnoses are particularly problematic, because they necessarily involve human judgment that is necessarily fallible. Yet judgment can be augmented by systems that facilitate effective diagnoses. For example, the turnaround time on tests could be reduced so that clinicians have more data on which to base their diagnoses. Electronic medical records reduce errors by ensuring that a complete, legible record is available instantly to all members of the patient care team (14). Improved communication among physicians and between the outpatient and inpatient settings allows decisions to be based on a more complete understanding of the patient's history and condition. Much remains to be done in these areas. The prevention of wrong diagnoses and delayed diagnoses represents an important area for future study (15).

Having established that healthcare-associated adverse events are common and problematic, the question remains: What proportion is truly preventable? The efficacy of infection control has been established by several studies. A 2003 review of these studies (16) found that infection control measures reduced rates of healthcare-associated infections by 10% to 70%. This broad range reflects the varying effectiveness of the interventions that were studied, the baseline infection rates, and the settings for the studies. Overall, the authors estimated that at least 20% of healthcare-associated infections could be prevented by effective healthcare epidemiology programs. Although this represents a cost savings of $6 to $7 billion per year (12), more recent studies suggest that the 20% figure underestimates the potential to reduce rates (17,18) even for the most problematic infections.

Given the large number of medication doses that are given each day in a busy hospital, eliminating errors may seem like a daunting task. However, studies have shown that most errors are due to illegible prescriptions, ambiguous abbreviations, overlooking known drug allergies, or writing for the wrong dose of drug (19,*20*,21). A simple but expensive solution is to use computer-based prescribing instead of a handwritten record. Studies have shown that computerized physician order entry of medication orders consistently reduces errors, although the effect on adverse outcomes varies among studies (14,*22*).

Thus, although healthcare in the hospital setting has the potential to cause harm, much of the harm can be prevented by an effective healthcare epidemiology program. Hospitals should be motivated to support such programs to improve outcomes, reduce costs, and comply with regulatory requirements *(23)*, even—and some might argue especially—in an era of limited resources (24,*25*).

BASIC PRINCIPLES OF HEALTHCARE EPIDEMIOLOGY

The criteria for the optimal infrastructure and essential activities for healthcare epidemiology have been published by expert panels *(26)* and accreditation organizations such as the Joint Commission *(27–29)*. Effective healthcare epidemiology programs are data-driven, evidence-based, outcome-oriented, and fully engaged throughout the institution and community (Table 4-1). Data are derived from active surveillance systems. Passive surveillance, such as asking physicians to report patient infections, may supplement but not replace active surveillance. The goal of surveillance is to provide data on which to base interventions. Surveillance data are used to calculate endemic rates for key infections and to identify outbreaks. Active surveillance traditionally involves review of medical records by team members. Because this requires significant time and cost, such active surveillance may be concentrated in areas that are likely to have the highest yield of infections or events, such as the intensive care units.

With the rise of electronic health records, active surveillance has become easier and may eventually make hospital-wide surveillance economically feasible (30,*31*). One issue is that most electronic health record programs are not designed to produce the specific reports that are needed for surveillance. For example, computer-based surveillance may be able to provide a list of patients who

TABLE 4-1

Attributes and Functions of an Effective Healthcare Epidemiology Program

Attribute	*Function*
Data-driven	Active surveillance is performed for infections and adverse events using standardized case definitions
Evidence-based	Data analysis is based on sound statistical principles using appropriate denominators
	Data are risk-adjusted when appropriate
	Results are compared to internal and external standards
	Interventions are based on scientific evidence whenever possible
Outcome-oriented	Programs are both reactive and proactive, responding to increases in event rates and working to reduce endemic rates
	Programs are compliant with regulatory requirements
Fully engaged	Multidisciplinary committees such as the infection control committee review data, provide input, serve as conduits to disseminate information, and identify ways to leverage resources to improve patient outcomes
	All areas of the hospital, including administration, are engaged in and take responsibility for the outcomes of the program
	Strong liaisons exist with community health officials to facilitate planning and emergency preparedness

had fever after a surgical procedure, but the computer is unlikely to be able to identify a postoperative wound infection accurately. Thus, there is still a need for the epidemiology team to review the individual patient data to confirm potential cases. Surveillance data may be augmented from other computerized sources available in the hospital, such as microbiology laboratory reports. Optimally, as hospital information systems become more sophisticated, the healthcare epidemiology team will be able to focus more on control and prevention and less on data collection.

To maximize results, surveillance should be evidence-based and objective. To this end, the Centers for Disease Control and Prevention (CDC) has established standard definitions for infections (32). Surveillance data should include both a numerator (number of cases) and an appropriate denominator (hospital inpatient days or device days). Crude event rates may be calculated from the data and compared to the hospital's historical rates. Risk adjustment is used to compare rates between populations or settings (33). It is also important to compare hospital rates to an external standard or "benchmark." The National Healthcare Safety Network (NHSN) is an Internet-based surveillance system that allows member hospitals to enter their data securely and compare their rates with other participating hospitals. Administered by the CDC, the NHSN system includes both infectious and noninfectious adverse events. In return, the network provides hospitals with risk-adjusted data that can be compared with peer hospitals and is able to produce reports based on aggregate data from member hospitals *(34,35)*. Data contained in the system are confidential.

Data analysis must be based on sound biostatistical principles, as described elsewhere in the text. Within this framework, attention and resources should be focused on the most clinically relevant findings. Thus, an outbreak of methicillin-resistant *Staphylococcus aureus* (MRSA) in the newborn nursery would provide more fertile ground for intervention than an increase in contaminated urinary specimens sent to the laboratory. It is important to note that relying on statistics alone may provide a false sense of accomplishment. For example, a hospital that merely tries to keep its rates within a preestablished confidence interval compared to historical rates will miss opportunities to improve endemic problems. Many hospitals previously tried to keep ventilator-associated pneumonia rates or catheter-associated bloodstream infection rates within 95% confidence limits of national norms. Recent evidence shows, however, that many of these institutions can eliminate these infections or achieve near-zero rates (17,18).

Effective healthcare epidemiology programs are both reactive and proactive. When analysis of surveillance data indicates an outbreak has occurred, effective programs respond promptly to locate the source and eliminate the problem. The healthcare epidemiology team works proactively to prevent adverse events and infections, thus reducing endemic rates.

Interventions should be logical and evidence-based. For infectious issues, a strong understanding of microbiology is essential. For example, an outbreak of *Legionella* pneumonia should prompt an examination of the water system and a review of procedures that aerosolize water. The presence of *Aspergillus* should raise concern about dust from nearby construction. Knowledge of the literature is also essential, because there are likely to be reports of similar outbreaks. In some cases, randomized controlled trials have been done and identify an optimal intervention (18) or show that an intervention does not work (36). When randomized trials are not available, a meta-analysis or systematic review may be useful (*37–40*,41). Finally, if no clear answer is available from scientific studies, the literature often contains consensus guidelines based on expert opinion. When there is no good study or consensus guideline to address a particular topic, top-notch healthcare epidemiology programs will publish their own results or design a study to address the issue.

Because adverse events occur in every area of the hospital, effective healthcare epidemiology programs are hospital-wide efforts, involving multiple disciplines and

functions. Many programs consist of a core team including infection preventionists, quality improvement specialists, a physician healthcare epidemiologist, an infection control committee, and a quality committee. This core team is responsible for organizing an effective surveillance system, analyzing data, producing reports, receiving input, and designing interventions. However, it is critical that the entire organization take responsibility for reducing infections and adverse events. For example, a campaign to improve hand hygiene would have optimal success if the director of nursing, the chief of staff, the hospital leadership, and unit directors all took responsibility for ensuring that standards are consistently met. To engage the entire organization, it is important that multidisciplinary committees receive regular reports from the healthcare epidemiology team. An effective infection control committee provides input to the team, identifies ways to leverage resources, and helps disseminate information throughout the hospital. Members should be chosen with these abilities in mind. Committees that specialize in quality improvement or safety play a similar role in managing infectious and noninfectious adverse events. Depending on the issue at hand, subcommittees may be formed from members with special expertise. An effective committee, therefore, does not simply receive reports. Rather, it assumes a level of responsibility for the outcome of the healthcare epidemiology program.

Outreach is a critical component of healthcare epidemiology. Hospitals have an important and growing role in the health of their community, especially in emergency preparedness (42,*43*,*44*). Hospital participation is crucial in community preparedness planning and the community should be part of hospital planning. In part, this is because of the resources available within the hospital that might be required on short notice in the event of a community emergency. More broadly, a coordinated response to an emergency is more likely to be effective and to instill public confidence in the process *(44)*. The hospital also benefits from close liaisons with emergency providers, resource managers, and community leaders. Healthcare epidemiology programs also can provide expertise, assistance, and support to public health and community leaders during community outbreaks as well as during response planning.

UNIQUE ASPECTS OF THE HOSPITAL ENVIRONMENT

The hospital environment presents several unique challenges to the epidemiology team. The hospital functions as a therapeutic milieu where treatments that improve patient health may simultaneously cause increased susceptibility to adverse events. Such is the case with treatments that are known to suppress the immune system, indwelling devices that serve as conduits for microbes, sedatives that increase susceptibility to falls, and antibiotics that cause resistant pathogens to replace normal flora. Moreover, populations at risk for adverse events may also serve as vectors for the events. For example, visitors with respiratory infections may acquire secondary infections in the hospital or may spread infection to others. Healthcare providers who do not observe hand hygiene standards are at risk to acquire and spread resistant pathogens such as MRSA. The 2009 novel H1N1 influenza pandemic demonstrated this dual role of victim and vector as providers acquired the virus at home and at work, providing opportunities to spread the infection within hospitals *(45)*.

As discussed above, inpatient populations in the hospital are transient. For some adverse events, such as falls or medication errors, the event is confined to the hospital stay, and it is relatively easy to attribute the event to the hospital setting. Because bacterial infections have a 2- to 4-day incubation period, infections acquired in the hospital may not become manifest until after discharge. This complicates classification of infections as healthcare-associated or community-associated. Stochastic definitions have been developed based on whether a patient has been in a hospital within a certain time frame. Such definitions are useful for surveillance, but are not necessarily accurate on an individual basis. In the past, some highly resistant bacteria were almost exclusively acquired in the hospital setting, and their mere presence was enough to identify them as hospital-associated pathogens. More recently, however, pathogens like MRSA and *Clostridium difficile* have begun to spread within communities, further complicating classification.

Because the hospital environment is so complex and because resources are limited, healthcare epidemiology programs often focus on patients at highest risk for adverse events and on adverse events that are highly likely to cause mortality and morbidity. It is important to realize that this is the tip of the iceberg. Thus, high-quality epidemiology programs will include both initiatives focused on high-risk settings such as intensive care units and hospital-wide initiatives such as hand hygiene programs. In some cases, interventions in a focused population may have the ability to improve outcomes throughout the hospital.

Healthcare epidemiology programs are increasingly involved with mitigating environmental hazards related to buildings, including construction, renovation, maintenance, and housekeeping activities. The facility's environment serves as a reservoir for microorganisms that may be implicated in healthcare-acquired infections and a potential source of patient or worker injury *(46)*. Healthcare epidemiology has multiple approaches to reducing the risk from the environment. Isolation precautions have been developed to restrict the spread of selected pathogens from patient to patient or from patient to healthcare worker. Barrier precautions such as gowns, gloves, and masks are an integral part of these measures. In most instances, there are no rigorous scientific studies to support recommendations for isolation (36,47,*48*). Rather, guidelines are based on interrupting the known means of transmission of pathogens.

The complexity of the hospital environment requires multifaceted interventions. For example, successful programs to reduce medication errors usually involve pharmacists, nurses, physicians, and health information technology experts, each of whom have one or more roles in the intervention. At times, a series of actions are combined together to create one unified intervention "bundle." In effective bundles, each individual action is evidence-based and has proven efficacy, and each compliments the others. Highly effective bundles are an important part of the modern approach to healthcare epidemiology (18).

CONCLUSION

As the science and practice of healthcare epidemiology have advanced, healthcare-associated adverse events are no longer considered an inevitable result of hospitalization. Once an unimaginable goal, zero rates are becoming a reality for some adverse events. In concert with this new reality, third-party payers are withdrawing reimbursement for events that they consider to be wholly preventable (49). Moreover, regulatory agencies have begun to incorporate these new expectations into their accreditation standards. In this sense, regulatory agencies and third parties function as motivators for hospitals to support healthcare epidemiology programs. Optimally, this movement will lead to the discovery of additional evidence-based interventions that can be incorporated into contemporary practice standards. This new culture has increased pressure on healthcare epidemiology programs to perform at the highest possible level.

CHAPTER 5

Data Collection in Healthcare Epidemiology

Stephen B. Kritchevsky and Ronald I. Shorr

Data for healthcare epidemiology come from three sources: direct ascertainment of information from subjects using questionnaires or direct observation; review of medical records; and electronic sources, such as billing records, laboratory records, and medication administration records. Although we provide an overview of each of these data sources, we emphasize the development of questionnaires. After data from any of these sources are collected, they are entered and organized (usually in a database) and analyzed, usually using a statistical package. We offer suggestions on the preparation and formatting of data to facilitate the transfer from data collection to data analysis.

QUESTIONNAIRES

Questionnaire Development

Questionnaires are often the most labor-intensive form of data collection but are required in situations where surveillance using electronic data sources or medical record review is inadequate.

After deciding what data need to be collected, the investigator has to decide how to collect it. This means developing the form(s) to guide data collection, identifying the data sources (e.g., individuals, proxies, medical records, direct observation), identifying data gatherers, and deciding on a mode of data collection. Decisions in each of these areas affect the others, and investigators should understand the trade-offs between them in order to make good decisions when planning an investigation.

Writing the Questions The first step in developing a data collection form is writing the questions to elicit the information required by the study. Good questions are clear and unambiguous and match the verbal skills of prospective participants. Poorly worded questions result in answers that are unreliable or uninterpretable. Although writing good questions is something of an art, there are several common problems that can result in bad questions.

Choosing Verbiage If respondents do not understand the words used in questions, they will not be able to answer them (or worse, they will answer them anyway). In general, the words used in the questions should be ones used by respondents in their usual conversation (e.g., use "help" rather than "assist" and "enough" rather than "sufficient"). Avoid medical jargon and abbreviations that may not be commonly understood. Be aware of regional or cultural differences in the meanings of words and the names of diseases (e.g., diabetes may be called "the sugar" by some respondents). Avoid using loaded words (i.e., those carrying excessively negative connotations).

Consider these questions:
Should smoking be banned in the hospital?
Should smoking be allowed in the hospital?

The word *banned* is loaded, and some answers to the question may be a reaction to the word itself rather than to the content of the question.

Ambiguous Questions One of the most difficult tasks in writing a question is asking it in such a way that the respondent has the same concept in mind when answering it as the investigator did when asking it. The investigator wanting to identify current cigarette smokers might ask: "Do you smoke?" Cigar and pipe smokers will answer this affirmatively, contrary to the investigator's intention. There may also be those who have very recently quit smoking (and may soon begin the habit again). They would answer no, but the investigator might want them classified as smokers for the purposes of the study. "Have you smoked two or more packs of cigarettes in the past 2 months?" is a better version of the question. Cigarettes are specifically named, and the amount of consumption and the period are specified. In some cases, visual aids such as pictures of products or models may be helpful in orienting the respondent.

In an outbreak investigation of central line infections, hospital personnel might be asked, "Did you see patients on [a particular ward]?" This question has two ambiguous referents. Does "see" mean "care for," or is the question intended to detect less formal contact as well? Also, does the investigator mean if the respondent has ever seen patients on a ward, or just during the epidemic period? A better phrasing might be, "Did you provide care for any patients on [the ward] since March of this year?"

Causes must precede effects in time. Therefore, when assessing the relationship between a behavior that may change over time and disease occurrence, it is important that the questions refer to the period prior to the onset of disease symptoms. Failure to make this clear can lead to

biased results if the behavior changes in the face of symptoms. Both the failure to elicit exposure information from the appropriate period and the inclusion of irrelevant exposure information can lead to bias.

Hypotheticals Avoid hypothetical questions. Consider a question that might be asked of nurses in an infection control project: "Is it important to wear gloves when placing an IV?" The question is problematic, because it may refer to either what is important in a hypothetical sense or what is personally important to the respondent. The responses will be a mixture of these two interpretations, with the investigator having no way of distinguishing the two.

Asking More than One Question Each question should try to elicit only one piece of information. Consider the question, "Have you experienced nausea, vomiting, night sweats, or loss of appetite?" This set of symptoms may be useful in arriving at a diagnosis, but in an epidemiologic investigation, it may be important to document each symptom individually for later use in applying a consistent case definition. Furthermore, respondents may focus on the last symptom named. A respondent may have had night sweats but answer, "No, my appetite's fine." A checklist is often used to systematically identify symptoms of potential interest.

Assumptions in the Questions Answers to questions that make tacit assumptions can be difficult to interpret. Consider the example from Kelsey et al. (1): "Do you bring up phlegm when you cough?" The question assumes that a cough is present. A negative response might mean that no phlegm is produced or that the respondent does not have a cough.

Vague Questions and Answers Avoid the use of words such as "regularly," "frequently," and "often," both in questions and as response options. Different responders will interpret these words differently. The potential for qualitative responses to introduce unwanted variability was vividly demonstrated by Bryant and Norman (2), who asked 16 physicians to assign a numerical probability to qualitative adjectives such as "probable," "normally," and "always." The numerical probability assigned to the word "probable" ranged from 30% to 95%. The probability assigned to "normally" ranged from 40% to 100%, and that to "always" ranged from 70% to 100%. Whenever possible, try to elicit a quantitative response.

Threatening Questions Care needs to be taken when asking questions of a somewhat embarrassing nature. Embarrassing questions concern respondent behaviors that may be illegal or socially undesirable or concern areas of life that may threaten the respondent's self-esteem. Research has indicated that the self-reported frequency of potentially embarrassing behaviors can be increased if long, open-ended questions are asked. Open-ended questions are those to which categories of set responses are not supplied by the investigator (as opposed to closed questions, in which the respondents select answers from a list of supplied alternatives). Bradburn and Sudman (3) contrasted various question styles ranging from short questions with fixed response categories to very long questions with open-ended responses. They also contrasted using the respondent's familiar term for the behavior versus a term supplied by an interviewer. Respondents were randomized in a $2 \times 2 \times 2$ factorial design into one of eight different question formats (i.e., long vs. short response format, open vs. closed response format, and familiar vs. standard wording). One short question (with standard wording and closed response format) read: "In the past year, how often did you become intoxicated while drinking any kind of beverage?" The respondents picked a response from a list of eight alternatives. The long form (with respondent's wording and open response format) read:

> *Sometimes people drink a little too much beer, wine, or whiskey so that they act different from usual. What word do you think we should use to describe people when they get that way, so that you will know what we mean and feel comfortable talking about it?*
> *Occasionally, people drink on an empty stomach or drink a little too much and become [respondent's word]. In the past year, how often have you become [respondent's word] while drinking any kind of alcoholic beverage?*

The respondents were given no response categories but asked to supply their own best estimate. The question format did not seem to affect the percentage of people reporting that they had engaged in an activity. It did, however, strongly influence the self-reported frequency of the activity. Those responding to long questions with open-ended responses using familiar terms reported significantly higher frequencies of the behavior of interest. The mean annual consumption of cans of beer calculated using responses from the long, open format with familiar wording was 320 cans; that calculated using the short, closed format with standard wording was 131 cans. Large differences in responses attributable to question format were seen for questions dealing with the frequency of sexual activity as well. Most of the difference was attributable to the use of an open-ended response format and longer questions. The effect of using familiar wording was weaker but was associated with consistently higher reported frequencies of potentially embarrassing behaviors.

Asking Questions about Events in the Past Asking individuals about the occurrence and/or frequency of specific events in the past is a special measurement challenge. An investigator whose study depends on the validity of human recall must be particularly attuned to the shortcomings of human memory. Respondents to epidemiologic questionnaires are often asked to perform one of three memory tasks: (a) recall whether a particular event occurred to the individual, (b) recall when the event occurred, or (c) recall how frequently it occurred. Research has shown that it takes some time for people to access their memory for the occurrence of events. Longer questions seem to be useful in giving respondents more time to recall events and may increase the percentage of events recalled (4). Nevertheless, people frequently forget specific events in their past. As a rule, an event is harder to remember if (a) it occurred a long time ago, (b) it is one of a series of similar events, or (c) the respondent attaches little significance to it (4).

People also frequently misplace remembered events in time. There is a tendency to judge events that are harder to recall as less recent and, conversely, there is a tendency to date events about which a lot of detail is recalled as more recent. This problem is termed "telescoping" in survey research (4). Consider the question: "Have you been to a doctor in the past 12 months?" Respondents frequently answer affirmatively if the visit was 15 months ago. People may remember the event better than its date and import the event into the time interval of interest.

Aspects of the design and administration of questionnaires can improve both remembering and dating events. Questions starting with recent events and working backward in time can improve recall. Also, providing date cues can help. One common technique is to provide the respondent with a calendar. Before asking about events of interest, the respondent identifies personally relevant dates such as birthdays and holidays. Then, the respondent is walked back through time and assigns dates to the occurrence of the events of interest with respect to the personal landmarks. As reported by Means et al. (5), a sample of George Washington University Health Plan enrollees was asked to try to recall all health plan visits in the past year. All study participants had at least four visits in the past year. Before using the landmarking technique, participants were able to recall 41% of the health plan visits recorded in the medical record. After the landmarking, 63% of health plan visits were remembered. In a separate study group using only the landmarking technique, 57% of visits were recalled. The use of landmarking also led to an improvement in dating accuracy.

The frequency of a behavior is often of epidemiologic interest insofar as it may serve to quantify the amount and/or rate of an exposure. Humans tend to rely on two strategies for recalling the frequency of events (4). The first is simply trying to remember every instance of a behavior over a period. The second is referred to as the event decomposition method. People first estimate a rate at which a behavior is performed and then apply it over the period of interest. For example, if a respondent is asked how many times she went to a restaurant in the past 2 months, she may figure that she goes to a restaurant twice a week, and therefore, she ate at a restaurant eight times in 2 months. In general, the decomposition method seems to lead to more accurate estimates than the recall of individual events. Investigators planning studies to measure the frequency of exposure may wish to structure questionnaires to explicitly elicit these frequency estimates.

PRETESTING THE DATA COLLECTION INSTRUMENT

Prior to full-scale data collection, it is useful to pretest all study procedures. This includes pretesting any data collection documents. The pretest may include a number of steps. An expert in the field should review the data collection forms. This expert should be able to identify any content omissions. The review by nonexpert colleagues can be useful to give overall impressions, to identify troublesome questions, and to determine if the skip patterns flow logically. In the next phase of pretesting, test the data collection procedures under study conditions on a number of potential study subjects (frequently 20–30). In this phase of pretesting, one can identify questions that don't work and whether the needed information is indeed available from the intended data source. If the data collection form is being used to elicit information from respondents, debrief your pretest subjects to discover what they had in mind while they were answering and how some questions might be asked better. A pretest also provides the opportunity to ascertain preferences among varying question wordings and answer formats.

Schlesselman (6) describes an example indicative of the kind of problems that a pretest can identify. In a study involving analgesic use, the following series of questions were tested:

Q. HAVE YOU EVER HAD FREQUENT HEADACHES?
Yes
No

Q. HAVE YOU EVER HAD VERY SEVERE HEADACHES?
Yes
No

Q. HAVE YOU HAD HEADACHES ONCE A WEEK OR MORE DURING THE PAST MONTH?
Yes
No

The third question was used as a filter for a series of questions relating to analgesic use for headache. The purpose of the questions was to identify individuals who were likely to be frequent analgesics users for headache relief. Schlesselman states, "The third question was included under the assumption that recall is better for the most recent period, and that a person with a history of recurrent headaches in the past would retain this pattern in the present." In pretesting, however, it was found that there were many patients who had frequent headaches but for whom the past month was atypical. Thus, contrary to the intention of the investigator, a number of study participants were skipping the series of headache-analgesic questions. In light of the pretest, the third question was modified to:

Q. HAVE YOU EVER HAD HEADACHES ONCE A WEEK OR MORE FOR AT LEAST ONE MONTH?

OPTIONS FOR ADMINISTRATION

The primary options for administering a questionnaire are respondent self-administered and interviewer-administered. Self-administered questionnaires are usually either given in a supervised setting or mailed to the respondent; however, there are an increasing number of questionnaires that are being administered using e-mail or the Internet. Interviewer-administered questionnaires can be administered either in person or over the phone. Each method has its advantages and drawbacks. Self-administered questionnaires are usually less expensive to administer but need to be simpler and shorter than interviewer-administered questionnaires. Also, when a portion of the study population is of low literacy, the use of self-administered forms results in unacceptable losses of information. Internet-based surveys can

be more complex but require that respondents have access to and are comfortable with computers and the Internet. Interviewer-administered questionnaires can be more complicated and longer, and the literacy of the respondent is not an issue. Also, the use of an interviewer permits the probing of the respondent for clarifications and elaborations. The major drawback of using an interviewer is the cost.

Differing modes of administration have their advantages and disadvantages. Mailed questionnaires are relatively inexpensive to administer, but response rates tend to be low (typically 40–60%). Response rates can be increased by a number of techniques such as hand-addressing the envelopes, using certified mail, using postage stamps instead of metered mail, and rewarding the respondent. Collecting data over the phone is more expensive than by mail, but the response rates are higher (frequently 75–85%). Completion rates for telephone interviews can be increased by sending an introductory letter to the home introducing the study. Using the phone as the sole mode of contact may introduce subtle biases into a study. The portion of the study population that does not own a phone is systematically different from the portion that does. Also, the ability to contact certain segments of a population may differ. For example, young, single, smoking males are harder to contact by phone than some other segments of the population. Internet surveys appear to be a reasonable substitute for mailed surveys given that respondents have Internet access. Initial response rates can be low but can be increased with reminder letters/e-mails (7).

Face-to-face interviews have the highest completion rates (up to 90%), and they are also the most expensive to conduct. In face-to-face situations, visual aids and more elaborate questioning techniques can be used, providing the opportunity to improve the quality of the collected data.

MEDICAL RECORDS

Collecting data from recorded information is a part of nearly all epidemiologic studies conducted in a hospital setting. Recorded data sources include diagnostic reports, physician notes, prescription records, and culture reports. In addition to routinely collected medical data, administratively collected data are also available from billing records, insurance claim files, etc. The advantages of recorded data are clear: they provide a concurrent source of information concerning the study subject's medical experience. However, the limitations of routinely recorded data should also be borne in mind. Data are put in the medical record by a number of different individuals who are not standardized in their recording habits, and they certainly do not record information with a particular epidemiologic study in mind. Two studies illustrate the problems with the medical record as a tool for epidemiologic research.

Massanari et al. (8) compared the ability of one hospital's medical records personnel to identify and code the presence of nosocomial infections to that of an epidemiologic surveillance system. They discovered that only 43% of nosocomial infections identified through epidemiologic surveillance were reported in the discharge abstract. On inspection of a sample of incongruent cases, 44% of the cases were missed by medical records, because the physician failed to document an infection. However, medical records personnel failed to note infections clearly recorded in the chart about 16% of the time. Other studies concerning the usefulness of the medical chart in infectious diseases investigations in the hospital have documented even poorer performance (9,10).

Gerbert et al. *(11)* compared four methods to determine whether specific drugs had been prescribed to chronic obstructive pulmonary disease patients. The methods were a physician interview, a chart review, a patient interview, and a review of a videotape of a physician–patient encounter. The four methods agreed only 36% of the time in determining whether the patient had been prescribed theophylline. According to the physician, 78% of patients were on theophylline, the medical chart indicated that 62% of patients were on the medication, and the videotape, 69%. Only 59% of the patients reported themselves to be on theophylline. The investigators determined that each method had good specificity (i.e., few respondents reported being on theophylline when they were not) and that the physician interview had the best sensitivity.

ELECTRONIC DATA

Electronic data come from two sources: administrative data, which are used by all hospitals primarily for billing, and clinical data, such as medication administration records, laboratory, and radiology reports. The richness of clinical data available to the investigator varies among hospitals.

Administrative data from hospitals include demographic information, admission and discharge dates, codes for principal and other diagnoses, procedure codes, disposition of the patient, and expected payment source *(12)*. Although universally available, administrative data should be used with great caution for healthcare epidemiology, primarily because of issues relating to sensitivity and specificity in diagnosis codes (13). In studies examining the reliability of discharge data forwarded to the Health Care Financing Administration, data items such as admission date, discharge date, date of birth, gender, and payment source were found to agree well with those found in the medical record (14). However, on review, the reported principal diagnosis agreed with that found in the medical record only 57% of the time. Similarly, Johnson and Appel (15) found that the diagnosis-related group reported to Medicare matched the one listed in the medical record approximately half of the time.

Even if data are reliably collected, the failure to understand how administrative databases are maintained can introduce artifactual findings. For example, Iezzoni et al. *(16)* found lower death rates among hospital inpatients with diabetes listed as a comorbidity in an administrative database. The reason was that the database accommodated only five comorbidities. Therefore, the relatively healthy patients (i.e., the ones with fewer acute problems) were the ones for whom the diagnosis of diabetes made it into the database.

Clinical data may be more useful for surveillance in healthcare epidemiology (*17*,18,*19–20*). Classen et al. *(19)*

described surveillance using the Health Evaluation through Logical Processing (HELP) system, of LDS Hospital in Salt Lake City, Utah. This system includes data from pharmacy, laboratory, surgery, radiology, admitting, microbiology, and pathology. Furthermore, clinical data (e.g., International Classification of Disease codes) and charge data are also a part of this system. Initial studies revealed that a computer algorithm identified more hospital-acquired infections than traditional surveillance methods, while requiring only 35% of the time *(20)*. Several subsequent investigations of infections (*21*,22,*23*) and adverse drug reactions (24,25) have been conducted using this system.

PREPARING DATA FOR STATISTICAL ANALYSIS

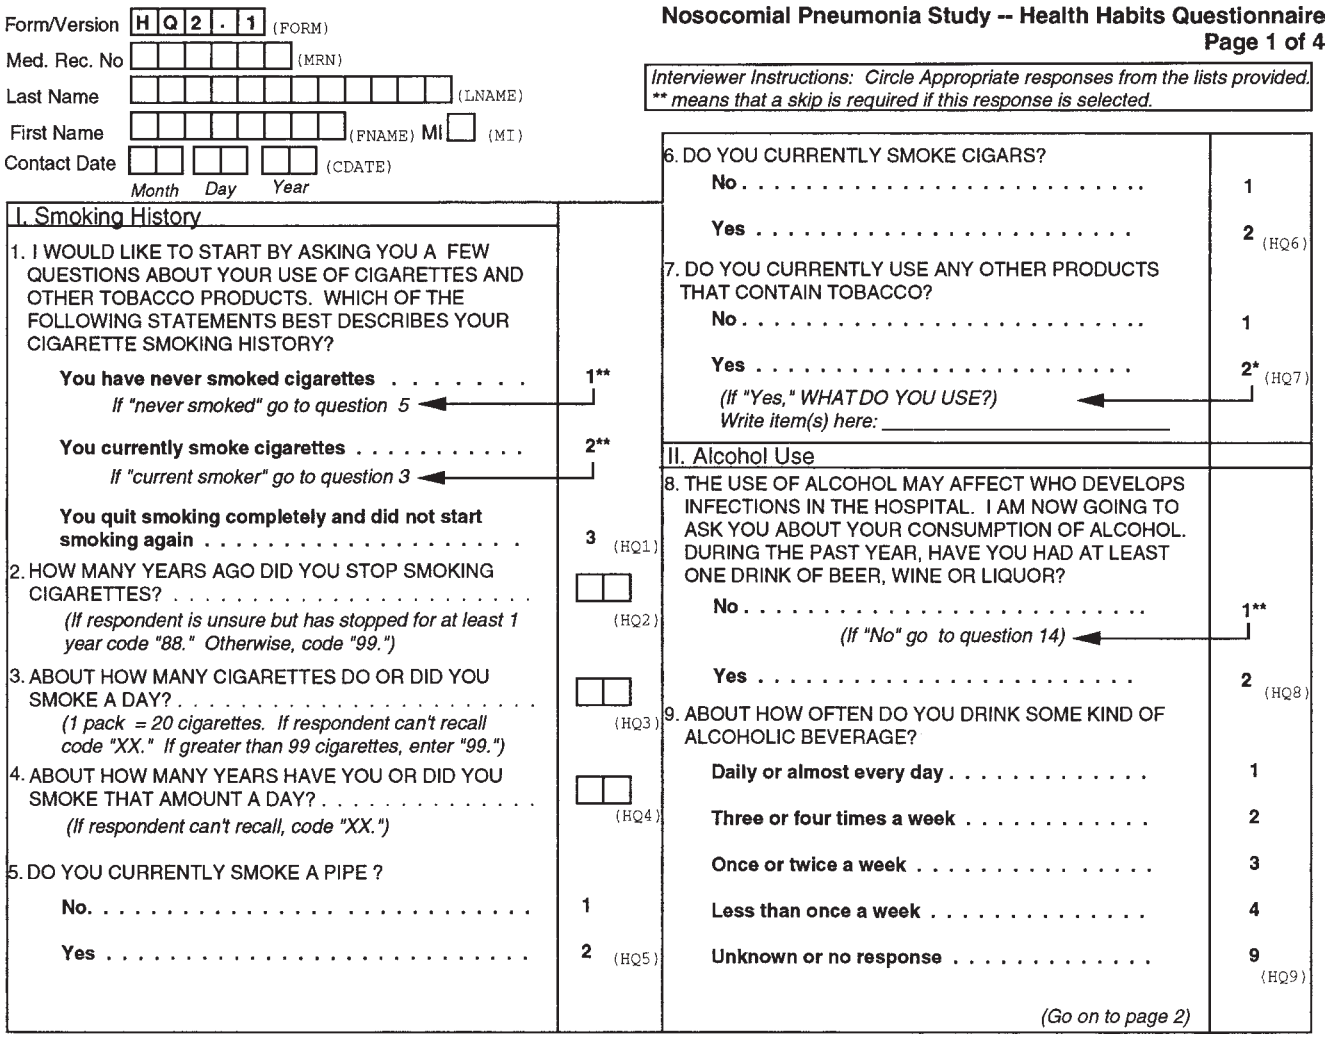
Organization of Data Collection

Attention to the format of a data collection document can speed data collection and data entry and increase data quality. The physical appearance of the data collection document is also important. A professional-looking tool can inspire the respondent's confidence in the investigator.

A data collection form has two sections: the header and the body. The header should contain a form code, a form version number, and a unique identifier corresponding to the participant about whom data are being collected. In healthcare epidemiology, it is tempting to use a patient's medical record number. However, it is necessary to assign a study identification number to place on the forms instead of a medical record number to protect patient confidentiality should the form become misplaced or lost. The identification number allows the data collected on the form to be linked with data collected from other sources. A code for the form and its version are useful in establishing the data's provenance after computer files have been generated.

The body of the basic data collection form has three elements: the questions, the responses, and the directions. In Figure 5-1, each element is typographically distinct. The questions are in all capital letters, the responses are in bold, and the directions to the interviewer are in italics.

The questions should flow in some sort of natural order. For instance, if the data collection form is being used to abstract a medical record, the questions should appear in the order that the information is found in the medical record. If the questionnaire is to be administered to an



Form/Version H Q 2 . 1 (FORM)

Interviewer Instructions: Circle Appropriate responses from the lists provided.
*** means that a skip is required if this response is selected.*

I. Smoking History

1. I WOULD LIKE TO START BY ASKING YOU A FEW QUESTIONS ABOUT YOUR USE OF CIGARETTES AND OTHER TOBACCO PRODUCTS. WHICH OF THE FOLLOWING STATEMENTS BEST DESCRIBES YOUR CIGARETTE SMOKING HISTORY?
- **You have never smoked cigarettes** 1**
  If "never smoked" go to question 5
- **You currently smoke cigarettes** 2**
  If "current smoker" go to question 3
- **You quit smoking completely and did not start smoking again** 3 (HQ1)

2. HOW MANY YEARS AGO DID YOU STOP SMOKING CIGARETTES? . . . . . (HQ2)
(If respondent is unsure but has stopped for at least 1 year code "88." Otherwise, code "99.")

3. ABOUT HOW MANY CIGARETTES DO OR DID YOU SMOKE A DAY? . . . . . (HQ3)
(1 pack = 20 cigarettes. If respondent can't recall code "XX." If greater than 99 cigarettes, enter "99.")

4. ABOUT HOW MANY YEARS HAVE YOU OR DID YOU SMOKE THAT AMOUNT A DAY? . . . . . (HQ4)
(If respondent can't recall, code "XX.")

5. DO YOU CURRENTLY SMOKE A PIPE ?
- **No.** 1
- **Yes** 2 (HQ5)

6. DO YOU CURRENTLY SMOKE CIGARS?
- **No** 1
- **Yes** 2 (HQ6)

7. DO YOU CURRENTLY USE ANY OTHER PRODUCTS THAT CONTAIN TOBACCO?
- **No** 1
- **Yes** 2* (HQ7)
  (If "Yes," WHAT DO YOU USE?)
  Write item(s) here: _____

II. Alcohol Use

8. THE USE OF ALCOHOL MAY AFFECT WHO DEVELOPS INFECTIONS IN THE HOSPITAL. I AM NOW GOING TO ASK YOU ABOUT YOUR CONSUMPTION OF ALCOHOL. DURING THE PAST YEAR, HAVE YOU HAD AT LEAST ONE DRINK OF BEER, WINE OR LIQUOR?
- **No** 1**
  (If "No" go to question 14)
- **Yes** 2 (HQ8)

9. ABOUT HOW OFTEN DO YOU DRINK SOME KIND OF ALCOHOLIC BEVERAGE?
- **Daily or almost every day** 1
- **Three or four times a week** 2
- **Once or twice a week** 3
- **Less than once a week** 4
- **Unknown or no response** 9 (HQ9)

(Go on to page 2)

FIGURE 5-1 A page from a data collection form from a study of nosocomial pneumonia.

individual, an introduction should be included, questions on the same topic should be grouped together, and when the topic of the questions changes, a short transition statement should be included. It may be a good idea to begin questionnaires with less challenging and personal questions. This gives the respondent an opportunity to become familiar with the interview situation and to develop some rapport with the interviewer.

A different form should be developed for each data source. This allows data entry to move forward on the sections of the data collection effort that have been completed. If multiple data sources are used in a study, consider using differently colored paper for each data form. This allows quick identification of misfiled forms and incomplete sets of data forms. Do not squeeze too much type on a page. Blank space allows data collectors to make annotations as needed.

Formatting Responses to Questions

Moving a concept to a study result involves three steps: (a) design of the data collection instrument, (b) data entry from data collection instrument to an electronic database, and (c) querying the database to obtain "flat files" suitable for statistical analysis. Because collected data are ultimately transferred to statistical analysis software, selecting appropriate formatting in the data collection instrument saves time and aggravation in the long term. Thus the adage "begin with the end in mind" is particularly germane to design of the data collection instrument.

Closed- or Open-Ended Responses An important decision is whether to have open-ended or closed-ended response formats. An open-ended response format allows the respondent to provide any answer (question 1 in Table 5-1) and is more appropriate for exploratory or hypothesis-generating research. A closed-ended response format requires the respondent to select an answer from a list of possible responses supplied by the investigator (question 2 in Table 5-1). Open-ended formats allow respondents to elaborate on the answer and to provide details that may be missed by a closed-ended format. In general, however, open response formats are to be avoided. Answers can be lengthy, hard to analyze, and hard to standardize. The problem with open-ended formats can be seen in question 1 of the table. Respondents could answer "big" or "old." The responses provided in the closed-ended format cue the respondent to the frame-of-reference of the question. Because of the opportunities for misunderstandings, questionnaires using open-ended responses often need to be administered by a trained interviewer to probe incomplete answers and to lead respondents if they do not understand the intent of the question.

The answers to open-ended questions need to be assigned codes for use in data analysis. Closed-ended response formats allow data collection forms to be precoded. This means that, prior to the administration of the form, responses have already been assigned the numerical codes to be used in the data analysis. When respondents pick a response, they actually mark its code (question 3 in Table 5-1).

If there are a great number of potential responses (e.g., a respondent's occupation or place of birth), a closed-ended response may be impractical. In this case, the response is recorded for coding at a later time.

TABLE 5-1

Examples of Three Different Question Response Formats

A question with an open-ended response format:

1. How would you describe your residence, that is, the place where you usually live?

   _____(answer here)

A question with a closed-ended response format:

2. How would you describe your residence, that is, the place where you usually live? *(Circle the correct response):*

   House
   Duplex
   Condominium
   Apartment
   Hotel
   Other

A question with a precoded closed-ended response format:

3. How would you describe your residence, that is, the place where you usually live? *(Circle the number of the correct response):*

House	1
Duplex	2
Condominium	3
Apartment	4
Hotel	5
Other	6

Closed-ended response categories should be exhaustive and mutually exclusive. That is to say, every possible response should be provided, and no two responses should be logically possible at the same time. It should be recognized, however, that closed-ended responses impose the investigator's preconceptions concerning the universe of possible responses. There are certain to be unanticipated responses. A compromise between closed-ended and open-ended formats can be made.

Coding "Other" Responses One can precode the most frequently expected responses and include an "other" category along with a space for recording what is meant by "other." These "other" responses can be logged and assigned codes during the data editing process. The value of accommodating "other" responses is illustrated by the experience of Kelsey et al. (1). In a case-control study of the etiology of lumbar disc rupture, participants were asked what type of chair they sat in at work. The main difference between case patients and control subjects was the selection of the "other" category by the case patients. The excess of "other" responses was attributable to the omission of motor vehicle seats as a response option. This led to the finding that the vibration associated with frequent motor vehicle use was associated with disc disease, a finding that was subsequently corroborated by further epidemiologic and biomechanical studies.

A common error is to omit the categories "not applicable," "unknown," and "refused" from response lists. Their omission causes a problem when editing the data. If a "not applicable" code is omitted, then when an item is indeed

not applicable, the question will be left unanswered. During editing, however, it is impossible to tell whether the question was skipped inadvertently or purposefully left blank. For record abstraction forms, a "not found" category is needed.

Do not try to force actual measurements into a closed-ended format; this may result in the unintended loss of information. Take, for example, the following question:

Q8. WHITE BLOOD CELL COUNT ON ADMISSION?
(*Circle the appropriate finding*)

Less than 10,000	1
10,000–15,000	2
More than 15,000	3
Not ordered	8
Not found	9

Collecting data in this manner automatically constrains the investigator to analyze white blood cell (WBC) count as a categorical variable. Although a categorical approach may or may not be appropriate, the investigator is further constrained, because the only categories that can be used in the analysis are those specified by the form. It is usually better to collect data in as much detail as the data source will permit, as this maintains greater flexibility in the data analysis. For example:

Q8. WHITE BLOOD CELL COUNT ON ADMISSION?
Q8. (*code -88,888 if not ordered, code -99,999 if not found*)

Again, special codes for "not found" and/or "not applicable" should be included to allow the later identification of missed items on the data form.

To ease data entry, the responses should be placed along the right margin of the form and presented as vertical lists (Fig. 5-1). Including question numbers with the responses helps data entry clerks keep their place when entering the data into a computer.

Often a number of questions do not apply to every study subject. Instructions to guide respondents past nonapplicable questions need to be clearly made. In the example (Fig. 5-1), in addition to the text instructions, visual cues are provided to guide the interviewer. Failure to skip properly can be a frequent source of error in filling out data collection forms. If the data collection form is to be self-administered by a study participant, try to keep the number of skips to a minimum.

Frequent skips are demanding even on experienced study personnel and can lead to errors in filling out study forms. Often, if there is only one question to be skipped, adding an additional response category can avoid the need for a skip instruction altogether. For example, consider the two questions:

4. DO YOU NOW SMOKE CIGARETTES?

Yes	1
No	2 (*If no, go to question 6*)

5. HOW MANY CIGARETTES DO YOU USUALLY SMOKE IN A DAY?

1 to 10	1
11 to 19	2
20 or more	3

In this situation, a skip can be avoided by dropping question 4 and providing a fourth response option in question 5: "I do not currently smoke cigarettes."

Use Numeric Rather Than Text Entry If questions are to be precoded, codings should be consistent throughout the form. Pocock (26) suggests using 1 for "No" and 2 for "Yes," because "No" is the more common response. Often an 8 is used for "not applicable" and 9 for "missing." Sometimes negative integers are used if the "8" and "9" could be valid responses.

Questions That Require Calculation Avoid questions that require calculation on the part of either the data collector or the respondent. If the number of days between two events is important, collect the actual dates of the events and calculate the difference later. Asking individuals to calculate introduces an additional opportunity for error.

Multiple Observations Occurring in the Same Subject It is not uncommon that data collection requires the management of multiple observations occurring in the same subject. Examples might be recurrent laboratory values over time, or the recording of multiple medications at a single point in time. If the number of measurements per subject is large or highly variable, it may be useful to have separate data collection forms for each collection time point. Forms can get lost or damaged if they are overhandled. The critical issue is to have a unique study identifier that allows the data to be combined from multiple sources in a study database.

Users should be aware that the management of data of this sort requires thought and may benefit from assistance from persons knowledgeable in database structure and management. The following example exhibits the issue:

Assume one is studying the response of a WBC count to the administration of an antibiotic. Counts are collected multiple times per day until discharge. One might consider laying out the data as follows:

Patient ID	WBC1	Time1	WBC2	Time2	WBC3	Time3	WBC4	Time4
1	X_1	T_1 h	X_2	T_2 h	—	—		
2	Y_1	T_1 h	Y_2	T_2 h	Y_3	T_3 h	Y_4	T_4 h

While this format is not wrong, it is generally more efficient and flexible to create a second data file, which is organized listing each WBC observation with the corresponding subject ID as:

ID	WBC	Time
1	X_1	T_1 h
1	X_2	T_2 h
2	Y_1	T_1 h
2	Y_2	T_2 h
2	Y_3	T_3 h
2	Y_4	T_4 h

This type of database is called a *relational* database. The data tables are related to each other through a common variable, in this case the ID. The advantages of such a database are (a) they provide a more efficient way to handle multiple observations, especially when the number of repeated measures is large or highly variable, (b) it is easier to create subcategories or flag observations, (c) it may also be easier to collect/enter data into this type of format, and (d) some statistical packages for modeling change over time require data in this general format The disadvantages of using a relational database are (a) it may require special knowledge of database architecture and (b) additional manipulation of the data will always be required prior to merging data back into the "parent" dataset.

CONCLUSION

Hierholzer (27) has called data the epidemiologist's sand. A lens maker takes sand, refines it, melts it, and, through a long process of grinding and smoothing, fashions a lens with which to see the world more clearly. Similarly, an epidemiologist takes data, refines it, and smooths it until a clearer picture of nature is revealed. If the sand is dirty or impure, the lens will be cloudy and distorted. If data are unreliable or invalid, the epidemiologist's understanding of nature will be clouded and distorted. By paying close attention to the data collection process, from the conception of the data collection document through the editing of the data after they are collected, the epidemiologist helps keep his sand pure so that, in the end, nature may be viewed with as much clarity as possible.

This chapter provided a practical overview of data collection in hospital settings. To find more complete discussions of issues surrounding the strengths and limitations of various data sources, and the design and administration of opinion surveys, consult several useful reviews that have served as the basis of this chapter (*11*,*28*,29,*30*).

CHAPTER 6

Practical Application of the Principles of Epidemiology to Study Design and Data Analysis

Joseph H. Abramson

Suppose that examinations of 200 workers in a hospital reveal that 24 are carriers of methicillin-resistant *Staphylococcus aureus* (MRSA). Does this mean a prevalence of 12% in the hospital's personnel?

A study of adults undergoing mandatory health examinations (1) revealed that MRSA carriage (based on nasal swabs) was about twice as high among nonsmokers (4.3%) as among smokers (2.2%); the difference was statistically significant ($p = .019$). Does this mean that smoking protects against MRSA carriage?

Suppose this study had not found a significant difference, that is, $p > .05$, would this mean that smoking has no effect on the prevalence of MRSA carriage?

Suppose that a program to encourage hand washing by personnel is followed by a reduced rate of *S. aureus* infections among patients. Does this mean that the program reduced the incidence of these infections?

Suppose we are told that a review of the literature has found 16 controlled trials that show that a certain treatment for MRSA is efficacious and 4 that do not (a highly significant difference: $p = .007$). Can we conclude that the treatment works?

The answer to all five of these questions is "No."

Why?

Read on.

MAKING SENSE OF DATA

Bias is the bugbear of epidemiologists (2). Bias does not here refer only to preconceived opinions and preference but (as defined by the *Dictionary of Epidemiology*) to any "error in the conception and design of a study—or in the collection, analysis, interpretation, reporting, publication, or review of data—leading to results that are systematically (as opposed to randomly) different from truth" *(3)*. Its commonest forms, in any kind of study, are *information bias*, which is caused by shortcomings in the collecting, recording, coding, or processing of data, and *selection bias*, which is the distortion produced by the manner in which subjects are selected for study or by the loss of subjects who have been selected. In an analytical study, bias may also be caused by *confounding*.

This chapter deals with ways of minimizing or dealing with biases and uncertainties, both when planning and conducting a study and when handling its results, in order to make the study as valid as possible, with reference both to the study's soundness (its *internal validity*) and, when relevant, to its generalizability or applicability in other contexts (its *external validity*).

The focus is on epidemiological studies, that is, on studies of the occurrence, distribution, and determinants of health-related states or events in specified populations. This is a rubric that embraces all studies in the field of healthcare epidemiology and infection control, except maybe some laboratory studies.

Separate consideration will be given to epidemiological studies of various types, namely, descriptive studies and analytical observational studies, and (more briefly) ecological and multilevel studies, program reviews, trials, and meta-analyses. *Descriptive studies* may be cross-sectional ones that describe a situation at or around a given time ("snapshots") or longitudinal ones (such as *surveillance* procedures) that describe changes or events in an ongoing way or during a given period ("motion pictures"). Descriptive studies of disease occurrence may be termed *prevalence studies* if they are cross-sectional and *incidence studies* if they extend over a period. Changes may also be appraised by comparing the findings of repeated cross-sectional studies. *Analytical observational studies* include *analytical cross-sectional studies*, which examine the associations between variables (e.g., between suspected causal factors and their assumed effects) that exist at or about a given time; *cohort studies*, which are follow-up studies of people with various degrees of exposure to supposed causal factors; *case–control studies*, which compare the characteristics and prior experiences of people with and without a given disease or other outcome; and *ecological and multilevel studies*, which use data about groups or populations as such, unlike other studies, which are based only on data about the individuals in the groups that are studied. *Program reviews* are observational or analytical studies of the operation and outcome of healthcare procedures or programs, *clinical trials and program trials* may be seen as epidemiological experiments that test the value of healthcare procedures or programs,

and *meta-analyses* are critical reviews and syntheses of different studies of the same topic.

These types of epidemiological studies are not mutually exclusive. A study may have multiple objectives. It may, for example, be both descriptive and analytical, as in a study of colonization of group B streptococcus in pregnant women and neonates that was not confined to a description of prevalence and susceptibility to antimicrobial agents, but extended to an exploration of the effects (on the colonization rate in the newborn) of possible risk or protective factors, such as prolonged labor or the administration of antibiotics to the mother *(4)*.

For each type of study, we consider the main biases and uncertainties that may arise and briefly enumerate the steps that can be taken when planning the study and when analyzing and interpreting the findings, so as to minimize these biases and uncertainties or permit account to be taken of their effects.

Although a number of statistical procedures are mentioned and numerical examples based on them are cited, these procedures are not explained. It is assumed that readers either have statistical consultants or collaborators, or themselves have a sufficient grounding in statistical principles to be able to make intelligent use of statistical software. A number of multipurpose commercial programs (such as those listed on Chapter 15, pp. 216–217) are available, but they have to be learned and may be difficult for an unversed nonstatistician to use. The Internet offers many simple interactive programs ("Web pages that perform statistical calculations") (5), and a plethora of shareware and freeware statistical programs is available for downloading (6). The user-friendly WinPepi programs (7) for epidemiologists, for example—which can be downloaded free from www.brixton-health.com with their extensive and fully referenced manuals—can perform all the statistical procedures mentioned in this chapter (except Cox regression analysis and multilevel analyses). WinPepi was used to provide all the numerical examples cited in the text.

There are numerous sets of publication guidelines for epidemiological studies—witness the title of a recent review (8)—and these checklists can serve as reminders of what kinds of data should be collected and what kinds of analyses should be done. Particularly useful are the STROBE (*St*rengthening the *R*eporting of *Ob*servational Studies in *E*pidemiology) (9) and (for randomized trials) CONSORT (*Con*solidated *S*tandards *o*f *R*eporting *T*rials) (10) guidelines.

Before embarking on a study of any kind, ethical matters must of course be considered. Confidentiality should be taken into consideration even if the study is based only on existing medical records, and informed consent should be obtained whenever special test procedures—even questioning—or interventions are required. Approval by an appropriate ethics committee may be needed.

DESCRIPTIVE STUDIES

Information bias

Epidemiological studies do not always have clear *purposes*. It is not always clear why the study was performed; that is, what it was hoped to achieve by performing it. But every epidemiological study should have clearly defined *objectives*, that is, an answer to the question "What knowledge is the study planned to yield?" These objectives dictate the variables to be measured, and these variables must be clearly defined.

We have been told, at the outset of this chapter, that a simple descriptive study, whose objective was presumably to measure the prevalence of MRSA carriage, revealed that 24 of 200 hospital workers were carriers of MRSA (1). A number of obvious questions come to mind.

What, for example, is meant by "carriers of MRSA"? First, what is the *conceptual definition* (the "dictionary definition" of the characteristic that it is hoped to measure)? Carriers of these bacteria with no evidence of acute infection, or all carriers? Persistent carriers only, or transient carriers also? And secondly, how was this concept translated into an *operational (working) definition*, expressed in terms of the method of examination? From what sites were swabs taken? If from nostrils, one or both? Once only, or repeatedly? What type of swabs? Were the swabs stored or used immediately? Which of the available tests for MRSA was used? Precisely what results, using these methods, were taken as evidence of MRSA carriage? (And, of course, were all the workers examined in the same prescribed manner?)

Once we know the conceptual and (especially) the operational definition of the variable, we can ask how *valid* the measurement was; that is, how well did it measure what the researcher wanted to measure? The validity of a measure or a method of measurement can be appraised by comparing the findings with a criterion (a reference standard or "*gold standard*") that is known or believed to be close to the truth, if such a criterion is available. For a "yes–no" (dichotomous) variable, validity can then be calculated (see Chapter 3, pp. 54–55) and expressed as *sensitivity* and *specificity*. The sensitivity of the MRSA measure tells us what proportion of the true carriers (according to the gold standard) are detected by the examination, and its specificity tells us what proportion of noncarriers are correctly classified as noncarriers. The false-positive rate is 100% minus the specificity. It may also be enlightening to calculate the *predictive value* of the findings—when MRSA is detected by the measure, what is the probability that it is truly present (*positive predictive value*)? and when it is not detected, what is the probability that it is truly absent (*negative predictive value*)? But it must be remembered that these calculated predictive values (unlike sensitivity and specificity) are dependent on the prevalence of the condition. For example, if sensitivity and specificity are both 90%, the positive predictive value can be shown to be 79% if the true prevalence is 30 per 100, 55% if the true prevalence of MRSA is 12 per 100, and only 32% if the true prevalence is 5 per 100. If no "gold standard" is available, other methods of appraising validity can be used (11), for example, by checking the results against other (although not necessarily better) measures of the variable (*convergent* and *discriminant validity*), against related variables (*construct validity*), or against subsequent events (*predictive validity*). Often, reliance can be placed on common sense—that is, a judgment that the measure is obviously valid (*face validity*). If the validity of a measure is not known, it is sometimes decided

to appraise it in the course of the study (e.g., by using a "gold standard" measure in a subsample) or in a pretest.

It may be helpful, although it is not essential, to also know how *reliable* (i.e., repeatable) the measure is; that is, whether the same result is obtained when the examination is repeated. High reliability does not necessarily mean that the measure is valid (what is more reliable—or less useful—than a broken watch?) But low reliability will always cast doubt on validity. Many measures of reliability are available. In this instance, use would probably be made of the *kappa* coefficient (see Chapter 3, p. 72) or the apparently preferable AC1 coefficient, which express the proportion of subjects who are classified in the same way each time, after allowing for the effect of chance agreement. If we were appraising a numerical measure, other indices of reliability would be appropriate, such as St Laurent's *gold-standard correlation coefficient (12)* and the *95% limits of agreement (13)*.

The question that was asked at the start of this chapter was "Suppose that examinations of 200 workers in a hospital reveal that 24 are carriers of methicillin-resistant *Staphylococcus aureus* (MRSA). Does this mean a prevalence of 12% in the hospital's personnel?" If there is no misclassification, the prevalence is obviously 12% in these workers—that is, in the very unlikely event that the sensitivity and specificity of the measure are both 100%. But if there is misclassification—and there almost always is—the prevalence is unlikely to be 12%. Suppose, for example, that only 5 of the 200 subjects (2.5%) truly have MRSA and that the measure of MRSA has a sensitivity and specificity of 90%. Then it can be expected that 90% of the 5 will be found to have MRSA (4.5 true positives), and so will 10% of the other 195 (19.5 false positives), so that the total number who apparently have MRSA will be 24 (12% of the 200). In other words, a true prevalence of 2.5% will yield an apparent prevalence of 12%. And, conversely, an apparent prevalence of 12% points to a true prevalence of only 2.5%. Taking account of misclassification, the prevalence of MRSA in these 200 workers would thus be only 2.5%. An appropriate computer program, such as WinPepi, can easily do this reverse calculation, if fed the sensitivity, specificity, and apparent prevalence.

Descriptive epidemiological studies are usually concerned with more than one dependent variable and may involve independent variables as well, since they often aim to describe the findings in different subgroups, for example, different age groups or occupational groups, or in patients with different diagnoses. A failure to define appropriate working definitions for any of the variables, sufficiently valid for the purposes of the study, may result in a study flawed by information bias.

Any deficiencies in the collection of data may bias the results. The case-finding procedures used in an outbreak investigation, for example, may be inadequate however clearly a case is defined. Information bias may also be caused by missing data and by deficiencies in the recording or management of data, for example, by errors or omissions in the recording of findings or in the transfer of data to a computer for analysis.

In a longitudinal descriptive study, information bias may be caused by any changes that occur with time in disease definitions, case notification systems, or case-finding methods.

Data collected by observation (e.g., clinical or laboratory examinations) are generally more valid than data collected by interviewing or questioning (except of course in studies of feelings or attitudes). Numerous factors may reduce the validity of data based on questions—faulty memory (recall bias), a tendency to give socially acceptable responses, the interviewer's attitude, the wording of the question, etc. (see Chapter 5, pp. 87–90). Medical records too are often disappointing as a source of valid data unless they have been planned and maintained as a basis for research; a high proportion of the healthcare-associated infections detected by a surveillance program may not appear in the diagnostic record *(14)*. All records maintained solely for administrative purposes may be problematic with respect to their completeness or accuracy. An examination of the feasibility of appraising the immunization status of hospital workers in England, for example, revealed that only 85% of hospital trusts knew the exact number of staff employed, and only 68% had records of all immunizations *(15)*.

The above considerations apply to all epidemiological studies, not only to descriptive ones—namely, the need for defined study objectives, for clear operational definitions expressed in terms of the methods of study, and (if face validity does not suffice) for assurance of the validity of these methods. Information on the validity of methods may be available from other studies, but this should be handled circumspectly, since sensitivity and specificity may be affected by the characteristics of the sample in which validity was appraised and may by chance be different in different samples.

Selection Bias and Sampling Variation

To return to the MRSA example, we have not been told how the 200 workers were selected. Can the findings be validly applied to "the hospital's personnel," or do they apply only to a not necessarily representative group of 200 workers? Were the 200 a *random sample*, chosen from the total personnel by using random numbers or a computer program that uses an algorithm that makes an as-good-as-random selection? Or, were they an equally representative *systematic sample*, selected (for example) by taking every fifth person in a list of all personnel? Or, on the other hand, were they a haphazard and possibly unrepresentative sample; for example, were they the more easily persuaded workers encountered in a particular part of the hospital at the time of the study and possibly only junior personnel to boot (because what researcher would want to get up the noses of senior physicians or nurses, and administrators?).

In whatever way the sample was selected—even if it was selected randomly—it would be helpful to be assured that the characteristics of the workers who were studied were in fact similar to those of the total personnel if the latter information is available. Was the sample sufficiently similar in age, sex, occupation, etc. to the population from which it was drawn to allay concerns about selection bias?

To reduce sampling variation, use is often made of *stratified random sampling*. Representativeness with regard to age and sex, for example, can be enhanced if the sample is made up of separate random samples selected from each age–sex stratum.

A common source of selection bias is the *loss of subjects*, that is, the loss of members of the selected sample, as a result of refusal, failure to find subjects, mishaps in the laboratory, etc. Were the 200 workers who were studied in the MRSA study the total selected sample, or were they part of a selected sample of (say) 300? If the latter, it would be helpful to know whether and how the workers who were lost differed from those who were included. May the reasons for noninclusion be connected with the variable under study?

Even if the sample in the MRSA study was a representative randomly selected one, we cannot be sure of the 12%. There are a very large number of alternative random samples that might have been chosen, and the findings in different random samples of workers would, by chance (*random sampling variation*), obviously differ. We cannot be certain that the true prevalence in the total personnel is 12%, just because the prevalence in one representative sample is 12%. The best we can do is to use a computer program to obtain a *confidence interval*, which we can interpret, with a given level of confidence, as expressing the range within which the prevalence probably falls. In this instance, we can be 95% sure that the prevalence is between 8% and 17%. If a lesser level of confidence satisfies us, the range is narrower—the 90% confidence interval is from 9% to 16%. If we want to be more certain of the result, we can compute the 99% confidence interval, which is wider, namely, from 7% to 19%. The confidence interval depends on the size of the sample; it is wider if the sample is small, and narrower if it is large. If the sample size was only 50, uncertainty would be greater, the 95% confidence interval being from 5% to 23% instead of from 8% to 17%. If the sample size was 1000, the 95% confidence interval would be narrow—from 10% to 14%.

If the sample was randomly selected and we ignore possible misclassification, we can thus conclude with 95% confidence that the prevalence in the hospital's personnel is between 8% and 17%. But if we assume a sensitivity and specificity of 90% (in which instance the adjusted prevalence is only 2.5%), the 95% confidence interval for prevalence ranges from just above 0% to 9%.

The *sample size* required in a descriptive study depends on the desired width of the confidence interval—if a more precise result is wanted, a larger sample is required. The basic requirements for the calculation of sample size (or for the computer program that calculates it) are a guess, a wish, and a precaution. If the aim is to measure a proportion or rate, a guess must be made at its expected value; to be on the safe side, a proportion of 0.5, or 50%, can be assumed—this is a "worst-case scenario" that maximizes the required sample size. If the aim is to measure a mean value, the expected standard deviation is required. The wish is for a narrow confidence interval—that is, a specified acceptable error (i.e., half the width of the confidence interval) at a given (say 95%) level of confidence. The precaution (required by some computer programs) is allowance for the expected loss of members of the chosen sample because of refusal or for other reasons; taking this into account ensures an adequate sample size despite the losses, but of course does not remove the possibility of bias caused by selective losses. The size of the population from which the sample is drawn may also influence the required sample size, but only if the population is very small.

In a study that sets out to measure more than one dependent variable, the sample size requirement will usually differ for different variables (with different expected frequencies). It then becomes necessary to either select the largest sample size or decide on a compromise that will sacrifice precision with respect to the less important variable or variables.

Planning a Descriptive Study

When planning a descriptive study (or any epidemiological study, for that matter), thought should be given to both information bias and selection bias.

To minimize information bias, clear operational definitions are required for all variables and (if categorical scales are used) for their categories; valid methods of measurement should be used, and they should be applied in a standard way. Validity should be measured if necessary. Quality control measures (including checks on correct performance and on reliability) should be built in; and data cleaning (16), including the correction of errors where possible, should be performed both before and during or after entry of data to the computer. Data entry can be made easier and more accurate by using software, such as the freeware programs EpiData (see p. 202) and Epi Info (see pp. 201–202) that provides help in the design of a data entry form, a data entry screen, and a data set and can apply rules and calculations during data entry, for example, by restricting data to legitimate values. A record should be kept of the amount of missing data.

In a *surveillance* program (see Chapter 89), which is an ongoing descriptive study of health data (permitting, *inter alia*, the detection of outbreaks) or healthcare data, standardized working definitions and standardized methods of reporting and recording are especially important and may be particularly difficult to enforce because of the involvement of a large and constantly changing body of observers.

Especially in studies that set out to describe beliefs, perceptions, or practices regarding health or healthcare, consideration should be given to the use of *qualitative methods*, whose findings are described in words rather than numbers, as well as the usual quantitative methods. These methods, based on (for example) observations, conversations and in-depth interviews, or focus group sessions, can provide useful insights concerning beliefs and behavior (although not their numerical prevalence) and ways of exploiting or changing them. Reluctance of health workers or members of the public to be immunized (e.g., against swine flu) and unwillingness of parents to have their children immunized can best be combated if the motivations for and against immunization are understood. If done properly, qualitative research is as rigorous as quantitative research, but it needs special skills and generally requires the involvement of professionals who have had the requisite training. The designs used in "mixed-method" studies that integrate qualitative and quantitative data collection and analysis include the use of qualitative data as a basis for planning quantitative data-collection methods, the comparison and integration of qualitative and quantitative findings, and the quantitative analysis of qualitative data *(17)*.

If a sample is to be used in a descriptive study, it should be a representative one (random or systematic), possibly selected after stratification, and large enough to ensure an acceptable degree of precision. Sampling generally requires a sampling frame, for example, a list of the subjects from whom the sample is to be selected. To sample newly diagnosed cases of a disease as they crop up, use may be made of systematic sampling, for example, every fourth case, or of a sampling scheme whereby a case is randomly selected from each successive block of (say, two or four) cases.

Efforts should be made to ensure full coverage of the sample. If the study is a longitudinal one, entailing repeated examination of the same subjects, it may be necessary to plan tracking procedures, including the collection of information about addresses, places of employment, and the whereabouts of family members.

To permit the assessment of sampling bias, so that its possible effect can be taken into account when interpreting the findings, the characteristics of the sample studied should be compared with those of the total study population, using whatever demographic or other information is available; and the characteristics of subjects lost from the sample (or those of a sample of the lost subjects) should, if possible, be compared with the characteristics of the sample studied. Records should of course be kept of the reasons for noninclusion in the sample, since they may point to possible bias.

In addition to these precautions to ensure the internal validity of the study, thought should be given to the usefulness of the results in other contexts, unless there is no intention to publish the results. There will usually be other health workers or researchers who will be interested in the applicability of the findings in their own healthcare services or populations, even if the study was planned to meet a specific local need. Care should therefore be taken to collect, and provide, any information about the group or population studied, or about the context, that may help others to decide on the relevance of the study findings elsewhere.

Analysis of a Descriptive Study

The analysis of a descriptive study is usually simple. The frequency distribution of each variable in the total study sample or its subgroups is tabulated; rates or proportions, preferably with their confidence intervals, are computed for "yes–no" or other categorical variables; and measures of central tendency and dispersion (see Chapter 3, pp. 50–51) are computed for metric (noncategorical) variables. One-sample significance tests (see Chapter 3, pp. 57–58 and pp. 61–62) can be used to see whether the rate or proportion, or the mean or median, conforms with some standard value or with an expected or other hypothetical value. And two-sample significance tests (see Chapter 3, pp. 58–64) can be used to make comparisons with findings elsewhere.

The possible effect of misclassification can be appraised, as in the above MRSA example. Occasionally, the effect of information bias can be controlled in other ways. If, for example, there is a constant bias in laboratory results, due to a mistake in the preparation of a standard solution, it may be rectified by applying a correction factor.

The possible effect of selection bias should be taken into account when interpreting the findings, particularly if there was poor coverage of the sample. Sometimes it is possible to control selection bias by statistical manipulations during the analysis. If there was a low response rate in one sex, for example, the findings can be weighted in accordance with the sex composition of the total study population to obtain an estimate that compensates for this selectivity. A disadvantage is that this is based on the assumption that, in each sex, the subjects included and excluded are similar, which is not necessarily true.

In a longitudinal study, such as a surveillance program, the analysis is complicated by the need to describe changes with time. Numerous statistical procedures are available for the appraisal of trends (18), with or without controlling for seasonal variation and with or without controlling for deviations that may be caused by extraneous factors, such as fluctuations in diagnostic criteria. Outbreaks may be detected by changes from the "endemic" baseline values. But algorithms for the early detection of outbreaks usually use surveillance data from multiple sites.

A need sometimes arises to combine the results of two or more case-finding methods that yield different and incomplete, but overlapping, lists of cases. An estimate of overall prevalence can then be obtained by feeding the numbers, including the numbers of overlaps, into a computer program that can use the *capture–recapture* (or a similar) technique (19). This procedure, which is based on assumptions that are not always met *(20)*, takes its name from its original use in estimating animal populations by capturing, marking, and releasing a batch of animals and then seeing how many of them are recaptured in the next batch of animals caught. Its earliest use in healthcare epidemiology was to estimate the number of hospital patients using methicillin *(21)*, followed by its use in the surveillance of healthcare-associated infections *(22)*, and it has since been used in many other studies of incidence or prevalence and of the effectiveness of ascertainment systems *(23)*. In a capture–recapture study based on notifications of invasive neonatal group B streptococcus infections, made separately by pediatric wards and by microbiological laboratories, for example, the analysis led to the conclusion that the total number of cases was about double the total notified number *(24)*. The capture–recapture technique may yield an overestimate if all cases have in fact been found or an underestimate if some types of case are "uncatchable" by any procedure.

ANALYTICAL OBSERVATIONAL STUDIES

The key feature of an analytical study is the examination and interpretation of *associations between variables*. This brings new possible biases and uncertainties in its train in addition to those besetting descriptive studies.

Associations between variables are usually detected by observing that the value of the dependent variable (e.g., the mean value, proportion, or rate) is different when the value of the independent variable (e.g., a suspected causal factor) is different. The difference in the values of the dependent variable may lie in the same direction as the difference in the values of the independent variable (a positive association) or in the opposite direction (a negative or inverse association). The *strength* of the association is measured by the extent of the discrepancy between the two values of the dependent

variable (say, the two rates), as measured by the ratio of the two values or by the difference between the two values. The further the ratio is from 1, the stronger the association. The discrepancy can be in either direction, depending on whether the association is positive or negative; ratios of 8 and 0.125 (i.e., one-eighth) point to associations of the same strength but different in direction. If the difference between means, rates, or proportions is used, the further it is from zero (in either direction), the stronger the association.

These two methods of measurement (using a ratio or a difference) do not necessarily lead to similar conclusions about the strength of the association or the factors affecting it. Etiological studies generally use ratios and assume that exposure to a risk or protective factor has a multiplicative effect; that is, exposure multiplies the risk of the condition under study by a given amount. The effects of different exposures can then be combined by multiplying them by each other. A multiplicative model is used in logistic regression analysis (see Chapter 2, p. 44) and Cox regression analysis (see Chapter 2, pp. 44–45). On the other hand, if a study is concerned with the absolute magnitude of a problem or with the resources needed to deal with it, it is more appropriate to use the absolute difference between risks or mean values and assume that an exposure has an additive effect; that is, exposure increases (or decreases) the risk or mean value by a given absolute amount. The effects of different risk factors can then be combined by adding them. This is the model used in linear regression analysis.

The ratios commonly used as measures of the strength of an association are rate ratios, risk ratios, odds ratios, and hazard ratios.

A *rate ratio* is the ratio of two rates that have person-time denominators (e.g., rates per 1,000 patient-days or per 1,000 person-years). A subject who was observed for 10 days would contribute 10 patient-days to the total denominator, as would 2 subjects who were each observed for 5 days or 10 subjects who were each observed for 1 day. Incidence and mortality rates (sometimes referred to as *incidence density* or *mortality density*) are of this type.

A *risk ratio* (confusingly, often also called a rate ratio) is the ratio of risks, which are measures that use count denominators, that is, the size of the population at risk (e.g., 10 cases per 1,000 subjects), and not person-time denominators. Prevalence (the number of cases at a given time) and cumulative incidence (the number of new cases during a given period) are measures of this type, as are simple proportions and percentages (which express the number of cases or episodes per 1 subject or per 100 subjects, respectively).

An *odds ratio* (see Chapter 2, pp. 23–24) is the ratio of two odds. An odds is the probability that something is present or will occur, divided by the probability that it is not present or will not occur. If the proportion of people exposed to a risk factor who develop a disease is 0.8, the odds in favor of the disease in this group is 0.8 divided by 0.2, or 4 (4 to 1). If the proportion of people not exposed to the risk factor who develop the disease is 0.2, the odds in favor of the disease in this group are 0.2 divided by 0.8, or 0.25. The odds ratio expressing the strength of the association is the ratio of these two odds, that is, 4 divided by 0.25, or 16.

Odds ratios have useful statistical properties, but may be hard to understand and are easily misunderstood. In the above example, use of the odds ratio, which is 16, gives an impression of a much stronger association than would be indicated by the risk ratio of 4 (0.8 in the exposed group divided by 0.2 in the nonexposed group).

Case–control studies yield odds ratios only (unless ancillary information is available), and not rate ratios or risk ratios. But if the condition under study is rare, there is little difference between the odds ratio and the risk ratio, and the odds ratio can be used as a substitute for the risk ratio. Under certain conditions, depending on the manner of selection of controls, the odds ratio observed in a case–control study can also be used as a proxy for the rate ratio (25).

Odds ratios are the ratios that are generally used in studies that employ logistic regression analysis, since the logistic coefficients provided by the analysis are the logarithms of odds ratios and can be converted to odds ratios by taking their antilogarithms. Some computer programs (like WinPepi) can use the logistic regression results to estimate risk ratios, risk differences, and other measures of effect that are less misleading than odds ratios sometimes are.

Hazard ratios are used in studies based on person-time denominators, particularly those using Cox regression analysis, where the hazard ratios are the antilogarithms of the computed coefficients.

Information Bias

As in a descriptive study, *information bias* may result from inadequate operational definitions of variables, inadequately standardized methods, errors in the recording or management of data, and (in a longitudinal study) from changes in disease definitions, case notification systems, or case-finding methods.

An especially insidious type of information bias, with effects that are not always easy to predict or control, may occur in an analytical study if the validity of a measure differs in different groups. For a "yes–no" variable, this effect is referred to as *differential misclassification*, as opposed to the *nondifferential misclassification* that occurs if validity, although not perfect, does not differ.

As an illustration, suppose that 20 of 100 men and 5 of 100 women report that they have had sexually transmitted diseases (STD). The observed risk ratio expressing the association between sex and a history of STD is then 4. If the sensitivity of the STD information is 80% in both sexes (with a faultless specificity of 100%)—that is, if most cases are reported and there are no false positives, and misclassification is the same in both sexes—our trusty software tells us that a true risk ratio of 5 would produce the observed risk ratio of 4. If there is nondifferential misclassification, the observed association is generally weaker than the true association. But now suppose that sensitivity is 80% in men and 40% in women. The true risk ratio that would give rise to an observed risk ratio of 4 would then be computed as 2. But if, on the other hand, sensitivity is 40% in men and 80% in women, the true risk ratio would be computed as 8. Differential misclassification can bias the result in either direction, and (without the aid of a computer) its effect is difficult to predict and difficult to compensate for.

In studies of the effect of a supposed risk factor on a disease, differential validity can express itself as diagnostic or exposure suspicion bias. *Diagnostic suspicion bias* can occur if the information about the disease comes from a subject, interviewer, or examiner whose report about the presence of the disease is colored by knowledge that there has been exposure to the risk factor and who is more likely to report the disease if there has been exposure. This is possible in a cohort study or a cross-sectional analytical study. *Exposure suspicion bias* can occur if the information about exposure comes from a subject, interviewer, or examiner whose report about the presence of the exposure is colored by knowledge of the presence of the disease. This is possible in a case–control study or a cross-sectional analytical study. Both forms of bias are less likely if there is effective blinding and if subjects, interviewers, or examiners are not aware of the study hypothesis.

Clearly, information on validity in different subgroups of the study population would be helpful when interpreting the findings.

In cohort studies, where information about exposure to risk factors is obtained at the outset of a follow-up period, this information may be biased if there are changes of exposure status during the follow-up period. Smokers may not remain smokers. This bias can be reduced by seeking and using information about these changes.

Selection Bias and Sampling Variation

The strength of associations observed in analytical studies is subject to sampling variation, and confidence intervals must be computed for the rate ratios, differences, or other measures used. The sample size required in order to obtain acceptably precise results can be calculated manually or by a computer program. If strength is measured by the ratio of two rates or proportions or odds, the calculation is based on the known or assumed value of one of the rates or proportions, the value of the ratio that it is wished to detect (at a given confidence level), and either the desired width of its confidence interval or the required power of a test to determine statistical significance. If strength is measured by a difference between two values, the calculation is based on the known or assumed standard deviations of the two values, the difference that it is wished to detect (at a given confidence level), and either the desired width of its confidence interval or the required power of a test to determine statistical significance. The expected loss of members of the chosen sample can also be taken into account. In a case–control study, the number of controls per case influences the required number of cases. Calculation of the required sample size is less simple if there are a number of independent variables.

The same possibilities of selection bias resulting from inappropriate sampling or incomplete coverage of the sample exist in analytical studies as in descriptive studies.

In addition, there are special issues to be considered in case–control studies and in cohort studies.

Case–Control Studies The study of associations in case–control studies is based on a comparison of cases (generally of a disease) with controls (who are free of the disease), with respect to their prior exposure to suspected risk or protective factors. To avoid bias, the controls should be drawn from the same population as the cases. They should represent the people who, if they had the disease in question, could have become cases in the study.

But many case–control studies are vitiated by the inappropriate selection of controls.

If the study includes all the cases occurring in a defined population, or a representative sample of them, suitable controls can be found by taking a representative sample of the individuals without the disease in the same population. This is relatively easy to do in a primary healthcare service that caters for a defined population, but it is not easy in a hospital-based study. Hospital cases with a given disease, for example, are usually drawn from an ill-defined catchment population. Even if the study is restricted to hospital cases living in a defined neighborhood, and it is practicable to select "community controls" drawn from the same neighborhood, it cannot be certain that the controls would have been treated in the same hospital if they had the disease. Population controls who are selected because of their relationship with the cases, for example, friends, neighbors, spouses, siblings, fellow workers, or classmates, may tend to resemble the cases in their circumstances, lifestyles, or (for blood relatives) genetic characteristics. In other words, there may be similarities between the cases and controls that have nothing to do with the disease and can lead to false conclusions about associations with the disease. Controls drawn from other patients in the same hospital also present problems. They do not have the disease in question, but they have other diseases, which may have their own associations with the risk or protective factors under consideration. Moreover, bias may be caused by differences between the hospital admission rates for different diseases (*Berkson's bias*, *admission rate bias*). To minimize these problems, controls with similar diseases or clinical pictures may be selected (e.g., cancer controls for cancer cases, or women referred for breast biopsies of suspicious nodules, but not found to have breast cancer, as controls for cases found to have cancer or precancerous conditions). Patients admitted after traffic accidents or for elective surgery, blood donors, or hospital visitors are sometimes used as controls, in the hope that they represent the population base. It is usually found that the use of community controls overestimates the association between the disease and the risk factor, and the use of hospital controls underestimates it *(26)*.

It is seldom easy to find a source of controls that is both convenient and free of possible bias. Each instance must be considered on its merits, and a careful choice made of the least of the alternative evils. It is sometimes decided to use two or more control groups (of different kinds) and to see whether different comparisons yield the same conclusion; discrepancies may throw light on the study's biases.

Cohort Studies A cohort study examines the associations between selected risk or protective factors and diseases (or other selected outcomes) by following up a sample (cohort) of subjects whose exposure is known and determining whether the outcomes occur. In a prospective cohort study, information about the status at the outset is obtained by examinations or interviews; and in a historical ("retrospective") cohort study, information about the initial status of the cohort is obtained from records of past exami-

nations or interviews. In both instances, loss of members of the cohort to follow-up can cause serious selection bias (*follow-up bias*). Bias is particularly likely if the reasons for loss to follow-up are illnesses, deaths, or other events or circumstances that may be connected with the outcomes under study.

Unless loss to follow-up is negligible, the lost subjects should be compared with the subjects remaining in the study to see whether they differ with respect to whatever demographic or other information is available, as well as their initial exposure status.

Confounding Effects

Confounding, or *confounding bias*, can be defined as the distortion of an association between variables by the influence of another variable. As a simple example, all studies show that children with larger feet tend to know more words. This is of course explained by the influence of an extraneous variable, namely, age, which is associated both with foot size and with vocabulary size. Older children have larger feet, and because they are older, they also know more words. If we studied children of the same age, we would probably find no association between foot size and vocabulary size.

An extraneous variable can have a confounding effect on the association between an independent variable **A** (e.g., hypertension) and a dependent variable **B** (e.g., a healthcare-associated infection)—that is, it is a *potential confounder*—if two conditions are met: (a) it must influence **B** (or be a stand-in for something that influences **B**); and (b) it must be associated with **A** in the population, but not because it is affected or caused by **A**; if it is caused by **A**, it is an intermediate cause in the causal chain connecting **A** and **B**, rather than a potential confounder. Diagrammatically, **A – C** $\rightarrow$ **B**, where **C** (the confounder) is linked with **A** and influences **B**, but not **A** $\rightarrow$ **C** $\rightarrow$ **B**.

Only if the associations of **C** with **A** and **B** are strong can there be a confounding effect of any importance.

If potential confounders are identified and measured in the study, a number of ways may be used to determine whether they actually have appreciable confounding effects or to control these effects in the analysis.

Methods used to control for confounding in observational studies include the following (see the illustrative studies described in Chapter 88, pp. 1322–1324):

1. *Restriction* of the study to a homogeneous group, with no variation in the potential confounder, for example, restriction of the study to a specific narrow age group.
2. *Matching*, for example, by selecting controls of the same age and sex as the cases in a case–control study. Matching alone does not prevent confounding, but may introduce bias by making the cases and controls unduly similar in their exposure to possible causal factors; but if matching is followed by stratification or a neutralization procedure, the bias is removed and the results are more precise than without matching. Matching on a variable that is affected by the exposure or by the disease may also introduce bias (25).
3. *Stratification*, that is, division of the study sample into strata in accordance with the categories of the suspected confounder (e.g., age–sex strata), followed by separate analysis of the association in each stratum.
4. *Neutralization* of the confounder by a statistical technique that holds the suspected confounder constant and thus nullifies its effect and computes an adjusted measure of the strength of the association. The adjusted measure is a fictional value, a "counterfactual" estimate of how strong the association would be if the suspected confounder were neutralized. The difference between the adjusted measure and the corresponding crude measure (i.e., without controlling for confounding) is an indication of the degree of confounding; small differences (say, of <10%) are often ignored. Methods of neutralization include standardization (see Chapter 2, pp. 32–33), the Mantel–Haenszel (see Chapter 2, p. 31) and similar stratification-based procedures, and linear, logistic, Poisson, and Cox regression analysis.
5. Use of a rather elaborate *propensity score* that expresses the effect of a set of possible confounders on the probability of inclusion in the treatment group (in a nonrandomized trial) or the group exposed to the suspected causal factor (in an observational study) and that can be held constant in the analysis (27).
6. Use of an *instrumental variable*, which, in an appraisal of an **A** $\rightarrow$ **B** relationship, is a variable **Z** that does not share a common cause with **B** and can affect **B** because of, and only because of, its effect on **A**; that is, **Z** $\rightarrow$ **A** $\rightarrow$ **B**. If the study shows an effect of **Z** on **B**, this can be taken as evidence for an effect of **A** on **B**, whatever confounders may be affecting the observed **A–B** relationship (25,28). An instrumental variable has been likened to a coin flipped to decide whether a subject in a trial will be put in a treatment or control group—it determines the treatment, but has no independent effect on the outcome *(29)*. To be useful, the instrumental variable must be strongly associated with the causal factor under consideration. As an example, if the day of symptom onset can influence a health outcome because of, and only because of, its effect on the quality of hospital care, an association between day of onset and the health outcome can be taken as unconfounded evidence for the effect of the quality of care on the health outcome. Similarly, meteorological data on sunlight exposure during pregnancy and the health of the neonate may provide unconfounded evidence for the effect of maternal vitamin D status *(30)*; and distance from a hospital has been used as an instrumental variable in appraising the effect of intensive treatment for myocardial infarction on the (possibly unfounded) assumption that geographical location is not in itself associated with severity of illness *(31)*. In one study setting, the doctor's prescribing preference (inferred from prior prescriptions) was found to be a useful instrumental variable in examining the effect of various drugs on mortality *(32)*.

It is also possible to explore the possible effect of unmeasured confounders by "*external adjustment*," that is, by using a set of assumptions that are not based on the study data (28,33). A sensitivity analysis (i.e., a comparison of the results when different assumptions are made) can show the strength of the association in scenarios that differ with respect to the assumed strength of the unmeasured confounder's association with the dependent variable and its prevalence in the two groups (cases and controls, or exposed and unexposed) that are compared. If the adjustment renders the association negligible or

nonsignificant, or reverses its direction, and the scenario is a plausible one, this points to a need to be circumspect when drawing conclusions or to measure and take account of extra variables. For example, if the observed odds ratio is 2 (with a 95% confidence interval of 1.2 to 2.9) and an odds ratio of 3 is assumed for the effect of the confounder, an appropriate computer program would indicate that the adjusted odds ratio becomes nonsignificant if the unmeasured confounder's prevalence is greater by 20% or more in one group than in the other (or by 30% or more if the prevalence in both groups is above 50%). If either of these scenarios is plausible, it can be concluded that confounding by an unmeasured confounder or confounders may explain the association's statistical significance.

Modifying Effects and Intermediate Causes

An analytical study is usually concerned not only with the existence and strength of associations but also with the factors that influence the associations. If the association between some factor and healthcare-associated infections is stronger in men than in women, sex is an *effect modifier*; or in statistical terms, there is *interaction* between the factor and the sex in their effect on healthcare-associated infections.

Effect modifiers are of obvious interest in studies concerned with causes and effects, since they are among the factors that influence (or "cause") the outcome that is under study, and their detection may point to new avenues of investigation. Information about effect modifiers may also have practical implications, for example, by identifying high-risk groups or pointing to possible practical healthcare procedures. Unlike confounding, which is an unwanted effect that we try to prevent or remove, effect modification is an effect that it is useful to find and report and investigate.

Effect modification may be detected and measured by stratification, that is, by comparing the strength of the association in different strata of the suspected modifier (e.g., in the two sexes) or by including interaction terms in linear, logistic, or Cox regression models. If there is interaction between factors **X** and **Y** in their effect on **B**, this means that **X** modifies the association between **Y** and **B** and **Y** modifies the association between **X** and **B**.

There may also be interest in studying *intermediate causes*. In a study concerned with the effect of **A** on **B**, for example, **C** might be an intermediate cause that is influenced by **A** and, in turn, influences **B**. Diagrammatically, $\mathbf{A} \rightarrow \mathbf{C} \rightarrow \mathbf{B}$. Information about intermediate causes too may have practical implications, since a healthcare procedure might target **C** rather than **A**.

Planning an Analytical Observational Study

Every study design has its advantages and disadvantages. Case–control studies are generally easier, faster, and less costly than cohort studies and require much smaller samples if the outcome is uncommon. However, they deal with only a single outcome, provide no direct measures of risk, and are particularly subject to recall bias and exposure suspicion bias and, if unsuitable controls are used, to selection bias. Cohort studies, on the other hand, are prone to diagnostic suspicion bias and follow-up bias.

In any analytical study, the list of variables to be studied should extend beyond the dependent and independent variables whose associations are the focus of the study. It should also include possible confounders and maybe possible effect modifiers and intermediate causes. These variables can be selected from a list of all the factors that are known or suspected to be appreciably associated with the dependent variables and that it is practicable to measure. Consideration should always be given to the possible inclusion of the "universal variables" that are so often of relevance in epidemiological studies, namely, sex, age, parity, ethnic group, religion, social class and related variables, and place.

The same precautions to minimize information bias should be taken as in descriptive studies: clear operational definitions for all variables and their categories; valid methods of measurement, applied in a standard way; quality control measures; data cleaning; computerized data entry; and a record of missing data. Blinding of anyone who may influence the findings may be advisable to minimize exposure suspicion bias and diagnostic suspicion bias.

If samples are to be used in an analytical study, they should be representative ones, large enough to ensure an acceptable degree of precision. In a case–control study, incident (i.e., new) cases are generally preferred to prevalent (i.e., existing) cases, both because they are closer in time to their causal factors and because this prevents bias caused by the absence of deceased or recovered cases (*Neyman's bias*, *incidence–prevalence bias*). To sample newly diagnosed cases of a disease as they crop up, use may be made of systematic sampling, for example, every fourth case, or of a sampling scheme whereby a case is randomly selected from each successive block of (say, two or four) cases.

In a case–control study where duration of exposure is taken into account by the use of person-time denominators, controls should be selected at the same time as the cases, rather than at a single point in time.

Efforts should be made to ensure full coverage, especially in studies entailing repeated examination of the same subjects, where it may be necessary to plan tracking procedures.

As in descriptive studies, the characteristics of the samples studied should be compared with those of the populations from which they are drawn and the characteristics of lost subjects (or of a sample of the lost subjects) should, if possible, be compared with those of the sample studied. Records should be kept of the reasons for noninclusion in the sample.

Thought should be given to the external validity of the study and its applicability in other contexts. Care should be taken to collect, and provide, any information about the group or population studied, and about the context, that may help others to decide whether the findings can be applied elsewhere.

To facilitate decisions on the practical usefulness of the findings, ways should be found of expressing them in terms—when it is appropriate and practicable to do so—of costs and of estimates of potential impact. Easily calculated estimates of the impact of exposure to a given factor on the incidence or prevalence of a given disease, for example, include the *population attributable fraction* (the proportion of cases attributable to the factor; see Chapter 88, pp. 1320–1321) and (if the factor can be eliminated) the *preventable fraction*.

Analysis of an Analytical Observational Study

The exploration of associations between variables provides the knowledge that an analytical study sets out to gain. But simple descriptive results are usually sought first. Examination of the frequency distributions of all relevant variables (in the total study sample or its subgroups) enables the investigator to find gaps, patterns, and inconsistencies, and "get to know" the data. As in a descriptive study, rates or proportions, preferably with their confidence intervals, may be computed for "yes–no" or other categorical variables and measures of central tendency and dispersion for metric (noncategorical) variables.

The next step is usually bivariate analyses, that is, the examination of relevant associations between pairs of variables—particularly relationships with the dependent variable or variables. In some studies, this may yield all the information that is required. In others, this process of "screening for associations" may facilitate decisions about the variables that should be included in subsequent analyses. (Bivariate analyses are sometimes called univariate analyses because a single independent variable is considered each time.)

Statistical significance and estimates of confidence intervals for measures of association should (at this and subsequent stages of the analysis) be computed by appropriate statistical procedures whose selection is determined by (for example) the variables' scales of measurement (dichotomous, nominal, ordinal, or metric), whether observations are paired or independent, whether count denominators or person-time denominators are used, and whether a normal distribution can be assumed.

The selection of variables that may act as confounders, and that should therefore be incorporated in subsequent analyses, may be based on the strength of their associations with the dependent variable or variables as demonstrated in the bivariate analyses. The selection may also be based on significance tests, eliminating the variable as a possible confounder only if p exceeds, say, .2 (25).

Multivariate Analyses The bivariate analyses are usually followed by multivariate analyses that involve more than two variables. There may be a temptation to jump in at the deep end and start with a multivariate analysis (e.g., multiple logistic regression), knowing that this will provide the main results required to meet the study's objectives, but most experts would consider it unwise to skip the prior examination of the data and their bivariate associations.

The simplest multivariate method of analysis is *stratification*. The sample is divided into strata, in accordance with the categories of a suspected confounding or modifying variable, so that the relationship between an independent variable and the dependent variable can be examined separately in each stratum, and the comparison of the results in the strata can be based on, say, risk ratios or odds ratios. Each analysis may have a single stratifying variable (e.g., sex), or there may be more than one stratifying variable (e.g., by stratifying by both sex and age).

The analysis of the stratified data generally uses the *Mantel–Haenszel procedure* (see Chapter 3, pp. 75–76) or a similar procedure. Different formulations are used for dichotomous, nominal, ordinal, and numerical dependent variables, for measures based on count denominators and person-time denominators, and for matched and independent observations. The Mantel–Haenszel analysis does two things. First, it provides a heterogeneity test that compares the associations observed in the different strata and may hence point to effect modification by the stratifying variable or variables. And secondly, it brings together the findings in the different strata by computing an adjusted odds ratio ("summary odds ratio," "underlying odds ratio") or an adjusted rate ratio or other measure that controls for the effect of the stratifying variable or variables. The adjusted measure can then be compared with the crude measure (based on unstratified data, and thus not controlling for the effect of the stratifying variable or variables). A discrepancy will suggest confounding by the stratifying variable or variables.

Here is a fictional example to make this clear. Imagine a cross-sectional epidemiological study that finds that MRSA carriage is associated with infrequent hand washing (<7 times a day), with an odds ratio of 2.8, and also with overweight (body mass index above 25), with an odds ratio of 3 (a crude association between MRSA infection and overweight has in fact been reported in a study of prison inmates) *(34)*. Suppose that we wish to see whether overweight has a confounding or modifying effect on the hand washing–MRSA association, using stratification and the Mantel–Haenszel method. To this end, we would stratify the sample by overweight, using two strata (overweight absent or present) or more than two strata (with different degrees of overweight). First, we would compare the odds ratios (expressing the association between infrequent hand washing and MRSA carriage) in the various strata. If these are all 2.8 or close to 2.8, overweight is not a modifying factor. But if they differ and the heterogeneity test gives a significant result, we would regard overweight as an effect modifier. But a word of caution: these heterogeneity tests have a low power to detect significant differences, and it is usually recommended that a p level of .1 or higher should be used as a cut-point for significance. Because of the low power of the tests, use may instead be made of indices of heterogeneity, namely, Higgins and Thompson's H (a value of 1.5 or more suggesting notable heterogeneity) and *I-squared* (the proportion of variation attributable to heterogeneity) (35). In this instance, let us imagine that the odds ratio for the hand washing–MRSA association is 1.5 in the "not overweight" stratum and 12 in the "overweight" stratum. This would clearly show that overweight has a modifying effect. (Remember that these findings are imaginary.)

Now let us look at the adjusted odds ratio computed by the Mantel–Haenszel procedure. This odds ratio should be compared with the unadjusted ratio (2.8). If there is an appreciable difference, this is evidence that overweight has a confounding effect on the hand washing–MRSA association. The adjusted measure then provides a better measure of the direction and strength of the association than the unadjusted measure, which is confounded by the effect of overweight. It should be noted however that if overweight is also a strong effect modifier, the adjusted measure may not be a very helpful basis for practical healthcare procedures. It is a kind of average and would obscure the information that the association between infrequent hand

washing and MRSA is very strong only in the overweight subjects, who might be selected as a high-risk group requiring special attention. The Mantel–Haenszel odds ratio in our fictional study is 2.9, very close to the unadjusted value of 2.8; in other words, in this case overweight is a modifier but not a confounder.

Stratification is unwieldy if there are more than one or two stratifying variables. Stratifying by age (say five age categories) and sex would mean 10 strata, and the addition of two more stratifying variables would boost the number of strata to 40 or more. Except in very simple studies, the multivariate method of choice is generally the use of a mathematical model that permits the simultaneous examination of relationships involving a number of independent variables, permitting estimation of the strength and statistical significance of their associations with the dependent variable, the identification of confounding and modifying effects, and the control of confounding effects. The available procedures, which use different models, include multiple linear regression, which assumes that effects are additive, and multiple logistic regression, which assumes that effects are multiplicative, as do multiple Poisson regression and Cox proportional hazards regression (which are appropriate for person-time data).

A decision must be made about the variables to be included in the regression analysis. Variables that are of interest as possible effect modifiers should obviously be included, and all potential confounders should be considered for inclusion. The selection of potential confounders may be based on the strength of the associations demonstrated in bivariate analyses and by comparisons of the findings in different strata. Sometimes it is decided to base the selection on a series of stepwise multivariate analyses in which a single variable is eliminated or added at each step. In stepwise "backward deletion" *all* the potential confounders are initially included; the variable with the smallest effect is then deleted, and this process is repeated until the removal of a further variable produces an appreciable difference (say of 20%) in the total effect. In stepwise "forward selection," one or two variables, e.g., age and sex, are included in the first analysis, and the potential confounder with the strongest effect is then added; this process is repeated until the addition of extra variables makes no important impact on the effect.

In some circumstances, the inclusion and neutralization of a variable that is *not* a confounder may introduce rather than remove bias (25). "Overadjustment" should be avoided.

The regression methods usually used are logistic regression analysis or (if duration of exposure to the suspected risk or preventive factor has to be taken into account) Cox proportional hazards regression analysis. If we apply logistic regression analysis in our fictional study of hand washing and MRSA carriage, using a model that includes infrequent hand washing, overweight, and the interaction between infrequent hand washing and overweight, the computer program will provide coefficients that can be transformed into odds ratios that are identical or very similar to those provided by the Mantel–Haenszel procedure, together with confidence intervals and significance tests.

Three precautions (often ignored) are worth noting with respect to logistic and Cox regression analysis. First, the analysis is invalid if the model is inappropriate in that it does not conform with reality—that is, if the effects of the various variables are not in fact multiplicative. For logistic regression analysis there is a simple goodness-of-fit test, comparing the observed findings with those predicted by the mathematical model, which should always be performed. Secondly, unless there is no interest in effect modification, interactions between variables should always be specified in the model; if the interactions turn out to be insignificant they can then be removed. And thirdly, a choice must be made between alternative analysis procedures—for example, conditional logistic regression should be used for matched data, and unconditional logistic regression in other instances.

Interpretation: Making Sense of Associations

Most analytical studies in the health field aim either to throw light on causal processes or to provide the means for predicting outcomes. They examine associations between variables and seek evidence that variables that are associated with the disease or other condition under study are risk factors (or preventive factors) that influence the development or severity of the condition, or, if they do not play an etiological role, that they can be used as predictors of the outcome (risk markers). Healthcare procedures directed at risk and preventive factors may, if these are modifiable, modify the outcome; and risk markers may identify individuals or groups at whom these procedures should be directed.

The first questions to be asked about an observed association concern the possible effects of bias. Is the association a true one, or may it be an artifact—a bogus association—attributable to information bias, selection bias, or confounding bias? May these biases have influenced the strength and direction of the association? And, on the other hand, if no association is observed, may biases account for its absence? If marked bias is strongly suspected and there is no way of correcting or controlling its effects, further examination of the observed association is usually pointless. Confounding should, if possible, be controlled by one of the methods mentioned above.

An association may be misleading for other reasons also. For example, in a follow-up study of persons selected because of their extreme values, they will tend, by chance, to have less extreme values the second time *(regression toward the mean*) if there is any degree of random variation. Hypertensives will tend to have lower pressures the second time they are measured. In an uncontrolled study this reduction might be spuriously attributed to treatment. An appropriate computer program can assess this effect or neutralize it in the analysis.

The strength of an association may be a measure of its importance—the stronger it is, the more likely that it is important. Attention should of course be paid to the confidence interval. Appraisals of strength are best delayed until possible confounders and modifiers have been incorporated into the analysis. Multivariate analysis can reveal that an association is stronger than it initially seems.

If effect modification is detected, its possible reasons should be considered.

Statistical Significance Anything may happen by chance. However strong the association that is observed between two variables, it may be fortuitous, unlikely though this may be. The absence of an association may also be a fortuitous occurrence. The question is not whether an observed association may have occurred by chance—the answer to which is almost always "Yes"—but whether we are prepared to regard it as nonfortuitous.

Significance tests (see Chapter 2, pp. 26–27) generally appraise the probability that there is no association (i.e., no difference in either direction); this is the *null hypothesis*. And the study hypothesis (the *alternative to the null hypothesis*) is that there is an association (a difference in either direction). A two-sided test should then be used. But if the study hypothesis is that there is difference in a particular direction, a one-sided significance test can be used. A one-sided test is more likely to give a significant result than a two-sided test, but it should be used only if it is warranted by a one-sided null hypothesis, stated before the test is performed.

If the probability that there is no association (p) is low, we can be reasonably sure that the association is not fortuitous. If the p value is under .05, for example, we can be 95% sure. But we can never be *quite* sure that the finding is not due to chance. And, on the other hand, if the test result is "not statistically significant," this does not necessarily mean that the association is fortuitous (any more than a negative sputum test for the tubercle bacillus necessarily means that a patient does not have tuberculosis). The verdict is "not proven." If samples are large, however, a "not significant" result may be taken to mean that there is unlikely to be a nonfortuitous association of any great strength.

We should mention that for some significance tests, the null hypothesis is that the means, proportions, or rates that are compared are different, not that they are the same, and its alternative (the study hypothesis) is that they are the same. These are *equivalence tests* and *noninferiority tests* that are conducted in order to decide, for example, whether a new treatment is as good as, or at least not worse than, an established treatment. In these tests, a low p value points to similarity and not (as in most significance tests) to a difference.

One of the questions asked at the start of this chapter was if a study of MRSA carriage showed no significant association with smoking ($p > .05$), this would mean that smoking has no effect on the prevalence of MRSA carriage. The answer is obviously "No," since even if there are no biases (and we do not know this), the negative significance test tells us only that there is no convincing evidence that there is no relationship, not that there is no relationship. "Absence of evidence is not evidence of absence" *(36)*. Even a strong association may be statistically nonsignificant if the sample is small, and we do not know the size of the sample in this study. Only if the study was based on a very large sample might we be reasonably safe in concluding that smoking has no effect.

Significance tests have "built-in errors." Using a significance level of 5%, purely random processes will produce a verdict of "statistically significant" in about 5 of every 100 significance tests performed, even if no real associations exist. This may be an important consideration if many tests are performed on the same body of data, and statistical procedures that take account of multiple testing are available.

Confidence intervals can be used to provide an indication of statistical significance. If, for example, the 95% confidence interval for a difference between two rates or means does not include 0, or if the 95% confidence interval for a rate ratio or odds ratio does not straddle 1, this usually means a significant difference (by most two-sided tests) at the 5% level.

Useful though it may be to know whether an association is significant, it must be remembered that it tells us nothing about the strength or importance of the association. A very weak association can be significant if the sample is large, and a strong association can be nonsignificant if the sample is small.

Significance tests should not be done when they are not needed. In some studies, especially in simple descriptive studies not based on random or systematic samples, the issue of fortuitousness may have little importance. For practical purposes it may be enough to know that patients with MRSA infections are concentrated in certain hospital wards or that these infections are much more prevalent in patients with certain disorders, without worrying about deciding whether these associations might have occurred by chance. In Bradford Hill's words, "there are innumerable situations in which (tests of significance) are totally unnecessary because the difference is grotesquely obvious, because it is negligible, or because, whether it be formally significant or not, it is too small to be of any practical importance" (37). There is little point in doing a significance test on an association that is likely to be an artifact or on one that is so weak that it would be of no consequence even if it were regarded as nonfortuitous.

Causal Inferences The question of causality is a knotty one. Using the findings of an observational study, how can we infer that the association between **A** and **B** is a cause–effect one? How can we infer that **A** (or a factor for which **A** is a proxy measure) produces or influences **B**—or, of course, that **B** (or a factor of which **B** is a proxy measure) produces or influences **A**? How can we infer that exposure to the one variable, or a change in its amount or quality, results in an alteration in the amount or probability or quality of the other variable?

There are two obvious prerequisites, without which an observed association cannot be regarded as definitely causal. First, the assumed cause must precede the assumed outcome. Time relationships are, of course, always known in trials. In an interesting impeccably performed randomized controlled trial of the effect of intercessory prayer on hospitalized patients with bloodstream infections, in which there was perfect blinding of patients and staff not only to the allocation of patients but even to the existence of the trial, it was found that patients who were prayed for had a significantly shorter duration of fever, a significantly shorter hospital stay, and a (nonsignificantly) lower mortality *(38)*. But the inference that this was a cause–effect relationship was somewhat vitiated by the fact that the praying took place 4 to 10 years after the patients' hospitalization. Time relationships may also be known in longitudinal observational studies and some case–control studies.

They may be uncertain in cross-sectional and in other case–control studies. However, it is essential that there should be at least a possibility that the assumed cause preceded the assumed outcome.

Secondly, the observed association must not be wholly attributable to selection bias, sampling bias, or confounding bias. The effects of bias are usually uncertain, and even in the best-planned and best-performed study there may be doubts about possible unknown or unmeasured confounders. Hence there is usually a degree of uncertainty about the validity of causal inferences.

All we can hope for is reasonable evidence for a causal relationship, strong enough to be used as a basis for decision and action. Basically, what we can do is see how well the facts fit in with what we might expect to find if the association was causal. This is not quite the same thing as "proving" a causal association, but it is the best we can do. The following additional criteria, taken together, may strengthen or weaken the case for causality, although none of them is essential or conclusive:

1. *Statistical significance* does not necessarily support the case for a causal association, but its absence weakens the case if the test is sufficiently powerful (which usually means "if the sample is large enough").
2. *Strength* of the association—the stronger it is, the more likely that it is causal, and not produced by bias or confounding. But a weak association may also be (weakly) causal.
3. *Dose–response relationship*—the case for causality is supported if there is a correlation between the amount, intensity, or duration of exposure to the "cause" and the amount or severity of the "effect." But a dose–response relationship does not "prove" causality, and nor does its absence disprove it; there may, for example, be an "all-or-none" response that appears only when a causative factor reaches a threshold level, or a relationship between cause and effect that is U- or J-shaped (or inverted U- or J-shaped) rather than linear.
4. *Time–response relationship*—if the incidence of the "effect" (e.g., the rate of new cases of a disease) peaks some time after a brief exposure to the "cause" and then decreases, this supports the case.
5. *Predictive performance*—if the study results provide new knowledge supporting an *a priori* hypothesis concerning a predicted effect, this supports the case; a failed prediction weakens the case.
6. *Specificity*—the finding that the "effect" is related to only one "cause," or that the "cause" is related to only one "effect," may be regarded as supporting the case. But a lack of specificity in no way negates a causal relationship.
7. *Consistency*—if the same association is found repeatedly, in different subgroups of the study population and in other populations or circumstances and in studies by other investigators or methods, this strongly supports the case. If results are inconsistent and the variation cannot be explained, this weakens the case.
8. *Coherence* with current theory and knowledge—in particular, the availability of a satisfactory explanation of the mechanism by which **A** may affect **B**—supports the case. But investigators can usually think up a plausible causal explanation for any association. If no plausible explanation can be suggested, a cause–effect relationship may be difficult to accept, but should probably not be ruled out. Incompatibility with known facts weakens the case.

These are not clear-cut hard-and-fast "rules of evidence." In the words of Bradford Hill's seminal paper on "association or causation": "None … bring indisputable evidence for or against the cause-and-effect hypothesis and none can be required as a *sine qua non*. What they can do, with greater or less strength, is to help us to make up our minds on the fundamental question, is there any other way of explaining the set of facts before us, is there any other answer equally, or more, likely than cause and effect?" (37). The appraisal of causality is thus a matter of judgment, which means that experts may differ in their conclusions. But there is no substitute for considered judgments based on the available evidence, as the basis for decisions about healthcare in situations where (as almost always) there is no completely valid answer.

At this point, let us return to one of the questions asked at the start of this chapter: "A study of adults undergoing mandatory health examinations revealed that MRSA carriage was about twice as high among nonsmokers (4.3%) as among smokers (2.2%); the difference was statistically significant (p = .019). Does this mean that smoking protects against MRSA carriage?" The answer must of course be "No" if only because the association may be attributable to confounding. We might think of age as a possible confounder, since (in many countries) the proportion of smokers is higher among younger than among older adults, and both healthcare-associated and community-associated MRSA infections have been found to be much less prevalent in younger than in older adults *(39)*. Actually, confounding by age could not have caused this association since although age was not controlled in the study that found the association, age was not associated with MRSA carriage in that study, which was conducted in Taiwan. The authors of the study suggested that "it might be that smoking creates a microenvironment in the nose that protects against the growth of *S. aureus*." But it might also be that the association was a chance occurrence, a fluke—significance tests may be misleading if many tests are done on the same body of data, and the test for the association with smoking in this study was 1 of 21 tests for associations. We should agree with the authors that this "requires further study," and wait and see whether the association is replicated in other studies.

ECOLOGICAL AND MULTILEVEL STUDIES

Ecological studies are studies in which the units of analysis are populations or groups of people, rather than individuals *(3)*. In other words, the variables whose associations are examined are the characteristics of the groups that are studied, and not the characteristics or experiences of the individual members of the groups. Analytical ecological studies may be cross-sectional or longitudinal.

Ecological studies permit the examination of factors that affect a whole group. These factors include *aggregate measures* (or *derived measures*) that summarize the attributes of individuals, such as the level of herd immunity or the prevalence of carriage of a microorganism, or *global*

measures that do not, for example, the accessibility of health services, or cultural norms affecting interpersonal contacts. In the context of healthcare-associated infections, ecological studies may aim to determine the effects of characteristics of the unit or ward in which the patient is treated, including the use of infection-control measures, personnel size, and personnel functioning, or characteristics of the hospital.

Examples of ecological studies are a 2-year study of two neonatal intensive care units in New York, where a multivariate analysis revealed an inverse relationship (in one of the units) between the number of hours of nursing care per day in the unit and the risk of bloodstream infections *(40)*; a Spanish study that found that the rising prevalence of *Clostridium difficile* infection in a large number of hospitals between 1999 and 2007 was strongly correlated with the rising prevalence of use of antimicrobials in the hospital *(41)*; and a study of a Danish hospital, where the incidence of healthcare-associated bloodstream infection remained stable during a 4-year period despite a significant increase in the amount of alcohol-based hand rub used *(42)*.

If operational definitions and methods of a study are in the investigators' control, ecological studies require the same precautions to prevent information bias as do individual-based studies. Unfortunately, it is often necessary to use information of questionable accuracy or appropriateness, collected for administrative or fiscal purposes by hospital administrations or obtained from statistical offices or other official sources. In such instances, circumspection in its use is essential.

The analysis should follow the same lines as in other analytical studies. Use is frequently made of the correlations between variables, so that ecological studies are sometimes called *correlation studies*. Possible confounding by other group-based variables should be, if possible, appraised and controlled.

Multilevel studies use both group-based and individual-based variables. They examine the effects of both sets of variables and can explore the relationships between their effects. Group-level factors may not only change the risk of an infection but also modify the association between individual-level risk factors and risk of an infection. Examples cited in a review of the potential value of multilevel studies *(43)*, with respect to the association between number of sex partners and the risk of an STD, are the effects of the prevalence of STD in the population, the degree of assortative (within-group) mating, and the availability of STD clinics. The effects of group-level factors can be estimated after adjustment for individual-level variables, and vice versa. Multilevel studies can thus pinpoint the possible value of interventions directed both at groups and at individuals.

An example in the field of hospital-associated infections is a Finnish study performed in 60 wards in 6 hospitals, which collected individual-level data concerning a number of risk factors, together with hospital-level data (a university hospital or not?), and ward-level data that emphasized work hours and measures of work stress and collaboration between personnel. Multilevel logistic regression analyses, controlling for hospital factors and patient-level risk factors, showed that the risk of infections was raised if the staff had long work hours or a high level of work stress, as expressed in a low trust of other unit members, a perceived imbalance between efforts and rewards, a poor collaboration between ward supervisors, and other indicators *(44)*.

PROGRAM REVIEWS

Evaluative studies of healthcare programs can be usefully categorized as program reviews or program trials (11).

Program reviews are studies that evaluate specific healthcare programs and are motivated by concern with the welfare of the patients, community, or population to whom care is given, with the intention of helping whoever runs and makes decisions about the program. They do not question or test the assumptions on which the program is based, for example, the assumption that certain procedures will have beneficial effects. They examine the operation and outcomes of the program, but are not concerned with cause–effect hypotheses or inferences.

Program reviews are basically descriptive epidemiological studies, and in principle they require the same precautions to avoid information bias and selection bias as do other descriptive epidemiological studies. However, there are two constraints: to be useful, a review must usually be rapid and (if possible) ongoing, that is, performed in real time; and the review is usually conducted in a service-oriented setting, where evaluation is not seen as a major priority, and little time and resources may be available for special information-collecting procedures. Very rigorous definitions, elaborate methods, and extensive lists of variables may therefore not be practicable.

Some associations between variables may be relevant and therefore examined in a program review. But, since no hypotheses are tested, attention need not be paid to confounding or to causal inferences. If there *are* hypotheses to be tested, the more rigorous methods appropriate in program trials (see below) should be used.

Like other evaluative studies, program reviews aim to collect objective facts that provide a basis for subjective decisions on the value of the program. The topics to be considered when defining the study objectives include the following (11):

1. The *requisiteness* of the program—to what extent is it needed? What is the extent and severity of the problems that the program aims to solve?
2. The *outcomes* of the program—the occurrence of desirable effects (*effectiveness*) and undesirable effects (*harmlessness*).
3. The *process*—the performance of planned activities by the program's personnel, and compliance and the utilization of services by the recipients of care.
4. The *structure*—the availability of personnel and facilities, and geographic and economic accessibility.
5. *Efficiency*—the cost incurred in achieving results: in monetary terms (the study of which requires special expertise) or in nonmonetary terms, for example, the number of nurses, hours of work, hospital days, hospital beds, waiting time, or screening tests required for a particular purpose.

6. *Differential value*—differences in the above features in different categories or groups or in different circumstances.

One of the questions asked at the start of this chapter was: "Suppose that a program to encourage hand washing by personnel is followed by a reduced rate of *S. aureus* infections among patients. Does this mean that the program reduced the incidence of these infections?" The answer is "No," since the reduction in the rate might well have other causes. A "Yes" answer would require a controlled study, using the stringent methods of a program trial. However, in a review of a program that does not question the assumption that hand washing by personnel can reduce the probability of *S. aureus* infections among patients, this would be regarded as a satisfactory outcome, indicative of the program's effectiveness.

Unless there is no intention to publish the results, there will always be other health workers or researchers who will be interested in the applicability of the findings in their own healthcare services or populations, even if the study was planned to meet a specific local need. Care should therefore be taken to collect, and provide, any information about the group or population studied, or about the context, that may help others to decide on the relevance of its findings elsewhere.

TRIALS

Clinical trials and program trials may be seen as epidemiological experiments designed to evaluate healthcare procedures or programs. *Clinical trials* evaluate therapeutic, preventive, rehabilitative, or educational procedures applied to individuals, and *program trials* evaluate intervention programs applied at a group level (i.e., in a total hospital or other care unit), possibly including, but not limited to, procedures applied to individuals.

Unlike program reviews, both clinical and program trials generally aim to produce generalizable results, applicable in settings other than that in which the trial was conducted. In addition to the precautions required to ensure the internal validity of the study, thought should be given to its usefulness in other contexts, and full information should be collected and provided about the characteristics of the samples, and the context in which the trial is performed.

To facilitate decisions on the usefulness of the findings, ways should be found of expressing them, when it is appropriate to do so, in terms of impact (such as attributable or preventable fractions) or the number needed to treat in order to cure or prevent one case, or cost.

Clinical Trials

Clinical trials are generally *parallel studies*, which compare outcomes (both desired and undesired), in independent groups of individuals who have been exposed and not exposed to the procedure being tested or exposed to different procedures. They may also be *externally controlled studies*, in which the exposed group is compared with data obtained from other sources, or "*self-controlled*" *studies*, in which the subjects are their own controls (before–after studies and crossover studies).

Uncontrolled trials are obviously of limited usefulness.

Externally controlled studies have obvious limitations because of possible differences between the experimental and control subjects with respect to their characteristics or management or manner of appraisal or the time at which they were treated. Even patients treated in the same way, but at different times, may have very different outcomes; variations of up to 46% have been reported in the death rates of control groups (who had the same treatment) used by the same investigators in different cancer chemotherapy trials *(45)*. This is an important consideration in studies using historical controls (patients treated in the past).

"Self-controlled" before–after studies avoid many possible confounding effects but are subject to biases connected with extraneous events, time-related changes, and other factors. "Self-controlled" crossover studies are practicable only for interventions that do not have protracted "carryover" effects, and their analysis requires special statistical procedures.

The following remarks apply to parallel studies.

Selection Bias and Confounding Bias A key feature of well-designed clinical trials is their avoidance of selection bias and confounding bias in order to ensure internal validity. This is accomplished by comparing groups that are initially similar, or have only chance differences, with regard to prognostic factors (factors that may affect the outcome), and it is generally achieved by *randomization*, that is, by a random allocation of individuals who are eligible and have given their informed consent. To make the groups even more similar, randomization may be performed after stratifying the subjects by chosen prognostic factors; or use may be made of *minimization (46,47)*, a technique that permits the control of more variables. The same eligibility and exclusion criteria are applied in each group.

If randomization or minimization is not used, the trial will have the same selection biases as an analytical observational study.

But even in the best run of clinical trials, the subjects may not all remain in their assigned groups throughout the study. Nor only may losses occur due to death or other reasons, but subjects may switch from one group to another, for example, because of noncompliance or a decision that, in the interests of their health, treatment should be stopped, changed, or started. These changes should be documented, and the resultant possible bias should be taken into account when the findings are analyzed and interpreted.

Whatever the internal validity of the trial, the generalizability of its results depends on who is studied and the circumstances of the study. External validity may be compromised by the study's eligibility and exclusion criteria or by selection bias, for example, the unreadiness of eligible subjects to participate. Internal and external validity may be inversely related—the more stringent the eligibility and exclusion criteria, the less generalizable the results may be. The trial's results may be applicable only to persons similar to the study's subjects, and then only if the setting is similar *(48)*. The results of a trial of selective decontamination of the digestive tract in critically ill patents, for example, might be generalizable only to intensive care units with a low prevalence of antibiotic-resistant bacteria *(49)*. An

assessment of the applicability of the results requires information not only about eligibility and exclusion criteria but about ethnic, socioeconomic, and other characteristics that may influence the outcomes, the proportion of eligible subjects who were included in the trial, treatment facilities and settings, etc. *(48)*.

Information Bias As in observational studies, precautions should be taken to avoid information bias. Standardized operational definitions and methods of measurement and ongoing monitoring of the performance of the study are particularly important in multicenter trials. If there is reason to believe that there may be bias if the subject or observer knows to which group a subject has been assigned, blinding (e.g., of subjects, clinicians, technicians, or other observers) is advisable; this may entail the use of placebo treatments and concealment of the allocation scheme.

Analysis The analysis should commence with a comparison of the groups (usually treatment and control groups) with respect to characteristics that may affect the outcome, in order to provide assurance that the groups are indeed similar, and that confounding by these characteristics need not be considered.

The main thrust of the analysis is a comparison of the outcome and (if known) the intermediate effects in the treatment and control groups. The effects of modifiers can be appraised by the same methods as those used in analytical observational studies.

If there were subjects who switched groups during the study, that is, by moving from a treatment to a no-treatment group, or vice versa, two sets of analyses are advisable. First, *intention-to-treat analysis*, that is, a comparison of the outcomes in the subjects originally allocated to each group. This minimizes confounding but may underestimate the efficacy of the procedure that was tested. And secondly, *per-protocol* (or *on-randomized treatment*) analysis, which compares the experience of subjects while they were still in their allotted groups. This generally overestimates the efficacy of the procedure and has the disadvantage that it is not based on randomized groups, so that possible confounding must be considered.

The easily calculated *NNT* or *number needed to treat* (to produce, avoid, or cure one case) may he a helpful yardstick for the value of the intervention, although it expresses only the results of a particular trial conducted on selected subjects over a particular time period and is easily misinterpreted as a measure of the probability that an individual person will benefit from the intervention *(50,51)*. Different NNT measures are appropriate for different purposes *(52,53)*—expressing, for example, the effect in the total population of a treatment or exposure to some factor, the hypothetical benefit in subjects who are exposed to the treatment or factor (*EIN*, or *exposure impact number*, expressing the effect of removing the exposure), or the hypothetical benefit in subjects who are not exposed (*NNE*, or *number needed to be exposed*).

Program Trials

Trials of healthcare programs are important and may have far-reaching implications. They are unfortunately beset with difficulties. The distinctive feature of an experiment designed to study the effects of an intervention is that it is the researcher who decides to whom the intervention will or will not be applied. Many trials of healthcare programs are not true experiments, but *quasi-experiments*, where the decision to run a program was not made by the researcher. The outcomes in a unit where the program is applied may be compared with those in a control unit, but the units cannot necessarily be regarded as similar, and such trials must be analyzed as if they were analytical observational studies. Before–after comparisons may be used, but it may be difficult to know to what extent the outcome is attributable to the program rather then to other causes.

Randomization would seem to be the answer, but even if a random allocation of two units is feasible, randomization is here irrelevant—the same differences will exist, and there will be the same possibility of confounding, whichever of the two units is exposed to the program. Again, the trial would have to be analyzed as if it was an analytical observational study.

For randomization to be effective, a reasonably large number of entities must be available for allocation. In a study of the use of disposable thermometers instead of electronic thermometers to prevent *C. difficile* infections, for example, 20 nursing units were randomly divided into two groups, one of which used single-use disposable thermometers exclusively and the other electronic thermometers, with a switchover after 6 months *(54)*. A number of program trials have been done by running a program in randomly chosen healthcare units, and not in others. For example, randomized controlled trials of the effects (on patients) of programs to encourage the immunization of personnel against influenza have been conducted in samples of long-term hospitals *(55)* and primary-care community clinics *(56)*. Villages, or groups of adjacent villages, can also be randomized, as in African studies that tested the value of community programs for the control of an STD as a means of preventing AIDS *(57,58)*. The validity of trials based on randomly allocated clusters of subjects can be enhanced if the clusters are stratified before randomization and the same inclusion and exclusion criteria and methods of study are used in each cluster *(59)*, and if the analysis uses special statistical procedures that take account of the tendency of members of a cluster to be similar to one another.

Randomization of individuals is sometimes practicable if the individuals cared for can be randomly allocated to an intervention program or to a control group or other program. The trial is then essentially a clinical trial, performed in order to evaluate a program. As an example, in three hospitals in Denmark a smoking intervention program, applied 6 to 8 weeks before elective hip or knee replacement, was tested by randomly allocating patients to this program or to a control group *(60)*. The rates of wound infection (with a positive culture) were 4% in the program group and 23% in the control group ($p = .002$).

If the evaluation of a program is based on a before–after comparison (a "*self-controlled*" study), attribution of the outcome to the program rather than to other causes can be reinforced by information about intermediate outcomes. The evaluation of an educational program for intensive care unit nurses concerning venous catheter insertion and care, aimed at decreasing the rate of blood stream infections, for example, would be strengthened by

information on changes in actual behavior, such as the frequency of inspections of the catheter site for tenderness, and prior hand washing *(61)*. With some programs, it would also be helpful to know what happens if the program is withdrawn.

Externally controlled program trials, which compare the outcome of a program with national or other data obtained from other sources, may have questionable validity, since definitions and study methods may be different, the populations may have different characteristics or circumstances, and the data may refer to different time periods.

Case–control studies can sometimes be used to evaluate programs, by comparing people who have experienced an undesirable outcome (cases) with controls, to see whether they differ in their prior exposure to the program. In the Netherlands, for example, the value of a cancer screening program was confirmed by a study of women who died of breast cancer and matched survivors, comparing their history of participation in the screening program *(62)*.

Meta-analyses

A meta-analysis (see Chapter 7) is a critical review and integration of the results of separate studies of the same topic (63). To avoid bias, it requires an exhaustive search for studies, clear criteria for their inclusion, and possibly (when appraising the quality of studies and extracting their findings) blinding to authors, institutions, and journals.

Google and Google Scholar, although handy and extraordinarily useful tools for most searches, are not sufficiently accurate, thorough, or up-to-date for this purpose *(64)*, and the searches are usually conducted in PubMed, which currently provides access to almost 20 million citations, and other special databases. The possible effect of unfound studies should be assessed, since *publication bias* is an established fact in the health field—negative or inconclusive studies are often "tucked away in desk drawers" or rejected by editors. A *fail-safe N* is therefore computed by WinPepi and other computer programs that perform meta-analyses; this is the number of unfound negative studies that would suffice to render the overall finding of the meta-analysis nonsignificant or trivial; if it is small, the results may be questioned.

When the studies have been found, the first step is to appraise their quality, using clear and objective criteria (this is a *qualitative meta-analysis*). This may lead to a decision to exclude some studies from the statistical analysis of results, to perform separate analyses of studies of higher and lower quality, to incorporate a measure of each study's quality in the analysis, or even to a decision to abandon the meta-analysis as fruitless and issue a call for better-designed studies.

The next step is comparison of the study results. This may be based on a significance test for heterogeneity or (since such tests have a low power) on indices of heterogeneity (Higgins and Thompson's H or I-squared) (35). Heterogeneity may be caused by (for example) differences in study design and performance (including differences in working definitions), differences between the characteristics of the subjects, and differences in the circumstances of the studies. The reasons for differences should be explored. This may yield information on modifying effects, which may be the most important benefit of the meta-analysis.

The optional next step is integration of the results, to produce an overall measure of the association. This may be done for all the studies together (an analysis that may be deemed unnecessary and not very meaningful if they are very heterogeneous), or, if they are not all regarded as "combinable," for subgroups of the studies. Analyses that exclude specific studies, one by one (*sensitivity analyses*), may help to pinpoint those that have an especial influence on the overall measure. The results of individual studies are usually measures of association—rate ratios, risk ratios, odds ratios, hazard ratios, differences, or standardized differences ("effect sizes"). These individual results can be combined by statistical procedures (offered by WinPepi and other software) that take account of sample sizes and avoid confounding caused by imbalances in sample sizes. Use is generally made of the Mantel–Haenszel method or other procedures that assume that the various individual results are estimates of the same fixed effect, or the DerSimonian–Laird random effects procedure, which assumes that the effects in the various studies differ and are randomly positioned about some central value. These procedures compute summary measures of association and estimate their confidence intervals. The results of studies of different types can be brought together in this process, provided that they used the same measures of association.

Interpretation of the findings and their practical implications must take account of the quality of the studies, possible biases, and generalizability.

The following final comments center on the last question asked at the start of this chapter, namely, "Suppose we are told that a review of the literature has found 16 controlled trials that show that a certain treatment for MRSA is efficacious and 4 that do not (a highly significant difference: $p = .007$). Can we conclude that the treatment works?"

Why is the answer "No"?

First, we are told that 20 trials were found. But trials are not easy to find. Were there in fact only 20? How were these 20 found? We do not know. Was the search systematic, and if so, what database or databases and what search terms were used? According to the *Cochrane Handbook* (65), an exhaustive hunt for randomized controlled trials in PubMed's computerized database requires 26 search terms over and above those specifying the topic of the trials.

Publication bias—that is, a tendency for negative or inconclusive trials to be "tucked away in file drawers"—is a bugbear of meta-analysis. Were any registers of controlled trials searched? Were unpublished studies sought in conference proceedings? Was a statistical test done for asymmetry of the funnel plot (a test indicative of a paucity of small negative studies)?

What is the *fail-safe N*?—That is, how many unpublished negative findings would suffice to make the difference nonsignificant or negligible?—Would a mere handful of studies do this if they were found?

Secondly, the statistical test comparing the figures 16 and 4, and yielding a p value of .007, gives the same weight to each study. But maybe the 16 positive studies were very small ones, whereas the 4 negative studies may have been large ones, whose results should carry more weight. Also,

no attention was paid to the strength of the associations. "Vote counting" (how many for? how many against?) is not an appropriate method. A Mantel–Haenszel analysis, based on the strength of the effect and sample sizes in each study, and yielding an overall measure of strength, with its confidence intervals, would be more convincing.

Thirdly, we know nothing about the quality of the positive and negative studies. What, for example, does "controlled" mean? How were the controls selected? Was randomization used?

Without extra information, we certainly cannot conclude that the treatment works.

Further investigation is needed (a recommendation by no means unfamiliar in epidemiological research).

PRACTICAL IMPLICATIONS

The findings of all epidemiological studies—descriptive or analytical, but especially those of analytical observational studies and trials—may point to a need for action as well as a need for further research. But whether it is the epidemiologist's job to make practical recommendations is a matter of opinion. Probably most epidemiologists would consider it a dereliction of duty if they did not do so and if they abstained from calling for the specific interventions whose potential value is indicated by their findings. They usually undertake their studies with the stated or unstated purpose of improving health or healthcare, and they wish to see their findings translated into action. If **A** was found to be a risk marker, then screening for **A** is advocated. If **B** is a risk factor, this calls for appropriate action to deal with it. If **C** is a preventive factor, then an appropriate educational or other prophylactic program is needed. If **D** is an effective and safe treatment, it should be used. If program **E** is effective, it should be introduced as a routine. And so on. These recommendations may extend beyond the healthcare facilities in which the studies were conducted. Many hospital studies of the burden of gastroenteritis, for example, have led to calls for the routine vaccination of children against rotavirus *(66)*.

But there is an opposite view. Not all epidemiological researchers really understand the process of policymaking. The respected epidemiological journal *Epidemiology* discourages policy recommendations in research reports, saying "it is simply too facile to toss off a policy recommendation in the closing paragraph of a scientific paper without giving the implicit decision analysis the due consideration it deserves. Making good health policy is complicated.… Our editorial policy is intended to avoid trivializing a complex process and to increase the likelihood that policy discussions are treated with the seriousness and depth of understanding that they deserve" *(67)*. An invited commentator on this decision said that he himself would make a policy recommendation only in the unlikely instance that he had information on all its potentially important consequences, including economic benefits and costs, and could conduct a formal decision analysis *(68)*. But another commentator dissented and cited examples in which he believed the inclusion of policy comments in scientific reports had had a material influence *(69)*.

For investigators who are not skilled in policy making and decision analysis, a prudent compromise is probably best: Sufficient details should be provided to facilitate decisions on feasibility and applicability—the characteristics of the subjects who were studied, the circumstances in which the study was performed, and the efforts required to achieve effects. Appropriate lines of action may then be suggested, but in a cautious and "iffy" manner, that is, with such provisos as "if this is feasible" or "if resources are available." Take care to translate the study findings, if possible, into quantitative indicators of cost and benefit that will be meaningful to decision makers (e.g., the number of screening tests required to detect one case, the number needed to treat in order to prevent or cure one case, or the attributable or preventable fraction of the disease or mortality load that can be attributed to a given factor or prevented by a given action) and do not hesitate to estimate and mention possible savings on hospitalizations or other costly procedures. Point to the lines of action suggested by the evidence and provide evidence-based motivation. But do not pontificate—leave the decision making to the decision makers. Softly, softly, catchee monkey.

CHAPTER 7

Meta-analysis and Systematic Reviews of the Literature in Healthcare Epidemiology and Infection Control

Nasia Safdar, Sanjay Saint, and Mary A.M. Rogers

With the growing use of evidence-based medicine and the increase in medical information available in both print and online sources, it has become increasingly difficult to keep up-to-date on medical advances. Systematic reviews and meta-analyses are important tools for summarizing the literature and critical appraisal, providing a valuable framework for medical decision making. Beyond their role in clinical medicine, systematic reviews and meta-analyses also may be used by researchers to synthesize evidence for specific hypotheses and by policymakers to examine benefits and harms of healthcare-related interventions. Recent data suggest that at least 2,500 new systematic reviews reported in English are indexed in MEDLINE annually (*1*). This chapter summarizes the key features of systematic reviews and meta-analyses, including general steps on how to undertake these methods, interpret the results, and critically appraise a published systematic review. In general, examples used will be relevant to healthcare epidemiologists, infection preventionists, and others with an interest in healthcare epidemiology and infection control.

DEFINITIONS

A *systematic review* is a synthesis of all evidence that addresses a specific research question. By using systematic, transparent methods to identify the relevant literature, with a view to minimizing bias, this method provides reliable findings from which conclusions can be drawn and decisions made (*2*,*3*).

The key characteristics of a systematic review are outlined in the *Cochrane Handbook for Systematic Reviews* (4). They are:

- A clearly framed research question with explicitly stated predefined eligibility criteria for studies
- A detailed description of methodology
- A comprehensive systematic literature search to identify all studies meeting the eligibility criteria
- An assessment of the quality and internal validity of the included studies
- A systematic analysis, presentation, and interpretation of the characteristics and findings of the included studies

A *meta-analysis* is a type of systematic review in which statistical methods are employed to summarize the results of independent studies (*5*). By combining information from all relevant studies, meta-analyses can often produce more precise estimates of the effects of healthcare than those derived from individual studies. Meta-analyses may also provide an assessment of the consistency of the evidence and an exploration of reasons behind the variation in effects across studies.

STEPS FOR UNDERTAKING A SYSTEMATIC REVIEW OR META-ANALYSIS

The general steps for conducting a systematic review or meta-analysis are:

1. Defining an appropriate healthcare question
2. Searching the literature
3. Assessing the studies
4. Synthesizing (or combining) the results
5. Placing the findings in proper context

FORMULATING THE RESEARCH QUESTION

Formulating a specific, answerable question is a critical first step when initiating a systematic review. Importance of the topic is consequential. If a research question is not worth answering, it is not worth answering *well*. One recommended approach is using the acronym "PICOS" to help formulate the research question (Table 7-1): the patient *p*opulation, the *i*ntervention of interest, the *c*omparator group, the *o*utcome of interest, and the *s*tudy design chosen. The more precise the definition of these five components, the easier it is to apply the systematic review framework (6).

The patient population of interest should be clearly defined in terms of age, characteristics of interest (disease or condition, such as mechanically ventilated

TABLE 7-1

Formulating a Research Question for a Systematic Review

	Patient or Problem	*Intervention*	*Comparison Intervention*	*Outcomes*	*Study Design*
Tips for building	Starting with your patient, ask "How would I describe a group of patients similar to mine?"	Ask "Which main intervention am I considering?"	Ask "What is the main alternative to compare with the intervention?"	Ask "What can I hope to accomplish?"	Ask "What are methodologically rigorous study designs?"
Example	In mechanically ventilated patients in the ICU	Does oral care with topical chlorhexidine	Compared with placebo	Reduce the incidence of ventilator-associated pneumonia	Randomized controlled trial

(Adapted from http://www.cebm.net/index.aspx?o = 1036. Accessed December 15, 2009. Asking Focused Questions.)

patients), and the setting, such as an intensive care unit (ICU). The interventions must be clearly and transparently reported. For example, for a question regarding the association between topical oral chlorhexidine and ventilator-associated pneumonia, it is important to detail the dose, frequency, method, and site of application. It is equally important to present details of the comparator under consideration, such as placebo or standard care. Definitions of standard care may differ among the primary studies in the systematic review. The outcomes of interest should also be clearly specified. For example, if ventilator-associated pneumonia is an outcome, a validated standardized definition should be used. Finally, study design considerations should be explicitly addressed. Many systematic reviews include only randomized trials, while others may choose to include both experimental and observational studies. The study question to be answered may drive the decision regarding what types of studies are to be included. Whatever the rationale may be, decisions regarding the population, intervention, comparison group, outcome, and study design should be clearly stated in the systematic review or meta-analysis.

DEVELOPING CRITERIA FOR INCLUDING STUDIES

A key component of a systematic review is the prespecification of criteria—the eligibility criteria—for including and excluding studies in the review (4). The patient population, interventions, comparisons, and outcomes laid out in the research question are used to derive the eligibility criteria. For the patient population, the definition should be sufficiently broad to avoid unnecessary exclusion of studies but should be narrow enough that a meaningful result is expected when they are considered in aggregate. Depending upon the condition of interest, the study population may be defined in the context of other characteristics such as sex, race, age, educational status, or venue of care (e.g., ICU, nursing home). Any restrictions with regard to population characteristics should be explicitly defined and the rationale provided. Table 7-2 provides a list of relevant questions to be addressed when evaluating the study subjects.

The intervention should also be described in detail. For those reviews in which there are slight variations in the intervention across studies, a table describing the elements of each intervention is helpful. Important considerations include decisions regarding trials with multiple interventions. The arms of the trial should be clearly stated and the comparison groups specified. This is of particular importance when the results will be pooled for meta-analysis. For example, the pooling of relative risks for septicemia that compare an intervention with usual care should be separate from the pooling of such relative risks when comparing an intervention with a placebo. Relevant questions regarding the intervention are listed in Table 7-3.

TABLE 7-2

Factors to Consider When Developing Criteria for "Types of Participants"

How is the disease/condition defined?
What are the most important characteristics that describe the participants?
Are there any relevant demographic factors (e.g., age, sex)?
What is the setting?
Should the participants be defined by a specific diagnosis?
Are there types of people who should be excluded?
How will studies involving only a subset of relevant participants be addressed (e.g., studies containing both pediatric and adult populations for age-specific systematic reviews)?

TABLE 7-3

Factors to Consider When Developing Criteria for "Types of Interventions"

What are the experimental and control interventions of interest?
Does the intervention have variations (e.g., dosage/intensity, mode of delivery)?
Are all variations to be included?
How will trials including only part of the intervention be handled?
How will trials containing the intervention of interest combined with other therapies be handled?

TABLE 7-4

Factors to Consider When Developing Criteria for "Types of Outcomes"

What are the main outcomes—those that are essential for decision making and clinically relevant?
What is the primary outcome that the review could address if sufficient studies were identified in order to reach a meaningful conclusion?
What are the secondary outcomes of interest that could provide clinical insight?
Is it important to collect information regarding side effects or other adverse effects?
Are there outcomes relevant to potential decision makers, including economic data?
Should data be collected regarding the type and timing of outcome measurements?

A clinically useful review will address clinically relevant outcomes. The outcomes for each study should be examined to determine the extent to which they are common across all studies. A decision is often necessary regarding handling of studies that have composite outcomes. For example, if the desired outcome is catheter-related bloodstream infection, should a study that fails to distinguish between catheter colonization and catheter-related bloodstream infection be included? Measurement of the outcome is also an important consideration, both in terms of the scale and timing. For example, if ventilator-associated pneumonia is an outcome, it would be important to take into account the variability in definitions used by investigators. Some studies may use a combination of clinical, radiographic, and lower respiratory tract sampling, while others may choose to use clinical and radiographic data alone or in combination with a sputum or tracheal aspirate specimen. In general, surrogate outcomes should be included with caution, because they may not always predict clinical outcomes accurately. Table 7-4 lists several outcome-related questions to be evaluated when conducting a systematic review.

The types of studies to be included in the review should be specified *a priori*. Most systematic reviews address evidence produced from randomized controlled trials. Randomized controlled trials are less likely to have selection bias, because proper randomization should prevent systematic differences between baseline characteristics of participants. Randomization of large groups of patients tends to equalize the distributions of subjects for both known and unknown potential confounders; such trials provide the best evidence of an unbiased treatment effect. Therefore, a systematic review of randomized trials has a distinct advantage. Even within randomized trials, however, there may be considerations related to study design such as whether cluster-randomized trials or crossover trials should be included (4). Importantly, there are some research questions in which a trial is not ethical or feasible. In these instances, a review of observational studies may be appropriate. Although estimates of treatment effectiveness obtained from observational studies—rather than randomized trials—are more likely to suffer from internal bias, the results may be more generalizable to broad patient populations due to the restrictive eligibility criteria usually inherent within randomized controlled trials.

The scope of the research question—either broad or narrow—is important at the outset. For example, a meta-analysis that targets whether topical oral chlorhexidine can prevent ventilator-associated pneumonia is narrower in scope than a meta-analysis that seeks to answer if oral decontamination (antibiotics and antiseptics) can reduce the risk of ventilator-associated pneumonia. Factors that should be considered when defining the scope of a review originate with underpinnings of the problem at hand, whether purely clinical, biological, and/or epidemiological. Extremely broad questions—for example, what is the epidemiology, clinical manifestations, diagnostic approach, treatment, and preventive options for ventilator-associated pneumonia—are often best addressed through a traditional narrative review.

Finally, a research question may need to be revisited over time. As evidence accumulates regarding a particular clinically relevant topic, it is important to update systematic reviews and meta-analyses with the results from the newly published studies. Therefore, systematic reviews are always time dependent and are most useful in clinical medicine when they contain all the most relevant literature available.

LITERATURE SEARCH

Systematic reviews require a comprehensive, objective, and reproducible search of multiple sources to ensure that all relevant studies are included. Healthcare bibliographic databases such as MEDLINE are a good place to start, although MEDLINE alone is not considered sufficient and should be supplemented with additional data sources. Currently, 5,200 journals in 37 languages are indexed in MEDLINE, and fortunately, PubMed provides free online access to MEDLINE. EMBASE is another electronically searchable database that is available only by subscription and has over 12 million records since 1974. While there is some overlap between EMBASE and MEDLINE, of the 4800 journals indexed in EMBASE, 1,800 are not indexed in MEDLINE, and of the 5,200 indexed in MEDLINE, 1,800 are

not indexed in EMBASE. Access to MEDLINE via PubMed is located at www.pubmed.gov and for EMBASE at www.info.embase.com.

The Cochrane Central Register of Controlled Trials (CENTRAL) is an excellent source of reports of controlled clinical trials. CENTRAL, published as part of the Cochrane Library, is updated quarterly. Although many of the records in CENTRAL overlap with MEDLINE or EMBASE, CENTRAL includes reports of clinical trials that are not part of MEDLINE or EMBASE, which may have been published only in specialized registers and other resources. If other reviews are of interest, Centre for Reviews and Dissemination is an excellent resource (http://www.york.ac.uk/inst/crd/).

Besides these key international databases, there are several national and regional databases that are useful to examine for additional studies. Many are available free of charge on the Internet. Table 7-5 lists examples of regional electronic databases (4).

When designing the search strategy, important considerations include whether the review is limited to randomized trials, whether the language of the publications will be inclusive or restrictive, the time period of the literature search, and whether data from unpublished studies are to be included. Assistance from an experienced healthcare librarian is highly recommended.

A balance between sensitivity and precision may need to be struck when undertaking searches to identify potentially relevant articles. Sensitivity is defined as the number of relevant reports identified divided by the total number of relevant reports in existence. Precision is defined as the number of relevant reports identified divided by the total number of reports identified. Article abstracts identified through a literature search can be quickly scanned for relevance to the research question; sensitivity is usually preferred over precision to ensure that the systematic review includes all potentially relevant articles.

In general, electronic databases can be searched using standardized subject terms assigned by indexers (MeSH for MEDLINE). The goal of the standardized subject terms is to ensure that articles using different words to describe the same concept are easy to retrieve. However, often the subject terms may not retrieve articles corresponding to the terms of interest. An additional challenge is that standardized subject terms may differ from one electronic database to the other; thus, a search must be customized to each database being searched.

The *Cochrane Handbook for Systematic Reviews* recommends that one way to identify controlled vocabulary terms for a database is to retrieve articles that meet the inclusion criteria and to note which subject terms have been applied to them. Those subject terms can then be put into the search to identify additional relevant articles. The "Explode" feature in MEDLINE searches narrower terms that are "under" the searched term in the MeSH hierarchy. The "Explode" feature in MeSH does not search related terms. For instance, using Explode with the MeSH term "Hepatitis" will find all articles indexed with more specific terms beneath it as well as general articles that are indexed simply, "Hepatitis." In MEDLINE, it is important to note that a report of a randomized controlled trial would be indexed as "Randomized controlled trial" while an article about randomized controlled trials would be indexed with the term "RANDOMIZED CONTROLLED TRIALS AS TOPIC." A comprehensive search strategy often includes, in addition to subject terms, a wide range of free-text terms such as pressure sore OR decubitus ulcer. Boolean operator terms such as "AND," "OR," and "NOT" are applied in searches to refine the search strategy by joining each search concept to the next. Figure 7-1 provides an example of combining search concepts to identify relevant records (4).

As most systematic reviews focus on randomized controlled trials, it is instructive to become familiar with a highly sensitive search strategy for identifying randomized trials in MEDLINE. There are two versions: a sensitivity-maximizing version and a sensitivity- and precision-maximizing

version. These were developed by the Cochrane Collaboration and are shown in Tables 7-6 and 7-7.

Bibliographic software such as EndNote is useful to keep track of references. It is important to ensure that any fields that relate to subsequently published comments, retractions, updates, or errata be included in the download of references from electronic databases to EndNote or another reference manager program.

Detailed documentation of the search process is essential so that it can be reproduced. For purposes of publication, the detailed search strategy may best be reported in an online appendix to save space. The steps for reporting the search strategy in the systematic review include listing all databases searched, with dates of the last search and the period searched. Language restrictions, if any, should be noted. If additional information has been requested from authorities in the field or the authors of the included studies, the names of people contacted and what information was obtained from them should be provided. Any conference proceedings should be listed as well as additional sources found through Internet search engine queries. The number of studies identified by each of the above approaches should be reported.

STUDY SELECTION

The study selection process requires an accounting of the articles that will be included, as well as a record of the number and reasons for exclusion of studies that do not meet the eligibility criteria. Depending upon the specificity of the search criteria, it is possible that a large number of records will be retrieved. Final selection should maintain the eligibility criteria as originally specified when the systematic review was initiated. It is possible that several reports detailing different aspects of the same study may be found, in which case, one should carefully assess the interventions and outcomes reported in each publication and the degree to which the eligibility criteria are satisfied. Duplicate publications may exist and often correspondence with the authors is required to clarify any uncertainties regarding the data presented. Reference management software also may assist in the identification of duplicate records.

Decisions regarding study inclusion should not rest on the opinion of a single reviewer. Rather, it is advantageous to include an expert in the area of clinical content as well as an authority in a related field or methodologist to avoid subconscious introduction of bias in study selection. Moreover, initial review should be blinded across the two reviewers. Disagreement between reviewers may require arbitration by a third independent expert, especially if the disagreement involves interpretation of study results. Agreement between authors can be measured using the kappa statistic; values of kappa between .40 and .59 reflect fair agreement, between .60 and .74 reflect good agreement, and between .75 and 1.00 reflect excellent agreement (*7*,*8*). The calculations necessary for determining kappa are given

TABLE 7-8

Data for Calculation of a Simple Kappa Statistic[a]

	Review Author 2			
Review Author 1	***Include***	***Exclude***	***Unsure***	***Total***
Include	*A*	*B*	*C*	I_1
Exclude	*D*	*E*	*F*	E_1
Unsure	*G*	*H*	*I*	U_1
Total	I_2	E_2	U_2	*K*

[a]Kappa = (PO–PE)/(1–PE), where PO (the proportion of studies for which there is agreement) = $(a + e + i)/K$ and PE (the proportion of studies for which one would expect there to be agreement based on chance alone = $[(I_1 \times I_2) + (E_1 \times E_2) + (U_1 \times U_2)]/K^2$.

in Table 7-8. Authors of systematic reviews should prepare a list of studies that, on first inspection, were thought to be eligible but later were excluded after careful review.

DATA EXTRACTION

Developing a data collection form is essential prior to data extraction. The form serves multiple functions; it provides a record of study eligibility and chronicles the steps in decision making—including agreements and disagreements regarding data collection. For those reviews in which a meta-analysis will be performed, it is the extraction tool for tabulating the estimates of effect, measures of variation, number of subjects, and other numerical data necessary for statistical pooling. Therefore, considerable thought and effort should be put into developing this collection form, also referred to as an "abstract" form. While details of the form may slightly vary, the basic template often stays the same and can be easily modified as necessary. Either electronic or paper forms may be used; the decision often rests on the preference of the author, accessibility to preprogrammed forms, and the number of studies to be included in the review. Regardless of which type is chosen, the data collection form should be piloted to identify areas of uncertainty and inconsistency.

When considering the data elements that need to be collected, authors should make an effort to eliminate unnecessary data and to focus on the key elements needed for the analysis. These key elements include author(s); date of publication; date(s) when data were collected on study participants; study design; particular features of certain designs such as single blinding, double blinding, and concealment of the randomization procedure; a description of the treatment/exposure in each of the study groups including whether a placebo or usual care was used as a comparator; and variables that describe the study population such as mean age, percentage of men/women, and other pertinent factors.

Numerical data should be recorded exactly as published in the original article; if additional calculations are warranted, these should be performed later. For studies in which both treatment and outcomes are binary, the numbers of subjects in each cell of a 2×2 table can be recorded. For studies that report odds ratios, relative risks, or mean differences, it is necessary to record measures of variability for these effects such as 95% confidence intervals or standard errors. For reviewers of randomized controlled trials, it is important to include the number of subjects randomized to each group, the number lost to follow-up, as well as whether the results reflect an intent-to-treat or compliance analysis. It is recommended that the guidelines established in the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) serve as a guide regarding the types of information necessary for collection (6).

Similar to the process used for decisions regarding study inclusion, more than one author should extract data and disagreement should be resolved by discussion. The kappa statistic may also be applied to key elements of data extraction to determine the extent of agreement.

ASSESSMENT OF BIAS

Just as in primary research, the validity of the studies within a systematic review should be assessed. Two general categories of validity are internal and external validity. Internal validity refers to whether a study has answered its research question in a manner that is free from both systematic error (i.e., bias) and nonsystematic error (i.e., random error or chance). External validity refers to the generalizability and applicability of a study's findings to a larger group of subjects. For purposes of systematic reviews and meta-analysis, an evaluation should be conducted of internal validity and the extent to which bias may affect each study's results.

Bias is the presence of systematic error. While some bias may be trivial, systematic error can also be of such magnitude as to invalidate study findings. A treatment effect may be either underestimated or overestimated if bias exists. Examining each study for methodologic flaws is a reasonable way to ascertain whether or not bias may be present. The risk of bias differs among study designs and is generally greater for studies without randomization. Important categories of bias are listed below.

Selection Bias

This bias occurs when there are systematic differences among the characteristics of the subjects in each group (or arm) at the beginning of the study. When randomization is correctly conducted on large numbers of people, selection bias should be avoided. However, when randomized trials are small or nonrandomized designs are utilized, this type of bias is a possibility. For evaluation of randomized designs, the reviewer should check the methods used for sequence generation during randomization and whether the allocation to study groups was concealed. Examples of studies at a higher risk of selection bias include those in which sequences were generated by odd or even date of birth or allocation was by the preference of physician or participant. A lower risk of selection bias would be likely if a computer random number generator or a random number table were used. Similarly, studies with higher risks of selection bias include those that incorporate alternating assignment or unsealed nonopaque envelopes. Allocation concealment yielding a lower risk of bias includes those instances whereby central telephone, Web-based, or

pharmacy-controlled randomization was utilized. Often it is preferable to employ a statistician who is not directly involved with the treatment or assessment of the outcome within the study, to design and conduct the randomization procedure. For evaluation of nonrandomized designs, the reviewer should check whether the patient characteristics were balanced across study groups or if such differences were accounted for during the analyses.

Performance Bias

This type of bias may occur when there are systematic differences in how the treatment or exposure is applied among the study groups. If one group is inadvertently given additional medications or procedures compared to another group, such differences may exacerbate the study's findings. Randomized controlled trials may utilize a placebo arm in which both the patient and the physician/investigator do not know the specific treatment; this element of study design is known as double blinding and it may suppress performance bias. If the study does not incorporate blinding or if blinding of the treatment is not feasible, the reviewer should evaluate whether the authors gathered additional information regarding possible differences among study groups and the degree to which these differences were addressed in the analyses.

Attrition Bias

When a study is conducted prospectively, it is possible that there may be withdrawals of patients over time. Systematic error due to differences in withdrawals among the study groups is known as attrition bias. The reviewer should carefully review the numbers of subjects initially randomized to each group as well as the numbers in each group at the end of the trial. How did the authors deal with the individuals who were lost to follow-up? Occasionally, authors will attempt to contact those persons who withdrew in order to assess the reasons for such withdrawal. When the study focuses on evaluating a pharmaceutical agent, sometimes this additional contact may give clues regarding the side effects of medications, which are often reasons for withdrawal. If enough information is available, the authors may compare the characteristics of the subjects for the initial group to the subset of patients who followed through to the end of the study. This may provide information regarding possible differences in treatment effects.

Detection Bias

This type of systematic error may occur when the outcome is assessed differently in the study groups. The definition of the outcome and how it was measured should be the same in all study groups, regardless of the type of treatment the subjects received. In some studies, it is possible to "blind" the persons who measure the outcome of the treatment status of the participants. For example, if the outcome is a positive blood culture for *Staphylococcus aureus*, the laboratory personnel are often blinded to what treatments the patients may have received.

There are other biases as well, including selective reporting of only certain outcomes. This type of bias is difficult to assess when only the published article is available for review, without additional information from the authors. It is also problematic to evaluate, because it is customary to publish multiple papers on different outcomes in various journals for a particular study. If the systematic review includes clinical trials, details regarding the entire study may be available on publicly available registration sites.

While widely used, it is not uniformly accepted that scales be used for assessing quality. Often such scales were developed for use in areas other than to which they are applied (e.g., Jadad score, developed to assess quality of trials in pain research), and moreover, they have been found to yield unreliable results (*9*,*10*). Because of these limitations, it is preferable to evaluate the extent to which bias was averted within each study. When incorporating bias assessments into analyses, the results may be graphed according to the risk of bias; pooled measures may be presented with subgroup analyses to examine the effect of the treatment at various levels of probable bias. Alternatively, studies at high risk of bias may be excluded from the meta-analysis.

STATISTICAL PROCEDURES IN A META-ANALYSIS

Initial Considerations

The mechanics of meta-analysis begins with the assessment of whether pooling, or summarizing a measure across different studies, is possible. Calculation of a pooled measure is contingent upon the availability of similar estimates of effect in each of the studies. It also requires that some measure of variability for these estimates are known, such as standard error, variance, or confidence intervals. For example, if there were 14 clinical trials testing the same hypothesis in which relative risks with their corresponding 95% confidence intervals were reported, then pooling may be attempted.

The most common types of measures to be pooled are comparisons between two groups that are expressed by a ratio—relative risk or an odds ratio. That is, within each study, the risk of the outcome (e.g., infection) in the exposed (e.g., immunosuppressed) would be divided by the risk of the outcome in the unexposed. For an odds ratio, the odds of the outcome in the exposed would be divided by the odds of the outcome in the unexposed. Hazard ratios may also be pooled, when available.

For meta-analyses of infectious diseases, considerations often involve recognition of the common methods by which infectious disease rates are expressed. Sometimes these are reported as the number of infectious disease episodes per 1,000 patient-days in the hospital or the number of infections per 1,000 device-days of observation. In other instances, the outcome may be expressed by cumulative risk such as the percentage of patients who experienced infection during their hospital stay. Since risk is time dependent and the length of hospital stay varies, it is preferable to use similar time periods for evaluating the risk of infection. For example, the risk of hospital readmission due to pneumonia in the 30 days postdischarge could be pooled if there were multiple studies with this outcome. The use of common measures such as episodes per 1,000 patient-days or infections per 1,000 catheter-days incorporates time in the denominator and, therefore, could be

pooled across studies. It is important to pool measures that express similar underlying quantities.

General Theoretical Considerations

In general terms, a pooled measure is a weighted sum. The estimates of effect from each study are arithmetically summed using weights:

$$\frac{\sum_{i=1}^{k} W_i Y_i}{\sum_{i=1}^{k} W_i},$$

where W indicates the weights and Y indicates the estimates of effect across all i through k studies. The weights often incorporate some derivative of the variation of the effect such as standard error or variance. Although the weights can incorporate the variation of the effect inherent within each individual study, these weights can also incorporate the variation of the effect across the various studies. This first approach, incorporation of within-studies variation (only), is known as a fixed effects model. The second approach, incorporation of both within- and between-studies variation, is known as a random effects model. The fixed effects approach makes the assumption that there is one true underlying effect in the reference population. The random effects approach assumes that there is a known underlying distribution of effects in the reference population.

Fixed Effects Models

The Mantel–Haenszel method of weighting may be used for summing a risk ratio, an odds ratio, or a risk difference (*11*,*12*). The calculations depend upon the study design and the characteristics of the variables, which determine the exposure and the outcome. In infectious diseases epidemiology, it is not uncommon to measure the incidence or risk of infection in one group of patients and compare this with the risk of infection in another group. As such, a 2×2 table may be constructed, where a indicates the number of patients exposed who developed an infection, b indicates the number of unexposed who developed an infection, c indicates the number of exposed who did not develop an infection, and d indicates the number of unexposed who did not develop an infection. In this situation, the Mantel–Haenszel method for pooling relative risks across studies is defined as such:

$$\hat{\mathrm{RR}}_{\mathrm{MH}} = \frac{\sum_{i=1}^{k} \left(\frac{b_i + d_i}{n_i}\right) a_i}{\sum_{i=1}^{k} \left(\frac{a_i + c_i}{n_i}\right) b_i},$$

where n indicates the total number of subjects in each i through k study.

Another fixed effects pooling method was developed by Peto and coworkers (*13*). Known as the Peto method, it is appropriate for odds ratios only and utilizes the expected versus observed number of events for calculation. Both the Peto and the Mantel–Haenszel methods perform well when outcome rates are rare, although unbalanced numbers of subjects in each arm (or in the exposed versus unexposed groups) are better assessed with the Mantel–Haenszel method. A more traditional method for pooling effects across studies is the inverse variance method, in which the inverse of the variance is incorporated as the weight. Since variance is calculable for many different types of statistics, this method has been utilized widely. In particular, mean differences may be summarized by incorporating the inverse of within-study variance as weights.

Random Effects Models

The random effects model assumes that, in addition to variability within studies, there are also real differences between studies. The weighting factor is more complex to include both these sources of variation. A common method utilized for pooling was described by DerSimonian and Laird and can be used to pool risk ratios, odds ratios, or risk differences (14). The inverse variance method may also be used in a random effects model to include both within- and between-studies variance. For example, mean differences in injury severity scores may be pooled using weights that incorporate within- and between-study variance. Since a random effects model considers both sources of variation, the results from a random effects model will, in general, yield more conservative results, and therefore wider confidence intervals, than a fixed effects model. When there is minimal variation between studies, the results from fixed effects and random effects models will be similar.

The Choice Between Fixed Effects and Random Effects Models

The choice of method initially involves a consideration of the underlying assumptions of fixed versus random effects models. A fixed effects model assumes that there is a single true underlying effect. For example, when repeated samples are taken from the same population, the pooled measure can be calculated using a fixed effects model. A random effects model assumes that the underlying effect follows a distribution of values and is often considered when the studies are conducted in populations with different characteristics.

It is not uncommon to calculate summary measures using both fixed and random effects models. If the results lead to similar conclusions, this can be directly stated. The Peto method (fixed effect) performs quite well when the outcome is rare, the numbers of patients in the treatment arms are balanced, and odds ratios are calculated as the estimates of effect. The Mantel–Haenszel method (fixed effect) is preferred when there are few studies with limited numbers of subjects within each study and when there is an imbalance in the numbers of subjects in treatment arms. For studies in which the outcome is continuous, the traditional weighting method of inverse variance is often used. If the purpose of the investigation is to explore the differences among studies, then a random effects model is appropriate. The reasons behind the variability across studies should be explored with consideration of the differences in the types of patients, design, and analyses of the individual studies. Often subgroup or stratified analyses may serve as a first step for this investigation, with more advanced statistics used secondarily.

Forest Plots

A useful technique for displaying the results of meta-analysis is the forest plot. A forest plot is a graphic depiction

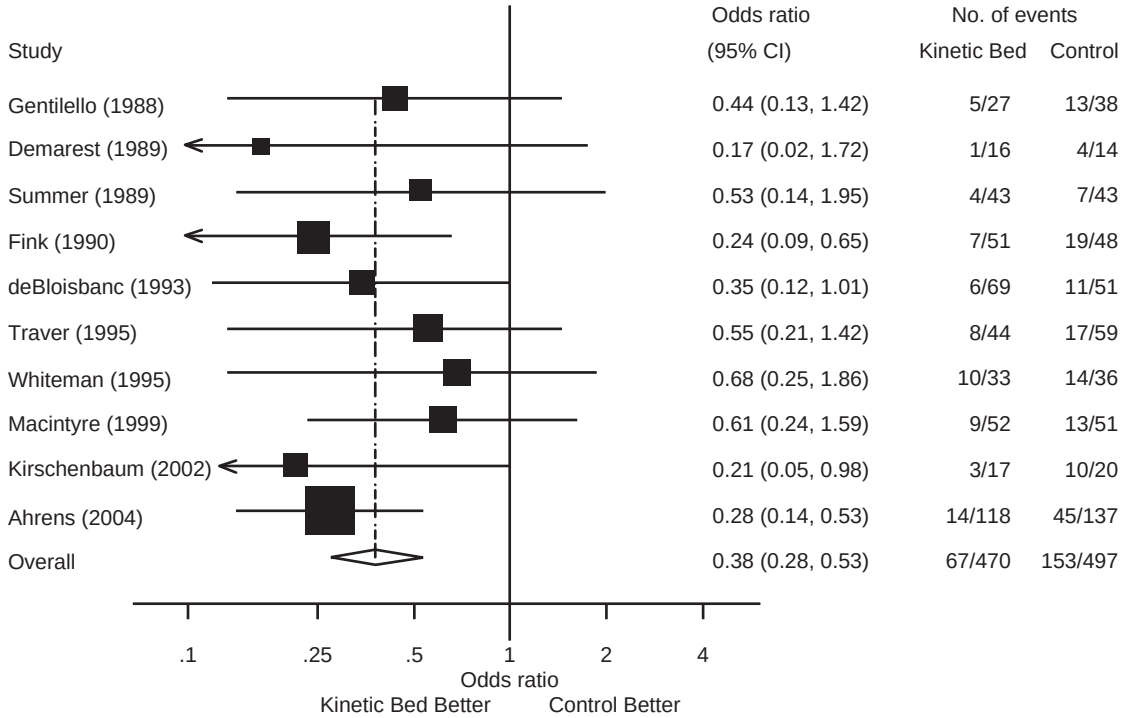

FIGURE 7-2 Forest plot showing the effect of kinetic bed therapy on the incidence of healthcare-associated pneumonia. (From Delaney A, Gray H, Laupland KB, et al. Kinetic bed therapy to prevent healthcare-associated pneumonia in mechanically ventilated patients: a systematic review and meta-analysis. *Crit Care* 2006;10(3):R70.)

of the estimates of effects and their variation within each study, as well as the summary measure. Figure 7-2 shows a typical forest plot. The results from each of the studies are displayed with the estimate of effect (in this instance, odds ratio) shown as a box, with its size proportional to the weights. The horizontal line indicates the 95% confidence interval. The null value (i.e., 1 for the odds ratio) is depicted with a solid vertical line and the pooled estimate of effect is shown with a dashed vertical line. Usually, the 95% confidence interval for the pooled summary measure is placed at the bottom of the plot in the shape of a diamond. There are variations to the appearance of the forest plot, depending upon the statistical programs chosen for generation.

Cumulative Meta-Analysis

Cumulative meta-analysis is a variation of traditional meta-analysis in which the individual studies are first sorted, usually by date (*2*). Each study-specific estimate of effect is included in the calculations one at a time so that the ensuing measure includes all studies before that date. This technique is often displayed via a forest plot and can signify trends over time. The final pooled measure using cumulative meta-analysis is the same as the pooled measure when using the traditional approach, but the forest plot will yield a different appearance. Since smaller trials for a given hypothesis tend to be published first and more definitive larger trials tend to be published at later dates, cumulative meta-analysis can visualize these effects over time. An example of such trends is shown in Figure 7-3 in a study which compared methods of rehydration in children with gastroenteritis.

HETEROGENEITY

In meta-analysis, heterogeneity refers to the variation in the estimate of effect across the studies. There are instances whereby the heterogeneity is so great that pooling the study-specific measures would not be appropriate. When this occurs, an investigation of the sources of heterogeneity is often conducted. Therefore, when study-specific estimates of effect are pooled in meta-analysis, this should be accompanied by an assessment of heterogeneity. Various quantitative measures and graphical techniques have been used to evaluate heterogeneity.

Quantifying Heterogeneity

Heterogeneity is commonly quantified by using Cochran's Q, I^2, or τ^2 (between studies variance). Cochran's Q is a statistical test in which weighted differences between study-specific measures and the pooled measure are summed (*15*). The test statistic follows a chi-square distribution and is calculated as follows:

$$Q = \sum w_i \left(\hat{\theta}_i - \hat{\theta}\right)^2,$$

where θ_i is the estimate of effect for each i study, θ is the pooled estimate of effect, degrees of freedom = k–1, and k is the number of studies. Because the number of studies tends to be limited in many meta-analyses, the power to detect differences among studies is often poor when using the Cochran's Q test. Therefore, the alpha level may be set at .10 instead of the traditional .05. If the resultant p value is <0.10, one would conclude that there is heterogeneity in the estimate of effect across the various studies.

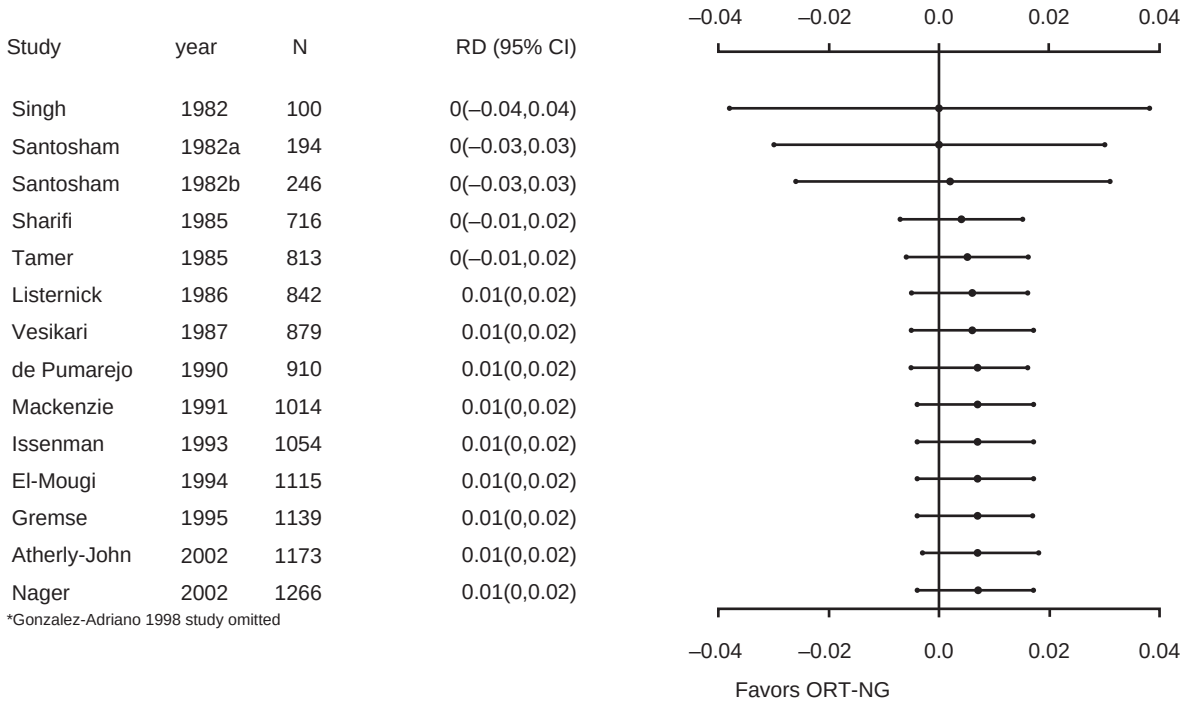

FIGURE 7-3 Example of a forest plot using cumulative meta-analysis that compares oral rehydration therapy-nasogastric with intravenous therapy in children with gastroenteritis. (From Bellemare S, Hartling L, Wiebe N, et al. Oral rehydration versus intravenous therapy for treating dehydration due to gastroenteritis in children: a meta-analysis of randomized controlled trials. *BMC Med* 2004;2:11.)

Another measure of heterogeneity is I^2, which indicates the percentage of total variability in effect size that is due to between-studies variation (16,17). I^2 is expressed as a percentage, with a minimum of 0% and a maximum of 100%; negative values are set at 0%. An advantage of I^2 is that it can be assessed across meta-analyses, so that the degree of variation found in one meta-analysis may be compared with that for a different meta-analysis. I^2 may be calculated as follows:

$$I^2 = \frac{Q - \mathrm{df}}{Q},$$

where Q indicates Cochran's Q test statistic, df = k–1, and k is the number of studies.

Between-studies variance is denoted by τ^2 and can be directly calculated and reported as well. Cochran's Q, τ^2, and/or I^2 may be presented on the forest plot as shown in Figure 7-4, which describes the effect of prophylactic fluconazole on patients with fungal infections. In a review of various graphical approaches, the forest plot was found to be more reliable than other types of graphs and a reasonably valid technique for the evaluation of heterogeneity (18).

EVALUATING PUBLICATION BIAS

While the initial steps of a meta-analysis involve a compilation of all studies that were conducted to evaluate a given hypothesis, it is possible that some studies may not be published. Such studies are more likely to be smaller with differences that are not statistically significant. With the establishment of registries of clinical trials and the requirement that trials be registered as a prior condition to publication, some of the earlier concerns regarding publication bias in meta-analyses of trials have been somewhat attenuated (*19*,*20*). Nevertheless, the possibility of publication bias should be addressed. There are several ways of evaluating publication bias, by either statistical testing or graphical techniques.

Funnel plots are the most common graphs used for evaluating publication bias. These entail plotting the study-specific estimates of effect against some measure of variability for each effect. Although there are variations to this approach, often the estimates of effect are plotted horizontally on the x axis and the measure of variation plotted vertically on the y axis. The plot gives an appearance of a funnel when the measure of variation is plotted inversely, so that the smaller studies will splay on the lower portion of the plot. Without publication bias, the funnel plot should appear symmetrical as shown in Figure 7-5. Contour-enhanced funnel plots include areas that denote contours or areas showing statistical significance and help the reader to assess whether small, nonsignificant studies may be systematically excluded (*21*). Asymmetry may indicate publication bias, although it does not provide definitive proof. Note that the location of the studies on the plot should splay from the true underlying estimate of effect, not necessarily the null.

Several statistical tests are available for assessing publication bias since visual inspection of funnel plots is subjective. If the estimate of effect is the odds ratio, Peters' test or Harbord's modification of Egger's test is appropriate for use (*22*,*23*). For meta-analyses in which the outcome is measured as a mean difference, Egger's test may be

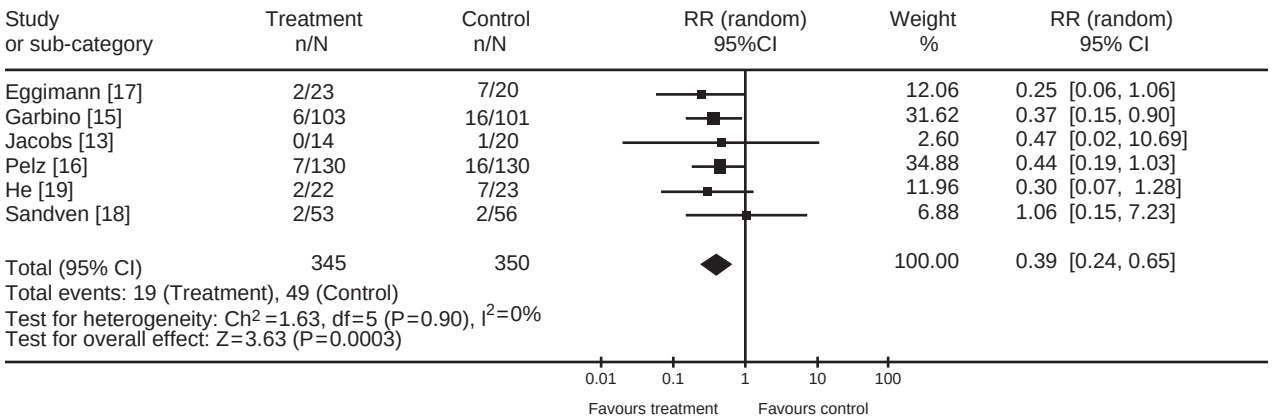

FIGURE 7-4 Forest plot showing the effect of prophylactic fluconazole on the proportion of patients with fungal infections. RR, relative risk; CI, confidence interval. (From Ho KM, Lipman J, Dobb GJ, et al. The use of prophylactic fluconazole in immunocompetent high-risk surgical patients: a meta-analysis. *Crit Care* 2005;9(6):R710–R717.)

used (*24*). Such tests may be conducted when there are at least 10 studies within the meta-analysis, but should not be considered conclusive evidence of the absence of publication bias. In this regard, a thorough initial search of the literature is superior to any posterior testing in a subset of studies.

PLACING THE FINDINGS IN CONTEXT

The results of the review should be interpreted in the context of the quality of evidence that was available for developing the systematic review. The GRADE (Grades of Recommendations, Assessment, Development and Evaluation) Working Group has developed a system for grading the overall quality of evidence (25). Factors that, if noted in a systematic review, would be considered to decrease the quality of the evidence are shown in Table 7-9. Common errors that are made in reaching conclusion include confusing "no evidence of effect" with "evidence of no effect." A true "no effect" is best observed by a fairly narrow confidence interval for the pooled measure that is centered around the null. When the data are inconclusive, it is recommended that it be stated as such. Conclusions should not extend beyond the results driven by the data and caution should be exercised when making recommendations for clinical practice.

Factors that are important for decision making beyond the results of the systematic review should be considered when making recommendations for clinical practice. These include patient values and preferences, and economic considerations. The external validity of the systematic review

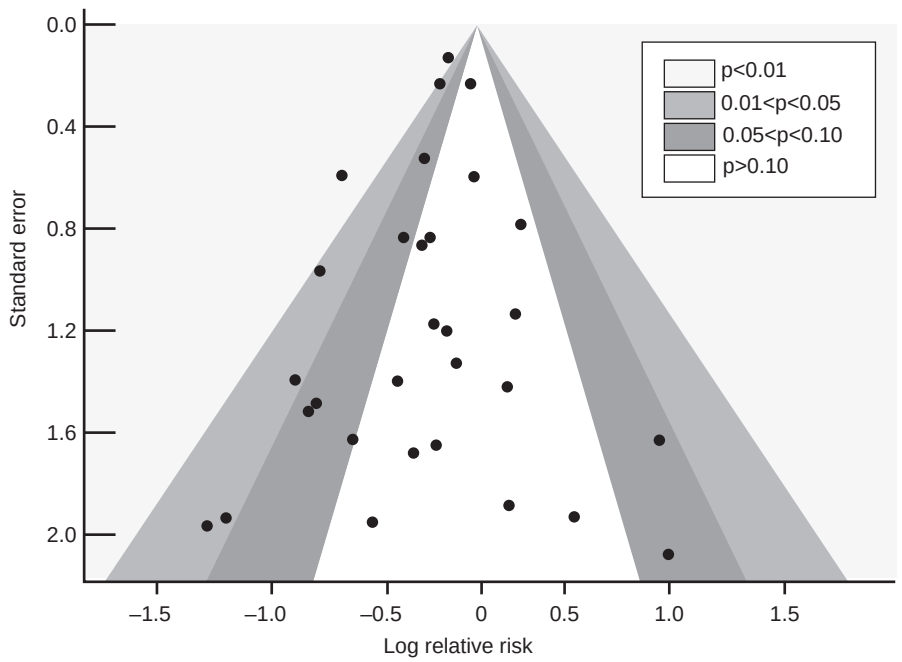

FIGURE 7-5 Contour-enhanced funnel plot.

TABLE 7-9

Factors that may Decrease the Quality Level of a Body of Evidence

Limitations in the design and implementation of available studies suggesting high likelihood of bias
Indirectness of evidence (indirect population, intervention, control, outcomes)
Unexplained heterogeneity or inconsistency of results (including problems with subgroup analysis)
Imprecision of results (wide confidence intervals)
High probability of publication bias

should also be taken into account when extrapolating the conclusions to populations not included in the systematic review.

A review should point out directions for future research. The acronym EPICOT has been proposed for reporting research recommendations (26):

E (Evidence): What is the current evidence
P (Population): (Such as) diagnosis, disease stage, risk factor
I (Intervention): Type, frequency, dose, duration
C (Comparison): Placebo, routine care
O (Outcome): Which clinical or patient-related outcomes will the researcher need to measure
T (Time stamp): Date of literature search or recommendation

For example, a review of chlorhexidine for preventing ventilator-associated pneumonia might conclude with "Current evidence suggests that topical chlorhexidine may be useful for preventing ventilator-associated pneumonia. However, variation in studies regarding the duration, dose and frequency of application creates heterogeneity making it difficult to draw robust conclusions. Future studies should examine, using a randomized controlled study design, the optimum dose and frequency of chlorhexidine oral care compared with oral care without chlorhexidine in all mechanically-ventilated patients, using invasive lower respiratory tract sampling for diagnosing ventilator-associated pneumonia."

PREPARING THE MANUSCRIPT

The PRISMA checklist can be useful when preparing the manuscript describing the systematic review (6). The following general principles serve as guidelines. The title should contain the words *systematic review* or *meta-analysis*, if possible, since this will distinguish the work from a traditional narrative review and will make it easier to retrieve in an electronic search. The abstract should be crafted with a great deal of thought since this may be the only part that many readers will peruse. The introduction section of the manuscript should describe the importance of the research question, existing gaps in the literature, and the rationale for undertaking the study. In the Methods section, in general, the following headings may be useful (unless the target journal has specific headings that are traditionally used for these types of manuscripts): data sources, data selection, data abstraction, assessment of study quality, data synthesis/statistical analyses, and proposed subgroup analyses. The Results section should describe the outcome of the literature search in a flow sheet and have a table describing the characteristics of the included studies. The main summary of results is usually represented as a forest plot. If a meta-analysis is not done, the summary estimate (usually shown as a diamond on the forest plot) may be omitted. The result of subgroup analyses may be placed in a table or figure. In the Discussion section, the authors should place their findings in the context of other studies that have been undertaken, explain how their results add to the current body of knowledge, and assess the implications for policy and future research. It is important to describe the limitations and how they were addressed within the review. The conclusions should be driven by the results and should take into account the limitations of the studies included in the systematic review. Finally, sources of funding and conflict of interest for all authors should be clearly described somewhere in the manuscript.

USEFUL READING AND RESOURCES

The *Cochrane Handbook for Systematic Reviews of Interventions* is an excellent resource for researchers undertaking a systematic review or meta-analysis. The handbook is available free online at http://www.cochrane-handbook.org/. For updates, see the following URL: http://www.cochrane.org/resources/handbook/.

ACKNOWLEDGMENT

We thank Ann Combs, MS, for her thoughtful comments on searching the literature.

CHAPTER 8

Investigation of Outbreaks

William R. Jarvis

Although the majority of healthcare-associated infections (HAIs) in a given healthcare facility are endemic (*1*), outbreaks of HAIs may occur, usually in a specific group of patients or location. In addition, healthcare workers (HCWs) are exposed to numerous infectious agents and may be at risk of spreading pathogens to patients and other HCWs (*2–4*).

An outbreak is an increase in occurrence of an event (infectious or noninfectious) above the background rate. This assumes that surveillance for such complications exists, so that a background rate is known or can be calculated from existing data. If such data do not exist, then a retrospective review must be performed to obtain these data to calculate the rate of these adverse events to compare to the "outbreak" rate. An outbreak may be one episode of a rare occurrence (e.g., group A streptococcal surgical site infection [SSI], anthrax, and vancomycin-resistant *Staphylococcus aureus*) or many episodes of a common occurrence (e.g., methicillin-resistant *S. aureus* [MRSA] infection). Outbreaks in healthcare facilities, although infrequent, can cause great concern, require extensive personnel and financial resources to investigate and control, generate adverse publicity, negatively impact on patient safety, and can be very time-consuming.

This chapter helps healthcare epidemiologists, infection preventionists, and others to determine when a cluster of infections or other adverse events among patients or HCWs merits an epidemiologic investigation and how to conduct such an investigation. Although the methods described can be applied to infectious diseases, chronic diseases, community outbreaks, occupational diseases or injuries, or any complication of healthcare delivery, this chapter focuses on outbreak investigations of HAIs.

IDENTIFICATION OF A POTENTIAL OUTBREAK

Routine surveillance for HAIs provide the data to enable infection control personnel to calculate infection or other adverse event rates, determine secular trends, and identify unusual pathogens or events, or increased infection or adverse event rates in patients or HCWs (see Chapter 88). The key to effective surveillance is to use common, accepted definitions and to calculate rates that permit valid interfacility or intrafacility comparisons (*5–9*) (http://www.cdc.gov/nhsn/PDFs/pscManual/17pscNosInfDef_current.pdf). Rate calculations using an inappropriate denominator may be misleading and suggest an outbreak is occurring when only a change in the population at risk has occurred. Similarly, the use of variably defined numerator events may lead to an apparent increase in the rate secondary to surveillance artifact. Outbreaks of infectious diseases that are not included in routine surveillance or that occur among patients in areas where routine surveillance may not be conducted may be identified in a variety of ways. Clinical nursing or medical staff may recognize that a number of patients have the same type of infection or regular examination of microbiology or other records may reveal an increase in the isolation of a particular microorganism, thus leading to the identification of a potential outbreak.

REASONS TO INVESTIGATE A POTENTIAL OUTBREAK

Objectives

Although any cluster of patients with HAIs can be investigated, the constraints of time and resources require that each investigation has specific objectives. The most important of these is the control of further transmission (*10*). Other important objectives may be to advance the field of healthcare epidemiology and infection control by describing etiologic agents, host, risk factors, virulence, or environmental factors; to assess prevention interventions; or to determine the quality of epidemiologic surveillance at the healthcare facility (11).

Evidence of HAI Transmission of Infectious Diseases

HAI transmission should be considered when (a) a cluster of similar infections occurs on one hospital unit or among similar patients, (b) a cluster of infections associated with invasive devices occurs, (c) HCWs and patients develop the same type of infection, or (d) a cluster of infections with microorganisms typically associated with HAIs (e.g., multidrug-resistant or opportunistic microorganisms)

occurs. These clusters merit investigation to determine if HAI transmission really is occurring and to institute appropriate control measures to terminate pathogen transmission. Selection bias frequently occurs in identifying outbreaks because unusual pathogens, or common microorganisms with unusual antimicrobial susceptibility patterns, are more easily recognized. For example, although *Escherichia coli* urinary tract infection outbreaks probably occur, they are either not recognized or not investigated, because the microorganism is the most common cause of urinary tract infection and typing of the genotying of strains—to document clonal transmission—usually is not performed. In contrast, a small cluster of unusual pathogens or common pathogens with unusual antimicrobial susceptibility patterns are easily and frequently recognized.

Determination of Risk Factors for Disease

Known host risk factors for HAI include the presence of invasive devices, severity of illness, or underlying diseases (*12–14*). In addition, environmental sources of pathogens can play a role, especially among immunocompromised patients (*15–19*). Investigation of outbreaks can further define both host and environmental risk factors for HAI. Infection control personnel should be constantly vigilant for complications associated with new technologies or changes in previously safe technologies (20,*21–23*).

Institution of Appropriate Control Measures

In outbreak situations, one often must introduce preventive interventions to control pathogen transmission and adverse outcomes before an investigation is initiated or completed. Control measures that have proven effective in similar HAI outbreaks in the past can be implemented immediately. This could include measures ranging from the simple (e.g., enhancing hand hygiene through in-service education sessions for personnel) to the complex (e.g., closing a unit to new admissions or removing a product or device). The potential benefit of more drastic measures should be carefully weighed against the potential harm to patients currently residing in the facility. Subsequently, the formal epidemiologic investigation of the outbreak may help focus control measures on specific infection control or procedural techniques (*10*).

FIRST STEPS

Once an outbreak is suspected and an investigation is contemplated, all levels of the healthcare facility's personnel (e.g., the chief of the affected service, head nurse for the unit, director of microbiology, and hospital administration) should be informed and must be committed to the investigation. The cooperation of a variety of healthcare professionals is essential to efficiently conduct an investigation and to implement control measures.

A second consideration during the early stages of an outbreak investigation is the availability of microbiologic isolates for antimicrobial susceptibility testing or molecular or nonmolecular typing. Unlike community outbreaks, typing of microorganisms in HAI outbreaks may be essential to proving chains of transmission because of the ubiquitous nature of microorganisms in the hospital environment (*18*,*24*). For this reason, microbiology laboratory personnel should be informed early in the investigation so that they can save requested specimens or isolates and be alert for additional isolates that may be part of the outbreak. Laboratory personnel also may suggest other specimens that should be collected from current or future patients who develop the adverse event being studied.

Finally, before beginning an investigation, available resources (e.g., personnel, supplies, and laboratory), the lead investigator, and the person to be responsible for statistical analysis of the data should be identified. Taking these steps before initiating an investigation will allow it to proceed smoothly later.

THE INVESTIGATION

A complete investigation involves many steps; the order of steps may vary and multiple steps may be performed simultaneously. These steps, although not specific to the healthcare setting, are a useful guide in conducting an outbreak investigation (Table 8-1).

Case Definition

One of the first tasks of the investigative team is to develop a working case definition based on the known facts of the outbreak. The case definition should include, at a minimum, the time, place, and person. In addition, other important factors, such as clinical and laboratory parameters (e.g., date of onset of illness, symptoms, signs, and

TABLE 8-1

Guidelines for Epidemiologic Field Investigations

1. Prepare for field work (e.g., administration, clearance, travel, contacts, and designation of lead investigator)
2. Confirm the existence of an epidemic
3. Verify the diagnosis
4. Identify and count cases or exposures
   - Create a case definition
   - Develop a line listing
5. Tabulate and orient the data in terms of time, place, and person
6. Take immediate control measures (if indicated)
7. Formulate hypotheses
8. Test hypotheses through epidemiologic studies
9. Plan an additional systematic study (or studies)
10. Culture environment and personnel based on epidemiologic data
11. Implement and evaluate control and preventive measures
12. Initiate surveillance
13. Communicate findings
    - Summarize investigation for requesting authority
    - Prepare written report(s)

(Modified from Goodman RA, Buehler JW, Koplan JP. The epidemiologic field investigation: science and judgement in public health practice. *Am J Epidemiol* 1990;132:9–16.)

TABLE 8-2

Examples of Case Definitions from Hospital Outbreaks Investigated by the CDC's Hospital Infections Program/Division of Healthcare Quality Promotion

1. "A case of multidrug-resistant tuberculosis was defined as any patient diagnosed with active tuberculosis from January 1989 through March 1991 whose *M. tuberculosis* isolate was resistant to at least isoniazid and rifampin" (*35*).
2. "An [anaphylactic reaction] was defined as hypotension (≥30 mm Hg fall in systolic blood pressure from the preinduction blood pressure) and at least one of the following during a general anesthesia procedure at hospital A from January 1989 through January 1991: rash, angioedema, stridor, wheezing, or bronchospasm" (*21*).

CDC, Centers for Disease Control and Prevention.

specific laboratory or diagnostic findings), epidemiologic parameters (e.g., a patient's presence on a specific ward or service during a specified time) may be included. In certain instances, one may include confirmed, possible, or probable cases of disease. The process of developing case definitions is an iterative one and should be based on balancing the need for an all-inclusive (sensitive) case definition at the beginning of the investigation and more specific case definition as the investigation proceeds and more data are acquired. Case definitions may vary from the relatively simple to very complex (*21*,*25*) (Table 8-2). Occasionally, the case definition may need to be refined as the investigation proceeds and more data are acquired.

Case Finding

Once an initial case definition has been developed, additional case finding can be conducted. The case definition should be applied to the source population without bias as to known or potential underlying host or environmental risk factors. Sources most commonly used for finding cases are discharge diagnosis or International Classification of Disease codes; microbiology, infection control, or transfusion records; emergency room, outpatient clinic, or dialysis clinic logs; or patient medical records in a cohort study—if the cases are limited to a single ward/unit or if the healthcare facility is very small (i.e., where charts can be reviewed in a short period).

Confirming an Outbreak

Confirming an outbreak begins with calculating the background rate of infection or adverse event and then comparing the outbreak period rate with the background rate. The outbreak period should include the time period from the possible incubation period for the first case of adverse event until the last case or time of the investigation. The background rate of the adverse event should be based on existing data, which can be collected from a variety of resources, including microbiology, infection control, or patient records. Data may have to be collected for a period of many months to years preceding the outbreak to determine an accurate background rate, particularly if the adverse event has a seasonal periodicity. Comparison of the outbreak period attack rate to the background rate can be performed using the rate ratio:

$$\text{Rate ratio} = \frac{\text{Attack rate during epidemic period}}{\text{Attack rate during background period}}$$

Pseudo-outbreaks are increases in the incidence of infections or adverse events that are not real. This can be due to false clusters of real infections/adverse events or real clusters of false infections/adverse events. Possible causes can be (a) clusters of positive cultures in patients without evidence of infection/disease (e.g., positive cultures for *Mycobacterium tuberculosis* in a patient with no clinical evidence of tuberculosis) or (b) a perceived increase in infections/adverse events because either the specific laboratory test had not been used (e.g., introduction of polymerase chain reaction testing for MRSA or *Clostridium difficile*) or surveillance was not previously being conducted for that particular problem or surveillance definitions, intensity, or methods have changed. Pseudo-outbreaks usually are due to either increased surveillance of an area or type of infection or laboratory errors (i.e., extrinsic or cross-contamination) (*26*–*29*). Hypotheses developed during the investigation of a presumed outbreak should include the possibility of a pseudo-outbreak, particularly if laboratory clustering of the positive cultures occurs (see Chapter 9).

Chart Review

Before beginning the lengthy process of reviewing medical records, one should determine which data are important to collect for each case-patient or case-HCW and design a questionnaire for ease of data collection (see Chapter 5 for details on questionnaire design). Some important categories of information to consider in most investigations are demographic variables (e.g., age gender, race, or ethnicity), underlying illnesses, severity of illness indicators (e.g., Acute Physiology and Chronic Health Evaluation or Pediatric Risk of Mortality scores) (*30*,*31*), ward/unit, duration of hospitalization; exposures to invasive devices or procedures, personnel or other patients, or medications; and clinical aspects of the disease/adverse event being studied (e.g., date of onset of illness, symptoms, and signs). For SSI outbreaks, surgical risk factors (e.g., procedure, operating room, surgeon, or surgical team members) or surgical risk index (*7*,*32*) must also be determined in addition to the other categories.

Descriptive Epidemiology

A line listing of the case-patients and pertinent demographic and clinical information serves as a useful tool to begin the process of describing the outbreak in terms of time, place, and person. Describing an outbreak in this way helps determine who is at particular risk for the adverse event that is being studied. In turn, knowing which

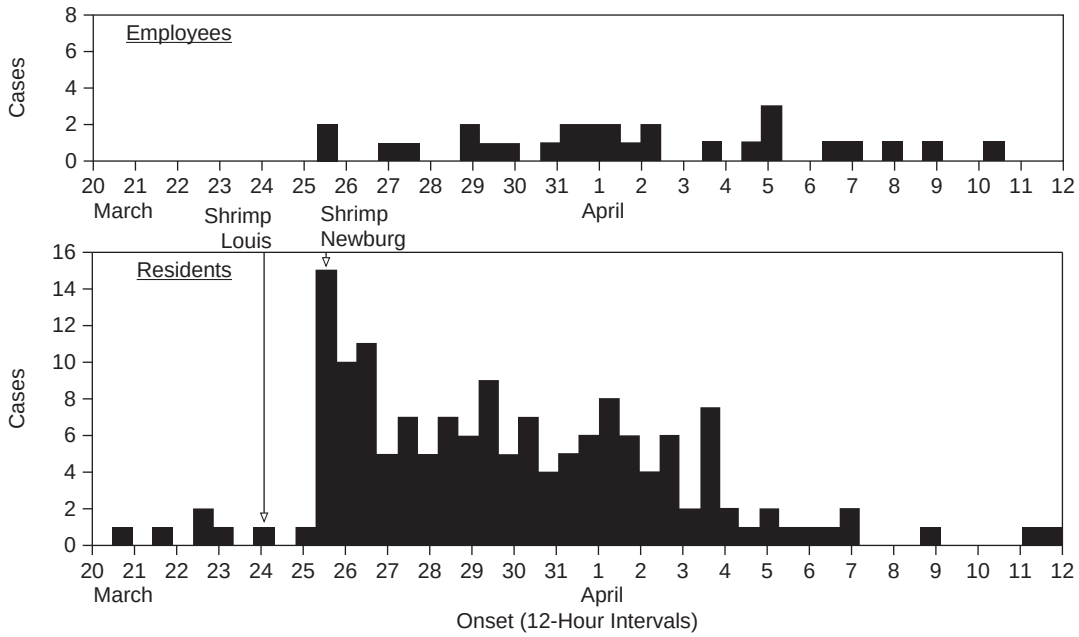

FIGURE 8-1 Epidemic curve from a common source outbreak with subsequent person-to-person transmission. (From Gordon SM, Oshiro LS, Jarvis WR, et al. Foodborne Snow Mountain agent gastroenteritis with secondary person-to-person spread in a retirement community. *Am J Epidemiol* 1990;131:702–710.)

population of patients or HCWs is at risk determines who should be included in further analytic studies.

Describing the outbreak over time is most easily done by graphing the case-patients or case-HCWs by onset of disease; the cases can be graphed by time (e.g., hours, days, months, or quarters), as appropriate. These graphs, often called epidemic or epi curves, can provide a great deal of information about possible sources and modes of transmission. For example, a common-source outbreak with subsequent person-to-person transmission is well illustrated by a foodborne outbreak in a retirement community (*33*) (Fig. 8-1). A high initial peak of onset of illness, indicating a point source of infection, followed by continued cases of illness is typical of an outbreak of gastrointestinal illness caused by a viral agent. Person-to-person transmission, on the other hand, usually is illustrated by an epidemic curve of longer duration with few, if any, peaks. A typical epidemic curve illustrating person-to-person transmission would be an outbreak of *M. tuberculosis* HAIs (*34*) (Fig. 8-2).

The epidemic curve of an outbreak caused by poor adherence to recommended infection control practices (e.g., poor hand hygiene compliance) or contaminated patient-care equipment also usually are spread over a long period. For example, an *Acinetobacter baumannii* outbreak related to reusable intravascular transducers that were not adequately sterilized between uses on different patients continued for over a year until the problem was recognized and the decontamination and disinfection technique was corrected (*18*) (Fig. 8-3). If HCWs and patients are both

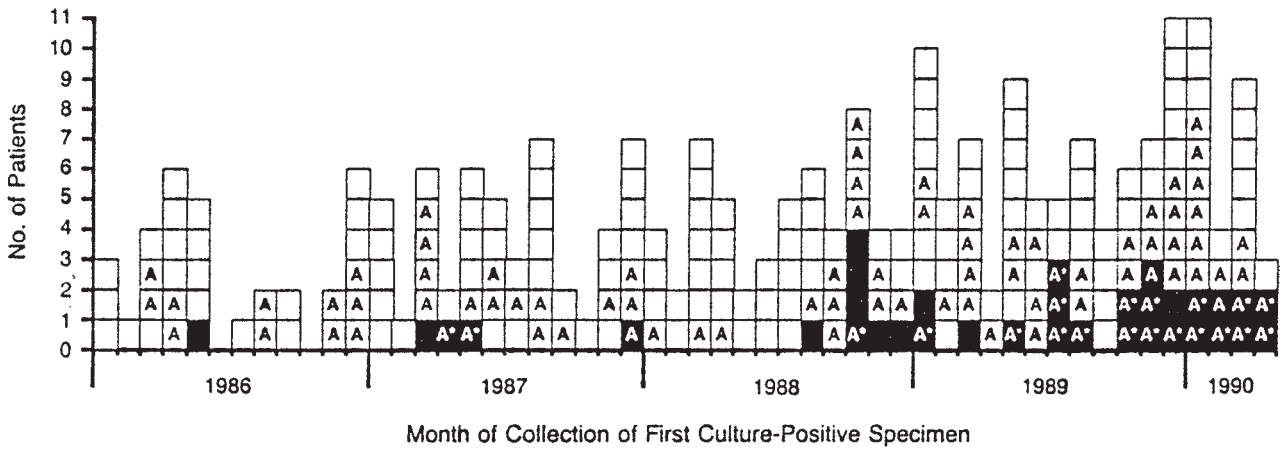

FIGURE 8-2 Epidemic curve illustrating person-to-person transmission. (From Edlin BR, Tokars JI, Grieco MH, et al. An outbreak of multidrug-resistant tuberculosis among hospitalized patients with the acquired immunodeficiency syndrome. *N Engl J Med* 1992;326:1514–1521.)

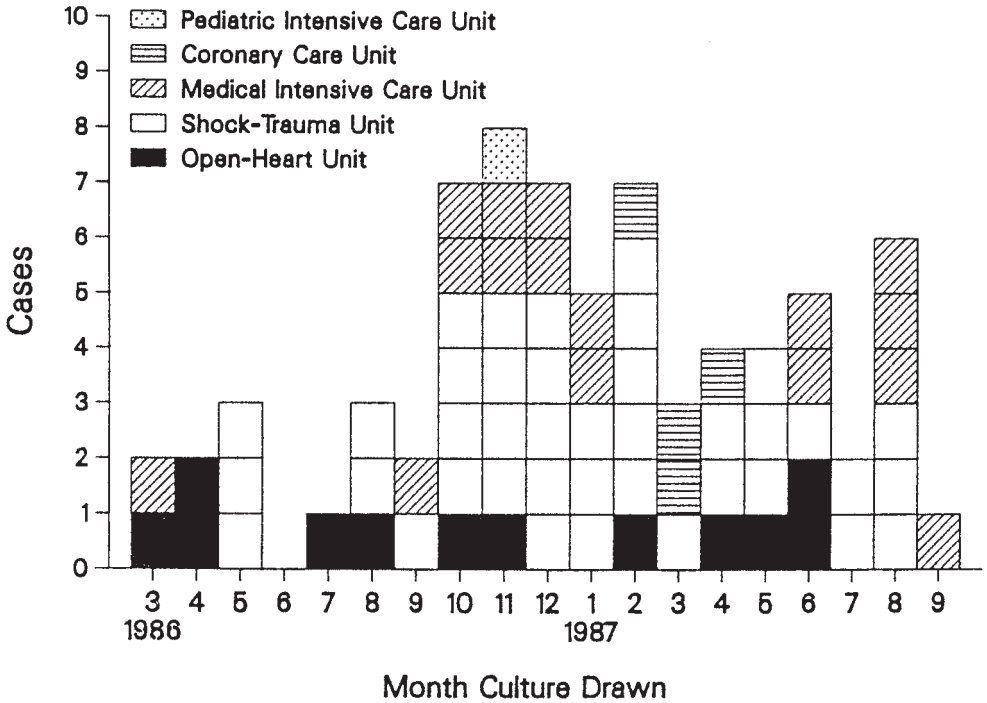

FIGURE 8-3 Epidemic curve of an outbreak caused by contaminated patient-care equipment. (From Beck-Sague CM, Jarvis WR, Brook JH, et al. Epidemic bacteremia due to *Acinetobacter baumannii* in five intensive care units. *Am J Epidemiol* 1990;132:723–733.)

affected by the outbreak, the dates of onset of disease/adverse event for patients and HCWs should be plotted both together and separately to determine if transmission occurred from patient to patient, patient to HCW, HCW to patient, or HCW to HCW.

At times, the location of the outbreak is limited to a certain ward, unit, or operating room and at other times to a certain type of ward (e.g., general surgical units). The location of the outbreak may provide a clue to the mode of transmission or to certain risk factors or exposures of particular patients.

For example, an investigation in a hospital with high tuberculin skin test (TST) conversion rates among patients and HCWs revealed that many of the TST converters were patients of or workers in the outpatient human immunodeficiency virus (HIV) clinic (*35*). The clinic had a large room with reclining chairs for patients with acquired immunodeficiency syndrome (AIDS) to receive intravenous medications on an outpatient basis. This room was immediately adjacent to two rooms with floor-to-ceiling sliding glass doors, in which aerosolized pentamidine was administered to patients with *Pneumocystis carinii* pneumonia; some of these patients had active tuberculosis. Because these treatment rooms were under positive pressure relative to the intravenous medication room, patients receiving intravenous medications, and HCWs administering the medications, were exposed to patients with *M. tuberculosis* infection when HIV-infected patients with active tuberculosis received aerosolized pentamidine. This occurred even if the isolation room doors were closed. In addition, air in the isolation rooms and waiting area was recirculated, causing a mixture of clean and potentially *M. tuberculosis* contaminated air to be circulated through the room. Thus, the location of a number of the cases led to identification of risk factors for acquisition of the disease (i.e., new onset of tuberculosis or TST conversion among AIDS clinic patients or HCWs exposed to patients with active tuberculosis) and to mode of transmission (airborne spread caused by poor isolation practices and inadequate ventilation systems).

By describing the case-patients in terms of demographics and underlying disease, one can define the at-risk population and determine possible exposures. Certain patient populations may be at risk because of either age or underlying disease-specific exposures. The entire population that meets these identified criteria is the group of patients that would have been identified as case-patients had they developed disease (*36*). This is the population from which controls or the cohort to be studied should be chosen for epidemiologic studies. The comparison population (controls or noncases) should have the same opportunity for infection/disease or adverse event as the case-patients.

Developing Hypotheses

Once cases are identified, and pertinent information from the medical records is abstracted, hypotheses about the cause of the outbreak can be generated. These hypotheses should be based on the available information, previously published literature, and expert opinion. Then, epidemiologic studies can be conducted to test the hypotheses.

In many situations, the number of cases in the cluster is very small (less than five cases) or personnel or financial resources are not sufficient to conduct epidemiologic hypothesis testing studies. Thus, a different approach, sometimes called "quick and dirty," is followed. In this situation, the line listing of the case-patients, which flowed from the case definition and case finding, is examined,

commonalities identified, and hypothesis generated about the most probable sources and mode of transmission. Then, a variety of control measures are implemented aimed at the most probable source and mode of transmission. After implementing these control measures, one continues to conduct surveillance for additional case-patients and one hopes that the outbreak is terminated. If the outbreak continues, either additional control measures may be implemented or it may be necessary to conduct the hypothesis testing epidemiologic studies.

Testing Hypotheses

Investigation of outbreaks is by nature retrospective to the development of the adverse event. Two types of retrospective analytic studies can be performed to test hypotheses formed in an outbreak investigation: case–control or cohort studies. Recently, such studies have been called "quasi-experimental" studies, as they are not prospective, randomized, placebo-controlled studies. The majority of recommendations for prevention of HAIs are based on such quasi-experimental studies. Each type of study (e.g., case–control or cohort) has inherent advantages and disadvantages, which should be taken into account before embarking on the study. A major consideration is whether the number of case-patients is sufficient to statistically identify or confirm the source and risk factors for infection/disease or adverse event (i.e., the statistical power of the study). If the number of cases is small, an epidemiologic study may be fruitless, as one may not identify a source or risk factor that is responsible (type II or beta error) or erroneously identify a source or risk factor that is not responsible (type I or alpha error).

Case–Control Studies The case-patients for a case–control study have already been selected by the occurrence of the outbreak. Choosing the appropriate controls is the next step. Case–control studies require the selection of study participants on the basis of disease/infection/adverse event status. For example, if 25 affected patients or HCWs (case-patients) are enrolled, a proportional number (25, 50, 75, etc.) of unaffected members of the at-risk population should be enrolled as controls. Specific risk factors for disease/adverse event then can be compared between case- and control-patients. Care should be taken to ensure that case-patients and control subjects have equal likelihood of the exposure (e.g., presence on the unit/ward for minimum lengths of time during which the potential source may have been present).

The main advantage of case–control studies is that they require a small number of subjects (cases [n] and controls [$1n$, $2n$, or $3n$]) and can, therefore, be conducted relatively quickly. In addition, because subjects are chosen on the basis of their disease/adverse event status (i.e., cases being ill and controls being well), case–control studies are well suited for infrequent or rare diseases/adverse events or diseases/adverse events with long latency periods. In addition, multiple exposures can be examined in the course of one study. This same feature, however, means that the design is backward (i.e., one selects subjects on the basis of disease/adverse event status and then looks backward in time to look at potential exposures). This may lead to uncertainty that the exposure actually preceded the onset of disease/adverse event. In addition, this backwardness may subject the study to both selection and recall bias. Another disadvantage of case–control studies is that they are unsuitable for rare exposures (disease/adverse event incidence rates cannot be measured because the population at risk has not been proportionately sampled) (see also Chapter 2). Most outbreak investigations use the case–control study design because of its efficiency (smaller number of case- and control-patients medical records to review) while still being able to assess multiple exposures/potential risk factors in one study. One disadvantage of the case–control study is that one cannot determine the relative risk (RR) of the identified exposures, but rather estimates this risk by calculating the odds ratio (OR) (see also Chapter 2).

Cohort Studies In contrast to case–control studies, cohort studies require the selection of study participants on the basis of exposure status. Such status can be determined on the basis of known facts about the case-patients or case-HCWs. Exposures that often are used to determine the cohort to be studied are underlying disease, being hospitalized on a particular ward, having a particular physician, or having undergone a particular surgical or invasive procedure. Once the cohort of diseased (cases) and nondiseased (noncases) patients is selected, specific risk factors for development of disease can be evaluated among the cases and noncases.

Because cohort study subjects are selected on the basis of an exposure and followed forward through time (albeit historical time) for the occurrence of disease, cohort studies have the advantage of a logical temporal sequence. The selection of subjects on the basis of exposure also facilitates studying rare exposures or the many effects of one exposure. Another major advantage of the cohort study design is the ability to calculate disease incidence rates for the affected population and the RR associated with the identified risk factors (see also Chapter 2).

Study Design The type of study that should be done and the population from which study subjects should be chosen depend on the particular hypotheses to be tested, the frequency of the adverse event, the duration of the outbreak, the number of case-patients identified, and so forth. Often, it is necessary to conduct several studies, each testing hypotheses from the different levels of the outbreak. Most of the data for the case-patients or case-HCWs for either type of study have already been collected in the initial data collection and chart review procedure. The same data should be collected for the control subjects (case–control study) or non-case-patients (cohort study), so that particular risk factors can be evaluated. Data should be collected similarly for cases and for controls or noncases.

Data Analysis

Descriptive Statistics Initial data analysis should consist of descriptive statistics (e.g., frequency tables for each independent or exposure variable). For example, if information collected for cases and controls or noncases includes age, gender, hospital ward, attending physician, and surgical procedure performed, the frequency of all of the values of those variables should be examined for the study population. This type of descriptive information is

TABLE 8-3

Frequency Distribution of Attending Physicians for Cases and Controls, Outbreak of Unknown Disease, Hospital X

Physician	*Number of Cases*	*Number of Controls*
A	14 (93%)	7 (47%)
B	0 (0%)	0 (0%)
C	1 (7%)	8 (53%)
Total	15 (100%)	15 (100%)

very useful to direct further analyses. For example, if the study population was exposed to attending physicians A, B, and C as shown in Table 8-3, further analyses might be conducted around events associated with attending-physician A.

Univariate Analysis: Categorical Variables Categorical variables (i.e., variables with values that can be sorted into categories such as ill or well, yes or no, male or female) are compared using the 2×2, or cross-tabulation, table. If a case–control study design has been used, ORs should be calculated by using the following formula:

$$\text{OR} = ad / bc$$

The OR is the odds that a person with the disease/adverse event was previously exposed to the risk factor of interest compared with the odds that a person without the disease/adverse event was not previously exposed to the risk factor of interest. Usually, the further away from 1.0 in either direction, the stronger the association between the variables. The OR estimates the RR (see later) when a case–control study design has been used. To continue with the previous example, if exposure to physicians A and C is compared with case or control status, exposure to physician A is associated with illness (Table 8-4).

When using a cohort study design, RR estimates can be calculated for the population, using the following equation:

RR = probability of being exposed divided by probability of being nonexposed or

$$\frac{a/(a+b)}{c/(c+d)}$$

TABLE 8-4

Two-by-Two Table Comparing Physicians A and C to Case–Control Status, Outbreak of Unknown Disease, Hospital X[a]

	Cases	*Controls*	*Total*
Physician A	14	7	21
Physician C	1	8	9
	15	15	30

[a]Odds ratio = ad/bc = (14)(8)/(7)(1) = 16.

The RR is the risk of development of the disease/adverse event if the exposure has occurred compared with the risk of development of the disease/adverse event if the exposure has not occurred. As with the OR, the further away from 1.0 the RR is, the stronger the association is between the variables. This calculation assumes that the study subjects have been selected on the basis of exposure; therefore, this calculation can only be used with a cohort study design.

Most statistical software packages also calculate 95% confidence limits (95% CI) around the OR or the RR. This calculation indicates that if the population were resampled a number of times, the OR or RR would fall within the calculated confidence limits 95% of the time. If the confidence limits surround 1.0, it is likely that for any given sample of the population, the real odds of disease/adverse event or RR could equal 1.0, indicating no association between the variables. Thus, 95% CIs are one indication of the significance of the OR or RR (see also Chapter 2).

Most statistical software packages also calculate a chi-square test from the 2×2 table to test the association between the variables. More commonly reported in the scientific literature than the chi-square value is the *p* value, which is based on the chi-square value. If the expected value in any of the cells of the 2×2 table is <5, the Fisher's exact test (FET) is calculated instead of the chi-square value. The *p* value for the FET is calculated directly from the 2×2 table in this instance, rather than by using chi-square tables. For either the chi-square test or the FET, the *p* value indicates the level of certainty one has that the association between the variables is not occurring by chance alone. Both the chi-square test and the FET require that the variables be mutually exclusive and independent.

Univariate Analysis: Continuous Variables Continuous variables, such as age or severity of illness measurement, are compared among the case- and control-patients or noncases by using measures of central tendency, most frequently the mean or median. If the data are normally distributed (i.e., plotting the values on a graph yields a bell-shaped, or normal, curve), the mean and its standard deviation should be calculated. If the data are not normally distributed, the median and range of the data values should be used.

Stratified and Multiple Variable Analysis Because many HAI are multifactorial, often it is necessary to control for one or more variables while testing another. For instance, SSIs frequently are related to the surgeon's skill (usually measured as the duration of surgery), the condition of the surgical site at the time of the operation (measured by a standard surgical site classification score), and the patient's underlying health status (measured by a variety of risk factor scores).

Analytic techniques to control for all of these factors usually start with simple stratification of the data. Other techniques include logistic or linear regression models (for categorical and continuous outcome variables, respectively), which require advanced statistical software and training. In some outbreaks, the number of case-patients may be too small to do either stratified or regression analysis. Furthermore, two or more variables may be linearly

associated so that the independent importance of each risk factor cannot be determined. Details on the use of univariate, stratified, and multivariate statistical techniques can be found in Chapter 3.

Use of Microcomputers The analytic techniques described in this section can be accomplished with the use of microcomputers. Statistical software packages, such as Statistical Analysis System (SAS Institute Inc., Cary, NC), EpiInfo Software (Centers for Disease Control and Prevention [CDC], Atlanta, GA), and others, offer a wide variety of features. Particularly useful is the Statcalc feature of EpiInfo. It allows calculation of the necessary sample size to find significant associations; direct input of data into cross-tabulation tables for calculation of ORs or RRs and their respective chi-square, FET, and *p* values; and direct input of data into a trend analysis model for continuous variables (*37*). Calculation of the power of the study or the sample size necessary to detect significant associations is essential before embarking on any outbreak investigation or epidemiologic study. Details on the use of microcomputers in hospital epidemiology can be found in Chapter 15.

MICROBIOLOGY LABORATORY ASPECTS OF THE INVESTIGATION

Once a potential outbreak has been identified, the microbiology laboratory should be notified immediately, so that all appropriate specimens and positive cultures can be saved. Because of the ubiquitous nature of microorganisms in the healthcare facility environment, typing of microorganisms thought to be related to an outbreak may be essential to determine if the infected patient is indeed part of the outbreak. The first line of typing of microorganisms is species identification. This is followed by biotyping and then antimicrobial susceptibility testing. For example, during an outbreak of SSIs caused by MRSA, a patient thought to be involved in the outbreak would be excluded as a case-patient if antimicrobial susceptibility testing revealed that he or she was infected with a methicillin-sensitive strain of *S. aureus*.

When antimicrobial susceptibility testing is insufficient to determine the relatedness of two microorganisms, other methods of typing can be used, including serotyping, phage typing, isoenzyme electrophoresis, and genetic fingerprinting techniques (e.g., pulsed-field gel electrophoresis, plasmid analysis, or restriction fragment polymorphism). These methods are further detailed in Chapter 94.

Although some research-oriented hospital laboratories may be capable of very sophisticated typing techniques, most infection control professionals require assistance in typing microorganisms from an outbreak. University, state health department, the CDC, or other laboratories may be able to assist with typing of isolates from an outbreak. It should be remembered that genetic or other typing of isolates can determine whether the isolates are the same strain (clonal) or not (nonclonal), but it cannot tell whether there is an outbreak or not. Outbreaks can be caused by clonal (common source) or nonclonal (intermittent person-to-person transmission because of inadequate hand hygiene) isolates.

ENVIRONMENTAL INVESTIGATION

A thorough investigation of an infectious disease/adverse event outbreak should include some inspection of the environment, particularly if an inanimate object is epidemiologically implicated as a possible means of transmission. For example, investigation of an outbreak of *Serratia marcescens* SSIs following breast reconstruction revealed that expandable breast implants were associated with a greater risk of infection than were nonexpandable implants. Furthermore, infections were more likely when the expansion procedure was performed in the surgeon's office (*38*). This led the investigators to sample solutions, water sources, and personnel from the surgeon's office that was involved in the expansion procedure. Positive cultures were obtained only from a specimen of saline taken from a partially used bag in the procedure room, allowing investigators to remove the contaminated solution and other bags with the same purchase date. Environmental cultures should not be taken randomly, because many surfaces are contaminated with numerous microorganisms, perhaps including the microorganism being investigated. Positive culture results from such random sampling may be misleading, difficult to interpret, and often confusing to investigators. Similarly, the first step in any outbreak investigation should not be widespread personnel or environmental culturing; rather such culturing should be based on the epidemiologic data identifying a potential source.

In addition to environmental cultures, outbreaks of diseases/adverse events caused by airborne microorganisms such as *M. tuberculosis* or *Aspergillus* spp. merit a thorough inspection of air-handling systems, isolation room airflow patterns, and infection control techniques. Again, neither routine environmental culturing nor selected culturing of the air or room is indicated; these should only be done when epidemiologically directed. Without epidemiologic direction, such culturing usually either misses the source or leads to uninterpretable results.

INTERPRETING RESULTS

The most important part of the investigation is the interpretation of results. Meaningful associations between exposures or risk factors and the development of disease depend on numerous factors: the quality of the study design and the study population, biologic plausibility (i.e., the measured association makes biologic sense), and the exposure's preceding the onset of the disease/adverse event (*39*). Other qualities that lend confidence to a significant association are the statistical strength of the association, consistency with other studies, and the presence of a dose–response effect (*39*).

INSTITUTING CONTROL MEASURES

Control measures can be instituted as soon as a potential outbreak is discovered. For example, increased attention to hand hygiene and other infection control techniques may halt transmission. In addition, published guidelines from the CDC, Association for Professionals in Infection Control

and Epidemiology, the Society for Healthcare Epidemiology of America, Joint Commission, World Health Organization, or other organizations may lend guidance for specific situations (*40–51*). If the investigation implicates a particular HCW or item of patient-care equipment, specific measures should be taken to rectify the situation.

EXAMPLE OF A HOSPITAL INVESTIGATION

An excellent example of an outbreak investigation in a hospital is the investigation of SSIs caused by an unusual human pathogen, *Rhodococcus bronchialis*, after open-heart surgery (52). This outbreak provided an opportunity to assess risk factors for infection with *R. bronchialis*, mode of transmission of the microorganism, and potential sources for this unusual HAI pathogen. Logical hypotheses for the source of SSIs after open-heart surgery included preoperative (e.g., nurses, physicians, or wards), intraoperative (e.g., operating room environment or personnel), or postoperative (e.g., recovery room or intensive care unit personnel) exposures. The investigators analyzed both categorical and continuous variables as measures of potential risk for infection and possible exposures as the source of infection (Table 8-5). The only factor significantly associated with infection was the presence of one operating room nurse, nurse A, during the operative procedure. Examination of nurse A's intraoperative practices revealed that she could have contaminated the sterile field after performing an activated clotting time (ACT) test that involved the use of a water bath for incubation of a tube of the patient's

TABLE 8-5

Categorical and Continuous Variables as Measures of Potential Risk for Infection

Potential Risk Factor	*Case-Patients (n = 7) (%)*	*Controls (n = 28)*	*Odds Ratio*	*p Value*

Ventilation	1 ± 0	1.6 ± 2.7	—	.6
Antimicrobial prophylaxis	4.2 ± 2.2	3.7 ± 1.0	—	.9

[a]Plus/minus values are means ± SD. ICU, intensive care unit; NC, not calculable.
[b]Cardiac index was defined as cardiac output in liters per minute per square meter of body surface area.
(From Richet HM, Craven PC, Brown JM, et al. A cluster of *Rhodococcus (Gordona) bronchialis* sternal wound infections after coronary artery bypass surgery. *N Engl J Med* 1991;324:104–109, with permission.)

blood. A revised hypothesis was that nurse A contaminated the sterile operative field after performing the ACT test; this would account for all of the cases of *R. bronchialis* SSIs during the epidemic period.

To prove that nurse A was responsible for all of the cases of *R. bronchialis* SSIs at the hospital, the investigators performed numerous cultures indicated by the epidemiologic data. These included cultures of nurse A's and nurse B's hands before and after each performed the ACT test; nasal swabs from all cardiac operating room personnel; swabs from nurse A's scalp, pharynx, vagina, and rectum; and swabs from environmental sites while nurse A was present in or absent from the operating room. Only cultures of nurse A's hands after performing the ACT test, nurse A's nasal swab, settle plates from the operating room while nurse A was present, and nurse A's scalp and vaginal cultures were positive for *R. bronchialis*. To identify the ultimate source of the microorganism, nurse A's operating room locker and her home were examined and selectively cultured. The neck-scruff skin of nurse A's dog and air vents at her home (where the dog would lay) were positive for *R. bronchialis*. Antimicrobial susceptibility testing and molecular typing showed that all of the outbreak isolates (i.e., patient, HCW, environment, and dog) were identical and distinct from nonoutbreak stock strains of *R. bronchialis*.

The role of the water bath used to incubate blood samples for the ACT test was analyzed by simulating what the scrub nurses would do during surgery and by using a colorless fluorescent dye in the water bath. After simulating the beginning of an open-heart procedure (e.g., performing an ACT test and opening sterile packs for the procedure), 8/11 circulating nurses contaminated the sterile field with fluorescent dye from the water bath. Also contaminated with fluorescent dye were all of the nurses' hands; some of the nurses' wrists, forearms, and scrub suits; the outer surface of the water bath container; the table surface; and the floor around the water bath. This simulation showed that although the bath water was culture-negative for *R. bronchialis*, the bath water, by wetting the hands of nurse A, provided the mechanism for the microorganism to be spread from nurse A's hands to the sterile field. Because nurse A was epidemiologically implicated in the investigation, cultures were obtained from a variety of sources highly likely to yield positive results. Random culturing of the operating room environment and other personnel earlier in the investigation would have been unfocused, increasing the work load on the laboratory without aiding the investigation, and most likely would have missed the source of the outbreak. Additional selected surgical personnel and environmental sources were included in the culture survey to avoid identification of nurse A as the probable source before confirming culture evidence could be obtained.

FINAL STEPS

After instituting control measures, assessing the efficacy of the introduced control measures is essential. Occasionally, more than one mode of transmission is present, and prevention interventions eliminate only one of the modes of transmission (*53*). In other situations, it is essential to ensure that previously accepted control measures really are adequate to terminate transmission (54,*55*).

Once an investigation is concluded, it is imperative that all of the concerned parties in the hospital and state or local health department, consultants, and other involved persons be told of the results of the investigation. In addition, if patient-care devices or products are implicated in the investigation, the appropriate divisions of the Food and Drug Administration or CDC should be alerted. Finally, during the course of the investigation, answering inquiries from the public and press may be necessary. It is good practice to have one person, usually from the public relations, risk management, or legal departments of the healthcare facility, respond to these inquiries. That person should be kept informed of all developments in the investigation.

Although the investigation of outbreaks is an interesting and challenging endeavor, it may be beyond the capability of a given infection control or epidemiology department because of financial or personnel resource constraints or lack of expertise in analytic and epidemiologic techniques. In such instances, assistance is available from state or local health departments, the CDC, university infection control or epidemiology departments, other facility infection control personnel, or private consultants.

RESULTS USING THIS APPROACH

From July 1987 through December 2005, the previously described approach to investigation of outbreaks was consistently applied by Epidemic Intelligence Service officers in the Investigation and Prevention Branch, Hospital Infections Program (currently the Prevention and Response Branch, Division of Healthcare Quality Promotion), CDC. In nearly 150 outbreak investigations, the source was identified and the outbreak was terminated (*4*,*16–18*, 20,*21,22*,*25*,*27*,*29*,*33–35*,*38*,54,*55–83*,84,*85–93*,94,*95–98*, 99,*100*,*101*,102,*103*,104,*105*,*106*,107,*108*,*109*,110,*111–114*,115,116,*117–127*,128,*129–140*,141,142,*143–155*, 156,*157*,*158*,159,*160–167*,168,*169–184*) (Table 8-6). The use of this approach has led to the identification of intrinsic product contamination [*Yersinia enterocolitica* from packed red blood cells (*58*), *Pseudomonas cepacia* in povidone-iodine disinfectant (*71*), aseptic peritonitis associated with peritoneal dialysis (*132*), gram-negative bloodstream infections associated with serum albumin (*137*), sepsis and death in neonates associated with contaminated glucose infusates (*138*), pyrogenic reactions associated with once daily administration of gentamicin (*154*), and *Mycobacterium gordonae* pseudoinfections traced to culture additive contamination (*26*)]. Many episodes of extrinsic product contamination involving either pyrogenic reactions and/or infection were detected that were associated with reprocessing of hemodialyzers (56,*60*,*63*,*85*,*93*,94,*96*, *103*,110,*111*,*118*,128,*139*,159). New modes of transmission were identified, such as *R. bronchialis* SSIs or *Malazessia furfur* infections in neonates traced to the HCWs' dogs (52,115); hepatitis A from prolonged excretion of the virus by premature neonates (*70*); many microorganisms from extrinsic contamination of the anesthetic propofol (20); anaphylactic reactions in patients and HCWs traced to latex exposure (*21*,84), aluminum, microcystin, or fluoride

TABLE 8-6

On-Site Healthcare-Associated Infections Outbreak Investigations, Hospital Infections Program/Division of Healthcare Quality Promotion, CDC, July 1987–December 2005

1987 [Outbreak name—state/country (reference number)]

1. Pyrogenic reactions in hemodialysis patients—Illinois (56)
2. *Malassezia furfur* infections in neonatal intensive care unit patients—Washington, DC (*57*)
3. *Acinetobacter* spp. bloodstream infections in intensive care unit patients—New Jersey (*18*)
4. *Yersinia enterocolitica* sepsis associated with red blood cell transfusion—Wisconsin/Texas (*58*)
5. *Pseudomonas cepacia* infection/colonization in attendees at a cystic fibrosis summer camp—Michigan (*59*)
6. Human immunodeficiency virus knowledge and compliance with CDC recommendations (NP)

1988

1. *Aspergillus flavus* pseudofungemia in bone marrow transplant patients—North Carolina (NP)
2. Methicillin-resistant *Staphylococcus aureus* surgical site infections in cardiac surgery patients—Tennessee (NP)
3. *Mycobacterium chelonae* infections in hemodialysis patients—California (*60*)
4. *Aspergillus fumigatus* surgical site infections in cardiac surgery patients—Tennessee (*61*)
5. Epidemic hemolytic anemia in hemodialysis patients—Pennsylvania (*62*)
6. Gastroenteritis in a retirement facility—California (*33*)
7. Pyrogenic reactions and/or bloodstream infections in hemodialysis patients—Arizona (*63*)
8. Hemolysis in pediatric hemodialysis patients—Texas (*64*)
9. Invasive candidiasis in hematology–oncology patients—France (*65*)
10. Disseminated intravascular coagulation in open heart surgery patients—California (*66*)

1989

1. *Serratia marcescens* bloodstream infections in intensive care unit patients—Illinois (*67*)
2. Surgical site infections in patients undergoing hip replacement procedures—Maine (*68*)
3. Hypotension in hemodialysis patients—New York (*69*)
4. *Rhodococcus broncialis* surgical site infections in cardiac surgery patients—Washington (52)
5. Hepatitis A infections in neonates in a neonatal intensive care unit—Hawaii (*70*)
6. *Pseudomonas cepacia* pseudobacteremia in infants—Texas (*71*)
7. *Xanthomonas maltophilia* infections in intensive care unit patients—Utah (*72*)
8. Group A streptococcal surgical site infections—California (NP)
9. *Salmonella* spp. gastroenteritis in patients and healthcare workers—Tennessee (NP)
10. *Pseudomonas cepacia* infections in cystic fibrosis patients—Pennsylvania (*73*)
11. Multidrug-resistant *Mycobacterium tuberculosis* infections in human immunodeficiency virus infected patients—Puerto Rico (*74*)
12. *Tsukamurella* spp. pseudoinfections traced to laboratory contamination—South Carolina (*27*)
13. *Mycobacteriun gordonae* pseudoinfections traced to intrinsic product contamination—Connecticut/Georgia (*26*)
14. Nosocomial infections in long-term care facility residents—California (*75*)
15. *Serratia marcescens* surgical wound infections following augmentation mammoplasty—North Dakota (*38*)
16. Allergic reactions in hemodialysis patients—Virginia (*76*)

1990

1. Group A streptococcus bacteremia in residents of a long-term care facility (*77*)
2. *Clostridium difficile* enteritis in a hospital—New York (*78*)
3. Drug-resistant tuberculosis in hospitalized AIDS patients—New York (*34*)
4. *Staphylococcus aureus* infections following clean surgical procedures—Michigan (*20*)
5. *Candida albicans* infections following clean surgical procedures—Illinois (*20*)
6. *Staphylococcus aureus* infections following clean surgical procedures—Texas (*20*)
7. Endotoxin reactions during clean surgical procedures—Maine (*20*)
8. Nosocomial transmission of drug-resistant *M. tuberculosis*—Florida (*35*)
9. *Enterobacter agglomerans* sepsis and bacteremia in postsurgical patients—Alabama (*20*)
10. *Enterobacter cloacae* bacteremia in emergency room and outpatient clinic patients—New Mexico (*29*)
11. Carbon monoxide poisoning in surgical patients—Georgia (*22,79*)
12. Inadvertent injection of HIV-contaminated material during nuclear medicine procedures—California and New Mexico (*80*)
13. Scleritis following cataract surgery—Florida (*81*)
14. Gram-negative meningitis and bacteremia in neonates in a neonatal intensive care unit—Guatemala (*82*)

TABLE 8-6

On-Site Healthcare-Associated Infections Outbreak Investigations, Hospital Infections Program/Division of Healthcare Quality Promotion, CDC, July 1987–December 2005 (*Continued*)

1991

1. Tuberculosis in renal transplant patients—Pennsylvania (*83*)
2. Anaphylactic reactions in pediatric patients—Wisconsin (*21*,84)
3. Pyrogenic reactions and bacteremia in hemodialysis patients—Ohio (*85*)
4. Multidrug-resistant *Mycobacterium tuberculosis* in New York City—New York (*25*)
5. *Aspergillus* spp. infections in immunocompromised patients—California (*16*)
6. Anaphylactic reactions in patients with spina bifida—Pennsylvania (NP)
7. *Klebsiella* sp. sepsis in neonates in a neonatal intensive care unit—Saudi Arabia (*86*)
8. Bacterial sepsis associated with pooled platelet transfusions—Ohio (*87*)
9. Anaphylactic reactions in pediatric patients—Oklahoma (NP)
10. Fungemia in neonatal intensive care unit patients—Louisiana (*88*,*89*)
11. Invasive aspergillosis in oncology patients—Pennsylvania (*90*)
12. Hepatitis A in healthcare workers in a bone marrow transplant unit—Florida (*91*)
13. Polymicrobial bacteremia in postcardiac surgery patients—Washington (*17*)
14. Bacteremia in hemodialysis patients—Texas (NP)
15. Hepatitis B among nursing home residents—Ohio (NP)

1992

1. Nosocomial transmission of multidrug-resistant *M. tuberculosis*—New York (*92*)
2. Pyrogenic reactions in hemodialysis patients—California (*93*)
3. Aluminum toxicity in chronic hemodialysis patients—Pennsylvania (94)
4. Nosocomial transmission of *M. tuberculosis*—Georgia (*4*,*95*)
5. Gram-negative bacteremia in patients undergoing hemodialysis—Maryland (*96*)
6. *Aspergillus fumigatus* sternal wound infections following open heart surgery—Pennsylvania (*96*)
7. Multidrug-resistant *M. tuberculosis*—New Jersey (NP)
8. Nosocomial transmission of multidrug-resistant *M. tuberculosis*—New York (*55*)
9. Nosocomial transmission of multidrug-resistant *M. tuberculosis*—New York (*98*)
10. Nosocomial transmission of multidrug-resistant *M. tuberculosis*—Florida (54)
11. *M. fortuitum* infections/pseudoinfections associated with bronchoscopy—Kentucky (99)
12. Nosocomial transmission of multidrug-resistant *M. tuberculosis*—New York (NP)
13. Complications of Lyme disease treatment—New Jersey (*100*)

1993

1. Endotoxin reactions during surgical procedures—Arizona (*20*)
2. *Serratia marcescens* infections in surgical patients—Arizona (*20*)
3. Invasive aspergillosis in cardiac transplant patients—New York (NP)
4. Nosocomial coagulase-negative staphylococcal bacteremia in neonatal intensive care unit patients—Kentucky (NP)
5. *Enterobacter hormaechei* bloodstream infections in neonatal intensive care unit patients—Pennsylvania (*101*)
6. *Norcardia farcinica* surgical wound infections after open heart surgery—Montana (102)
7. Adverse reactions and death during hemodialysis—Illinois (*103*)
8. Bloodstream and surgical site infections due to vancomycin-resistant enterococci—New York (104)
9. Surgical site infections due to methicillin-resistant *Staphylococcus aureus*—Tennessee (NP)
10. Nosocomial vancomycin-resistant enterococcal infections—Maryland (*105*)
11. Intravascular catheter complications in intensive care unit patients—Arizona (*106*)

1994

1. Bloodstream infections associated with outpatient infusion therapy—Rhode Island (107)
2. Pulmonary complications associated with total parenteral nutrition—Hawaii (*108*)
3. *Acremonium kiliense* endophthalmitis following cataract surgery—Pennsylvania (*109*)
4. Possible HIV transmission in a dialysis center—Colombia (110)
5. Acute hepatitis B infections in hemodialysis patients—Texas (*111*)
6. Acute hepatitis B infections in hemodialysis patients—California (*111*)
7. Bloodstream infections in pediatric oncology patients—California (*112*)
8. Methicillin-resistant *S. aureus* (MRSA) infection colonization in wrestlers—Vermont (NP)
9. *Clostridium difficile* gastroenteritis in hospitalized patients—Canada (*113*)
10. Postoperative *Ochrabactrum anthropi* meningitis in pediatric patients—Utah (*114*)

1995

1. Nosocomial transmission of *Malassezia pachydermatis* in neonatal intensive care unit patients—New Hampshire (115)
2. Bloodstream infections in home infusion therapy patients—Texas (116)
3. *Salmonella sundsvall* infection in neonates in a neonatal intensive care unit—Oklahoma (NP)
4. *Serratia marcescens* infections in neonatal intensive care unit patients—Massachusetts (*117*)
5. *Enterobacter cloacae* bloodstream infections in hemodialysis patients—Canada (*118*)
6. Pyrogenic reactions in patients undergoing cardiac catheterization—Colorado (*119*)

1996

1. *S. marcescens* infection in cardiac intensive care unit patients—Pennsylvania (*120*,*121*)
2. Vancomycin-resistant enterococcal infections—Indiana (*122–124*)
3. Bloodstream infections associated with needleless devices—Indiana (*125–127*)
4. Fatal illness in a hemodialysis center—Brazil (128)
5. *E. cloacae* bloodstream infections in neonatal intensive care unit patients—Puerto Rico (*129*)
6. Hepatitis C infections possibly associated with intramuscular immune globulin—Texas (NP)
7. *S. aureus* bloodstream infections among patients undergoing electroconvulsive therapy at a psychiatric hospital—Mississippi (*130*)
8. Bloodstream infections in pediatric intensive care unit patients—Georgia (*131*)
9. Bloodstream infections in pediatric outpatients—Georgia (NP)
10. Aseptic peritonitis in peritoneal dialysis patients—Pennsylvania (*132*)
11. Vancomycin-resistant *S. epidermidis* bloodstream infection in a patient—Virginia (*133*)
12. Invasive aspergillosis in rheumatology patients—Maryland (*134*)
13. *Acinetobacter* species bloodstream infection in neonatal intensive care unit patients—Bahamas (*135*)
14. Neurologic (loss of hearing and vision) symptoms after hemodialysis—Alabama (*136*)
15. Bloodstream infections associated with serum albumen—Kansas (*137*)
16. Overwhelming sepsis and death in newborn nursery patients—Brazil (*138*)

1997

1. Bloodstream infections in hemodialysis patients—Maryland (*139*)
2. Nosocomial vancomycin-resistant enterococcus colonization/infection—Indiana (NP)
3. Vancomycin-resistant enterococcus colonization/infection in patients in hospitals and long-term care facilities in a region—Iowa, Nebraska, South Dakota (*140*,141)
4. Nosocomial bloodstream infections in sickle cell anemia patients—Georgia (NP)
5. *S. aureus* with reduced susceptibility to vancomycin—Michigan (142)
6. *S. aureus* with reduced susceptibility to vancomycin—New Jersey (142)
7. Pyrogenic reactions in cardiac catheterization patients—Brazil (*143*)
8. Dementia in solid organ transplant recipients—Maryland (NP)
9. Creutzfeldt–Jakob disease possibly associated with a dura mater transplant—Florida (*144*)
10. *Microbacterium* spp. bloodstream infections in oncology patients—Maine (*145*)
11. *Pseudomonas aeruginosa* infections in neurosurgical patients with external ventricular devices—Arizona (*146*)
12. Infections in pediatric oncology patients with indwelling central vascular catheters—California (*147*)

1998

1. Red eye syndrome associated with red blood cell transfusion—Michigan, Washington, Oregon (nationwide) (*148*)
2. Corneal degeneration after ophthalmologic surgery—Missouri (*149*)
3. *Malassezia pachydermatis* infections in neonates in a neonatal intensive care unit—Kentucky (NP)
4. Postcoronary artery bypass graft sternal wound infections—Wisconsin (*150*,*151*)
5. Hemolysis in hemodialysis patients—Nebraska, Massachusetts, Maryland (nationwide) (*152*)
6. Vancomycin-resistant enterococci in a long-term care facility setting—Illinois (*153*)
7. Pyrogenic reactions in hospitalized patients receiving parenteral gentamicin—California (nationwide) (*154*)
8. Vancomycin-resistant enterococcal infection/colonization among residents of acute and long-term care facilities—Iowa, Nebraska, South Dakota (141)
9. Gram-negative bloodstream infections in bone marrow transplant patients—Washington (*155*)

1999

1. *S. marcescens* bloodstream infections in surgical intensive care unit patients—Pennsylvania (156)
2. Cellulitis, sepsis, and death in neonates in a neonatal intensive care unit—Indonesia (NP)
3. *Klebsiella pneumoniae* bloodstream infections in neonates in a neonatal intensive care unit—Colombia (*157*)

5. Nosocomial sepsis and meningitis in neonates in a neonatal intensive care unit—Brazil (*158*)
6. *S. liquefaciens* bloodstream infections and pyrogenic reactions in hemodialysis patients—Colorado (159)
7. Nosocomial transmission of extended spectrum beta-lactamase-producing *Escherichia coli* and *Klebsiella pneumoniae* in long-term care facility patients—Illinois (*160*)
8. Vancomycin-resistant enterococcal infection/colonization among residents of acute and long-term care facilities—Iowa, Nebraska, South Dakota (141)

2000

1. Transmission of hepatitis C virus among patients at a hemodialysis center—Ohio (NP)
2. Investigation of possible nosocomial transmission causing relapse in TB patients (NP)
3. Adverse reactions associated with transfusion of leukocyte-reduced red blood cell units—multistate outbreak (*161*)
4. Postcoronary artery bypass graft surgical site infection (NP)
5. Community-acquired methicillin-resistant *S. aureus* and *S. aureus* with reduced susceptibility to vancomycin—New Jersey (*162*)
6. Pyrogenic reactions and death in renal dialysis patients—Ohio (*163*)
7. Transmission of hepatitis C virus in a hemodialysis center—Wisconsin (NP)

2001

1. Methicillin-resistant *S. aureus* infections among a college football team—Pennsylvania (NP)
2. Outbreak of skin infections with methicillin-resistant *S. aureus* in a state correctional facility (NP)
3. Possible nosocomial transmission of *M. tuberculosis* by contaminated fiberoptic bronchoscope—Pennsylvania (NP)
4. Catheter-related bloodstream infections in hemodialysis patients (NP)
5. Methicillin-resistant *S. aureus* infections in an American Indian community—Washington (NP)
6. Outbreak of invasive aspergillosis among renal transplant patients (NP)
7. Outbreak of *E. cloacae* bloodstream infections in a pediatric inpatient population—Missouri (*164*)
8. Outbreak of saline-filled breast implant contamination with *Curvularia lunata* among women who underwent cosmetic breast augmentation surgery—Alabama (*165*)
9. Adverse events and deaths associated with laboratory errors at a hospital—Pennsylvania (*166*)
10. Outbreak of sepsis and death associated with *Klebsiella pneumoniae* in neonatal intensive care unit patients—Cairo, Egypt (*167*)

2002

1. Hospital outbreak of *Candida parapsilosis* bloodstream infections—Mississippi (NP)
2. Multistate investigation of postoperative clostridial infections in patients undergoing knee surgery and allograft implantation—Minnesota (168)
3. *Enterobacter sakazakii* meningitis in a neonatal intensive care unit (NP)
4. Postoperative surgical site infections in patients who underwent orthopedic procedures and allograft implantation—California (*169*)
5. Outbreak of vancomycin-resistant *S. aureus* infections—Michigan (*170*)
6. Nontuberculous mycobacteria soft tissue infections associated with cosmetic injections—New York (NP)
7. Hospital outbreak of *Candida parapsilosis* bloodstream infections (*171*)

2003

1. Outbreak of vancomycin-resistant *S. aureus* infections—Pennsylvania (*172*)
2. *Mycobacterium tuberculosis* associated with nosocomial transmission in a hospital—Guatemala (NP)
3. *Phialemonium* infections among renal dialysis patients—Illinois (*173*,*174*)
4. Community-associated methicillin-resistant *S. aureus* skin and soft tissue infections—Hawaii (*175*)

2004

1. Postoperative group A streptococcal infections following allograft implantation—Colorado, Oklahoma (*176*)
2. Nosocomial transmission of *M. tuberculosis*—Taiwan (NP)
3. Fatal rabies in organ transplant recipients—Texas (*177*)
4. Outbreak of *Acinetobacter baumannii* infections—Maryland (*178*)
5. Outbreak of *Burkholderia cepacia* associated with contamination of albuterol and nasal spray (*179*)

(*Continued*)

TABLE 8-6

On-Site Healthcare-Associated Infections Outbreak Investigations, Hospital Infections Program/Division of Healthcare Quality Promotion, CDC, July 1987–December 2005 (*Continued*)

2005

1. Investigation of *S. marcescens* infections in cardiac surgery patients—Kentucky (*180*)
2. Outbreak of *Burkholderia cepacia* infections in an oncology clinic—Georgia (*181*)
3. Investigation of *S. marcescens* infections in cardiac surgery patients—California (*180*)
4. Outbreak of community-associated methicillin-resistant *S. aureus* skin and soft tissue infections—Georgia (NP)
5. Recovery of *Ralstonia* spp. from neonates—Pennsylvania (*182*)
6. Multistate outbreak of *B. cenocepacia* colonization and infection associated with the use of intrinsically contaminated alcohol-free mouthwash (*183*)
7. Multistate outbreak of toxic anterior segment syndrome, 2005 (*184*)

NP, not published.

toxicity in hemodialysis patients traced to an aluminum pump (94,*103*,128), inadequate water disinfection (128), or exhaustion of a reverse osmosis filter (*103*), respectively; *Mycobacterium fortuitum* infection or pseudoinfections from inadequate bronchoscopy disinfection (99); *Nocardia* SSIs traced to a colonized anesthesiologist and his contaminated home environment (102); bloodstream infections traced to needleless devices used in home infusion therapy (107,*112*,116,*125–127*); the role of the nursing shortage on increasing infection rates (*106*,*120*); and others. In addition, risk factors for transmission of *M. tuberculosis* (*34*,*35*,*74*,*83*,*92*) to patients and HCWs in healthcare settings were identified, and interventions were implemented and documented to terminate such transmission (54,*55*,*98*). Similarly, risk factors for the emergence and transmission of vancomycin-resistant enterococci were identified (104,*105*,*122–124*); then interventions (including active detection and isolation including active surveillance testing and barrier precautions) were implemented and shown to be effective in reducing or eradicating transmission on a ward (104,*105*), in an entire hospital (*124*), or in an entire region of a state (all acute care and long-term care facilities) (141). In addition, new and emerging HAI pathogens were identified, such as *M. furfur* in neonates (*57*,115), *Y. enterocolitica* in red blood cell products (*58*), *P.* (now *Burkolderia*) *cepacia* in cystic fibrosis patients (*59*,*73*), multidrug-resistant *M. tuberculosis* (*4*,*25*,*34*,*35*,54,*55*,*74*,*83*,*92*,*95*,*98*), nontuberculous mycobacteria in hemodialysis patients (*60*) or bronchoscopy patients (99), *R. bronchialis* or *Norcardia farcinica* in cardiac surgery patients (52,102), *Enterobacter hormaechei* in neonates (99), *Akremonium kiliense* in surgical patients (*109*), *Ochrabactrum anthoropi* in pediatric patients (*114*), vancomycin-resistant enterococci (104,*105*,*122–124*,141), and *S. aureus* with reduced susceptibility to vancomycin (142).

This approach has worked well for infectious and noninfectious diseases/adverse events and in all types of healthcare settings and countries. The success of this approach illustrates the value of a combined epidemiologic and laboratory investigation; the power of using these tools together is much greater than using either one alone. When appropriately implemented, this outbreak investigative approach identifies the source and mode of transmission, assists in evaluating the efficacy of the interventions, and ultimately and effectively protects patients and HCWs by preventing further infection/disease/adverse events.

CHAPTER 9

Pseudoinfections and Pseudo-Outbreaks

Cheston B. Cunha and Burke A. Cunha

From an infection control and clinical perspective, pseudoinfections are interesting and important. On a daily basis, there are many concerns confronting infection preventionists (IPs) in reviewing clinical and microbiologic data. Given the high volume of microbiologic data generated per day, it is understandable that IPs particularly take notice of common microorganisms cultured/demonstrated from unusual body sites (for the microorganism) (e.g., *Streptococcus pneumoniae* from a wound culture) as well as unusual microorganisms cultured/demonstrated from any body site (e.g., *Chromobacterium violaceum* from respiratory secretion cultures). Potential pseudoinfection should be suspected either when an unusual microorganism is cultured from a usual body site (e.g., *Alcaligenes [Achromobacter] xylosoxidans* cultured from the urine) or when a common microorganism is isolated from an unusual body site (for the microorganism) (e.g., *Bacteroides fragilis* cultured from the cerebrospinal fluid [CSF]). The clue to possible pseudoinfection is a discrepancy between clinical findings and the typical manifestations of the isolate at the body site cultured/demonstrated (e.g., *Pseudomonas fluorescens* cultured from the blood in a patient with pneumonia). IPs should then determine by epidemiologic investigation whether the isolate represents a *bona fide* infection or pseudoinfection.

An abrupt increase in incidence of a microorganism relative to its prevalence in an institution should suggest a potential outbreak. Outbreaks are clusters of the same infection occurring over a limited period of time but must be differentiated from pseudo-outbreaks. A pseudo-outbreak may be defined as a cluster of pseudoinfections due to the same microorganisms cultured/demonstrated from the same site in multiple patients. Whenever a pseudoinfection is suspected, infection control should conduct an appropriate epidemiologic investigation to try and determine the common source of microbial contamination and mechanism of specimen contamination.

Infectious disease clinicians deal with other problems trying to correlate microbiologic results with clinical findings. On a daily basis, physicians must differentiate colonization from infection not only for accurate record keeping/diagnostic purposes but also to avoid unnecessary treatment of colonization, which may predispose to antimicrobial resistance.

Some patients with pseudoinfections are empirically treated with antimicrobial therapy before the diagnosis of pseudoinfection is realized. The more potentially serious the infection (e.g., bacteremia, meningitis, pneumonia), the more likely pseudoinfections will be treated empirically with antibiotics. In some cases, whenever an isolate is clearly unrelated to the clinical presentation (e.g., *Bacillus subtilis* isolated from the CSF in a patient with altered mental status), pseudoinfection is likely and empiric antibiotic therapy is used less often.

Epidemiologic investigations associated with pseudoinfections are one of the most interesting aspects of infection control. Pseudoinfections and pseudo-outbreaks should be reported to guide others facing similar epidemiologic quandaries. The pseudoinfection literature provides a wealth of information that is instructive and useful to IPs in conducting a focused epidemiology investigation to determine the potential source of microbial contamination.

PSEUDOBACTEREMIAS

The first type of pseudoinfection described was pseudobacteremia, which remains the most frequently reported pseudoinfection. Microorganisms associated with pseudobacteremias have been varied, but the most frequently implicated microorganisms have been *Bacillus* species, *Pseudomonas* species, or *Streptococcus* species. The most common sources of pseudobacteremia have been contaminated culture media, contaminated antiseptic solutions, or contaminated blood culture vials. Inadequate needle sterilization of blood culture autoanalyzer parts has also been responsible for some pseudobacteremias. Less commonly, pseudobacteremias have resulted from contamination of blood specimens in the laboratory. Rarely, actual infections have occurred from accidental reflux of microbial contaminated blood into patients during venipuncture (1,*2*,3,*4–31*,32,*33–50*,51,*52–72*) (Table 9-1).

PSEUDOMENINGITIS

Pseudomeningitis is the second most common type of pseudoinfection and should be suspected when nonneuropathogens are cultured from CSF in patients with altered mental

TABLE 9-1

Pseudobacteremia

(Reference) Year	*Microorganisms*	*Number Affected*	*Number Infected*	*Number Treated*	*Cause/Source*
(1) 1969	*Escherichia coli*	7	0	7	Contaminated penicillinase in blood culture media
(*2*) 1972	*Acinetobacter lwoffi*	27	3	4	Contaminated penicillinase in blood culture media
(3) 1973	*Moraxella nonliquefaciens*	8	1	1	Contaminated tube holders of blood culture tubes
(*4*) 1974	*Bacillus* species	26	0	0	Contaminated blood culture media
(*5*) 1976	*Pseudomonas cepacia*	79	3	4	Contaminated benzalkonium chloride used for venipuncture
(*6*) 1976	*Flavobacterium Meningo-septicum*	6	0	0	Contaminated chlorhexidine solution used for venipuncture
(*7*) 1976	*Serratia marcescens*	40	0	0	Cross-contamination of blood cultures with nonsterile blood collection tubes
(*8*) 1977	*Acinetobacter lwoffi*	11	0	2	Improper blood culture technique in a mist tent heavily contaminated with bacteria
(*9*) 1978	*Pseudomonas maltophilia*	25	1	3	Cross-contamination of blood cultures with bacteria from nonsterile blood collection tubes
(*10*) 1979	*Staphylococcus aureus*	11	0	5	Blood cultures contaminated by a colonized (nasopharynx) laboratory technician
(*11*) 1980	*Clostridium sordellii*	11	0	0	Contaminated thimerosal solution/diaphragms of blood culture media
(*12*) 1980	*Acinetobacter lwoffi*	22	0	0	Blood cultures contaminated
(*13*) 1980	*Staphylococcus aureus*	5	0	0	Blood culture media contaminated by physician
(*14*) 1980	*Aerococcus viridans*	7	0	0	Inadequately disinfected blood culture bottle stoppers
(*15*) 1981	*Pseudomonas cepacia*	30	0	0	Contaminated povidone-iodine solution used for venipuncture/disinfection of blood culture bottle stoppers
(*16*) 1981	*Enterobacter cloacae*	7	0	1	Contaminated thrombin in blood culture collection vials
(*17*) 1981	*Klebsiella pneumoniae*	13	7	6	Contaminated sampling needle in automated blood culture analyzer
(*18*) 1981	Gram-negative bacilli	75	0	NK[a]	Improper blood culture collection technique
(*19*) 1981	*Pseudomonas cepacia*	16	0	2	Contaminated povidone-iodine solution
(20) 1982	*Klebsiella pneumoniae* *Streptococcus pyogenes* *Staphylococcus epidermidis*	2 1 1	0	1	Inadequate needle sterilization in automated blood culture analyzer
(*21*) 1982	*Bacillus* species	36	0	0	Contaminated syringes
(*22*) 1982	*Serratia marcescens*	17	0	NK	Improper blood culture collection technique
(*23*) 1982	*Serratia marcescens*	16	0	2	Cross-contamination with blood gas specimens
(*24*) 1982	*Pseudomonas aeruginosa*	17	0	0	Contamination of blood culture processing equipment
(*25*) 1983	*Bacillus* species	15	0	0	Contaminated cotton swabs used to disinfect blood culture bottles
(*26*) 1983	*Pseudomonas stutzeri*	24	1	21	Contaminated green soap solution
(*27*) 1983	*Enterobacter faecalis*	8	0	2	Cross-contamination in automated blood culture analyzer

[a]NK, not known.

status. The microorganisms most often implicated in pseudomeningitis are aerobic gram-negative bacilli/coccobacilli. The recovery of nonneuropathogens from the CSF in patients with altered mental status should suggest pseudomeningitis. As with other types of pseudoinfections, pseudomeningitis should be suspected when there is a discrepancy between the clinical presentation and the findings typical of the neuropathogen (e.g., *Candida albicans* isolated from the CSF in a neonate with fever and neurologic findings). Since *C. albicans* is a rare cause of fungal meningitis, the *C. albicans* cultured from the CSF should suggest the possibility of pseudoinfection. In pseudomeningitis, the source of specimen contamination is usually due to extrinsic contamination of lumbar puncture kit materials (e.g., slides, CSF tubes, CSF culture media). Alternately, contamination of CSF has occurred during specimen processing in the laboratory. Because of the mortality/morbidity associated with bacterial meningitis, patients with pseudomeningitis are likely to be given empiric antimicrobial therapy (73,*74–76*,77,*78*,79,*80–88*,89,*90–94*) (Table 9-2).

PSEUDOPNEUMONIAS

Mycobacteria, fungi, or, less commonly, aerobic gram-negative bacilli are microorganisms most often responsible for pseudopneumonias. Pseudopneumonias and pseudopneumonia outbreaks have frequently been associated with contaminated bronchoscopes. In practice, due to suboptimal cleaning/disinfectation, microbiologic contamination of bronchoscope parts (e.g., biopsy forceps, brushes), the stage is set for potential pseudopneumonias. Contaminated aqueous solutions used in respiratory therapy as well as topical anesthetics not uncommonly have been implicated in pseudopneumonias/pseudopneumonia outbreaks. Because most pseudopneumonias have been caused by mycobacteria or fungi, empiric antibacterial therapy for pseudopneumonias has been less frequent than with pseudobacteremias or pseudomeningitis (95,*96–114*,115,*116–132*,133,*134–142*,143) (Table 9-3).

TABLE 9-2

Pseudomeningitis

(*93*) 2002	*Acinetobacter baumannii*	1	0	1	Contaminated culture media
(*94*) 2003	*Flavimonas oryzihabitans*	1	0	1	Contaminated culture media

PSEUDOHEPATITIS AND PSEUDODIARRHEA

Recently, pseudohepatitis has been reported as another type of pseudoinfection due to cross-contamination of pipettes. Pseudodiarrheas, like pseudopneumonias, have been associated with contaminated endoscopes/endoscope cleaning solutions (*144–150*,151) (Table 9-4).

PSEUDOURINARY TRACT INFECTIONS

Urinary tract infections (UTIs) are a relatively uncommon cause of pseudoinfection. Potential mechanisms for pseudo-UTIs are either contamination of the urinary drainage collecting system in catheterized patients or contamination during urine specimen processing in the laboratory. A pseudo-UTI should be suspected if the urinary isolate cultured is not a usual uropathogen or pyuria is not present (*152–157*) (Table 9-5).

OTHER PSEUDOINFECTIONS

Various other pseudoinfections have been associated with contaminated transport media or contaminated disinfectants/soap solutions. Specimen contamination by laboratory technicians has also been reported (*158–163*,164, *165*,166,*167–169*) (Table 9-6).

EPIDEMIOLOGICAL ASPECTS OF PSEUDOINFECTIONS AND PSEUDO-OUTBREAKS

IPs, infectious diseases clinicians, and healthcare epidemiologists should be alert for potential pseudoinfections/pseudo-outbreaks. IPs are often the first to suspect a pseudoinfection. Pseudoinfections should be considered when there is a discrepancy between clinical findings and the usual manifestation of the isolate (at the body site from which specimens have been stained/cultured). Pseudo-outbreaks are clusters of pseudoinfections due to the same isolates from the same body site in different patients (Tables 9-7–9-9).

(*167*) 2009	*Serratia marcescens*	30	0	0	Contaminated saline solution
		Pseudotracheitis			
(*168*) 2010	*Burkholderia cepacia*	178	0	0	Contaminated disinfectant solution
		Pseudotoxic shock syndrome			
(*169*) 2010	*Clostridium sordellii*	6	0	2	Contaminated anaerobic cultures

[a]NK, not known.

TABLE 9-7

Pseudoinfections: Clinical and Epidemiological Considerations

- *Specimen contamination*
  - Isolate *unrelated* to clinical infection due to blood specimen contamination by skin flora during blood collection (e.g., CoNS culture from blood in a patient with CAP)
- *Colonization vs. infection*
  - Isolate is a *potential* pathogen (at the site cultured) but *no clinical signs of* infection (e.g., *Staphylococcus aureus* cultured from nonpurulent wound [serous/serosanguineous drainage])
- *Possible outbreak*
  - Cluster of same microorganisms cultured from the same site in multiple patients
- *Possible pseudoinfection/pseudo-outbreak*
- Culture of a *usual microorganism from an unusual body site* (for the isolate) (e.g., *Streptococcus pneumoniae* from urine in a patient with a UTI)
- Culture of *an unusual microorganism recovered from a usual body site* (for the isolate) (e.g., *Hafnia alvei* from sputum in a patient with pneumonia)
- *Outbreak pseudoinfection/pseudo-outbreak*
  - The patient's clinical presentation is *concordant* with isolate's typical manifestations (at body site cultured) (e.g., *Serratia marcescens* in blood cultures from multiple patients)
  - Investigate epidemiological aspects and potential common denominators
  - There is a *discrepancy* between the patient's clinical presentation and the isolate's usual clinical manifestations (at the body site cultured) (e.g., *Bacillus cereus* cultured from the CSF)
  - Investigate potential common sources of specimen contamination

UTI, urinary tract infection; CoNS, *Staphylococcus epidermidis*/coagulase negative staphylococci; CAP, community-acquired pneumonia.

TABLE 9-8

Pseudobacteremia: The Clinical Approach

Bacteremia	***Pseudobacteremia***
• Fever/chills	• Fever/chills (if present) *may* be due to ◦ Another infection ◦ Noninfectious disorder ◦ Antipyretic therapy
• Differentiate positive blood cultures from bacteremia	• *Exclude* blood culture (skin flora) contaminants
• *High-grade (2/4–4/4) blood culture* positivity usually indicates bacteremia[a]	• Isolate is *unusual* regardless of site cultured
• *Low-grade blood culture* positivity (e.g., blood cultures with skin flora, e.g., staphylococci (1/4–1/2), *usually not* indicative of bacteremia[a])	• Isolate is *not unusual* but site is *unusual* • There is *discordance* between the patient's *clinical findings* and the isolate's usual manifestations (*at the site cultured*) (e.g., *Pseudomonas fluorescens* bacteremia in a patient with pneumonia[b])

[a]With certain microorganisms (e.g., *Brucella*, *Listeria*), a single positive blood culture is indicative of bacteremia.
[b]*Pseudomonas fluorescens* is not a cause of either community-acquired pneumonia or healthcare-associated pneumonia.

TABLE 9-9

Pseudobacteremia: Epidemiologic Investigation

Potential Sources	*Investigative Approach*	*Items to Culture*
• Skin disinfectants	• Try to find other contaminated lots with the same microorganism as the one involved in the outbreak	• Culture unused disinfectant fluids from lots involved in the outbreak looking for same microorganism cultured from the blood
• Vacutainers, syringes, or needles	• Look for potentially contaminated lots with the same microorganism involved in the outbreak	• Culture unused disposable syringes (inside lumen and plunger) vacutainer threads where needle is attached, and needle hubs involved in the outbreak looking for same microorganism cultured from the blood
• Intravenous fluids	• Look for turbidity in the infusate (turbidity may not be present). Determine which unused IV infusion solutions (bottles/bags) are involved in outbreak	• Culture infusate from bottles/bags of lots involved in the outbreak looking for same microorganism cultured from the blood
• Intravenous tubing/connectors/ filters and disposable IV devices (reused)	• Look for cracks/breaks in equipment (may be gross/microscopic). Collect reused disposable devices (e.g., pressure transducer domes for culture). Culture entry and exit ports and any removable parts	• Culture filters and interior of reused disposable devices involved in the outbreak looking for same microorganism cultured from the blood
• Blood culture autoanalyzers	• Check temperature of injecting needle; assess nearness to open window/ vents. Correlate work shifts with time of culture positivity to determine possible link between events and personnel. Inquire about technician activities/habits during shifts when positive cultures were processed	• Check temperature of injecting needle after heating; when cooled, culture needle tip for same microorganism cultured from the blood • Culture tops of rubber caps/gaskets of blood culture bottles before applying antiseptic to rubber caps/gaskets looking for same microorganism cultured from the blood • Culture transport/culture media from lots involved in outbreak looking for same microorganism cultured from the blood

CONCLUSION

Pseudoinfections probably occur more commonly than they are reported. IPs should undertake appropriate epidemiologic investigations when a potential pseudoinfection is suspected to try and determine the source of contamination during the process of specimen collection and processing. Pseudoinfections should be reported in the literature since reports may provide vital information to guide investigative efforts to determine the source and mechanism of microbial contamination. The early recognition of pseudoinfection is also important to avoid the needless expense and potential complications of unnecessary empiric antibiotic therapy.

SECTION II
Healthcare Quality Improvement

CHAPTER 10

Creating a Culture of Excellence

Ulises Ruiz and José Simón

This chapter examines how the existing systems of healthcare fall short of what their quality should be, what the evolution of the concept of quality in healthcare has been. It also outlines what approaches are available for creating a culture of excellence that allows for improvement of the quality of care, patient safety, and risk management, through a renewed management approach focusing on the patient as primary customer. The existing challenges for creating a new culture and implementing new approaches are discussed. Integration of approaches for a comprehensive journey toward excellence is advocated.

THE NEED TO IMPROVE THE HEALTH SYSTEM MANAGEMENT FOCUS ON PATIENT SAFETY

There is evidence of an ever-increasing incidence of adverse events in healthcare delivery in many countries. The facts show an alarming reality.

A 1991 Harvard study in the United States found that 4% of patients suffer some kind of harm in hospital: 14% of the incidents lead to death and 70% of the adverse events result in short-lived disability.

In Europe, an "Atlas of Avoidable Death 1985–1989" following healthcare services intervention, carried out by the European Community Working Group on Health Services, was published in 1997. The atlas counts the existing *cases of "unnecessary disease and disability and unnecessary untimely deaths" as measures of the quality of medical care. An excessive number of such unnecessary events was taken as a warning signal of possible shortcomings in the healthcare system which warranted further investigation (1).*

In the year 2000, the Hospitals for Europe Working Party on Quality of Care found 10% of adverse events as a result of hospital admissions.

In its *The World Health Report 2000, Health Systems: Improving Performance,* WHO analyzes the deficiencies of health systems around the world and when dealing with *The Potential to Improve* it states that: *This report finds that many countries are falling short of their potential….There are serious shortcomings in the performance of one or more functions in virtually all countries (2).*

Along this line, the scientific literature has shown the existence of so-called medical errors and how they can be prevented. A large study found that adverse events occurred in 3.7% of hospitalizations, leading to death in 13.6%. Over half of these adverse events resulted from errors that could have been prevented *(3,4).*

Basic considerations about errors in medicine, comparison of the aviation model to the medical model, and offering system changes to be implemented following the Total Quality Management approach can be found in Leape's Special Communication: *Error in Medicine* (5). The number of deaths associated with adverse events was also quantified *(6).*

Facing the problem, the Institute of Medicine (IoM) sponsored a National Roundtable on Health Care Quality, which stated among its conclusions that: .. *Serious and widespread problems exist throughout American medicine. … Very large numbers of Americans are harmed as a direct result. Current efforts to improve will not succeed unless we undertake a major, systematic effort to overhaul how to deliver healthcare*

services, educate and train clinicians, and assess and improve quality (7). Similar findings about the gaps in US healthcare were published as a Final Report to the President *(8)*.

These findings about patient safety in US medical care prompted the IoM to examine this issue through a Committee on Quality in Health Care in America, which released its landmark report *To Err is Human: Building a Safer Health System* in November 1999, establishing for the first time the results of an in-depth study that names medical errors as the nation's leading cause of death and injury. The report indicates that medical errors kill more than 44,000 people in US hospitals each year, which is more deaths than from motor vehicle accidents [43,458], breast cancer [42,297], or AIDS [16,516], and the total national costs of preventable adverse events are estimated between $17 billion and $29 billion.

The IoM report states in its conclusions that the current rates of injury from care are inherent properties of current system designs rather than poor performance by individual providers and that safer care will require new designs, outlining a four-pronged approach to prevent medical mistakes and improve patient safety (9).

Following a direction by the U.S. Presidency, the Quality Interagency Coordination Task Force (QuIC) developed the report *Doing what counts for patient safety: Federal actions to reduce medical errors and their impact*, stating the strategy of identifying prevalent threats to patient safety and reducing medical errors. It provided an action plan to implement the administration's initiative designed to help prevent mistakes in the Nation's healthcare delivery system *(10)*.

A second report of the IoM's Committee on Quality in Health Care in America, *Crossing the Quality Chasm: A New Health System for the 21st century*, addressing additional quality problems focuses on how the healthcare delivery system as a whole can be designed to innovate and improve care in all its quality dimensions for all Americans, considering a basic premise: *The purpose of the healthcare system is to reduce continually the burden of illness, injury* and *disability, and to improve the health status and function of the people of the United States*.

The Committee proposed six aims for improvement: (a) safety, (b) effectiveness, (c) patient centeredness, (d) timeliness, (e) efficiency, and (f) equity. However in assessing the capacity of today's US healthcare system to achieve these six aims, the Committee considers that: *In its current form, habits and environment, American health care is incapable of providing the public with the quality health care it expects and deserves*. It also states that *The current care systems cannot do the job. Trying harder will not work. Changing the system of care will* (11).

Studies conducted in the past decade in several countries discovered the magnitude of such problems in developed countries. The percentage of adverse events attributed to hospital admissions is similar in the different countries: Australia 16.6%, Britain 10.8%, Canada 7.5%, Japan 11%, Denmark 9%, New Zealand 12.9%, and Spain 9.3%.

Consequently, patient safety has become a global issue, much of which is being aimed at designing new approaches for improving healthcare systems worldwide: IoM (USA) report of the Quality Interagency Coordination, to the president, February 2004, WHO: the International Alliance for Patient Safety launched in October 2004, European Union: patient safety as a specific theme within the UK's and Luxembourg's 2005 EU Presidencies, and a *Patient Safety Summit* in November 2005.

All around the world, the performance of healthcare systems is being questioned and approaches to improve their design and performance have recently been directed outside the health sector. This is so, even though traditionally the authority to define and interpret the meaning of healthcare practice has been located solely within the healthcare professions where, for a long time, the know-how of other industrial and service sectors has been considered not applicable.

QUALITY OF CARE—A LASTING ISSUE IN HEALTHCARE

Historically, quality of care has been a major concern for leading healthcare givers. In the Hammurabi code (2000 BC), the physician causing the death of a wounded warrior would have the fingers of his hand amputated. The Hippocratic Oath (IV c.b.c) established standards for medical ethics. In the Middle Ages, throughout Europe physicians and surgeons were organized as guilds and needed recognition to act as such. In the United States, authorization to practice medicine appeared in 1760 and the first medical association, the Medical College, was founded in 1787.

In the modern ages, Florence Nightingale's observations for improving the quality of care in military hospitals during the Croatian war in the 1860s, where varied outcomes puzzled her, are the first attempt for improving hospital care.

The Flexner report in 1910 established standards for medical education, and Codman, a surgeon at Massachusetts General Hospital, introduced the concept of End Result Follow-Up in the decade of 1910. The American College of Surgeons was funded in 1913 to translate Codman's idea into a Minimum Standard for Surgical care and established a Hospital Standardization Program by 1917.

The Joint Commision on Accreditation of Hospitals originated out of this program in 1951, now known as the Joint Commission (TJC), which revised, expanded, and updated the previously established American College of Surgeons standards of care in hospitals.

In the 1960s, both Donabedian and Williamson introduced each in their own way, approaches in healthcare similar to those used in industry for product quality assurance.

Avedis Donabedian established a common denominator framework for both explicit and implicit inspection, defining structure, process, and outcome for care *(12)*. In the early seventies, researchers started investigating the reasons for the large variation found in the process of care among the practitioners, the hospitals, and the geographical regions *(13)*. In the late seventies, research by the Rand Corporation established an experimental design for evaluating the effect of different healthcare insurances on the processes and outcomes of care *(14,15)*.

Also in the sixties, John W. Williamson introduced his *Health Accounting* approach. Unfortunately, it was not well known and not recognized as a valid approach to managing quality in healthcare.

Aware of these changes, the Joint Commission changed its policy and its approach through the Agenda for Change in 1986, establishing criteria beyond the Donabedian framework and looking for the effects of healthcare on the customers *(16)*.

In the early 1980s, a European Community (EC) Concerted Action Project on Health Services and "Avoidable Deaths" initiated research on results from a series of conditions for which mortality is considered largely avoidable, given timely and appropriate medical intervention.

More recently, using developed information systems, data bases have been established where individual professionals and healthcare organizations can search for resources utilization and adherence to care protocols. Reaction of professionals to these data has been mixed. A successful use of this kind of information system has been reported by Wennberg *(17)*.

It is noteworthy to mention that all these key issues are a common rallying point in modern quality improvement approaches and are being considered as such in the so-called Excellence Models (Baldrige and EFQM) and more recently in the 2008 version of ISO 9000.

TJC is applying the same key issues in its approach, but differs in the methodology and tools applied implementing it as organizational criteria. Paul M. Schyve, Senior Vice President, TJC states: "Successful mechanisms are also likely to provide more detailed information about performance … while creating evaluation processes … through incorporating aspects of the Baldrige and EFQM approaches … likely to create a special focus on the safety of care, incorporating aspects of the ISO 9000 approach to quality management" (18).

For the past two decades, the industrial and service sectors have been looking for new managing paradigms in order to improve their performance, and their methods and techniques are being increasingly translated and used in the health sector. At present, patient safety and risk management are the priority issues for all these approaches.

HEALTH PROFESSIONAL, QUALITY OF CARE, AND ORGANIZATIONAL QUALITY

In the past, errors in medicine were considered the responsibility of caregivers rather than addressing underlying system design faults. The blame and punish approach to errors has been prevalent and still is being considered valid in many health systems, services, and organizations. Licenses are lost and health professionals are sued for error-induced injuries. Yet only rarely are these so-called medical errors due uniquely to the carelessness or inappropriate conduct of an individual health professional.

In the health services sector, services provided by healthcare professionals to individuals are central to the professional responsibility of the staff in the provision of care/service. However, responsibility for care and responsibility for running the organization should be clearly differentiated, as well as the dual role of physicians when they are both care givers and administrators of their own clinical service as a unit of the whole organization. Thus, the traditional professional bureaucracy approach currently employed by most hospitals in the developed world is shifting to focusing on organizing rather than on organizational structures.

However, the traditional hospital's dual authority structure may represent a source of tension, stemming from a difference in cultural perspectives between hospital administration and medical staff.

The administrative arm of a hospital is built upon a bureaucratic structure and is therefore more mechanistic in nature, encouraging conformity and efficiency through standardized rules and regulations. The administrator's allegiance is to organizational goals and he/she prefers a proactive approach and long-term goal setting *(19–21)*.

The medical profession, on the other hand, is founded on collegiality. It thrives on clinical autonomy and self-regulation, adopting a more reactive, independent problem-solving approach, with a preference for immediate outcomes. The medical staff possess a strong allegiance to their patients and their profession. Their orientation is more technical in that it is rooted in the natural sciences. As a result, the medical culture has historically tended to resist administrative constraints *(19–21)*.

There is a need to break down the traditional boundaries that separate physicians, hospital administrators, pharmacists, technicians, and nurses by shifting away from a culture of blame and by working together to systematically design safer, more effective, and efficient systems.

Today's healthcare centers and services are complex organizations where the work of each professional is part of a system that has to be constantly in perfect running condition, ensuring an efficient, effective, and safe operation for the benefit and safety of the patient who enters such a system, looking for care (22).

Healthcare professionals, both caregivers and administrators, have been confronted for two decades with a most perplexing issue on how to improve the quality of the healthcare system without losing traditional roles and responsibilities *(23–25)*, while facing an increasing recognition that healthcare providers have to respond to the preferences and values of the patients as their customers *(26,27)*.

As a result, two different perspectives for quality issues in healthcare, currently considered complementary, developed. First was the classical Quality Assurance approach cherished by healthcare providers *(28)* and second, the more recent approach of Total Quality Management imported from the industry and service sectors *(29)*. The healthcare organization continuous quality improvement trade off (CQI) reconciles both approaches through participation and active commitment of both managers and caregivers in the search of quality (22,*30*).

The service perspective for health systems as a nuclear concept for CQI has been, for the past decade, the focus of extensive quality research studies *(31)*. Factors such as customer satisfaction *(32,33)*, return behavior *(34)*, recommendations to others *(35)*, choice behavior *(36)*, and interactions with employees *(37)* have been considered when analyzing quality in health systems.

In the health sector today, approaches such as Quality Control (QC), Quality Assurance (QA), Business Process Reengineering (BPR), Continual Quality Improvement (CQI), Total Quality Management (TQM), and tools/techniques such as ISO 9000:2000, Six Sigma, and Balanced

Scorecard (BSC) are complementary methodologies to achieve what is considered Organizational Excellence as per models such as the Baldrige model in the United States, the EFQM model in Europe, and the Deming model in Japan.

Presently, it is recognized that assuring the quality, safety, and social justice of the care provided to patient-customers is a requirement for both public and private health services, beyond the basic public health measures. Therefore, a new healthcare system has to be designed for the 21st century (11,*38*), recognizing that criteria set in some of the oldest European public health services are also falling short of their expectations.

This urgent call to action for healthcare entities to reengineer their work processes, placing safety as a paramount institutional objective, requires a marked change in healthcare sector thinking, since no substantive enduring changes can be made without successfully remaking the existing organization's culture and reshaping the way members think, behave, and approach their work *(39,40)*.

Culture and Organizational Change

Recognition is growing among healthcare leaders of the need for a culture change within their organizations. Culture change is not a program with a completion date, nor is it a quick fix. It is an ongoing journey—a journey that requires leaders to understand the current state of the organization, establish a clear vision, align behaviors, and instill accountability.

Organizational culture is considered as a manifestation of internalized assumptions or "taken-for-granted" understandings that are shared by an organization's members on such matters as the interactions between humans, institutions, and their environment; therefore, members must find meaning in their professional and personal existence *(21)*. These assumptions are expressed through the values, beliefs, attitudes, behaviors, language, customs, goals, policies, and operations of an organization *(39,41)*.

Historically, in the healthcare sector, a "safety" culture has been one that integrates the Hippocratic maxim of "first do no harm" into the very fiber of its identity, infuses it into the norms and operations of an entire organization, and elevates it to the level of a top priority mission enshrined in formal corporate statements as a guiding principle that governs the work and is applied to its day-to-day practices.

Even though the "patient safety movement" is now clearly underway as generally accepted, "Improved safety must be our specific, declared, and serious aim, beginning at the top of our organizations" (42). It has to be emphasized that culture is at the very heart of an organization and plays a key role in helping organizations respond to the many challenges they now face when searching for a culture of safety as an organizational priority *(43–45)*. Specifically referring to the historical healthcare institutions accreditation culture, safety initiatives cannot be viewed just as a means of complying with yet another external mandate, but must be perceived by the entire membership as being integral to the organization's mission and vision.

Safety must be the dominant characteristic of all high-risk industries, including healthcare. The manner in which a healthcare organization balances the issue of safety with other organizational priorities will shift its culture toward or away from a safety orientation. Safety cannot be treated as an adjunct to the strategic decision-making process. As a general concept, a safety culture is what emerges as a result of a concerted organizational effort to move all cultural elements toward the goal of safety, including an organization's members, its systems, and work activities; it must be front and center and implemented at all levels of the organization *(46,47)*.

To this end, the organization must set safety goals and objectives that apply across the institution and down to the departmental level. Patient safety issues should appear as regular agenda items for discussion and implementation at all levels of the organization in order for safety to be sustained as a priority. Given the sweeping changes that will be necessary to bring about organizational safety in healthcare institutions, now more than ever, good leadership from both clinical and nonclinical arenas is an essential prerequisite to transforming an organization's culture. According to experts in the field of organizational change, no substantive transformations will take place within an organization without the skill, visible commitment, and guiding example of a recognized leadership. Effective leadership sets the expectation and tone for an organization by articulating the institutional vision through empowering messages and by reinforcing "doing the right thing" as a corporate priority *(45)*.

However, healthcare organizations have unique structures and are subject to societal expectations that must be accommodated within an organizational value system. But actually, they share many common challenges and objectives with large corporations in the industrial and service sectors. They all hire people with goals and ambitions, and with expectations as to how they will be treated, accepted, rewarded, and promoted.

All too often, however, employee expectations and those of the organization are not fully aligned. This may be true despite what the organization professes as its objectives. For employees, it is the culture of the organization that is the reality, not the mission statement that hangs on the wall.

Leaders must redefine the meaning of shared responsibility and accountability. Organizational cultures and the training and socialization of the numerous professional groups in healthcare also add to the considerable heterogeneity of value systems within healthcare organizations. These contribute to another challenge confronting healthcare managers—competing or conflicting values within a unit or the entire organization.

Four key elements of values-based leadership are required for healthcare managers who seek to develop as values-based leaders: (a) recognize your personal and professional values; (b) determine what you expect from the larger organization and what you can implement within your sphere of influence; (c) understand and incorporate the values of internal stakeholders; and (d) commit to values-based leadership.

A culture that is quality and safety oriented is characterized by a strong, broad-based working alliance that shares ownership of the organization's vision. The alliance is strengthened by the collaboration of "centers of power" within the organization, represented by critical segments of the hierarchy, including executive and medical staff.

The greater the solidarity and sense of ownership across the organization, the greater the willingness to

share responsibility and accountability for achieving the vision of safety *(48)*.

Everybody in the organization has a task, and all tasks can be considered as being a "process"; "process thinking" defines the new management paradigm.

Process Thinking

Modern health services constitute integrated processes. Care is delivered through core processes that follow the patient from the time of referral/request until after the discharge, including follow-up. Core processes, however, depend on a number of vital inputs in the form of supporting processes. Furthermore, achieving an integrated process approach is critical for assuring efficient healthcare risk management.

The identification of processes, their interaction, and their control and applying a system of processes within an organization are referred to as "the process approach."

A process is a unique combination of people, tools, methods, and materials that add value to an input to attain an output in goods and services.

Regardless of what their end products or services are, the concept of "process" can be applied to each and everyone.

When used within a quality management system, such an approach emphasizes the importance of:

1. Understanding and meeting requirements
2. The need to consider processes in terms of added value
3. Obtaining results from process performance and effectiveness
4. Continual improvement of processes based on objective measurement

Tasks (processes) link together to form systems that are aimed at achieving an end goal whose quality is prescribed in specified requirements and the goal of customer satisfaction. An individual task will have its own set of specified requirements to satisfy. Every task can be analyzed into the constituent elements that it needs or supplies.

The quality of task output depends as much on the quality of the inputs received at the workplace as it does on how well the task is actually performed or, as one might say, how well the process is system controlled. This basic fact has often been forgotten and people have been blamed for results not within their control.

In order to function effectively and efficiently, an organization has to identify and manage different linked activities where the output from one process becomes the input to another one.

The application of a system of processes within an organization, together with the identification and interactions of these processes, and their management, referred to as the "process approach" is the required foundation for establishing a quality management system.

Quality Management Systems

Quality management systems are the basis for the successful operation of an organization; it allows for systems control and systematic management, and process thinking is the nuclear concept for assuring its implementation.

The concept of a quality management system in healthcare emerged in the last century as a new paradigm in the healthcare improvement arena, where concepts such as quality of care, adverse events, cost of care, cost management, customer satisfaction, patient empowerment, and evidence-based practice established a new glossary for healthcare professionals.

Therefore, in the health services sector, requirements for quality management have to be interpreted differently than in industry and other types of business for the following reasons:

- Healthcare services are characterized by the physical and mental involvement of the patient in the process of care provision. Thus, the provision of care is based on the continuous interaction between healthcare professionals (providers) and customers.
- The customer may have little knowledge of the professional aspects of the service delivered. The relationship between the patient and the professional is an unequal one considering the professional input; choices will be highly influenced by the professional.
- Commonly, the purchase and the receipt of health services are separated (so-called third-party payment). Thus, the provider may have to satisfy different quality demands from its two main customers: the patient and the purchaser.
- Healthcare services are characterized by complexities such as relations and interactions between patients, healthcare professionals, health suppliers, insurers, industry, and governmental bodies. In addition, health services are subject to constant change introduced by evolving technologies.

Nevertheless, by the use of a quality management system, processes that are directly or indirectly related to the health services provided can be controlled to meet these requirements.

This new approach to healthcare management has required finding an acceptable methodology for measuring, assessing, and comparing organizational performance through valid standards and recognizing self-assessment and accreditation results, and has been, consequently, a high priority in technically developed countries *(49)*.

Even though the efficacy of quality management as a strategic orientation of the organization that impacts on the immediate and future performance and sustainable competitive advantage appears important, more data are still needed; the findings of a study on small and large hospitals in the United States has reinforced past anecdotal claims of success *(50)*.

Furthermore, the realization of total quality management in everyday practice required the availability of preexisting technologies, standards procedures, and numerical representations on where to anchor the new "customer"-oriented focus culture that confronts the traditional medico-scientific "patient" concept of quality healthcare (51).

Healthcare is more than a decade behind other high-risk industries in its attention to ensuring safety, and safety is the first critical step in improving quality of care considering management of risk a priority.

Patient safety has become a priority issue after the IoM report, and it appears that sectors such as that of aviation

can be a good benchmark for safety and risk management within the healthcare sector (52). It seems, therefore, that healthcare organizations can benefit from learning from other sectors that have implemented risk management in an integral approach toward a continuous improvement culture. Management of risk should be an integral part of any healthcare sector reform.

Risk Management in Healthcare

Traditionally, risk management in healthcare has been driven by insurance and litigation rather than the "holistic" approach that has evolved since the mid-1950s out of the manufacturing and insurance companies. This more formal approach to effective risk management is being accepted as a required management practice both in the private and public sectors and has led to the development of professional risk management associations in many countries *(53)*.

Increased interest in risk management in healthcare has developed since the 1960s when it originated in the United States, and spread to other English-speaking countries like the United Kingdom, Australia, and New Zealand. The growing recognition of the importance of a holistic risk management process has led to the development of generic standards for the healthcare sector in these countries and in some European countries *(54–56)*.

It has been generally accepted that health services is a high-risk business, and even though, at present, management of risk in health services is far behind other high-risk industries such as the aviation industry, management of risk should be considered an integral part of any health services management reform.

Unfortunately, in health services, even though risk is managed continuously, it is not yet managed as systematically as it could be, and therefore, all health services managers and staff should recognize the importance of effective risk management for becoming a modus operandi in any health service institution *(57)*.

Risk management follows a series of process steps, but it is also a system with a culture of consultation and communication. It requires a logical analysis of facts and data, and management structures so that the culture is understood and the process is followed *(58)*.

It also requires a proactive approach. In any system where safety is critical, as in health services, it is not acceptable to wait for loss before identifying the need for improvement. Risk management involves identifying potential problems in advance of the problem becoming critical. Risk should be managed continuously since all decisions involve risk of some kind or another.

The generic risk management process can be applied at all levels of an organization—strategic, operational, and tactical, and it involves the following steps *(59)*:

- *Identification of risks*, involves examining all sources of risk from the perspective of all stakeholders, both internal and external.
- *Analysis of risks*, in order to separate the minor acceptable risks from the major risks, and to provide data to assist in the evaluation and treatment of risks.
- *Evaluation of risks* requires comparing the level of risk found during the analysis process with previously established risk criteria, and establishing priorities for action.
- *Treatment of risks* considering acceptable and the nonacceptable risks.
- *Risk recovery* after an adverse event has occurred.
- *Continuous monitoring and review* are closing the loop steps essential for keeping the process updated.

Risk management should be an integral part of any health service system and should cover risk management activities related to patient care, personnel, documentation, data and communication, management, departmental procedures, and environment (60).

Besides taking accountability of the environment, risk management includes the realization of opportunities for introducing new approaches where a lack of action exposes the organization to unnecessary risks *(61)*.

Risk can arise from both internal and external sources and might include an adverse event during the care process, occurrence of an avoidable complication to the current health issue, occurrence of an avoidable side effect that is not categorized as an adverse event, failure of equipment, a threat to physical safety, a breach of security, a breach of legal or contractual responsibility, and fraud.

Therefore, management of risk and patient safety should be addressed at all levels of the healthcare institution, from the organization's top management to all the process owners. It includes the organization's CEO, the medical, nursing, general administration, and other directors, as well as the intermediate management, that is, heads of administration, clinical departments or services, and technical units.

Total Quality Management

It can be said that the successful implementation of this new quality management approach requires a conceptual break with the traditional interpretation of medical practice quality located solely within the medical profession. The total quality management approach involves every single component and every single person of the healthcare organization, that is, the totality of the organization. Everybody in the organization has a task, and all tasks can be considered as being a "process"; "process thinking" defines the new management paradigm.

Once the quality management systems are operating, the organization is managed according to the established requirements that are set from whatever managing approach the organization has chosen to follow.

OPTIONS FOR IMPROVING HEALTH SYSTEMS

Traditionally, healthcare organizations in the United States and other English-speaking countries have adopted an operating model based on an assessment approach that originated with the American College of Surgeons in 1917 and was further developed by the Joint Commission for Accreditation of Hospitals in 1954, today's JCAHO. Similar approaches for local accreditation of healthcare organizations have evolved in the UK and the Netherlands, and in some other European countries, as well as in Canada, Australia, and South Africa.

However, today there is a movement toward convergence of traditional approaches and managerial approaches for operating and assessing healthcare organizations. Their standardization and comparability within a country and among different countries are becoming a requirement for improving healthcare systems around the world. Political, commercial, and social forces also favor this convergence (18).

At present, healthcare organizations can follow several managing approaches and tools or methodologies that have been useful in industry and service sectors and have shown their promise when applied in the healthcare sector. We will consider the following:

- ISO International Standard for Quality Management ISO 9000:2000 series
- Baldrige National Quality Program: Criteria for Performance Excellence
- European Foundation for Quality Management Excellence Model
- Balanced Scorecard
- Six Sigma
- Lean Management
- Lean Six Sigma

ISO International Standard for Quality Management ISO 9000:2008 Series

Health services are increasingly becoming international markets. Over the past years, there has been a growing awareness that quality management systems may be applied to the health services sector to improve quality and safety, and ultimately promote public accountability for healthcare providers and policymakers.

National approaches vary, and different organizations may choose different methods and approaches to quality management. The ISO standards provide an international standardization framework for quality management systems and their evaluation.

Recognition of quality on the basis of commonly held standards facilitates mutual recognition between organizations. Consequently, there is a strong case for ISO compatibility with national quality management systems in the health services sector, especially in cross-border contracting situations.

The International Organization for Standardization

Established in the manufacturing and engineering industries after the Second World War, the ISO is a worldwide federation with members in 176 countries, and it has awarded over 982,832 international certificates (62).

The ISO has developed over 12,000 standards, of which the ISO 9000 series on quality assurance released in 1987 and revised in 1994 and 2000 has been seen as the most applicable to healthcare *(63)*.

The revised ISO 9000:2000 series, published in December 2000, moved its focus from quality assurance to quality management systems in convergence with the Excellence Models.

The ISO 9000:2000 series comprises a harmonized pair of standards, 9001 and 9004, with the same approach, structure, and vocabulary. ISO 9001:2000 establishes the criteria for certifying quality management systems in organizations, and ISO 9004:2000 offers guidelines for process improvement once quality management systems are operative.

The ISO 9000:2000 series *promotes the adoption of a process approach when developing, implementing and improving the effectiveness and efficiency of a quality management system to enhance interested party satisfaction by meeting interested party requirements (ISO 9001:2000, 0.2 Process approach)*.

The ISO 9001:2000 was revised in 2008 as ISO 9001:2008; ISO 9001:2008 was developed in order to introduce clarifications to the existing requirements of ISO 9001:2000 and to improve compatibility with ISO 14001:2004 (Environmental Management).

ISO 9001:2008 does not introduce additional requirements nor does it change the intent of the ISO 9001:2000 standard. ISO 9001:2008 is intended to be generic and applicable to all organizations, regardless of type, size and product category. It is recognized, however, that not all the requirements of this standard will necessarily be relevant to all organizations. Under certain circumstances, an organization may consider the exclusion of the application of some requirements of ISO 9001:2008 from its QMS. ISO 9001:2008 makes allowance for such situations, through subclause 1.2 Application (http://www.iso.org/iso/home.htm).

The model of a process-based quality management system shown in Figure 10-1 (Quality Management Process Model) illustrates the process linkages covering all the

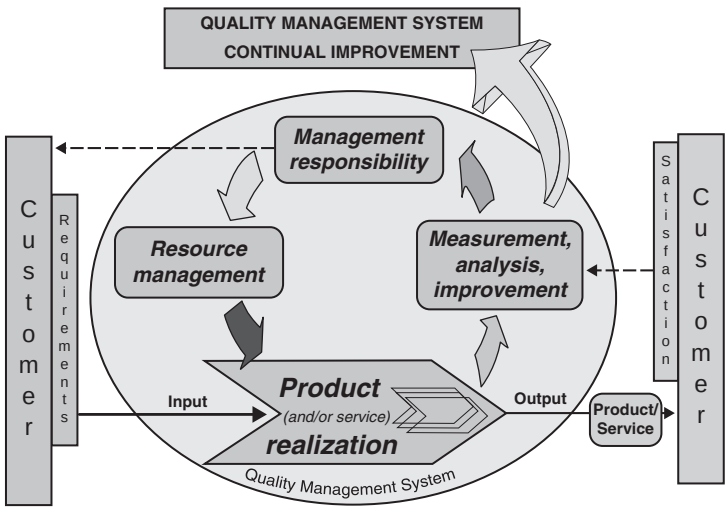

FIGURE 10-1 Quality Management Process Model. (Modified from ISO-9001:2008: Quality Management Systems Requirements, December 2008. http://www.iso.org/iso/home.htm.)

requirements established in the ISO 9000:2000 standard. This illustration shows that customers play a significant role in defining requirements as inputs. Monitoring customer satisfaction requires the evaluation of information relating to customer perception as to whether the organization has met the customer requirements.

ISO Guidelines for Healthcare Respected internationally as a credible system for addressing quality management issues, ISO 9000:2000 was written for industry, and so the language used is often inappropriate for healthcare services and can be confusing when healthcare personnel try to implement a quality system. The need for language clarification led to the US and EU initiatives described below.

USA: **IWA 1-The ISO-Industry Workshop Agreement 1, for Health Care, 2001** An *ISO 9004:2000 Guideline for process improvement in health service organizations* was published by ISO in September 2001 as IWA 1 (ISO's first Industry Workshop Agreement) to be used in defining the fundamentals of the healthcare organization's quality system and improvement methodology, not as a substitute for traditional accreditation (64).

The proposal for these guidelines was made jointly to ISO by the Healthcare Division of the American Society for Quality (ASQ-HCD) and the Automotive Industry Action Group (AIAG) representing the "Big Three" automotive companies: Ford, Chrysler, and General Motors.

The ASQ-HCD considered that the new series ISO 9000:2000, to be published in 2000, were easily applicable to the health sector as a way to implement quality management systems in healthcare organizations and improve the overall quality of care.

IWA 1 addresses the systems' deficiencies and the establishment of needed foundations for performance improvement in healthcare systems and organizations:

> *The goal of this document is to aid in the development or improvement of a fundamental quality management system for health service organizations that provides for continuous improvement, emphasizing error prevention, the reduction of variation and organizational waste, e.g. non-value added activities.*
>
> *(IWA 1 Introduction)*

These guidelines are not intended for use in third-party certification, although it could be used in the improvement of healthcare services through quality management systems in the health sector, certifiable to ISO 9001:2000.

EU: CEN/TS 15224:2005 (E) This *CEN/TS 15224-Guide for the use of EN ISO 9001:2000 in health services* has been published by CEN (European Committee for Standardization) in 2005 and was developed as a Technical Specification (TS) by a task force, CEN/BT/TF 142, of health experts including experienced physicians, nurses, and health administrators, representing different sectors and levels in the European health services sector.

Having identified the problem of language interpretation across many of the healthcare organizations across Europe that are implementing ISO 9001, the group brought together participants from the European Union to ensure the broadest range of experience, expertise, and engagement. The Swedish Standards Institute was nominated to chair the group.

The group's aims were to provide guidance for a more consistent approach to interpretation and consequently easier implementation of the ISO 9001 standard in healthcare, and to raise awareness among healthcare professionals of the importance of a systematic approach to quality management and how this can contribute to patient safety.

The guide provides an interpretation of each clause of the ISO standard intended to aid the healthcare professional when implementing a quality management system. The guide is not intended for certification purposes on its own.

This CEN/TS was limited initially to 3 years. In November 2007, the former task force decided to propose a revision of CEN/TS 15224, aiming at a Sector-specific standard as a European Norm (EN) to be developed by a Project Committee, CEN/Technical Committee 362 PC.

EU:CEN/TC 362 PC— *Healthcare Services—Quality Management Systems—Requirements Based on ISO 9001: 2008*

The task force, renamed CEN/TC 362 PC, agreed to produce a sector-specific standard, an EN, based on ISO 9001:2008 and EN/TS 15224:2005.

The requirements in this EN are based on ISO 9001:2008, with interpretations and specifications for healthcare organizations. The requirements have been modified according to the specific healthcare environment. New requirements have been added when considered relevant. This EN includes requirements related to clinical risk management but does not include requirements on environmental aspects according to ISO 14001.

> *This standard*
>
> *1. Gives requirements for systematic approaches for the organization's needs to produce health services with good quality*
>
> *2. Can be used by management on all levels in the health care organization, internal and external parties including certification bodies to assess the organization's ability to meet patients' needs and expectations*
>
> *3. Is applicable to all health care organizations regardless of structure, organization, owner, size or type of health service provided*

The EN will be ready for publication by the end of 2011.

US Malcolm Baldrige National Quality Program: Criteria for Performance Excellence

Created by the US Congress in 1987, the Malcolm Baldrige National Quality Award (MBNQA) criteria and processes (Fig. 10-2) are being reviewed every 2 years and improved so that they remain relevant and reflect current thinking.

The improvements made for the 1997 criteria are noteworthy. Improvements to the criteria's name, framework, wording, and rules have given them a new look, without changing their essence. Originally, the booklet describing the criteria was called Award Criteria; it is now called Criteria for Excellence.

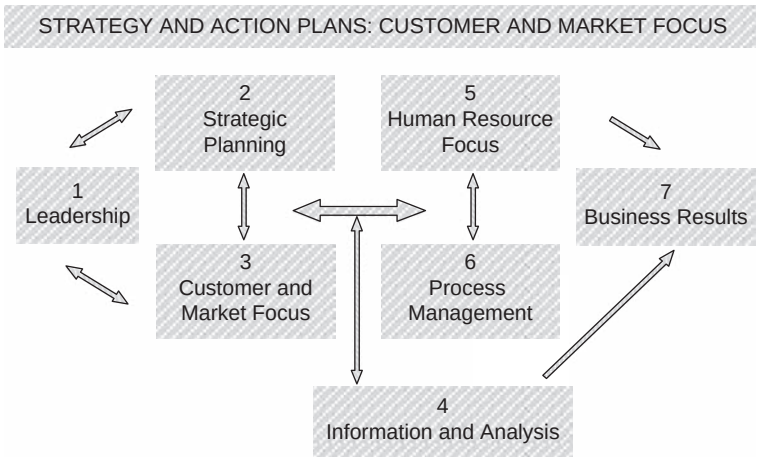

FIGURE 10-2 Malcolm Baldrige Excellence Model. (Redrawn from http://www.nist.gov/baldrige/publications/hc_criteria.cfm.)

The criteria are designed to help organizations use an aligned approach to organizational performance management that results in:

- *Delivery of ever-improving value to customers, contributing to marketplace success*
- *Improvement of overall organizational effectiveness and capabilities*
- *Organizational and personal learning*

The focus of the MBNQA is enhancing competitiveness. Its central purpose is educational; it should encourage the sharing of competitive learning and "drive" this learning, creating an evolving body of knowledge nationally. Its content reflects two key competitiveness thrusts:

1. Delivery of ever-improving value to customers
2. Systematic improvement of company operational performance

> *The criteria are built upon a set of interrelated core values and concepts. These values and concepts……. are embedded beliefs and behaviours found in high-performing organizations. They are the foundation for integrating key business requirements within a results-oriented framework that creates a basis for action and feedback (65).*

Overall, the MBNQA criteria provide an integrated, result-oriented framework for designing, implementing, and assessing a process for managing all operations.

For more than a decade, the healthcare community has been interested in applying the MBNQA criteria to healthcare. Its potential usefulness was advanced by Hertz and als *(66)*:

> *A Baldrige Award program in health care could facilitate and accelerate the extension of the knowledge base of important concepts and results measures for quality management and improvement and could greatly enhance the sharing of successful strategies.*

Since 1998, Baldrige Health Care Criteria have been available to healthcare organizations either to perform a self-assessment as an internal improvement effort or as the basis for an award application.

Self-assessment against all seven Categories of the Health Care Criteria allows the organization to identify strengths and to target opportunities for improving its processes and results.

Submitting an award application has other valuable benefits. Applicants receive a detailed feedback report based on an independent external assessment conducted by a panel of specially trained and recognized experts.

The framework of the Baldrige Business Criteria for Performance Excellence is adaptable to the requirements of all organizations including healthcare organizations. However, it is not assumed that these requirements are necessarily addressed in the same way.

The Baldrige Model in Health Care has been used in several healthcare organizations in the United States, and its implications have been discussed over the past decade.

Early experiences show that the Baldrige criteria can be used by healthcare organizations to conduct internal evaluations, resulting in improvement of the organization's effectiveness *(67,68)*. The Baldrige management framework was found to be useful for identification of areas of improvement and areas of achievement within a sample of VHA hospitals *(69)*.

Empirical evidence has been provided from 220 hospitals that the 19 dimensions of the Baldrige criteria lead hospitals to improvement on some dimensions of performance *(70)*.

Therefore, a specific way for addressing the Baldrige criteria has been developed as Health Care Criteria for Performance Excellence. This adaptation to healthcare is largely a translation of the language and basic concepts of business excellence to similarly important concepts in healthcare excellence.

According to the *2009–2010 Health Care Criteria for Performance Excellence:*

> *The Health Care Criteria for Performance Excellence have evolved significantly over time to help organizations address a dynamic environment, focus on strategy-driven performance, address concerns about governance and ethics, and, most recently, consider the key decisions driving both short-term success and long-term organizational sustainability.*

The Criteria have continually progressed toward a comprehensive, integrated systems perspective of overall organizational performance management

(http://www.baldrige.nist.gov/HealthCare_Criteria.htm).

Since 2002, the Malcolm Baldrige National Quality Award has been received by eight US healthcare institutions (http://www.baldrige.nist.gov/index.html).

EU EFQM Excellence Model

EFQM was founded in 1988 by presidents of 14 major Europeans companies, with the endorsement of the European Union. At present, more than 600 organizations all over Europe are involved. The main aim is to promote quality management through the external assessment of an award scheme (the European Quality Award and national awards, inspired by the example of the Baldrige Award in the United States). A reference model that could be used for self-assessment was established in 1989: the *European Foundation for Quality Management Excellence Model, 1989* (*www.efqm.org*).

The EFQM Excellence Model (Fig. 10-3) is the most widely used organizational framework in Europe and extends to global markets, reaching more than 30,000 organizations worldwide. Used as a tool for assessment, it delivers a picture of how well the organization compares to similar or very different kinds of organizations. Used as a management model, it can be used to define aspirations for the organization's capability and performance.

The EFQM Excellence model is a nonprescriptive framework for understanding the connections between what an organization does, and the results it is capable of achieving. It is used to structure a logical and systematic review of any organization, permitting comparisons to be made with a high-performing organization. It is also used to define what capabilities and resources are necessary in order to deliver the organization's strategic objectives. The model has its roots in the philosophy of total quality management and that recognizes that there are many approaches to achieving sustainable excellence.

The EFQM Model framework is structured on the following fundamental concepts:

- Customer focus
- Leadership and constancy of purpose
- Management by processes and facts
- People development and involvement
- Continuous learning, innovation, and improvement
- Partnership development
- Public responsibility

The premise on which the model is built is that excellent results with respect to performance, customers, people, and society are achieved through leadership driving policy and strategy, people, partnership, resources, and processes.

The enablers' dimensions ultimately lead organizations to excellent results: excellence in customer satisfaction, employee satisfaction, impact on society, and key performance results.

The EFQM Excellence Model is a practical tool to help organizations establish an appropriate management system and measure where they are in their path toward excellence, helping them to understand the gaps and then stimulating solutions.

The model has been revised periodically. The previous Excellence Model 2003 has recently been reviewed and revised to align the framework with current business needs and trends as the 2010 Model. All changes were presented at the EFQM Forum in September 2009 (http://ww1.efqm.org/en/EFQMForum2009/tabid/291/Default.aspx).

In the revised model, the emerging trends and topics that have more emphasis are "creativity and innovation," "sustainability," "corporate governance," "organizational agility," "risk management," "promoting products and services," and "supplier management.' Sustainability is now firmly on the agenda of management boards around the world. EFQM supports organizations in defining what sustainability means, providing approaches for its implementation and ensuring consistency between apparently conflicting responsibilities toward shareholders, employees, and society.

The model conceptualizes organizations by discerning five enablers' dimensions and four results dimensions in an operative structure.

Further information about the changes for the 2010 Model can be found through the Transition Guide at http://www.efqm.org/en/PdfResources/Transition_Guide.pdf.

In 1996, EFQM developed a specific guide for using the European Excellence Model in healthcare, but in 1999

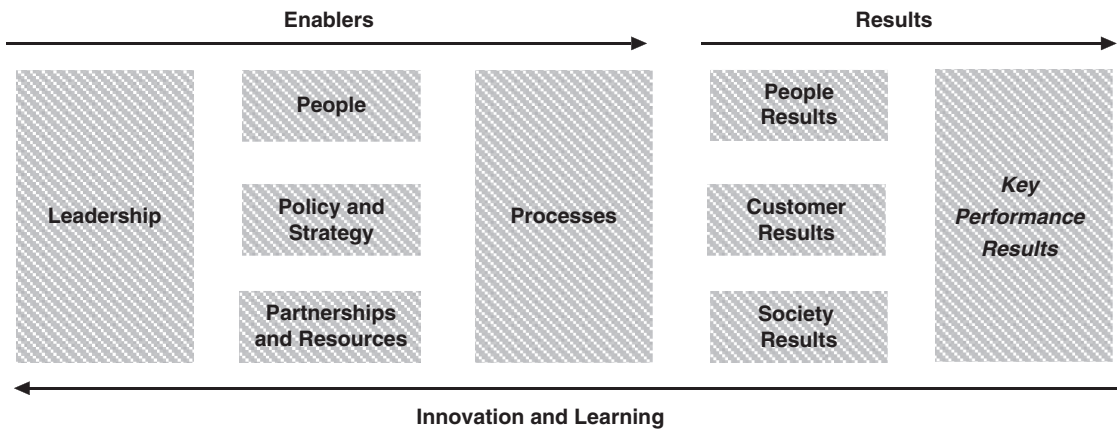

FIGURE 10-3 EFQM Excellence Model. (Redrawn from http://www.efqm.org/en/PdfResources/EFQM_Ex_Mod_Teaser.pdf)

the model was revised and a common framework is being applied to all sectors, industry as well as private and public service sectors, including healthcare.

Within the EFQM membership, there are about 40 members who are health practitioners, both from the public and the private sector communities, notably in Austria, the Netherlands, Spain, and Turkey among others, and there are a significant proportion of members who are linked in some way or other to the health sector.

The European Excellence Model is being used in healthcare organizations of different European countries (*71*,*72*,73,*74*,*75*).

Balanced Scorecard

The BSC, in combination with the Models of Excellence, is a useful tool to guide strategy development and implementation in healthcare organizations, bringing added value to the Total Quality Management approach (http://www.balancedscorecard.org/Home/tabid/36/Default.aspx).

The BSC (Fig. 10-4) is a framework proposed by Robert Kaplan and David Norton in 1992 to facilitate translation of strategy into action. It summarizes succinctly in a short document a set of leading and lagging performance indicators grouped into four different perspectives: financial, customer, internal processes, and learning and growth *(76–81)*.

The BSC has evolved from its early use as a simple performance measurement framework to a full strategic planning and management system. Kaplan and Norton describe the innovation of the BSC as follows:

> *"The balanced scorecard retains traditional financial measures. But financial measures tell the story of past events, an adequate story for industrial age companies for which investments in long-term capabilities and customer relationships were not critical for success. These financial measures are inadequate, however, for guiding and evaluating the journey that information age companies must make to create future value through investment in customers, suppliers, employees, processes, technology, and innovation."*

The BSC helps organizations translate strategy into operational objectives that drive both behavior and performance. It describes and helps implement and manage strategy at all levels of an organization by linking objectives, initiatives, and measures to that organization's strategy.

It is also a process that the organization uses to foster consensus, alignment, and commitment to the strategy by the management team and the people within the organization at large.

It provides an enterprise view of a healthcare organization's overall performance by integrating financial measures with other key performance indicators around customer (patient, physician, and payer) preferences, internal clinical and business processes, and personal learning, development, and growth (*82*,*83*,84).

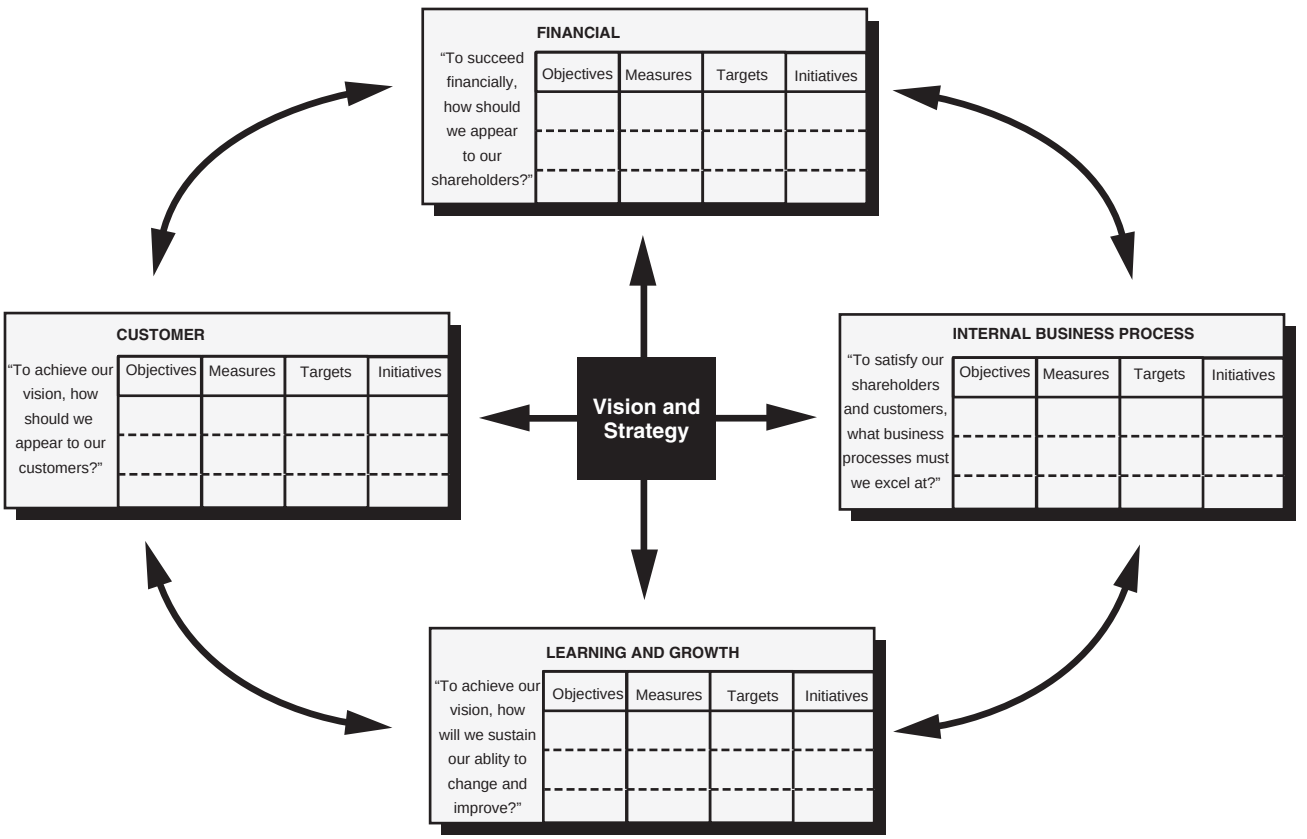

FIGURE 10-4 Balanced Scorecard framework. (Redrawn from Kaplan RS and Norton DP. "Linking the balanced scorecard to Strategy." *California Management Review*. 39/1 (Fall 1996): 53–79. ©1996, by The Regents of the University of California. Reprinted from the California Management Review, Vol. 39, No. 1. By permission of The Regents.)

A first Best Practices Conference on *Saving lives, saving money: and how healthcare organizations use the Balanced score card to achieve results* was held in Cambridge, Massachusetts, USA, in April 2002, and it focused on how healthcare organizations use the BSC to achieve results; it was organized by the Balanced Scorecard Collaborative (http://www.bscol.com).

The BSC is being used in healthcare institutions. It has been reported that the scorecard (a) is relevant to healthcare, but modification to reflect industry and organizational realities is necessary; (b) is used by a wide range of healthcare organizations; (c) has been extended to applications beyond that of strategic management; (d) has been modified to include perspectives, such as quality of care, outcomes, and access; (e) increases the need for valid, comprehensive, and timely information; and (f) has been used by two large-scale efforts across many healthcare organizations in a healthcare sector, which differ, namely, in the units of analysis, purposes, audiences, methods, data, and results (84).

Six Sigma

Six Sigma methodology was pioneered at Motorola Corporation in the 1980s. The methodology is based on rigorous statistical process control. It augments the traditional quality tools with exacting statistical analysis and a systematic problem-solving approach, targeting the root causes of variations, and redefining processes for long-term results. It strives to produce products and services with only 3.4 defects per million, meaning Six Sigma in statistical terms (http://www.isixsigma.com/).

Six Sigma can, thus, be considered a business quality improvement tool through improving process performance. It requires four steps, where data collection and analysis become the core of the Six Sigma projects. The Six Sigma methodology is known as DMAIC:

1. Define
2. Measure
3. Analyze
4. Improve
5. Control

It should be emphasized that Six Sigma is also a business culture approach, since the goal is to establish a culture of quality improvement at all levels of the organization by implementing improvement actions designed by specifically trained working teams.

In the healthcare sector, Six Sigma, as a philosophy seeking near-zero errors and being, somehow, an extension of failure mode and effect analysis, is ripe for its implementation by healthcare managers and practitioners concerned for patient safety and are already implementing a total quality management approach (*85*,*86*,87).

Six Sigma methodologies can help toward the abovementioned goals and can change the face of modern hospital and healthcare delivery systems. It can reduce variability and waste, translating to fewer errors; improve customer satisfaction; and provide better processes, greater patient satisfaction rates, and happier and more productive staff. The popularity of Six Sigma is growing in the healthcare industry.

At present, to reduce the errors and to move toward perfection, most of the hospitals are now pursuing Three Sigma or Four Sigma quality levels.

It is thought that the healthcare industry will not be able to achieve Six Sigma and should be aiming for Four or Five for most processes. However, Six Sigma is an achievable target for healthcare. There are multiple healthcare organizations that have currently achieved the Six Sigma level of performance, and certainly, it is not acceptable at many healthcare organizations to be at the Four to Five Sigma level, and they are striving to achieve the Six Sigma level of improvement. Errors in healthcare processes by sigma level are shown in Table 10-1 (Source: GE Healthcare).

Furthermore, figures in Table 10-2 illustrate that being 99% effective is just not good enough for appropriate patient safety in healthcare delivery.

Six Sigma is being increasingly used in healthcare (http://healthcare.isixsigma.com). Its use has been recently assessed through a national survey of Six Sigma programs in US healthcare organizations. The survey supplements the literature supporting the effectiveness of the Six Sigma methodology in healthcare (87).

Furthermore, a first 2-day conference on *Six Sigma for Health Care Providers* in San Francisco, in September 2001, up to the WCBF's 8th Annual Lean, Six Sigma and Process Improvement in Healthcare Summit in 2009 (www.wcbf.com/quality/5091) reflects the interest for this approach in healthcare.

TABLE 10-1

Errors in Healthcare Processes by Sigma Level[a]

Sigma Level	*Patients with Misplaced Personal Items*	*Coding Errors Requiring Correction*	*Phone Calls Exceeding the 2-min-on-Hold Limit*	*Defects/Million Opportunities*	*Percent Yield*
3 Sigma	3,660 every day	770/d	257 each day	66,800	93.32000
4 Sigma	340 every day	72/d	24 each day	6,210	99.34900
5 Sigma	12 every day	13/wk	5 each week	230	99.97700
6 Sigma	6 every month	10/y	3 each year	3.4	99.99966

[a]GE Healthcare.

TABLE 10-2

99% Error Free Is Not Enough for a Patient Safety Policy

3.8 Sigma: 99% Error Free	*6 Sigma: 99.99966 Error Free*
(10,700 error opportunities/ million)	(3.4 error opportunities/ million)
Wrong prescriptions 200,000/y	Wrong prescriptions 68/y
Incorrect surgery 5,000/wk	Incorrect surgery 1.7/wk
Wrong landing approach 2/d	Wrong landing approach 1/5 y

Lean Management

Similar to Six Sigma, the Lean approach focuses on process performance, making it possible to achieve dramatic improvements in cost, quality, and time. However, whereas Six Sigma is focused on reducing variation and improving process yield by following a problem-solving approach using statistical tools, Lean is primarily concerned with eliminating waste and improving flow by following the Lean principles and a defined approach to implement each of these principles.

Lean is a thinking process more than a simple to-do list of tools; the role of the leaders within the organization is the fundamental element of sustaining the progress of lean thinking. Lean thinking can be described as a closed loop, as shown in Figure 10-5.

The core idea of lean involves determining the value of any given process by distinguishing value-added steps from non–value-added steps, and eliminating waste (or *muda* in Japanese) so that ultimately every step adds value to the process.

Many of the key principles were pioneered by Henry Ford, under the termed "flow production." Following World War II, the Toyota Motor Company adapted Ford's principles as a means of compensating for its challenge of limited human, financial, and material resources. They, therefore, revisited Ford's original thinking and invented the Toyota Production System (TPS), which was one of the first managerial systems using these principles throughout the enterprise to produce a wide variety of products at lower volumes and with many fewer defects than its competitors.

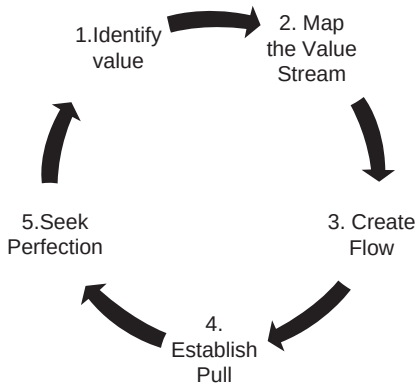

FIGURE 10-5 Lean thinking. (Redrawn from http://www.lean.org/WhatsLean/Principles.cfm.)

For Toyota, TPS was not just a production system; it was also a business system, incorporating all aspects of bringing a product to market, including design, supplier management, production, and sale. As such, it means organizing and managing product development, operations, suppliers, and customer relations using principles, practices, and tools to create precise customer value—goods and services with higher quality and fewer defects—with less human effort, less space, less capital, and less time than the traditional system of mass production.

The basic principles of TPS development have been:

- Add nothing but value (eliminate waste)
- Center on the people who add value
- Flow value from demand (delay commitment)
- Optimize across organizations

Much of the TPS way of thinking is based on the work of W. Edwards Deming, his philosophy of Total Quality Management and his interpretation of the original Shewhart *control chart*. He taught, among other things, that managers should stop depending on mass inspection to achieve quality and, instead, focus on improving the production process and building quality into the product in the first place.

The term *Lean* was first coined in 1988 at the MIT Sloan School of Management and the thought process of Lean was described by Daniel T. Jones, James P. Womack, Daniel Roos, and members of the International Motor Vehicle Program at MIT (*88*). In a subsequent publication *Lean Thinking*, James P. Womack and Daniel T. Jones described what are considered the five Lean principles *(89)*.

The five-step thought process for guiding the implementation of Lean techniques is easy to remember, but not always easy to achieve (http://www.lean.org/):

1. Specify value from the standpoint of the end customer by product family.
2. Identify all the steps in the value stream for each product family, eliminating, whenever possible, the steps that do not create value.
3. Make the value-creating steps occur in tight sequence so the product will flow smoothly toward the customer.
4. As flow is introduced, let customers pull value from the next upstream activity.
5. As value is specified, value streams are identified, wasted steps are removed, and flow and pull are introduced, and then begin the process again and continue.

The Lean methodology has a bias for action to rapidly improve processes and drive results and is used to accelerate the velocity and reduce the cost of any process (be it service or manufacturing) by removing waste.

Lean implementation is therefore focused on getting the right things, to the right place, at the right time, and in the right quantity to achieve perfect work flow while minimizing waste and being flexible and able to change.

Lean methodology is founded on a mathematical approach known as Little's Law:

$$\text{Lead time of any process} = \frac{\text{Quantity of things in process}}{\text{Average completion rate / unit of time}}$$

The lead time is the amount of time taken from the entry of work into a process (which may consist of many

activities) to the time the work exits the process. Lean contains a well-defined set of tools that are used to control and then reduce the number of things in process, thus eliminating the non–value-added cost driven by those things in process. Lean also contains tools to reduce the quantity of things in process.

Lean Healthcare System Leaders today in a wide range of industries, nonprofit organizations, government agencies, healthcare, and other areas are finding ways to apply the principles of Lean as a means of producing goods and delivering services that creates value for the customer with the minimum amount of waste and the maximum degree of quality.

Lean thinking is not typically associated with healthcare, where waste—of time, money, supplies, and good will—is a common problem. But the principles of Lean management can, in fact, work in healthcare in much the same way as they do in other industries *(90)*.

Proper implementation of the five simple Lean tools and techniques—5 Whys, 5S, Kanban, Visual Controls, and Standard Work—can help any organization launch its Lean transformation.

Hospitals cannot continue to operate as they have in the past. Some hospitals started experimenting with Lean methods in the 1990s and, at present, there are many examples of the positive impact Lean is having in hospitals throughout the world reflected in diverse worldwide networks such as, among others, *Australasian Lean Healthcare Network; Agency for Healthcare Research and Quality Innovations Exchange; Institute for Healthcare Improvement; NHS Confederation; Lean Enterprise Institute, United States;* and *Lean Enterprise Academy, United Kingdom*.

To maximize value and eliminate waste, leaders in healthcare must evaluate processes by accurately specifying the value desired by the user; identifying every step in the process (or "value stream") and eliminating non–value-added steps; and making value flow from beginning to end based on the pull—the expressed needs—of the customer/patient *(90)*.

By reducing the percentage of non–value-added work and thereby increasing the percentage of value-added work through a Lean transformation, hospital quality levels can improve significantly, and huge cost savings can be realized. Cost savings can then be redistributed to other QI initiatives. By concentrating efforts on identifying, acknowledging, and eliminating non–value-added work or waste, hospitals can realize their most fundamental goal of providing superior quality healthcare to their patients *(91)*.

It follows to redesign the patient journeys through their hospital. The results include eliminating unnecessary waits for patients, a drastic reduction in length of stay, no longer wasting staff time, freeing up emergency and elective capacity, and slashing the overtime and agency burden. Focusing on the patient journey and effectively synchronizing all the support activities also provide the essential context for delivering higher quality and safer care for patients (*92*,*93*,94,*95*).

It has to be emphasized that Lean Thinking in healthcare is neither about cost, nor about "efficiency" or staff cuts; it is about improving the safety and quality of healthcare by applying a series of continuous incremental improvements. Therefore, a hospital's Lean transformation cannot be an overnight success story, as changing old mindsets and organizational cultures takes time.

Lean Six Sigma

A combination of Lean and Six Sigma has synergy and creates a win–win situation. Both approaches require a process focus, and both include customer drivers, either to define what needs to be improved (Six Sigma) or to define value (which then drives process improvement).

Lean seeks to improve flow in the value stream and eliminate waste, doing things quickly. Six Sigma uses the DMAIC framework and statistical tools searching root causes to understand and reduce variation. It is about doing things error free.

A combination of both provides an over-arching improvement approach incorporating powerful data-driven tools to solve problems and achieve rapid process improvement with added value at lower cost. Potentially, this could increase productivity, improve quality, reduce costs, improve speed, create a safer environment for patients and staff, and exceed customer expectations *(96)*.

The key is to find the optimal combination of both approaches, adopting the Lean idea of focusing on what adds value and then using Six Sigma tools to help understand and reduce variation when the value stream is established.

The philosophy of Lean provides the strategy and creates the environment for improving flow and eliminating waste. Six Sigma helps to quantify problems, makes evidence-based decisions (this prevents wasting time on anecdotal evidence), helps to understand and reduce variation, and identifies root causes of variation to find sustainable solutions.

The UK NHS Institute for Innovation and Improvement has found Lean Six Sigma a promising improvement methodology that incorporates the best of Lean and the best of Six Sigma.

INTEGRATED APPROACH

Healthcare institutions have not been generally considered up to now as companies that might be managed efficiently. They have been administered rather than managed. The healthcare organizational structure requires nuclear changes so that modern accepted managerial approaches to excellence can be successfully applied. Therefore, it seems that finding the appropriate management systems for healthcare organizations in technically developed countries is becoming a high priority.

It seems that taking time to find an acceptable methodology for measuring, assessing, and comparing organizational performance through valid standards, as well as recognizing self-assessment and accreditation results in valid measures of performance *(97)*.

The traditional approach to external evaluation of healthcare organizations was a breakthrough when the American College of Surgeons established the Hospital Standardization Program in 1917. In 1950, a growing number and complexity of hospitals required revision of the standards and support of the entire medical and hospital field, resulting in the establishment of the JCAHO in 1951 *(98)*. However, the performance of the healthcare

organizations in the United States was challenged by the 1999 report of the IoM in the United States.

Accepting the fact that voluntary certification and accreditation represent a necessary recognition by service payers of healthcare organizations as suitable providers, self-assessment driving solely to certification or accreditation by an external organization should not be the only way to manage the knowledge gathered from this exercise.

The most important drivers of breakthrough improvement are leadership, creativity, and innovation. Executives must lead and mentor their people in the right directions and assure that their actions are linked to strategic performance. They need to deploy limited resources to the highest impact areas and not try to solve every problem in the hospital.

To accomplish this, they need to understand the existing improvement methodologies and how to integrate their approaches into an overall business improvement strategy.

However, generally, through the last half of the past century, the debate for identifying the best quality management approach in healthcare systems has focused on the their differences and benefits and hardly on their potential synergies *(99,100)*. Recently, **s**imilarities and differences among TQM, Six Sigma, and Lean as effective quality management models in healthcare systems have been discussed (101).

Piece-meal application of quality control methods, quality assurance schemes, and quality management philosophies, and their assessment through diverse external evaluation approaches has proved their insufficiency for dealing successfully with quality management systems and with patient safety.

Integration of the diverse methods, schemes, philosophies, and approaches for establishing a culture of self-assessment and continuous quality improvement in a journey toward excellence seems to be an alternative to be explored.

To move from the old organizational structures of healthcare institutions to a new organizational and managerial design, deliberate transitional steps are necessary. If carefully designed and well placed, these transitional measures will permit policy to evolve along consensual lines and can signal the overall direction of change, reassuring stakeholders that change is taking place smoothly and that the most immediate problems are being dealt with. It also helps to ensure that longer term systematic objectives are not compromised by short-term political imperatives *(102)*.

It has been shown that interactive integration of some of the best accepted quality management approaches can be carried out successfully according to the following scheme (103):

1. The initial step implies the early implementation of process thinking as the basic stepping stone for the continuous quality improvement journey toward excellence. It means that in order to function effectively and efficiently, an organization has to identify and manage all its linked activities, or processes, since the output of one is generally the input of another.
   The system of processes within the organization has to be defined and managed. The new ISO 9000:2008 promotes the adoption of a process approach, and therefore, at present, ISO 9000:2008 is the best tool for implementing "process thinking" and quality management systems in an organization.
   Understanding, systematizing, and controlling processes is the best way available today for preventing processes and system failures as well as human errors, as it is done in the high-risk sector of aviation. It could be a reliable approach for increasing patient safety in the healthcare sector.
2. As a second step, once the quality management system is in place, the healthcare-specific standards like those offered in the traditional healthcare accreditation approaches, should be implemented.
3. Once the organization is working effectively, efficiently, and safely, an excellence model can be established as a reference for the organization's pursuit of excellence.
   Initially, using an Excellence Model for self-assessment, an organization will have a good understanding of its own strengths and weaknesses at the process level. Scoring according to the model will offer a reference point for internal comparisons for periodical self-assessments and improvement actions and also for external benchmarking.
4. The BSC can be used at this point to provide the strategic focus needed to prioritize action and allocate resources.
   The Six Sigma approach can be easily integrated into existing quality management efforts through detailed data analysis, becoming part of the strategic plan, so that benefits such as reduction in costs of poor quality and improved profitability will be obtained.
5. Lean Management seems to be, up to now, a very effective scheme for managing healthcare systems and can be implemented as an alternative single approach for identifying, acknowledging, and reducing the percentage of non–value-added work, so that hospitals can realize their most fundamental goal of providing superior quality healthcare to their patients and redistributing the resulting cost savings to other quality of care and patient safety initiatives.

CONCLUSIONS

1. In general, all over the world, the performance of the healthcare systems falls short of acceptable requirements.
2. These shortcomings are not related to the economic health of the country or to its expenditure in healthcare.
3. Adverse events during healthcare focus priorities on patient safety and risk management.
4. In order to improve, approaches used in other sectors such as the service sector and the industrial sector can be applied to the healthcare sector, where, in fact, the concept of quality management systems has emerged as a new paradigm for managing healthcare systems and organizations.
5. Process thinking is the nuclear concept for the quality management systems and is the focus of most of the recognized approaches to quality improvement.

6. All of the existing approaches aim at continuously improving the organization, and many can integrate synergistically in a stepwise journey in pursuit of excellence. Therefore, integration of ISO 9000, Excellence Models, BSC, Six Sigma, and, more recently, Lean Management approaches, together with traditional accreditation, offer a logical stepwise journey toward excellence.

CHAPTER 11

Selecting Improvement Projects

David Birnbaum

Epidemiology, as a process for logical inquiry, has much in common with systems analysis or industrial engineering (also known as management engineering) (1). Similar perspectives and complementary methods shared by these disciplines make them ideal for managing healthcare quality improvement (2). However, to succeed, these disciplines must be applied in a supportive setting and on worthwhile quality improvement projects. There are underlying principles and precedents of both successes and failures; these can serve as important guides to anyone contemplating extension of epidemiologic skills from familiar areas of infection control to less familiar areas of quality improvement. Healthcare as a business sector has lagged far behind the cutting edge of other industries in advancing its methods to assure and improve service quality. Healthcare organizations have generally failed to use the full potential of epidemiology in discerning alternative strategies and informing consensus on best practices; exploring the natural course of conditions; performing cost-benefit and effectiveness analyses; surveying patient preferences; measuring organizational effectiveness; establishing indicators, criteria, and other measures; and designing and evaluating surveillance systems (3,4). Although it is noteworthy and unfortunate that epidemiology is not listed among team leadership in seminal reference books and motivating reports (5,6), this reflects the simple fact that relatively few healthcare epidemiologists rose to embrace challenging new opportunities.

Although some of the language in general underlying principles for selecting improvement projects might introduce foreign concepts, the principles are not complicated. Mozena and Anderson (7) list the following essential criteria to consider:

- Impact on patient care or external customer
- Impact on favorable patient outcomes
- Magnitude of potential cost savings
- Cost of implementation
- Difficulty of implementation
- Ability to measure performance of process
- Potential benefits outweigh cost of the project
- Deals with key business issue
- High error rate
- Availability of data
- Impact on profitability
- Potential for success
- Impact on ongoing quality
- Ability to quantify results
- High visibility to customers or patients
- Elimination of rework
- High risk to patients or employees

A National Demonstration Project on Quality Improvement in Health Care reported that nomination and selection of projects often are run by steering committees (a quality council) but that the best ideas come from "listening to the voice of the customer" (in which external customers are patients who receive services and internal customers are staff members who collectively provide and support service delivery) (8). Surveying customer opinion is an active way to listen; design and conduct of surveys are familiar grounds in epidemiology. Epidemiologists also may be more aware than most about the distinction between measuring patient satisfaction, patient safety, and service quality of healthcare (9). Relating service attributes to customer expectations may involve less familiar but still simple techniques such as Quality Function Deployment matrices (a simple two-dimensional matrix in which the strength of association between specific items and categories of customer expectations is summarized) (10,11). However, all of these criteria and methods are disjointed considerations. What is needed to bring efficiency and acceptance is an effective system for their implementation.

GUIDANCE FROM HISTORICAL PRECEDENTS

Three precedents bear consideration as effective systems to select improvement projects. Although two were successful quality improvement systems, they failed to persist and become today's North American gold standard models. Williamson's Achievable Benefits Not Achieved (ABNA) system to identify and prioritize potential projects (12) has a remarkable track record among alternatives (13). Similarly, the so-called Denver Connection of the same era is a story of successful amalgamation and reorganization of two hospitals in a way that put quality improvement supported by real-time performance data

analysis as the centerpiece of medical staff departmental meetings and continuing medical education (encouraged by board-level involvement while the usual array of advisory committees was eliminated) (14). Finally, the Institute of Medicine's (IOM's) Model Process for semiquantitatively ranking alternative projects is instructive for its mathematical approach (15).

Dr. John W. Williamson developed systems for health accounting and ABNA during an impressive body of work that spans decades on the faculty of the Department of Health Services Administration at the Johns Hopkins University School of Hygiene and Public Health, Medicine and Medical Informatics at the University of Utah School of Medicine, Regional Medical Education Center of the Salt Lake Veterans Affairs Medical Center, and service on government commissions. Health accounting, conceptualized in the early 1960s, is "a management model to integrate continuing education and patient care research into an ongoing cyclic function to systematically improve the quality of medical care" (16). It is an evidence-based outcome-focused approach that selects project priorities through ABNA, a formal, efficient process refined in the 1970s. Although proven effective and cost-effective in a wide range of applied research and demonstration projects at the American National Institutes of Health, Veterans Administration, and elsewhere, Williamson acknowledges that the most successful application of his system to enhance national quality is in the Netherlands (16). The fact that Williamson's name and work are unfamiliar to so many throughout North American hospitals and healthcare leadership is hauntingly reminiscent of the history of W. Edwards Deming. Deming's influence took decades to return to North America, heeded by American manufacturers only after Japan capitalized on Deming's leadership to outperform their American counterparts (and later heeded by health service organizations decades after that!) (17). Williamson stresses the following:

1. The importance of applying principles of epidemiology, sampling, and simple statistical testing to QA-focused reviews
2. The necessity of a multidisciplinary team approach to QA, in which the consumer was the most important member of the team
3. The need to use structured group judgment methods for establishing priorities, criteria, and standards as well as QA action decisions under the usual conditions of factual uncertainty
4. The need for a unique set of statistical methods for QA that allowed comparison of measured results against consensus standards that reflected reasonably achievable projected outcomes

Consistent with concurrent surveillance methods that have become a mainstay of contemporary infection surveillance programs, Williamson recognized long ago that chart-based audits as a basis for quality assurance may be misleading and severely limit the potential impact of programs to improve quality (16). His ABNA process consists of selecting a team (ideally 7–11 persons, including "at least four knowledgeable and respected staff physicians" and representatives of other functional areas and the lay public) and then supporting that team through two 2-hour meetings 3 to 4 weeks apart. The first meeting is a training session simulating the later priority-setting session. A master list of potential topics developed during the training session, together with team recommendations on additional "data, literature, or consultation" required, provides an indication of support materials that will be needed at the second session. Ideally, these are gathered during the 3- to 4-week hiatus. There are seven tasks in the priority-setting meeting:

1. Introductory remarks by the moderator clarify meeting purpose, tasks, and timing of the 2-hour session and review the ABNA framework (5 to 10 minutes).
2. A simple four-column form is distributed so that individual team members can each list as many topics as they wish, listing along one row for each topic:
   a. exactly who (what group) will benefit
   b. for what health problem
   c. from what action(s)
   d. by which provider(s)

   A cue sheet is provided to give examples of various patient characteristics, health problem characteristics, provider characteristics, and (inter)action types that might be considered. Time is given to work individually (10 minutes).
3. Each team member, sequentially, is then asked by the coordinator to nominate one problem from their list. The coordinator develops a summary chart; in addition to the four columns identified in step two, when acting as coordinator, I found it helpful to list in two additional columns an indication of whether the intervention is known to work (nature of evidence for efficacy or effectiveness) and whether it is feasible (information on cost, cost-effectiveness, case study, etc.). Discussion is limited to clarification at this stage, and the process repeats until all the most promising ideas from each member's list are presented (30 minutes).
4. Individuals then vote in an "initial weights" column on their form to assign a priority rank (high to low on a five-point scale) for each project nominated (5 minutes).
5. The coordinator then collects the votes, anonymously recording both initial individual weights and their sum for each nominated project. This information, superimposed on the summary chart, is projected back to the group (10 minutes).
6. Discussion of results, one topic at a time, then examines whether priority ranking is tightly or widely dispersed, the strength of evidence, and other detailed considerations. On completion of comprehensive discussion, members are then asked to vote again on every topic, in a "revised weights" column on their form. The coordinator again collects and records votes anonymously (50 minutes).
7. The highest-ranked ABNA topics are then forwarded as recommendations from the team, along with any further recommendations for additional data or evidence required for any of the topics. The meeting is adjourned, the team thanked for completing its work, and special teams of qualified individuals then take responsibility for moving approved projects forward.

Meanwhile, also in the 1970s, radical changes under the amalgamation of the medical staffs at Denver's Swedish

Medical Center and Porter Memorial Hospital occurred. Radical change was needed because as Dr. William Robinson, Director of Medical Education, noted, "In spite of the hundreds of physician hours devoted to medical staff activities, little actually was accomplished. It was almost impossible to demonstrate that quality of care was in any way influenced by the physicians' repetitive, duplicative, unrewarding medical staff activities." The usual litany of committees was reduced to just three (executive, professional activities, and credentials). A reduced number of subcommittees composed of small numbers of individuals, the bulk of whom were not physicians, served these committees, and much of the quality-related work was shifted from committees to medical staff departments supported by the work of subcommittees or research and education department employees. Medical staff members were strongly encouraged to ask questions at their departmental meetings about quality issues, and then make policy decisions based on evidence delivered soon thereafter (answers supplied through real-time research capacity in their own institution) (14).

Although successful into the 1980s, by the turn of the 21st century, the Denver Connection was so far dismantled that it no longer even existed in the institutional memory of Porter Hospital's present administration! Porter and Swedish, partners of the so-called Denver Connection formed in 1972, went their separate ways in 1992. These two hospitals serving health needs of southeast Denver had remained separate corporate entities, yet collaborated successfully for many years following formal merger of their medical staff organizations. That merger was initiated by the doctors, not by the administrators, for the purpose of improving quality of care. Administrative support grew following demonstrated successes, and the hospitals cooperated in division of complementary health services, instead of duplication of what the other offered solely to compete. That was before big business entered sickness. Ultimately, poor quality of management in emerging, large, managed-care corporations led to unexpected deficits in profitability of operations, and corporate vision shifted to preoccupation with that debt. A grass-roots anticompetitive way of serving the community's health needs could not sustain itself in the face of powerful market forces and growing business empires awash in corporate debt. Personal ideologies in administrative leadership compounded the difficulty of making effective alliances, and mistrust grew where open communication once thrived. Key participants later interviewed conveyed a sense of loss and regret, a realization they participated in something very unique and beneficial that was lost for illogical reasons ("nobody had any appreciation what we were doing was special or unique … only in retrospect we came to appreciate the specialness of what we were doing."). The influence of accreditation programs in this saga was noteworthy only for its lack of influence (18). It is tempting to speculate that this visionary effort thrived because it followed characteristic principles that seem to distinguish great companies from others (19) and that the Denver Connection ultimately fell when it strayed from core values and these fundamental principles.

The IOM Model Process to set priorities in health technology assessment addresses similar dimensions as ABNA, but in a more quasinumeric than nominal group consensus manner. The IOM priority score for each technology, instead of being assigned by consensus ranking, is calculated as $\Sigma W_1 \ln S_1 + W_2 \ln S_2 + \ldots + W_7 \ln S_7$, where W_i represents the criterion weight and S_i the criterion score for ($i = 1$–7).

1. Prevalence (e.g., cases per 1,000 persons)
2. Burden of illness (e.g., difference in quality-adjusted life years of individuals with vs. without the condition under consideration)
3. Cost (total direct and indirect costs per person with the condition)
4. Variation in rates of use of the technology (coefficient of variation)
5. Potential to change health outcome (subjective assessment on a five-point scale)
6. Potential to change costs (subjective assessment on a five-point scale)
7. Potential of assessment result to inform ethical, legal, or social issues (subjective assessment on a five-point scale)

The first three criteria are objective measures; the remaining four are subjective and are addressed by one or more expert panels. Criterion weighting values are arbitrary choices; the process described has an expert panel select one criterion as least important, which then is assigned weight of one. Mean weights given by panel members for each of the remaining criteria, relative to the least important one, then determine the other six weights. After discussion of results to resolve any wide disagreement, results of a second vote are final. Pilot test results with small conventional and mailed response panels are examined in the IOM report, which gives the following values: $W_1 = 1.6$, $W_2 = 2.25$, $W_3 = 1.5$, $W_4 = 1.2$, $W_5 = 2.0$, $W_6 = 1.5$, and $W_7 = 1.0$. Logarithms of criterion scores are used to make the model multiplicative rather than additive, thus responsive to relative rather than absolute differences in scores (algebraically, the formula can be restated as $\Sigma W_i \ln S_i$, which equals the product ΠS_i^{wi} for $i = 1$–7). Subjective item scales, therefore, run from a value of one for least likely to five for most likely.

Health accounting provided a philosophy, the Denver Connection a forum, and ABNA a method all consistent with today's emphasis on evidence-based practice and continuous quality improvement (CQI). What lessons should one take from these all-but-forgotten precedents? Williamson reflects on lessons learned from 25 years of experience (16), naming three premises on which quality assurance or improvement is based and five principles that evolve from it:

- Because it is an inherent management function encompassing both effectiveness and efficiency of any healthcare activity, the main issue is not whether but how well it is conducted.
- As a healthcare management function, it involves the same clinical problem-solving principles whether applied at an individual, institutional, regional, national, or international level.
- As a scientific endeavor, it must be built on a foundation of the health sciences integrated with other disciplines

(including philosophy, quantitative disciplines such as epidemiology, education, social sciences, business and management, economics, and informatics).
- It must start with clarification of individual and organization values, must be supported by management of incentives, and will be successful to the extent that it is internally motivated.
- Although it must be organized along sound management and administrative principles, it will be successful to the extent that responsibility for excellence moves closer to the bedside.
- It is inherently interdisciplinary, so it will be successful to the extent that it is comprehensive in membership and vision.
- Attention should be focused on carefully targeted problems selected by consensus methods, not dispersed in shotgun approaches or restricted to narrow problems defined by audit of single data sets.
- It must be subjected to ongoing analysis of costs and accomplishments to ensure that it maintains effectiveness and adapts to changing times.

Clearly, these premises and principles are not consistent with chart audits conducted behind closed doors, at accreditation-mandated intervals, by discipline-specific advisory committees that regarded patients or their families as recipients of care rather than members of a team. They also are not consistent with quality being viewed as a destination (viz., no evidence of negligent care) rather than as a journey, or with centralizing authority in a quality council. The Denver Connection clearly represented a journey outside the map of externally mandated routes and vaguely defined directions. It decentralized autonomy, predated by decades the Health Care Financing Administration (HCFA) (subsequently renamed the Centers for Medicare and Medicaid Services, CMS) instigated removal of infection control committees as a Joint Commission on Accreditation of Healthcare Organizations (JCAHO, subsequently renamed The Joint Commission, TJC) requirement, inspired one other hospital to disband that committee despite accreditation standards (20), and set a coordination role for administration in an era when command and control was the norm. In short, neither of these precedents was typical of conventional programs during their era, and they documented successes in their publications. Instructively, ABNA and the Denver Connection challenged but failed to change convention and in this one is warned about the importance of establishing protective legislative, board, and administrative political perimeters around vital programs (17,18).

SURVIVAL AS A MANAGER OF CHANGE

Discussion of timing and perception is not obvious in the previous list by Mozena and Anderson but is inherent in the ABNA process. Healthcare epidemiology often succeeds when implementing interventions that are motivated by frank outbreaks of disease, but may not be as successful in convincing administrators to adopt new programs during normal times when competing against business cases or political agendas of line departments. One can take lessons from the social policy cycle recognized in public administration and must recognize the importance of marketing to create a sense of need before attempting to satisfy that need ("deals with key business issue" criterion). Later steps recognized in the policy cycle are familiar ground to the evidence-based nature of epidemiology; however, an initial stage of creating shared understanding of any problem (because all parties can agree on the data but disagree on the theory or meaning explaining that data and, therefore, on direction of actions required) and, second, articulating that vision to ensure sufficiently widespread acceptance or readiness to act are politically astute *(21)*:

- Identify issues
  - Problem defined
  - Problem articulated
- Policy analysis
  - Collect relevant data and information
  - Clarify objectives and resolve key questions
  - Develop options and proposals
- Undertake consultation
- Move toward decisions
- Implement
- Evaluate

Healthcare must operate in a businesslike manner but must retain at its core the values inherent in principles underlying healthcare professions, because care cannot be viewed simply as a commodity to sell. "Patients do not value healthcare *per se*, they value health; "health care" is an intermediate good that people consume (based on expert advice) in hopes of deriving a health benefit. Many patients, and especially those under duress of serious illness, do not have the time, interest, or ability to gain sufficient knowledge to be equally informed as their healthcare provider. So, no matter how much information patients receive, choosing your surgery is never going to be like buying a car" *(22)*. Our primary focus should be on improving quality, not on cutting cost. If experience in other industries is any guide, improving quality will lead to cost reductions. To motivate change in a business environment, program managers should consider principles of economic application to recognize the diminishing effectiveness of different arguments (excellent arguments: improving operating costs, increasing production rates, and improving product quality; good arguments: improving customer relations, improving labor relations, and increasing job pride; fair arguments: reducing injury rate, giving legislative compliance, and reducing liability potential; and poor arguments: enhancing public relations or providing personal satisfaction) *(23)*. The experience of clinical microbiology laboratory directors who have been successful at proving cost-effectiveness as a new business skill is pertinent *(24)*. Administrators may be more interested in projects that promise to lower variable rather than fixed costs, work with cost rather than charge data, and show benefit using adjusted cost estimates. Adjusting cost estimates for a diagnosis-related group (DRG) probably is not familiar to most healthcare epidemiologists, but epidemiologists are aware of the "shifting base" bias potential that is inherent in an indirect adjustment (standardization)

calculation *(25)* that hospital administrators tend to apply to compensate for differences in severity of patients within DRGs. A stronger than ever emphasis on transparency and public reporting also is pertinent. The task today is to improve quality while also rebuilding public confidence in the safety of patient care—a task that requires honest, balanced reporting in context to explain what is being done well, what could be done better, why certain projects are given priority over others, and what progress is being made.

MANAGEMENT OF CHANGE TO ACHIEVE QUALITY MANAGEMENT

Quality management is a sustained, systematic approach to improving quality. Quality management requires an ability to chart the best courses (a task for which the technical skills of epidemiologists generically are well suited) and to help all workers pursue specific targets along those courses. The latter task requires communication and organizational development skills and methods complementary to epidemiology. Chapters in this section are integrated and meant to be read together, unlike chapters of other sections in this book. They offer complementary insights from experienced professionals of various backgrounds, and it is important to recognize that no one background likely offers all the attributes needed for successful improvement project management. A framework for considering roles, strengths, and weaknesses is provided in Figure 11-1.

STARTING ON A PATH THAT LEADS TO SUCCESS

When introducing CQI programs, it is essential to avoid early failures, because they are a dispiriting enemy of progress in promoting continuous improvement. Rather than lose momentum by failing at the start, it is better to begin with small yet meaningful projects, be successful, attract champions who sustain progressive projects, and mobilize new converts into groups that do more over the long term.

Two aspects identified in previous lists, *availability of data* and *collect relevant data and information,* are fundamental to decision criteria, policy cycles, and design of surveillance programs. Quality of healthcare data (in terms of precision, accuracy, and reliability) has been considered extensively by epidemiologists *(26–29)*. Therefore, this is an aspect in which the core "process" knowledge of healthcare epidemiologists can guide decisions about which noninfectious disease problems to study, whether to use available data sources, and which supplementary surveillance tools should be developed. Although other specialists probably have more "content" knowledge than the healthcare epidemiologist about a given noninfectious disease, interdisciplinary collaboration between process and content experts is more likely to lead to success.

Benchmarking often is mentioned as a source of guidance. Recent volumes describe successful and cost-effective improvement projects. Although the best way to select the right improvement projects for a given organization is to understand the needs, expectations, resources, culture, and values of that organization and its own customers, there also is merit in benchmarking the success of others. Early volumes of *Quality Profiles (30)*, for example, profile a selection from more than 1,100 quality improvement initiatives; these were chosen by an advisory board of experts in quality improvement from health plans, trade associations, government organizations, and individuals from National Committee for Quality Assurance (NCQA) and Pfizer (the sponsors of the volume). According to its authors, case studies selected for the second edition demonstrate more sophistication and more refined use of data than initiatives in the first edition (18 months earlier). Since then, additional volumes have been made available (at *http://www.qualityprofiles.org/index.asp*). Forum opportunities represent another source of research funding, benchmark information, and networking opportunities. A noteworthy example is the Breakthrough Series Collaboratives and Pursuing Perfection program *(http://www.ihi.org/IHI/Programs/StrategicInitiatives/PursuingPerfection.htm)* of the Institute for Healthcare Improvement. Clinical practice guidelines provide another basis for evaluating quality of care to identify opportunities for improvement *(31)*, an area in which the Agency for Healthcare Research and Quality (*http://www.ahrq.gov*) has a lead role, but it is important to remember that "listening to the voice of the customer" implies attempting to delight customers with unexpected extras of valued quality rather than focusing just on fixing deficient care. Comprehensive reference books devoted to this topic have now been produced by professional societies, such as the American College of Medical Quality *(32)*.

CHECKPOINTS ALONG THE JOURNEY

Ensuring that project teams have sufficient time, skill, and information to make critical assessment of data from internal or external sources is an obvious but often overlooked checkpoint. Another checkpoint is influence of those teams among peers and organizational hierarchy. Availability alone is not sufficient justification for allocating resources. Credibility, willingness, and readiness form a better basis for selecting team members for each project; processes for team activities must be efficient and effective; and training needs of teams must be met. If outside assistance is needed to bring in expertise with quality improvement methods, then a resource to consider is CMS-supported Quality Improvement Organizations (see *http://QIOSynergy.org*).

Last, but not least, the journey must be chronicled in ways that are meaningful to all stakeholders. Deming's famed 14 Points for Management and the enumeration of "Deadly Diseases" advocate driving out fear, shifting focus from short to long term, and eliminating recognitions based on essentially random chance allocations, or just doing well as an individual in the system at short-term

Focus	*Allied Health Care Professions*						*Quality Professionals from Other Industries*			
	Medical or Nursing Directors	Primary Providers		Clinical Support		Healthcare Epidemiologists	With Professional Degree		Without Degree

Process Improvement Technical Skills (eg: CQI, Lean, 6-Sigma)										
Other (content vs. process expertise)										

FIGURE 7-2 A Framework for Successful Improvement Project Management.

quotas rather than attempting to improve the system. Thus, Deming advocates eliminating practices such as traditional "employee of the month" and subjective annual employee performance rating *(33)*. In their place, CQI activities, supported by administrative models oriented toward building learning organizations and reinforced by team-building morale-boosting recognition for actual achievements, have merit. As part of your chronicle, an annotated inventory of current quality-related activities should be maintained. If quality assurance and improvement are viewed in the context of a surveillance system to detect and prevent adverse trends, then familiar methods to evaluate surveillance system performance readily apply. A three-part form developed for this purpose is shown in this chapter (Table 11-1A–11-1C).

Similarly, in each project, maintaining a newsworthy log of project progress and events should be an archivist's responsibility. This inventory and log can be used to promote interdisciplinary communication throughout an organization and its surrounding community, and to serve as a basis to continuously monitor the value and cost-effectiveness of current measures. In addition, as a gauge of institutional culture and readiness to change, these documents can provide insight into the types of projects likely to succeed or fail at any given period in an organization's journey toward quality. Since its inception in 1987, thousands of businesses have used the more structured Malcolm Baldrige Award (*http://www.quality.nist.gov/*) application process as a way to chart progress on that journey. Education and health categories were formally added to the award program in 1999; in recent years, healthcare organizations predominate among the types of applicants. The comprehensive Baldrige program provides a wide-ranging audit, as do other award programs patterned after it, but a less formal annotated chronicle of an individual institution's own history also has unique worth. We may have been slow to recognize the importance of sharing success stories in social and scientific exchanges *(34)*.

External review programs that acknowledge competence and reveal organizational deficiencies or other opportunities for improvement include familiar accreditation programs, International Organization for Standardization (ISO) certification, the American Baldrige Award, the Japanese Deming Award, and others. They are not identical; thus, it is important to appreciate the relative merits of the model that each establishes. It has been noted that "Baldrige and JCAHO standards are both based on the concepts of CQI but differ in so many ways that direct comparison is difficult" *(35)*. Baldrige criteria have tended to be more general; accreditation agency criteria have been more specific and prescriptive. The Baldrige Award also differs from ISO 9000:94 certification, but the new ISO 9000:2000 standard reportedly has the same focus as Excellence Models such as Baldrige or European Foundation for Quality Management (see Chapter 10 for more detail). As the Baldrige Web site described, "The purpose, content, and focus of the Baldrige Award and ISO 9000[:94] are very different. The Baldrige Award was created by Congress in 1987 to enhance US competitiveness. The award program promotes quality awareness, recognizes quality achievements of US organizations, and provides a vehicle for sharing successful strategies. The Baldrige Award criteria focus on results and continuous improvement. They provide a framework for designing, implementing, and assessing a process for managing all business operations. ISO 9000 is a series of five international standards published in 1987 by the ISO, Geneva, Switzerland. Companies can use the standards to help determine what is needed to maintain an efficient quality conformance system. For example, the standards describe the need for an effective quality system, for ensuring that measuring and testing equipment is calibrated regularly and for maintaining an adequate record-keeping system. ISO 9000 registration determines whether a company complies with its own quality system. Overall, ISO 9000 registration covers <10% of the Baldrige Award criteria." The Baldrige information Web pages also acknowledge that both the U.S. Baldrige Award and Japan's Deming award are based on the same purposes (to promote recognition of quality achievements and to raise awareness of the importance and techniques of quality improvement), but note that the Baldrige Award focuses more on results and service, relies on the involvement of many different professional and trade groups, provides special credits for innovative approaches to quality, includes a strong customer and human resource focus, and stresses the importance of sharing information (see *http://www.quality.nist.gov/* for more information about the award). Another recent development is HF-2 Business Operating Systems (BOS) for Health Care Organizations: Requirements for Process Improvements to Achieve Excellence *(36)*, which evolved from an Industry Workshop Agreement 1 effort to make ISO 9000 more specific to the healthcare industry.

LEADERSHIP

Epidemiology has long been recognized as providing the scientific foundation for public health and the evidence-based resource for health planning. Unfortunately, dissatisfied customers rather than healthcare epidemiologists have been leading recent movements to initiate change and improvement in healthcare. Although the automotive industry has quality problems of its own, it recognized 20 years ago that healthcare tops its list of direct costs in the construction of automobiles *(37)*. Now 20 years later, having not seen significant innovation and progress within healthcare, the automotive industry's division within the American Society for Quality (ASQ) became the driving force for radical redirection in healthcare leadership by demanding ISO certification of its suppliers and funding consensus meetings to support initiatives of ASQ's Health Care Division that led to ISO's Industry Workshop Agreement 1 (6). There is no reason for epidemiologists to take a back seat while others drive, for as Dr. John Millar, vice-president of the Canadian Institute for Health Information, observed to a room filled with healthcare epidemiologists and infection control professionals during a symposium on "Collaborations to Improve Health Care Quality," "you folks have more expertise than most people who could be in this game" *(38)*.

Quality Program Survey Form (TABLES 11-1A–C)

TABLE 11-1A

Section I: What Does Your Program Assure?

Quality assurance involves systems of monitoring to confirm that a specified level of quality is delivered, and systems of controls to maintain or adjust performance. As an initial step in designing an appropriate program, you need a clear understanding of current objectives and an inventory of existing activities. Section I should be completed, independently, by all participants (e.g., the manager, director, and administrator for each quality program).

Completed by: Date (dd/mm/yy): / /

1. Please attach a copy of your statement of program philosophy, purpose, or mission.
2. Please complete the following section to list your current goals and objectives; date of last review/revision; associated monitoring and/or control activities; and whether these are mandated by external requirements. Continue on the reverse side if necessary.

Goal/Objective #1:_____

Date Adopted (dd/mm/yy): / /

Monitoring Activities: Control Activities:

Circle as appropriate: STATUTORY, PROFESSIONAL, ACCREDITATION requirement

Goal/Objective #2:_____

Date Adopted (dd/mm/yy): / /

Monitoring Activities: Control Activities:

Circle as appropriate: STATUTORY, PROFESSIONAL, ACCREDITATION requirement

Goal/Objective #3:_____

Date Adopted (dd/mm/yy): / /

Monitoring Activities: Control Activities:

Circle as appropriate: STATUTORY, PROFESSIONAL, ACCREDITATION requirement

Goal/Objective #4:_____

Date Adopted (dd/mm/yy): / /

Monitoring Activities: Control Activities:

Circle as appropriate: STATUTORY, PROFESSIONAL, ACCREDITATION requirement

(Adapted from MMWR 1988;37(S5) By Applied Epidemiology)

TABLE 11-1B

Section II: How Is It Being Assured? Program Structure

For each of the Monitoring Activities listed in Section I, please answer the following questions. Use one page for each activity under each numbered Goal/Objective. Section II should be completed, independently, by the program manager (e.g., Infection Preventionist), the program director (e.g., Healthcare Epidemiologist), and the administrator to whom they report.

Completed by: Date (dd/mm/yy)://

3. This page relates to Goal/Objective #_____ Activity_____
4. Is there written documentation (policy, procedure, instruction, etc.) covering this activity?
   Yes *No* If yes, please attach a copy or indicate location.
5. How will this activity help to assure quality? (check all that apply)
   __ Establishes baseline levels/monitors trends
   __ Detects incidents to prevent recurrence
   __ Detects incident-producing conditions before injury or damage results
   __ Other (specify):
6. How will the information be used? By whom? Give examples
7. What information is requested or collected?
8. What sources of information are used (e.g., medical record, lab reports, incident reports, professional activity summary reports, committee records, etc.)?
9. Who has responsibility for reporting or collecting this? Describe the flow of information.
10. What percentage of actual events is detected?
    - Have program sensitivity and specificity been measured formally?
    - How are minimum sample sizes or sampling frequencies determined?
11. After data analysis, to whom are reports sent? How frequently? Who has authority to act on this information?
12. Have objectives for this activity changed over the past 2 years; if so, why?

TABLE 11-1C

Section III: How Well Does the System Work?

For each monitoring activity listed in Section II, please answer the following questions. Use one page for each numbered Goal/Objective activity. Section III should be completed by your program director; questions 19 and 20 should also be answered by your administrator.

Completed by: Date (dd/mm/yy)://

13. This page relates to Goal/Objective #_____ Activity_____
14. What method(s) is (are) used to analyze the data collected?
15. What are the time delays from actual incidence to
    - Detection: _____ (unknown)
    - Reporting: _____ (unknown)
    - Analysis: _____ (unknown)
    - Dissemination: _____ (unknown)
    - Action: _____ (unknown)
16. What problems or biases can affect the activity?
17. What are the costs (in dollars or hours per week) for data collection, analysis, and dissemination? Please indicate whether the figure is known (i.e., charted to a cost center), estimated, or unknown.
18. Does this cost include everyone involved?
19. What decisions or outcomes has the activity effected? Check and provide examples:
    - ___ Prompted review or corrective action:
    - ___ Validated good performance:
    - ___ Provided support for a (change in) policy or procedure:
    - ___ Influenced allocation of resources:
    - ___ Influenced educational priorities/programs:
    - ___ Other:
20. Is there a mechanism for ongoing evaluation of this activity's value? If yes, give details.

CHAPTER 12

Conducting Successful Improvement Projects

Marisel Segarra-Newnham and Ronald G. Berglund

In the *Third Edition of Hospital Epidemiology and Infection Control* edited by C. Glen Mayhall, there are two chapters (Chapters 10 and 12) on quality methods and the selection of improvement tools to bring about effective healthcare changes (1,2). In Chapter 10, a basic improvement method using design, monitor, repair, and improve was reviewed and applied to a surgery center. As part of this method, root cause analysis (RCA), is/is-not analysis, benchmarking, brainstorming and affinity diagrams, and a plan-do-check-act (PDCA) cycle were utilized (1).

Chapter 12 on "Selecting Change Implementation Strategies" described the use of a PDCA cycle of improvement applied to a variety of projects including decrease in medication errors in the veterans affairs (VA) health system with the use of computerized physician order entry (CPOE) and bar-coded medication administration (BCMA) and the implementation of an outpatient intravenous antibiotic therapy program, among others. Issues that were handled particularly well and lessons learned from mistakes along the way were reviewed (2).

In this edition, we will combine Chapters 10 and 12 of the previous edition, will provide additional tools that can be utilized for improvement projects, and will describe potential applications for these tools. We hope to provide ideas on how to select the most effective tool to conduct a successful improvement project. We will review recent literature on BCMA and CPOE implementation. We will review PDCA and apply the method to the medication reconciliation process. The A3 process will be introduced and applied to patient transport within a medical center. A summary table will provide a listing of various tools and techniques along with potential applications.

THE VETERANS EXPERIENCE OF IMPLEMENTING BCMA

The impetus to create a paperless medication ordering system continues unabated since the late 1990s. CPOE systems are expected to affect the high proportion (56%) of medication errors that occur during prescribing *(3)*. A medication error is defined as "a failure in the process of treatment that leads to, or has the potential to lead to, harm to the patient" *(4)*. A goal of Institute of Medicine (IOM) was to have handwritten orders eliminated by 2010. However, currently only about 10% of hospitals have a CPOE system; nonetheless, this number had doubled in 10 years (5). The VA health administration is usually given as an example of a system that successfully implemented CPOE. Transition to a computerized medical record is not easy since old habits are hard to break. Consistency in enforcing the use of technology and having administrators and supervisors who themselves use and understand the system are key.

Designing good computerized systems should be a clear goal, because using automation that has been poorly designed and tested will only make it easier and faster to achieve undesirable results. Automation appears to work well for repetitive tasks while the human can spend their time with more complex tasks that require discernment, communication, cooperation, creativity, and flexibility *(6)*. Humans are still needed to make complex decisions *(7,8)*. These systems will avoid reliance on memory, recall, or vigilance. While the latter issues may not be totally eliminated, they should not be the main way to avoid errors and patient harm. In the planning process it is imperative to include as many end users as possible so that their opinions and desires can be incorporated into the process, and leave their "finger prints." This nurtures the sense of "ownership" giving incentive to participate in the new process despite the unknowns and frustrations.

While CPOE eliminates the hassles of trying to decipher a prescriber's handwriting, it can create new types of "problem orders." For instance, errors due to "typos," appearance of double dosing *(9)*, drop down menu errors by selecting the wrong drug or route or dosage *(3)*, and inflexible formats (10) may occur. Clinicians also may report "alert overload" if too many alerts are sent after an order is entered (11). Anecdotal evidence and reports show that the rate of ignoring or overriding these alerts increases with time (11). It is important to provide useful decision support information and to ensure that only clinically significant interactions or dosing errors require an override *(12)*. One way to decrease problems with ignoring critical drug interactions is to force the prescriber to specify a reason to "override" the order; however, that alone should not be used by the pharmacist as a reason to dispense a medication without further review. In some cases, providers just enter several characters to "bypass" this alert. The technology is not advanced enough to recognize the randomly entered key strokes as nonsense. The availability

of a clinical pharmacist specialist in patient care areas has been shown to decrease medication errors in the intensive care unit and other settings (*13*,14,*15*).

As discussed in Chapter 12 of the *Third Edition*, the VA launched a major change in the control of medication by instituting BCMA for all inpatient medications. It has been several years since the initial trials were preformed at several VA hospitals, and the data collected have been used to improve the ongoing processes. In 2009, Mims et al. (16) reviewed the BCMA system and the quality monitoring program that identifies and corrects the problems discovered when implementing it within the VA. Their research determined that major problems of using BCMA included:

1. No bar code labels on drugs, which is a supply chain problem
2. Missing doses, which is a process problem due to a lack of standardization for administration of medications
3. Labels that do not scan, which is both a supply chain and process error
4. The medication scans but issues a "Drug not Found" error caused by software and hardware problems
5. Misplaced medications caused by automated packer, process error, and design error
6. Mislabeling (medications or patient) errors caused by a lack of quality control

While the initial compliance data were as low as 91% for bar code accuracy (ability of scanner to read the bar code correctly), the data for the fourth quarter of fiscal year 2007 reported successful scans of 98% for the correct dose or correct patient. While the authors concluded that a quality-monitoring program that uses best practices had corrected the problems, a success rate of only 98% equals more that 40,000 errors per 1 million opportunities of identifying the wrong dose or wrong patient. This rate may be considered too high.

In an earlier article published by the Joint Commission (JC), 15 best practice recommendations for BCMA were listed to help non-VA hospitals to implement this system. The best practice list was the result of their study of nursing information specialists and 30 unstructured interviews with diverse stakeholders (17). Some of the recommendations are to create interdisciplinary committees, train all users, avoid double-documentation systems, and verify allergy information displayed in the computer prior to medication administration.

These recommendations were selected without the use of the models identified in Chapters 10 and 12 of the *Third Edition* of this book. The authors of this chapter suggest that it is important to verify the extent to which a problem is mitigated by following the recommendations provided by the JC article since these recommendations "might even create unintended consequences that generate new paths to failure" and that evaluation should be ongoing (17).

IMPLEMENTATION OF BAR CODING TECHNOLOGY

BCMA systems have been suggested as a way to decrease medication errors related to the administration phase by adding another system check to the ones already performed by the pharmacist and the nurse in a phase of medication use where errors may be less likely to be detected (18). The BCMA system incorporates the "five rights" that the nursing profession is familiar with right patient, right drug, right dose, right time, and right route. Nationally, the VA has reported a 75% decrease in the wrong medication being dispensed after implementation of BCMA *(19,20)*. The baseline error rate was not reported. The use of BCMA in the VA started in 1999 and is currently on version 3.0. There are several errors that are possible to be introduced in the process; some of the most common errors are process workarounds such as performing steps out of sequence, adding steps that are outside policy, or omission of steps (i.e., manually entering a bar code instead of using the scanner, scanning medications in advance) (17,18). In some instances, scanning of multidose vials may be a problem *(20)*. Similar to CPOE, education and testing by clinicians who will use the system are important steps in order to avoid underestimating the change that is required to adopt new technology *(20)*. Teams should be multidisciplinary, and duplicate systems should not be used for more than 2 weeks to avoid duplicate orders and dosing or facilitating providers who will not make the switch (17). It is important to have management involved and to provide examples to employees *(20)*.

In a recent article, a research team evaluated errors and outcomes related to implementation of CPOE *(21)*. One of their findings was that "inconsistent communication in CPOE poses a significant risk to safety." About 20% of the errors reported in this study could have resulted in significant harm if not caught by a pharmacist. Using the best sample from this study in which 99.8% of the orders were correct and the 2007 BCMA report in which 98% of the time the correct dose and correct patient were identified (16), we could infer that the combination of CPOE and BCMA could lead to a total compliance rate of 97.8%. Thus if the goal of BCMA and CPOE is to reduce medical errors, combining them could theoretically add to the problem. Many of the issues listed by Patterson et al. (17) are reported by this study group as well, using a different computer system.

It is apparent that attempts to fix separate parts of the medication system itself may not be the best method, especially if this is not done in a systematic way. In implementing these new technologies, there was no consistent tool used for project management. Using a tool such as PDCA or the more detailed A3 process could lead to greater user satisfaction of the computer systems and maximum efficiency and effectiveness. Next we describe the successful use of a PDCA cycle to improve medication reconciliation.

TOOLS FOR QUALITY IMPROVEMENT

PDCA Cycle Example for Medication Reconciliation for HIV Inpatients

Our *PLANNING STAGE* consisted of reviewing our system and the literature. Theoretically it would be easier to reconcile medications if a patient is followed in the same institution for all their healthcare needs; however, even with a computerized medical record shared between inpatient and outpatient providers errors can still occur due to loss of information upon transfer between settings *(22)*. While

teamwork and the goal of seamless coordination of care are important, they may be difficult to achieve if the information is not shared equally within an institution. Integrated systems are important. In some cases, different software programs are used within the same hospital, making communication more difficult. A review of hospital discharges for patients of the HIV clinic in 1999 at the West Palm Beach VA revealed that a high percent of patients were receiving incorrect doses or medications for treatment of HIV or related opportunistic infections. We learned that most of these admissions were not related to HIV, and a consult to the infectious diseases (ID) service was not always done. To improve education of inpatient internal medicine providers, who are not well versed in the treatment of HIV disease, the ID clinical pharmacy specialist was asked to follow patients admitted to the hospital if the ID service was not formally consulted to facilitate transfer between inpatient to outpatient setting and vice versa. For the majority of our clinic patients, the pharmacist was the professional most familiar with their history, besides their primary care ID physician.

The *DO STAGE* consisted of implementing a system whereby the pharmacist would receive an electronic-mail alert whenever an ID clinic patient is admitted to the hospital. When the pharmacist receives the e-mail, the patient is visited and their inpatient and outpatient medication regimens are reconciled. The review includes most recent clinic visits notes. Any discrepancies are reviewed with the attending physician and a "pharmacy admission progress note" is written to document any changes or recommendations. The information is then forwarded to the ID clinic staff for their information. The *CHECK STAGE* showed us that at least half of the recommendations provided were to avoid a potential medication error and the rest were to provide information to the inpatient provider, and we were able to publish this experience *(23)*.

The system continues 10 years later with a slight decrease in the number of interventions needed per patient. The *ACT STAGE* consists of ongoing evaluation, providing education, and making changes as needed. The process in our facility has improved information sharing between the inpatient and outpatient setting. Our experience shows that even if a computer system and facilities are shared, miscommunication can still occur due to lack of familiarity with current protocols. The pharmacist serves also as a source for medication information and education for providers and patients *(24)*.

The PDCA cycle is an excellent tool when the process to be improved requires minimal resources and involves one or two departments instead of larger projects such as introducing new technology (i.e., BCMA).

THE A3 PROCESS

It is obvious that implementing a system requires a process that starts at the beginning and finishes at the end. It sounds simple, but as can been seen from the paragraphs above, incomplete planning requires a lot of rework and creates many problems. One popular technique being used globally is the *A3 process*. This process is a structured problem-solving approach that uses a tool called the A3 problem-solving report. The report is adapted from Toyota Production Principles and has been applied in healthcare settings. We have adapted the approach by articulating 10 steps to proceed from problem identification to resolution in a fashion that fosters learning, collaboration, and personal development. The problem solver records the results of investigation and planning in a concise, two-page document (the A3 report) that facilitates knowledge sharing and collaboration. The term "A3" derives from the paper size used for the report, which is the metric equivalent to 11 inch × 17 inch paper. We have focused on the problem-solving report, because it is the most basic style, making it the best starting point. Why use it? Most problems that arise in organizations are addressed in superficial ways, what some call "first-order problem solving." That is, we work around the problem to accomplish our immediate objective, but do not address the root causes of the problem so as to prevent its recurrence. By not addressing the root cause, we encounter the same problem or same type of problem again and again, and operational performance does not improve. The A3 process helps people engage in collaborative, in-depth problem solving. It drives problem solvers to address the root causes of problems, which surface in day-to-day work routines. The A3 process can be used for many situations, and in our experience, when used properly (e.g., all of the steps are followed and completed), the chances of success improve dramatically.

Steps of the A3 Process

Step 0: Identify a problem or need
Step 1: Conduct research to understand the current situation
Step 2: Conduct a RCA (Root Cause Analysis)
Step 3: Devise countermeasures to address root causes
Step 4: Develop a target state
Step 5: Create an implementation plan
Step 6: Develop a follow-up plan with predicted outcomes

The results of steps 0 to 6 can be recorded on an A3 report.

Step 7: Discuss plans with all affected parties
Step 8: Obtain approval for implementation
Step 9: Implement plans
Step 10: Evaluate the results

The A3 report goes hand in hand with steps 0 to 6 of the A3 process. The purpose of the A3 report is to:

1. Document the learning, decisions, and planning involved with solving a problem
2. Facilitate communication with people in other departments
3. Provide structure to problem solving so as to maximize learning

Note that the A3 process is rooted in the more basic PDCA cycle and also incorporates an RCA. Steps 1 to 4 are the PLAN step of the PDCA cycle. Steps 5 and 9 are part of the DO step and steps 6 and 10 are part of the CHECK step. Based on the evaluation, another problem may be identified and the A3 process starts again (ACT). This process is a good match for projects that require multiple disciplines to interact and improve a program. We provide an example of applying the A3 process to solve long patient transportation times at a medical center.

A CASE STUDY IN A3 PROBLEM SOLVING

Long Patient Transportation Times

The Context At Community Medical Center (CMC), two types of patients are sent to the diagnostic departments for procedures: outpatients and inpatients. The outpatients come to the hospital, register, complete the procedure, and leave on the same day. The inpatients reside in the clinical departments overnight and are sent to the diagnostic departments for various procedures depending on the medical necessity. Once the procedure is complete, the patient is returned to the clinical department.

Some of the outpatients who come for the procedures are elderly and frail and therefore unable to walk to the diagnostic department. It is the responsibility of the transportation department to provide a transporter for the patient to get to the appropriate department for procedures. Similarly, it is the responsibility of the transporter to get inpatients to the diagnostic department when they are scheduled for a procedure. The diagnostic departments (i.e., Operating Room, Radiology, Nuclear Medicine, Cardiology, Endoscopy, and Emergency Room) in CMC regularly reported that patient transporters took an exceedingly long time causing delays in treatment and patient waits, and they blamed the transporters for the delays. Many thought that the transporters were having long coffee breaks and that transport was taking over half an hour to bring patients to their appointments. The transportation manager decided to address the issue with an A3 process and report.

A group of individuals representing the diagnostic departments (i.e., Radiology, Endoscopy, Special Procedures, Cardiology), Nursing, Transportation, and Quality Risk Management met to discuss the issue and initiated the A3 problem solving method. These individuals formed the core A3 problem-solving team. To understand the problem first hand, the transportation manager and four transporters observed the current process. They observed the process for requesting transportation for patients every day for 10 hours over 10 days. The manager also contacted and interviewed different individuals in the diagnostic departments and the clinical departments to get first hand information about the process. The transportation manager observed all nursing stations and procedure areas, and noted a process full of miscommunications. For example, a ward secretary said she would call a transporter right away, but she actually made the call 37 minutes later, 3 minutes before the procedure. This happened frequently. The procedure department and the nursing station never communicated as to the expected patient transport times or procedure times. The patient's nurse often was not aware that the patient was going to a procedure, so the patient medications were not always administered for the procedure. In addition, using a self-devised form, the manager of transportation completed a patient transportation survey. In his survey, he measured the time difference between the transporters receiving a request from the diagnostic department to the time the patient was transported to the diagnostic department or the procedure area. The results of 23 patients surveyed over a 3-day period (January 15, 2003–January 17, 2003) showed an average request to delivery time of 56 minutes. The actual patient transport time was only 5 minutes and the rest was preparation time and delays in communication. The communication delays caused additional delays in procedures, resulting in unhappy patients, clinical workers, and physicians. In the current state, somebody from the diagnostic department, usually a technician called or paged the transporter. At other times, somebody from the department called the ward secretary on the floors who then called the registered nurse (RN) and the transporter. The transporter did not know who was paging. Sometimes, the message the transporter received said, "Bring down John Doe to Radiology." There was no information on the room number, bed number, floor, or area. The transporter did not know from where the person was paging and did not always know whom to call to clarify. They only knew that a patient needed to be transported. A great deal of time was thus expended by the transporter on patient search. If the information was complete and the patient was ready for the procedure, the transporter reached the patient and transported him or her to the diagnostic department without delay. However, in many situations when the transporter reached the patient (usually inpatients), they were not ready and were in need of medications, bathroom break, IV change, or other needs. In those situations, as the patient was not ready for transport, the transporter contacted the nurse. The transporter left the room and waited for the call from the nurse when the patient was ready for the procedure. The transportation manager created a drawing of the current state (patient ready for transport) on the A3 report with appropriate icons and arrows to indicate the flow of information and patient through the system (see Fig. 12-1). On the current state drawing, he recorded the shortest (9 minutes), longest (177 minutes), and average transportation time (56 minutes) from the data collected earlier. The problems he identified were no written message to request a transporter and late arrival by the patients at the diagnostic departments. These are depicted as "storm clouds" on the current state diagram.

The A3 problem-solving team brainstormed the root causes to the problems using the "5-Whys" approach. The 5-whys tool is used to develop root causes for a problem. Brainstorm all the possible causes of the problem. Ask: "Why does this happen?" As each idea is given, the facilitator writes it as a branch from the appropriate category. Causes can be written in several places if they relate to several categories. Again ask "why does this happen?" about each cause. Write subcauses branching off the causes. Continue to ask "Why?" and generate deeper levels of causes. Layers of branches indicate causal relationships. When the group runs out of ideas, focus attention to places on the chart where ideas are few.

The analysis of the first "storm cloud" revealed that the staff members calling from the diagnostic department were often too busy to send written messages to the transporter or to the floors, and therefore, the message lacked complete information causing delays. The analysis of the second "storm cloud" revealed that because the RNs or the ward secretaries were sometimes not aware that a patient needed a procedure, they failed to prepare the patient on time, which eventually led to late arrival of the patient at the diagnostic department.

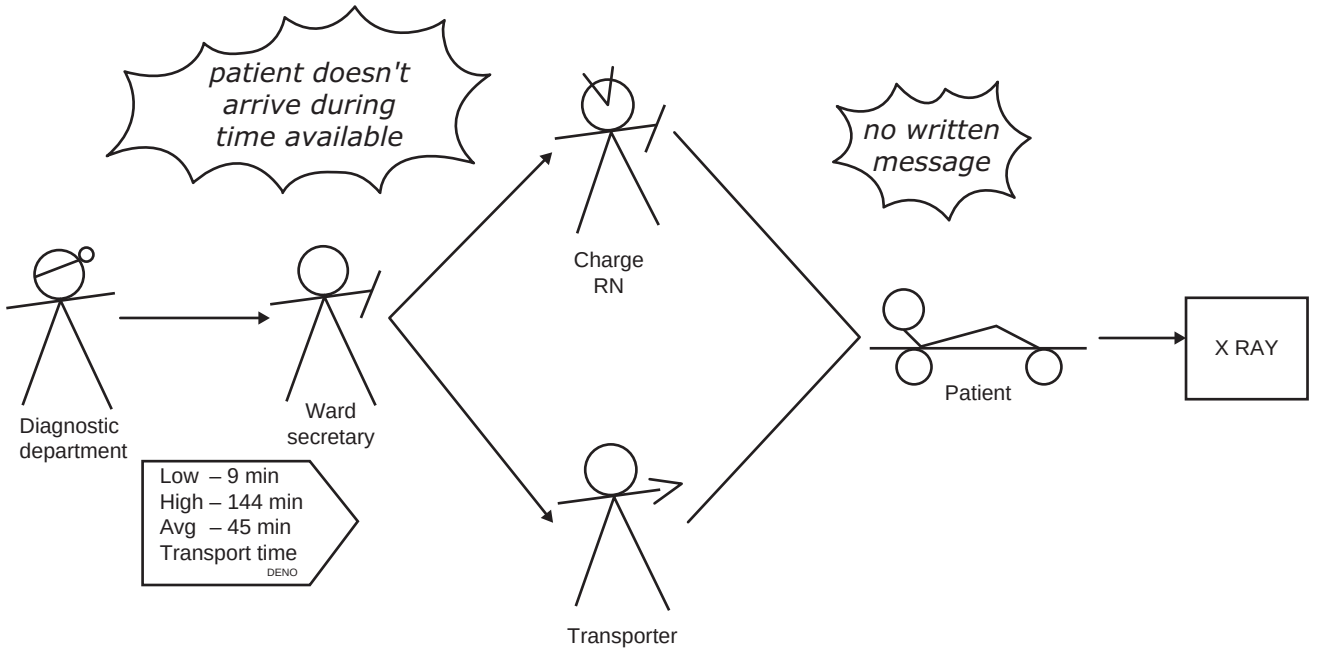

FIGURE 12-1 Current state of patient transport.

Based on the understanding of the current state and the associated root causes, the team embarked on devising the target state. The transportation manager termed the problem solving as "Road to Recovery." In the target state, the staff in the diagnostic department (usually a technician in Radiology or Endoscopy, or ward secretary in Surgery) would page both the charge RN and the transporter at the same time. The information included in the page would be complete information for effective transport of the patient to the diagnostic department (i.e., patient's first and last name, medical record number, room number, destination, etc.). The charge RN would attend to the nursing care patient needs and the transporter would attend to the comforts during transport such as shoes, blankets, chairs/stretcher, etc. If everything was found in order, the patient would be transported to the diagnostic department for the procedure. On completion of the procedure, the diagnostic department would page the transporter who will return the patient back to their room. The transportation manager drew the target state drawing on the A3 report as illustrated in Figure 12-2.

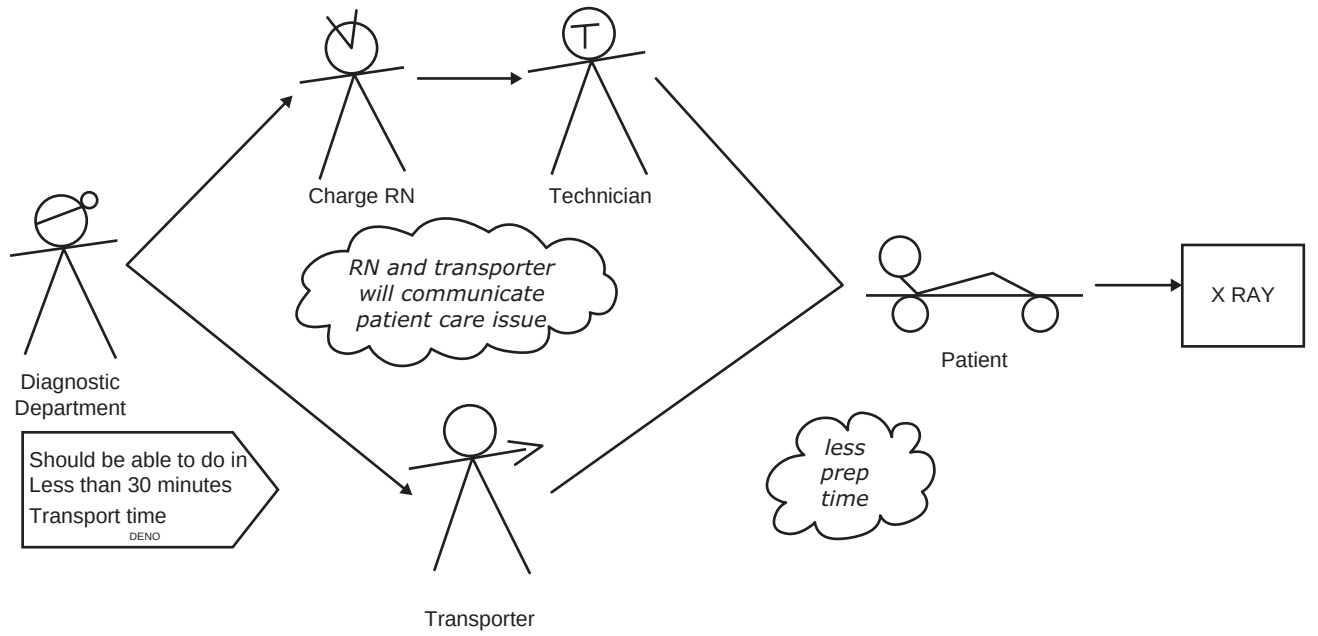

FIGURE 12-2 Patient transport procedure goal.

The specific countermeasures to achieve the target state were as follows:

- Diagnostic departments will beep the charge RN and the transporter at the same time.
- The page will include specific information, and a reference card.
- The charge RN (or designee) and the transporter would attend the patient, with specific responsibilities.
- Make the patient aware of the ensuing procedure.

As part of the implementation plan, the team created a specific action plan. First a designated transporter and a staff member responsible for communications in CMC developed a "group page" whereby two or more people could be paged simultaneously by the diagnostic departments. Second, the transportation manager and the charge RNs met and developed a patient tracking sheet (a log sheet for the floor staff to sign off when the patient is transported). Third, the transportation manager and the designated transporter developed a reference card that contained the pager numbers of the charge RNs of each clinical department and the transport pager number that the diagnostic departments should page. It also listed the information to be communicated by the diagnostic department when asking for a patient transport. This information includes:

- Name of the department from where the message is paged
- First and last name of the patient
- Patient's Medical Record No.
- Room No.
- Patient's destination

The reference card also contained the step-by-step procedure for requesting a transporter by the diagnostic departments. The transportation manager sent copies of the sheet to every department to ensure safe, accurate, and efficient transport of patients.

To ensure smooth implementation of the improved process, the transportation manager met with key individuals in all clinical departments on a one-on-one basis, explained to them about the necessity of the new process, and got their feedback on the new process and how it could be improved. He also had meetings with the house supervisors to get them on board with the new process.

The transportation manager set the target time from request to delivery at 30 minutes. The rationale was that most procedures are scheduled in 30 minutes increments. He carried out follow-up surveys at regular intervals to continue to assess transport time, and improvement in transport times was documented over 2 years, from average transport time of 15 minutes in March 2003 to 9 minutes in May 2005.

The transportation manager felt that the A3 process was very effective for problem solving in healthcare. He found the A3 process a very important tool for evaluating problems and/or processes. It allows a team to look at how a process flows and where the problem or work around area may be. It promotes team work on solving problems by giving a global and unbiased look into procedures. This process also incorporates other tools that quality managers are familiar with such as PDCA and RCA. Two other tools that could be used to solve these types of problems would be the Scribble Pad (a version of a RCA to solve existing problems) which could be deployed when problems of implementation are first discovered. The second tool is called TRIZ. This method is based on logic and data utilizing structured algorithms to solve problems and to facilitate "outside of the box" thinking. Additional information can be found on the Internet (25).

TABLE 12-1

Tools for Quality Improvement Projects and Potential Application

Tool	*Goal and Project Type*
PDCA	Small improvement in process already well established requiring minimal resources (i.e., medication reconciliation, home antibiotic infusion service)
RCA	Evaluation of causes for single or related events (i.e., medication errors)
A3 process	Introduction of new technology or redesign of a process involving significant amount of resources or multiple disciplines (i.e., patient transport, BCMA implementation)

PDCA, plan, do, check, and act; RCA, root cause analysis; BCMA, bar-coded medication administration.

SUMMARY

The A3 process along with PDCA and RCA are tools that can be used for improvement projects. Determining which one to use depends on the type of project, the familiarity with the tools by the persons involved, and the time available for problem solving. Most clinicians involved in quality improvement are familiar with the PDCA process; however, the A3 process, while having more steps can ensure a more complete evaluation of the process and can be useful for most projects. Table 12-1 provides a summary of possible applications for different improvement tools.

As healthcare organizations move forward to automate and improve medication processes, it should become an expected norm that many different "PDCA" cycles or A3 processes will be occurring simultaneously, and in fact every system will be continuously monitored and evaluated, and the question of "how can we further improve?" should continually be asked.

CHAPTER 13

Public Reporting of Healthcare-Associated Infections

Ingi Lee and Patrick J. Brennan

BURDEN OF HEALTHCARE-ASSOCIATED INFECTIONS

In 2000, the Institute of Medicine (IOM) published "To Err is Human: Building a Safer Health System" *(1)*. This report documented the extent and impact of medical errors on patient quality and safety, and identified potentially preventable outcomes, including healthcare-associated infections (HAIs).

The Centers for Disease Control and Prevention (CDC) defines an HAI as "a condition resulting from an adverse reaction to the presence of an infectious agent or its toxin that occurs in a patient in the healthcare setting and is not present or incubating on admission" (2). Several reports have tried to estimate the prevalence and impact of HAIs on the US health system. Over the past decade, there has been a 36% increased incidence in HAIs *(1,3)*. The CDC estimates that 5% to 10% or 2 million of hospitalized patients develop HAIs annually *(4,5)*. HAIs are associated with approximately $28 to $45 billion in annual attributable costs and 90,000 to 100,000 in annual overall deaths *(5–7)*. The impact of HAIs on morbidity and mortality appears to vary based on the type of infection. Umscheid et al. (8) reported that catheter-associated bloodstream infections (CABSIs) and ventilator-associated pneumonias (VAPs) account for greater than 66% of HAI-related mortality and are associated with up to five times higher mortality rates compared to other HAIs. These figures regarding patients with HAIs are not only significant in themselves but notably higher than those found in uninfected patients. The 2007 statewide HAI surveillance data from the Pennsylvania Health Care Cost Containment Council (PHC4) reported that mortality rates (12.2% vs. 2%), lengths of stay (mean: 19.7 days vs. 4.4 days; median: 15 days vs. 3 days), and hospital charges (mean: $191,872 vs. $35,168; median: $87,655 vs. $19,748) were all higher in patients with HAIs *(9)*. However, it is unclear what proportion of these differences are directly attributable to infection, since these patients often have underlying comorbidities or have undergone more complex procedures that place them at increased risk for HAIs.

Although there is consensus that HAI rates can and should be decreased, estimates of the proportion of HAIs that are largely preventable vary. Clinical evidence supports the notion that substantially decreasing HAIs, at least for discrete periods of time, is possible. For example, the Pittsburgh Regional Healthcare Initiative, which comprises hospitals in southwestern Pennsylvania, initiated a multifaceted infection control intervention in 2001 with the goal of decreasing CABSIs in intensive care units. The intervention included five components: (i) promoting targeted evidence-based catheter insertion practices (e.g., maximum sterile barrier precautions, chlorhexidine for skin disinfection, and avoiding femoral site insertion), (ii) developing an educational module on CABSI prevention strategies, (iii) promoting standard tools for recording adherence to recommended practices, (iv) providing a standardized list of supplies in catheter insertion kits to adhere to recommended insertion practices, and (v) collecting and distributing data on CABSI rates to participating hospitals. CABSI rates decreased 68% over 4 years, from 4.31 to 1.36 per 1,000 central line days *(10)*. Using data from studies such as this, several overall reductions have been calculated. Reports issued from the CDC Study on the Efficacy of Nosocomial Infection Control calculated that a third of HAIs could be decreased by instituting appropriate infection control programs (*4*,11). A 2010 study by Umscheid et al. (8) estimated that the proportions of preventable HAIs may vary based on the type of infection. They calculated that catheter-associated urinary tract infections (CAUTIs) may be the most preventable (up to 65–70% or 95,483–387,550 CAUTI annually); followed by CABSIs (up to 65–70% or 44,762–164,127 CABSI annually), VAPs (up to 55% or 95,078–137,613 VAP annually); and lastly, surgical site infections (SSI) (75, 526–156,862 SSI annually) (8). They also estimated that CABSIs were associated with the highest number of preventable deaths and highest impact costwise (8).

HOW PUBLIC REPORTING MAY MOTIVATE A DECREASE IN HAIS

Since 2000, there has been growing public and media interest in calling attention to the burden of HAIs, with the emergence of several consumer organization–led efforts including the Consumer Union Stop Hospital Infections and the Reduce Infection Deaths campaigns *(12–14)*. This increased attention to the burden of HAIs combined with the IOM report, continued efforts to reduce healthcare costs, and public dissatisfaction with the quality of healthcare,

resulted in an increased call for public reporting and the implementation of state and nationwide initiatives mandating public disclosure.

Proponents, including the CDC, believe that making performance information publicly available is an important component of HAI elimination efforts. They advocate that public reporting could potentially decrease HAI rates, and in turn decrease HAI-related mortality and costs, via one of three potential pathways: the selection pathway, the change pathway, and/or the reputation pathway (*15*,16,*17*,*18*). In the selection pathway, consumers would use publicly available information to inform their selection of what they view to be the safest hospitals and providers. Therefore, protecting or improving market shares would motivate efforts on the part of the hospitals or providers. In the change pathway, providing feedback on existing problems or quality deficits would be sufficient in motivating hospitals and providers to implement evidence-based interventions that could decrease HAI rates. In the reputation pathway, maintaining or improving their public image would provide the motivation for hospitals and providers to change. Although each of these pathways may play a role, a study by Hibbard et al. *(18)*, which compared private confidential reporting, which would stimulate change via the change pathway, versus public reporting, which would stimulate change via the reputation pathway, found that the reputation pathway may be the strongest driver to change.

Public reporting is not limited to HAIs, but has also been used to measure other healthcare outcomes and processes of care. The Centers for Medicare and Medicaid Services (CMS) has several programs to publicly disclose healthcare information to consumers including the National Voluntary Hospital Reporting Initiative, the Premier Hospital Quality Incentive Demonstration Project, and the Nursing Home Quality Initiative.

IMPORTANT COMPONENTS OF PUBLIC REPORTING

Healthcare Infection Control Practices Advisory Committee

Due to the increased interest in public reporting, the Healthcare Infection Control Practices Advisory Committee (HICPAC), a federal advisory committee that provides infection control guidance to the Department of Health and Human Services and the CDC, convened in 2005 to provide guidance in helping policymakers in the creation of public reporting systems. This report enumerated the following principles that HICPAC believed were essential for successful public reporting: (a) identifying appropriate measures of healthcare performance, (b) identifying patient populations for monitoring, (c) case finding, (d) validation of data, (e) resources and infrastructure needed for a reporting system, (f) HAI rates and risk adjustment, and (g) producing useful reports and feedback (*19*,20).

Identifying Appropriate Measures of Healthcare Performance

HICPAC recommended a comprehensive approach to identifying an appropriate measure of healthcare performance. This would include measuring both process and outcome measures *(21–23)*. Process measures (e.g., adherence rates of central line insertion practices), which are currently recommended by the National Quality Forum and required by CMS and the Joint Commission on Accreditation of Healthcare Organizations, would potentially provide a simpler comparison than outcome measures. Appropriate process measures have an unambiguous 100% target, should be valid across a variety of healthcare settings, and do not require adjustment for a patient's underlying HAI risk. The outcome measures (e.g., CABSI) should be selected based on multiple factors including the prevalence, severity, and preventability of the HAI; and the ability to accurately detect and report the infection (*19*,20,*24*).

Identifying Patient Populations for Monitoring

Collecting hospital wide HAI rates is difficult at most hospitals due to resource limitations. Therefore, HICPAC recommended that monitoring be focused on populations where HAIs are more frequent and where prevention strategies would make the most meaningful impact.

Case Finding

HICPAC also advocated the use of standardized case-finding methods (e.g., review of medical records, administrative data sources such as the *International Classification of Diseases, 9th revision, Clinical Modification* [ICD-9-CM]). Standardization is important since differing merits and limitations may be associated with each method and the use of different methods may yield inconsistent results, resulting in potential surveillance bias (i.e., hospitals with more comprehensive case finding will report higher HAI rates due to their surveillance method).

The best methods to measure HAIs have not yet been clearly defined. Although using ICD-9-CM codes, which were developed for payment purposes, for HAI surveillance may be relatively facile, there appears to be significant limitations to this method. A study by Sherman et al. (25) reported that ICD-9-CM has a 61% sensitivity and 20% positive predictive value in identifying HAIs (i.e., CABSI, CAUTI, VAP, and SSI). Stevenson et al. (26) also reported that administrative coding alone may be insufficient for HAI surveillance. Stone et al. (27) performed a comparison of HAI identification using two different methods (i.e., Patient Safety Indicator vs. CDC definition for CABSI) and found that they resulted in discordant results.

Validation of Data

Validation of data was recommended by HICPAC to ensure that the information is complete, accurate, and comparable among hospitals.

Resources and Infrastructure Needed for a Reporting System

Hospitals are limited in the infection control resources that are available to them. Therefore, HICPAC recommended allocation of adequate resources (e.g., trained infection control personnel), in addition to an effective infrastructure (e.g., data collection forms and training manuals) to collect accurate data and to produce useful reports. HICPAC also stressed the importance of balance to ensure that the efforts used to comply with public reporting do not detract from necessary patient care and prevention efforts.

HAI Rates and Risk Adjustment

Reported infection rates should be adjusted for factors that may be associated with HAI risk to allow for reasonable comparison across hospitals. This would account for and not unfairly handicap those hospitals that treat higher-risk patients or perform higher-risk procedures that may be associated with increased risk.

Producing Useful Reports and Feedback

HICPAC recommended that the released reports need to be clear, interpretable, and useful to the public. The reports should also include limitations of the data and the methods used for risk adjustment. Lastly, future studies need to evaluate whether this additional information does help consumers make informed decisions, or whether it misleads or results in confusion.

Association for Professionals in Infection Control and Epidemiology

In addition to the guidance provided by HICPAC, the Association for Professionals in Infection Control and Epidemiology (APIC) released a position paper in March 2005 *(28)*. This document supported the public's right to know, but acknowledged that there were current limitations to the usefulness of public reporting. A few of the potential limitations included limited resources necessary to accurately capture surveillance data (which are often extracted manually), and that ensuring fair comparisons of HAI rates across hospitals may be difficult given the differing levels of complexity in the patient populations, treatments, and procedures offered. APIC listed the following nine recommendations, echoing the guidance from HICPAC, that they believed were necessary in public reporting of HAIs: (a) standardized surveillance monitoring of the same outcome (e.g., HAI) and process (e.g., evidence-based healthcare practices demonstrated to decrease HAI) measures; (b) standardized methods to collect, risk adjust, analyze, compare, and report data; (c) development and implementation of computer systems to help improve the efficiency, accuracy, and effectiveness of infection surveillance programs; (d) involvement of infection control experts in the design, implementation, and evaluation of systems for publicly reporting infection data; (e) mechanism to ensure that data reported will be useful and not misleading for consumers and to provide information back to hospitals to help implement changes in infection control programs; (f) consumer education on infection prevention strategies and the meaning of publicly released reports; (g) adequate support and resources to prevent infection control personnel and other healthcare resources from being diverted away from necessary infection prevention activities and toward data collection; (h) research to determine the impact of public reporting of HAIs; and (i) adequate funding and infrastructure to support public reporting.

STATE LEGISLATION ON PUBLIC REPORTING

In December 2006, the Consumer Union Hospital Infection Disclosure Act advocated for hospitals to collect and submit quarterly reports on SSI, VAP, CABSI, and CAUTI rates to their respective state health departments *(29)*. State agencies would then make the risk-adjusted data publicly available on their state websites. This document also required state health departments to create advisory committees that would include hospital representatives, healthcare professionals including physicians and nurses, epidemiologists, researchers, consumer organizations, health insurers and health maintenance organizations, and health insurance purchasers. A number of states have implemented reporting of HAIs based on this document within a range of varying frameworks *(30)*.

In 2004, Pennsylvania became the first state to require public reporting of HAIs. Pennsylvania instituted their public reporting requirement in phases. All acute care hospitals were initially required to submit data on cardiovascular, neurosurgical, and orthopedic SSIs. The list of reportable infections evolved over time until it encompassed all HAIs, including SSIs, CABSIs, CAUTIs, and VAPs. The PHC4, an independent state agency originally established in 1986 by the General Assembly and the Governor of the Commonwealth of Pennsylvania to promote control of healthcare costs, was tasked with collecting statewide HAI data and reporting this information annually. Surveillance data are not collected from billing data. Instead, HAIs are reported by individual hospitals with an increasing number of hospitals using a form of electronic surveillance (although not all hospitals utilize the same system). In addition to providing overall HAI rates, PHC4 then presents data categorized by "peer groups" comprised of hospitals that may be more similar in the patients they treat and the services they offer. PHC4's 2007 report included surveillance data for 1,578,600 patients from 165 general acute care hospitals in Pennsylvania *(9)*. They reported that 27,949 patients had acquired HAIs. This was the first year that PHC4 was able to compare infection rates to prior years. In comparison to 2006, the overall HAI rates decreased 7.8% from 19.2 per 1,000 cases to 17.7 per 1,000 cases, with decreased rates noted for CAUTIs, VAPs, CABSIs, and SSIs.

Over the past 6 years, additional states have followed and expanded upon the Pennsylvania experience. In 2005, Florida became the first state to release hospital-specific HAI rates through a website called Florida Compare Care (http://www.floridacomparecare.gov) created by the Florida Agency for Health Care Administration. Utilizing the data to make comparisons among hospitals, however, is difficult due to a lack of standardization in data collection. As of March 2010, 27 states have passed state legislation requiring public reporting of HAIs, 5 have allowed for voluntary or confidential reporting, and five have not formally passed legislation but have formed task forces or advisory committees to pilot programs for public reporting (Table 13-1). Of the remaining states that do not have state legislation, many have bills pending *(31)*. With a few exceptions, the agency responsible for reporting is typically the state's department of health; and both statewide as well as hospital specific statistics have been made available *(30)*. A majority of these hospitals have utilized NHSN for reporting with NHSN noting increased hospital enrollment from 300 to >2,400 hospitals at the end of 2009 (*9*,32). The remaining states have not mandated the source from which surveillance data should be obtained *(33)*.

TABLE 13-1

Public Reporting of HAI by State

States with legislation requiring public reporting of HAI (year)
- Alabama (2009)
- California (2008)
- Colorado (2006)
- Connecticut (2006)
- Delaware (2007)
- Florida (2004)
- Illinois (2003/amended 2005)
- Maine (2009)
- Maryland (2006)
- Massachusetts (2008)
- Minnesota (2007)
- Missouri (2004)
- New Hampshire (2006)
- New Jersey (2007)
- New York (2005)
- Ohio (2006)
- Oklahoma (2006)
- Oregon (2010)
- Pennsylvania (2004/amended 2007)
- Rhode Island (2008)
- South Carolina (2006)
- Tennessee (2006)
- Texas (2007)
- Virginia (2005)
- Vermont (2006)
- Washington (2007)
- West Virginia (2008)

States with confidential reporting of HAI to state agencies (year)
- Nebraska (2005)
- Nevada (2005)

States with voluntary public reporting of HAI (year)
- Arkansas (2007)
- Arizona (2006)
- Wisconsin (2009)

States with a task force or committees established to guide public reporting of HAI (year)
- Alaska (2006)
- Georgia (2006)
- Indiana (2005/amended 2007)
- New Mexico (2007)

FEDERAL LEGISLATION ON PUBLIC REPORTING

Quality measurement initiatives including public reporting of HAIs have also been addressed on the federal level by the US Congress and CMS. The Healthy Hospitals Act of 2009, which requires public reporting of HAIs by hospitals or ambulatory surgical centers, was introduced to Congress and is currently in the first step of the legislative process. The CMS Hospital Quality Initiative was started in 2003 to provide healthcare-related information that would help consumers make informed decisions. Although the program started with voluntary reporting, data for certain medical conditions including pneumonia are now required for full Medicare reimbursement *(12)*.

IMPACTS AND CHALLENGES OF PUBLIC REPORTING ON HAIS

Although most states have mandated public reporting of HAIs, the impact of these efforts is unclear. In 2005, HICPAC requested that the CDC conduct a systematic review of existing literature to evaluate the effectiveness of public reporting on healthcare quality (*19*,20,34). The authors identified 10 studies for inclusion. However, there were no studies that addressed HAIs. In addition, most had methodological flaws including the study design used (none were randomized controlled studies), lack of adjustment for potential confounders, and suboptimal definitions of outcome measures. Highlighted findings from the selected studies are as follows. Two studies reported that improvements in outcomes noted from public reporting systems were likely due to secular trends *(35,36)*. Two other studies, however, did report an association between public reporting and decreased cardiac surgical mortality *(37,38)*. These studies adjusted for secular trends and utilized risk-adjusted mortality as the outcome measure. However, it remains unclear whether these surgical outcomes are generalizable to medical outcomes, including HAIs. McKibben et al. (34) argued that deaths or complications related to surgical procedures may be easier targets for improvement since the responsible healthcare organizations and surgical teams can be readily identified. In contrast, there are likely multiple factors that place a patient at risk for HAIs, and these factors may not be able to be well delineated. With the evidence review by the CDC, HICPAC concluded that there was insufficient evidence to recommend for or against public reporting of HAIs (*19*,20,34).

Since then, there have been a number of additional studies published evaluating the effect of public reporting. The most recent systematic review on this topic was performed by Fung et al. *(39)* and included 45 studies published from 1986 to 2006. Again, none of these studies evaluated HAIs. Overall, the authors reported that public reporting modestly affected consumer selection of health plans, but not hospitals. A synthesis of 11 studies, largely descriptive in nature, found that public reporting stimulated quality improvement efforts on the part of hospitals. However, there were inconsistent data regarding public reporting on improved effectiveness, patient safety, and patient centeredness.

Several additional studies published also found that publicly reported data did not meaningfully affect consumer selection of healthcare providers and/or hospitals *(40,41)*. They reported that the decisions, particularly more urgent treatment decisions, were largely influenced by recommendations from family and friends. A study by Mazor et al. *(15)* found that consumers preferred and were best able to compare hospitals when presented with short simple reports. However, this information was not sufficient in itself for decision making. Consumers also relied on additional factors including prior experience, reputation, and insurance coverage. The less-than-expected impact of public reporting on consumers' decision making may result from nonstandardization of reported data. Rothberg et al. *(42)* conducted a study comparing the results from five websites that ranked local hospitals in Massachusetts based on four diagnoses. They found that there were significant inconsistencies and a lack of correlation in the results available from these sites. This nonstandardization of data reporting and interpretation could decrease the usefulness of publicly available data.

SUMMARY

HAIs, infections that are acquired in the healthcare setting, are associated with significant morbidity and mortality. There has been growing healthcare, media, and public interest in decreasing HAI rates, many of which are believed to be preventable; however, the proportion of HAIs that are actually preventable is unclear with reported rates varying from 33% to 70%. Public reporting of HAI has been advocated as an important component in decreasing HAIs with legislation or regulations passed in a majority of states. Consumer organizations have argued that making this information publicly available is imperative for consumers to make informed decisions and could in turn, be a strong motivator for healthcare providers and hospitals to institute changes and make the elimination of HAI a top priority. Despite the increase in public reporting, there is wide variability in how this information is collected and reported, and there is inconclusive data regarding the impact of public reporting on patient safety and quality, particularly for HAIs. Further research will be important to evaluate whether these measures have been able to decrease rates of HAI, and to help identify limitations that may help to increase its effectiveness.

CHAPTER 14

Working with the News Media in Public Communication

Marjorie Kruvand

Outbreaks. Pandemics. MRSA. E. coli. H1N1. Salmonella. C. diff. West Nile virus. Surgical-site infections. Mandatory infection reporting. These are some of the challenging topics that public health professionals, healthcare epidemiologists, and infection preventionists deal with in their efforts to protect the health of patients, employees, and the public. Increasingly, these topics have also captured the attention of the news media and the public. Communicating with the public is an increasingly important responsibility of hospitals and other healthcare facilities, government agencies, and healthcare organizations. Working with the news media is an essential way in which this occurs.

Your institution, organization, or agency may want to communicate proactively or reactively on a health issue in the hope that the public will become informed, take action, change their behavior, or be reassured. Or a reporter may contact you, seeking information or expert opinion on an issue involving your institution or community—or beyond. When a new "superbug" surfaces, every time there is an outbreak, whenever a journalist needs help deciphering the "alphabet soup" of pathogens or understanding the difference between causation and coincidence, you may be a logical resource for the news media because of your experience and expertise.

Yet many public health professionals avoid talking with reporters because they predict the story will be marred by misrepresentation, sensationalism, and inaccuracy (1). These fears are frequently overblown, however, and the outcome can be improved by an understanding of how the news media works as well as preparation and practice. Anyone can learn effective communication skills to help them become more confident and comfortable talking with reporters and improve the likelihood of a getting a story that is accurate and fair. And the more often you talk with reporters, the better you will become.

This chapter provides an overview of the news media and details how the media landscape has changed drastically over the last decade or so. It describes what guides the work of reporters and what they are looking for from you. It walks you through what to do after a reporter calls and before, during, and after an interview. It also introduces the practical skills and communication techniques that can make anyone a stronger communicator, and, hopefully, lead to long-term, mutually beneficial relationships with reporters. And finally, it suggests additional resources for information and training.

THE ROLE OF THE NEWS MEDIA IN PUBLIC COMMUNICATION

The public gets most of its information about health and science from the news media. The news media is a critical vehicle, as well as one of the most accessible, for communicating scientific and medical information *(2)* as well as the principal arena in which scientific issues and controversies come to the attention of decision makers, interest groups, and members of the public *(3)*. The news media serve as brokers between health, science, and the public, "framing social relationships for their readers and shaping the public consciousness about science-related events…. Through their selection of news, journalists help to set the agenda for public policy" *(4)*. The news media also forcefully shape how policy issues related to health and scientific controversies are defined, symbolized, and eventually resolved *(3)*.

Health and Science News

More than half of Americans get information about health and science from television, 22% from newspapers, 12% from the Internet, 8% from radio, and 3% from magazines *(5)*. Studies show that the public is interested in news about health and science: 35% of Americans surveyed in 2009 said they enjoy keeping up with science news "a lot" and an additional 41% said they enjoy keeping up with it "some" (6).

In another survey, 95% of Americans said they were "very interested" or "moderately interested" in news of medical discoveries and 92% said they were "very interested" or "moderately interested" in scientific discoveries—higher than the percentages who said they are "very interested" or "moderately interested" in the economy, agriculture, local schools, military and defense policy, or international and foreign policy *(5)*.

Public health news has all the ingredients for compelling stories, according to Maryn McKenna, a former public health reporter at the *Atlanta Journal-Constitution*:

> *Public health stories have urgency, drama and novelty. They are complex, what a public health scientist would call "multifactorial." Frequently they arise out of the near-universal dread of the new and frightening (7).*

Public Knowledge—and Why It Matters

Despite solid public interest in news of health and science, public understanding of complex health and scientific topics is quite low. In fact, surveys repeatedly show that ignorance, superstition, and irrational thinking often prevail over knowledge *(1)*. When US adults were quizzed in 2009, respondents correctly answered an average of eight of the 12 questions, or 65%; only 10% got all 12 questions right (6). Among the findings: 46% of respondents did not know that antibacterial antibiotics will not kill viruses.

Eighty-five percent of US scientists surveyed in 2009 said it was a major problem that the public did not know much about science (6). Lack of public understanding about health and science can help foster a society in which "science is often misrepresented and arguments about values are often presented as if they are legitimate scientific disputes" (1). Other arguments supporting the need for increased scientific literacy are being able to make better personal choices in everyday life, being encouraged to follow and participate in policy debates, and being more likely to support scientific and medical research (8):

> *We need an informed public if social policies are to be decided on reasonable and rational grounds. Everything from the future of health care and how it's paid for, to taxation on fuel, could benefit from a wider appreciation of the wider science (9).*

Stereotypes and Strained Relations

There has been considerable debate over the intellectual divide of science and the humanities into "two cultures," which was proposed in 1959 by C. P. Snow, an English physicist, civil servant, and novelist. Among its manifestations is a perceived gap between "scientists who don't speak English and reporters who don't speak science," which has kept the two professions "worlds apart" (10). Others contend that the gulf between scientists and journalists is neither as wide nor as unbridgeable as some suggest. As *Nature*, the British science magazine, editorialized:

> *Science and journalism are not alien cultures, for all that they can sometimes seem that way. They are built on the same foundation—the belief that conclusions require evidence; that the evidence should be open to everyone; and that everything is subject to question. Both groups are comprised of professional skeptics. And whether it's directed towards an experiment or a breaking news story, each can appreciate the other's critical eye (11).*

Still, there is an "enormous scope for mutual misunderstanding and suspicion" between journalists and scientists (8). Part of the reason is that the professions "demand two completely different standards of evidence" (10). Language use is another major source of tension: "What is for a scientist being precise is for a journalist splitting hairs. Necessary scientific qualifications translate as uncertainty or the hedging of bets in the media" (8). As Kathy Sawyer, a former science reporter for the *Washington Post*, put it:

> *Science is slow, patient, precise, careful, conservative and complicated. Journalism is hungry for headlines and drama, fast, short and very imprecise at times (10).*

The vast majority of scientists rarely talk with the news media. Forty-five percent of US scientists surveyed in 2009 said they never talk with reporters, 31% said they did so rarely, and only 3% said they did so often (6). A survey of more than 1,600 scientists in Britain by the Wellcome Trust found that only 29% had talked with the news media in the previous year *(12)*.

Yet neither profession can accomplish the task of communicating with the public without the other:

> *If reporters don't understand what a scientist is saying, how can they translate it for their audience? Or, put another way, if scientists aren't clear and concise, how can they expect reporters to get the story right? (13).*

How Scientists Perceive Reporters

Scientists view journalists as "imprecise, mercurial and possibly dangerous" (10). Scientists complain that reporters don't understand the basics of scientific methods, including the proper interpretation of statistics, probabilities, and risk. As a result, the news media oversimplify complex issues (10).

US scientists have negative views about news coverage of science (6). Seventy-six percent said they believe it is a major problem that the news does not distinguish between well-founded findings and those that are not, and 48% said oversimplification is a major problem. Only 15% of US scientists rated television coverage of science news as excellent or good, while 83% said it was fair to poor. In contrast, 36% of the US scientists rated newspaper coverage of science as excellent or good, while 63% rated it as fair or poor (6). In Britain, only 6% of scientists surveyed said they trusted journalists at national newspapers to provide information on scientific facts, and 11% were confident of journalists' ability to discuss the social and ethical implications of science *(12)*.

How Reporters Perceive Scientists

Journalists see scientists as "narrowly focused, self-absorbed, cold-eyed and arrogant" (10). Dan Fagin, a former environmental reporter for *Newsday*, put it this way:

> *Scientists now are more reluctant than ever to venture out of their ivory towers. Shunning messy public controversies, they tend to communicate only to each other and through the rarified language of peer-reviewed journals (14).*

British scientists surveyed by the Wellcome Trust acknowledged that the public sees them as doing poorly in public relations *(12)*.

Reporters contend that scientists don't appear to grasp that news is a perishable commodity that must be made relevant to readers and viewers. Journalists also complain that scientists are too wrapped up in esoteric jargon and are unable—or unwilling—to explain their work simply and cogently (10).

Quality of Health and Science Reporting

Even journalists acknowledge the imperfections of today's health and science reporting: it tends to be quickly produced, brief, superficial, and easy for the audience to digest *(15)*. Coverage is heavy on lifestyle and fitness

stories, profiles of desperate cases and "rescue medicine," and "disease-of-the-month" features. There is an increased reliance on news releases and fewer investigative pieces. Andrew Holtz, a former health reporter at CNN, contends that "much local TV health and medical news coverage looks like the media equivalent of a 99-cent drive-thru menu: quick, cheap, but ultimately unnourishing" *(16)*.

Part of the problem stems from journalists' uncertainty about their fluctuating role in society: should they be cheerleaders, interpreters, watchdogs, critics, or some combination? One science journalist describes the professional challenge this way:

> *Is our job to describe the bigger picture, or simply report what is 'new'? Should we present black-and-white versions of reality that lend themselves to stark headlines, rather than grayer complexities that are harder to distill into simple truths? (17).*

In addition, reporters tend to cover health and science as a series of disconnected events, dangers, or breakthroughs:

> *The unfortunate practice of treating science this way encourages the incorrect belief that scientific results are final, immutable end points. Thus, when new scientific research modifies prior findings, the public feels misled, as if scientists keep pulling the rug out from under them (13).*

Reporters believe more interaction and engagement is needed with scientists and public health professionals. But they contend that the onus has been placed squarely on themselves: While journalists are frequent visitors to hospitals, research labs, and offices of government agencies, they say it is rare to see a scientist in the newsroom (13).

WHY WORK WITH THE NEWS MEDIA?

Your first instinct might be to shun talking with reporters. You may have heard anecdotes about interviews gone wrong. You may think you are too busy, or believe your boss or colleagues would frown on it as self-promotion (10). You may think what you have to say is too esoteric for reporters to understand or too difficult to translate into everyday English. Or you may believe that the news media is an arena in which "important work is all too often misrepresented or hyped" (1). But these knee-jerk reactions are insular and ultimately counterproductive. As the editors of *Nature* asserted:

> *Science, with its inherent uncertainties, can be hard to put across to the public. But blaming 'sloppy' journalism is too easy. If researchers are to make their points effectively, they should learn more about how the media work (18).*

Some public health professionals refuse to talk to reporters yet are quick to criticize when the news media get the story wrong or miss the story entirely. Public health professionals, healthcare epidemiologists, and infection preventionists cannot have it both ways: they cannot criticize the media for the poor quality of information communicated to the public or leaving the public in the dark about important issues while refusing to talk with the news media. Dr. William R. Jarvis, who was an official at the U.S. Centers for Disease Control and Prevention for 23 years before becoming a consultant, says: "If you don't have experts talk to the media, people with much less expertise or no expertise will be talking and there could be a huge amount of misinformation out there."

Increased Reliance on Experts

The news media increasingly depend on experts for three main reasons: to offer facts, to increase credibility, and to provide objectivity *(19)*. Most often, experts are used to provide and verify facts and background information *(20)*. A study of *The New York Times, Los Angeles Times*, and *Washington Post* found that nearly twice as many experts were quoted in 1990 as in 1978 *(21)*. Research on Danish newspapers also found that the number of experts has increased dramatically over the last 40 years *(22)*. Reporters increasingly include more experts to make stories more interesting and relevant by highlighting conflict and tension:

> *… Since the requirement of maintaining professional objectivity precluded journalists from personally judging the statements or actions of those involved in news stories, persons having no part in the conflict—'persons of authority'—were brought in as referees and critics. Experts from academia and the research sector were perfect for this role (22).*

Several other factors have encouraged greater use of experts, including increased media competition. Reporters have also compensated for low levels of public trust in journalism by using experts to augment their own credibility *(22)*. Another factor is the growing complexity of the news; 60% of local television health reporters surveyed said they must frequently find a health expert to explain complicated information because of the technical nature of medical news *(23)*.

Reporters as Conduits

Reporters see themselves as conduits to the public. "As they see it, the job they are doing is to stand in for their audience, asking the questions that the general public wants answered" (8). Working with the media to provide important information to the public thus helps provide a public service.

Another reason to talk with reporters is that it can establish or reinforce your expertise and raise your profile. Being quoted in the media may contribute to funding opportunities, career advancement, and greater prestige. Examples of successful communication with the public are looked upon favorably in an era of increased competition for government and private funding. Thirty-seven percent of US scientists surveyed in 2009 said it was either very important or important for career advancement to have their research covered by the news media (6).

The institution, organization, or agency for which you work also benefits from media coverage because of increasing pressure to elevate its prestige, establish trust and credibility, attract funding, and preserve its viability *(22)*. Being mentioned in news stories can thus have significant practical value.

HOW THE NEWS MEDIA WORKS

In many democratic countries, media organizations are privately owned by families or corporations, including large chains and international media conglomerates. The news media serves more or less successfully as an independent "Fourth Estate," raising awareness of issues, interpreting events, keeping an eye on government and big business, and serving as advocate and critic. In other countries, such as China, media organizations are owned and operated by the government and used to help advance governmental aims and policies. In still other countries, the news media is nominally independent but subject to explicit or implicit state interference or pressure.

Types of media organizations include daily and weekly newspapers (national, regional, and local) and their websites, television stations and networks (including cable television), radio stations and networks, magazines, Internet news sites, blogs, and wire services such as the Associated Press and Reuters, which distribute news among member media organizations. Recent changes in the media landscape will be discussed later in this chapter.

Generalists and Specialists

Reporters are typically intelligent and inquisitive: "Journalists are no less professional than the scientists they deal with; all but a few want to report accurately and fairly" (8). The vast majority of reporters are college graduates, but their degrees tend to be in the liberal arts. Many reporters focused on subjects such as English and history and avoided mathematics and science. Reporters are likely to be knowledgeable about a variety of topics, but their knowledge tends to be a mile wide and an inch deep. This is especially the case with general-assignment reporters, so called because they are assigned to cover whatever stories the editor deems newsworthy that day. General-assignment reporters may cover a city hall meeting one day and report on sewer problems or a factory shutdown the next. This broad-but-shallow knowledge of many reporters is in stark contrast to public health professionals and epidemiologists, who are experts in a narrow field or subfield.

While most reporters are generalists, others are specialists assigned to cover a specific "beat," in which they are responsible for identifying and developing news in that subject area. Beat reporters have more specialized knowledge than general-assignment reporters and some receive specialized professional training. Reporting on public health requires a particular set of skills that differ from those of other journalists, including a basic familiarity with biology, lab science, and clinical medicine; the ability to decipher budgets and politics; and a lack of fear of math *(7)*. A handful of US reporters who cover health or science news have medical or doctoral degrees.

How do you assess a reporter's knowledge of a technical topic? How do you communicate without talking down to them or oversimplifying? If a reporter does not understand what you are saying, he or she will have no chance of translating the information and or communicating it accurately to their audiences. "*How much do you already know about… ?*" or "*Would like me to bring you up to speed on… ?*"are ways in which you can politely assess the extent of the reporter's knowledge at the beginning of the interview and offer to fill in any gaps. Reporters will appreciate this even if they claim to be the highly knowledgeable about the topic.

What Reporters Are Like

Reporters are skeptical, curious, and have a "seen-it-all-before" attitude. They are hungry for great stories, especially stories no other reporter has (called *scoops* or *exclusives*). Reporters are trained to follow a set of organizational routines that guide their work. As part of the newsgathering process, reporters are supposed to rely on credible sources and accurate information and to provide balance in their stories by including the viewpoints of both sides (or all sides). Reporters are driven by deadlines. By the time they contact you, they will probably have their story almost written. They may have a specific spot in the story in mind where they would like to insert a quote or two from you. While this may seem unnatural to you, it is an efficient way for reporters to work (13).

Selling the Story

Reporters first have to "sell" their editor on the merits of the story in the hope of getting prominent placement, such as the front page of the newspaper or the lead story on a television or radio newscast:

> *Journalists sometimes feel the need to play carnival barkers, hyping a story to draw attention to it. This leads them to frame a story as new or different—depicting study results as counterintuitive or a break from the past—if they want it to be featured prominently or even accepted by an editor at all (17).*

Reporters then try to "sell" the story to their audience through vibrant storytelling, human interest, compelling writing, colorful language, and relevant examples. Depending on the nature of the story, the goal may be to get the audience to pay attention, become informed, take action, become outraged, or feel reassured.

Constraints on Reporters

Reporters face a number of constraints that make their job more challenging. The first is time. Reporters are busy and overworked. Deadlines curb the amount of research reporters can do and the number of sources they can contact while limiting the time available for double-checking facts.

Space is another restraint. Increasingly, there is inadequate space and air time to tell complex stories. Glen Nowak, director of the division of media relations at the CDC, said scientists and physicians erroneously believe that they "should be providing all the nuances and caveats that would be found in a journal article" in a news story and "use as much space and time as it takes to get the information out there properly." But he notes that this isn't a realistic expectation in journalism (24).

Reporters must also compete with their colleagues within their own media organization for prime space or position for their stories, which can sometimes lead to sensationalism and hype. And copy editors, who write the headlines, can exacerbate the situation by highlighting the most controversial or sensational aspect of the story.

Complexity is another constraint journalists face. Reporters seek to provide balance by using a number of experts on both or all sides of an argument (8,13). But instead of clarifying complex issues, providing multiple contrasting viewpoints in stories can muddle things further. Reporters sometimes do not evaluate the quality of, or weight of evidence behind, competing claims, or are incapable of doing so (25). In these instances, stories may give the impression that all of the experts are equal and leave it up to the audience to decide which to believe:

> *The new media model routinely accords equal time and weight to two opposing points of view without regard to whether one might be factually demonstrable and the other off the deep end (26).*

Of course, the audience is no better equipped to evaluate the validity of competing claims than the reporter.

A Quest for Definitive Answers

Reporters share a desire with their audience for things to be black or white, not shades of gray. "Grayness" is difficult to handle in news stories, and reporters often pursue a quest for definitive answers even when none can exist. As a result, reporters would like epidemiologists and public health officials to communicate in ways they have been trained *not* to communicate: no careful qualifiers, no litany of exceptions, no hedging. Reporters strive to categorize things as safe or unsafe, people as heroes or villains, and issues as either a "Cause for Big Concern" or "Not to Worry." A reporter's dilemma is: will the information in my story lull the public into a false sense of security or needlessly alarm them?

Old Risks, New Risks

Reporters also face ideological constraints. Old, familiar risks are not as newsworthy as new, exotic ones (25). An example is the seasonal flu, which kills an estimated 36,000 Americans a year *(27)* but garners hardly any news coverage, while the H1N1 flu has received extensive coverage though the death toll to date has been substantially lower *(28)*. Every year before the beginning of flu season, Glen Nowak of the CDC says he faces the challenge of getting the news media to report on the need for people to get flu shots. While he gets some stories every year, Nowak said coverage "won't continue unless there's some new development and some new angle, some new idea, some new research, something new. At the end of the day, the first three letters of news are n-e-w" (24).

Controversy almost always makes better news than consensus. Questions about who is making the decisions, whether the decision makers can be trusted, and whether the public has a say can also add an element of uncertainty and suspicion to stories. In addition, old stereotypes are often perpetuated in the news media: government officials lack credibility, nongovernment organizations are always altruistic and have no agendas of their own, and corporations are interested only in profit. For all these reasons, the public may find it challenging to sort out important public health risks from inconsequential ones based on the amount and tone of media coverage.

What Reporters Want

What do reporters want from you? What they *say* they want is what you are well qualified to provide information, explanation, putting risks or a situation in context, future implications, and opinion. The following examples show how public health professionals and epidemiologists have been used in recent news stories:

Epidemiologists and Public Health Professionals in the News

To Educate:

> *"The message to parents and pediatricians is: vaccinating your child against the chickenpox is also a good way to reduce their chances of getting herpes zoster."*
>
> *Dr. HungFu Tseng, an epidemiologist at Kaiser Permanente in Pasadena, CA, in an article by Reuters (29).*

To Explain:

> *"This epidemic is different from the typical flu season, and we're having to respond in a different way. It's spreading like wildfire in the community and we need to protect the patients who are most vulnerable."*
>
> *Dr. Rekha K. Murthy, director of hospital epidemiology at Cedars-Sinai Medical Center, in a* Los Angeles Times *story on hospitals limiting visitors because of H1N1 (30).*

To Evaluate:

> *"This is going to be a huge help to the infection-control crowd," said Marcia Patrick, a nurse and board member of the Association of Professionals in Infection Control and Epidemiology… "How can we not do this? It would truly be penny-wise and pound-foolish. And it's the right thing to do for patients."*
>
> *Story in* The New York Times *about two new studies suggesting that hospitals could stop infections by tackling bacteria patients bring in (31).*

To Warn the Public about Health Risks:

> *"Many persons who may end up consuming these products may not be aware of those health risks. Are we prepared to let the philosophy of 'Buyer Beware' prevail when it comes to our food?"*
>
> *Dr. Tracy Murphy, Wyoming state epidemiologist, in a story in the* Wyoming Eagle-Tribune *about the illegality of selling raw milk in Wyoming (32).*

To Reassure the Public:

> *"There are no safety concerns with these lots of H1N1 vaccine. The concern is that the recalled vaccine may not be strong enough to provide full immunity. However, children in this age group should have adequate protection because we already recommend that they receive two doses of the vaccine."*

Dr. Megan Davies, an epidemiologist with the North Carolina Department of Health and Human Services, in a story in the Winston-Salem Journal *about the recall of some H1N1 vaccine (33).*

To Put Health Risks in Context:

"The bottom line here is that we still have high rates of influenza due to H1N1 in many parts of this province, in many parts of the country, in many parts of the United States and the European Union. And we cannot afford to let down our guard against this illness. We would rather saturate the population with vaccine rather than virus."

Dr. Arlene King, Ontario's chief medical officer of health, in a story in The Globe and Mail *about not becoming complacent about the H1N1 virus (34).*

To Offer Comment or Opinion:

Dr. Joseph F. Perz, a healthcare epidemiologist with the federal Centers for Disease Control and Prevention, said sometimes hospitals "assume health care workers know better" when it comes to basic infection control practices. "But I think we would like to see more attention paid to reviewing the basics when it comes to delivering IV medications or injections," he said.

Story in the South Florida Sun-Sentinel *about 1,800 hospital patients given tests by a nurse alleged to have knowingly violated infection control protocols (35).*

To Discuss Implications:

Dr. Paul Holtom, hospital epidemiologist at Los Angeles County-USC Medical Center, noted that the 1918 Spanish flu outbreak, which killed 50 million people, first struck in the spring, lost steam, then came back strong in the fall. "We really don't know what's going to happen," said Holtom. "These influenza outbreaks tend to ebb and flow."

Story in the San Bernardino County Sun *about the decline in H1N1 cases in California (36).*

Reporters want more from experts, however. First and foremost, reporters look for accessibility and rapid response; the most interesting information in the world is of no use if it arrives after a reporter's deadline. That means a reporter needs to be able to track you down quickly via phone or email. If possible, you should also suggest other sources the reporter may contact.

Second, the information or comment should be pithy, colorful, quotable, and memorable, which will help reporters in "selling" the story to their editor and, ultimately, to their audience. An example is the expressive metaphor used in the following story about mandatory reporting of hospital infection rates:

Staph infections "tend to ride in on instruments of medical progress," said Dr. Steve Schmitt, an infectious-disease expert from the Cleveland Clinic (37).

Language should be clear and simple, as this quote about predicting future deaths from the H1N1 virus demonstrates:

Michael T. Osterholm, director of the Center for Infectious Disease Research and Policy at the University of Minnesota, agreed that trying to guess how many would die by spring was "calling the score at halftime" (28).

Numbers should be used sparingly and selectively. An example is this quote in a magazine story about autism and vaccines:

"Out of the 100-odd million vaccines a year, we have just a handful of children" who develop a serious injury, says Dr. William Schaffner, a Vanderbilt University vaccine expert (38).

Other effective techniques include offering familiar comparisons to aid public understanding, providing information that can be presented visually, and telling a story. For example, comments from Mary J. Gilchrist, director of the Bureau of Laboratory Sciences in the Massachusetts Department of Public Health, and Dr. Richard T. Ellison III, hospital epidemiologist for UMass Memorial Medical Center, helped shape a news story about public health and hospital officials working to track down the source of a listeria outbreak into a compelling narrative that resembled an episode of the television drama *CSI*:

The recent listeria outbreak linked to three deaths and one miscarriage could have gone on indefinitely without the "detectives" at the state's public health laboratory, who tracked down, fingerprinted, identified and photographed the dangerous strain of bacteria, and then posted the prints in a national computer database to safeguard others (39).

Finally, since controversy is a valued ingredient in news stories, reporters encourage experts to weigh in on points of disagreement. An example is this story about whether New Jersey should have spent millions of dollars on antivirals that have so far gone unused:

"If you had a novel strain causing a pandemic that was responsive to antivirals and your state had no stockpile, I could predict that the public would be pretty upset," said Dr. Eddy Bresnitz, the state epidemiologist in New Jersey, which has bought 850,000 of the 900,000 courses available under the federal cost-sharing program. He acknowledged, however, that if the antivirals expire, "that's a lot of dollars flushed down the drain" (40).

RECENT CHANGES IN THE NEWS MEDIA LANDSCAPE

There have been enormous changes in the media environment over the last 25 years. Several trends have coalesced into a perfect storm buffeting the news industry and sending it "perilously close to a free fall" (41). The industry's business model has been upended by the recession, new

technology, the loss of readers and viewers, and the migration of advertising to the Internet. US newspaper ad revenues fell 23% between 2007 and 2009 and local television ad revenues fell by 7% in 2008, hastening a steady decline already in progress (41).

Other trends include the advent of the 24-hour news cycle. News is no longer just delivered at set times, such as a 6 PM nightly television newscast or when the daily newspaper is thrown on your front lawn. News is now available immediately—on demand, around the clock. Instead of depending on information pushed out to the public by media organizations, people increasingly pull information from the Internet on their own time and terms, hunting and gathering the exact information they want. This has made it considerably more challenging for journalists to cover the news. Information must be constantly updated and freshened, and pundits are increasingly being called on to offer opinion and commentary when new information is scarce. The public is left with a constantly changing smorgasbord of information lacking in context and interpretation:

> *… a problem that is worsening in this era of the 24/7 news cycle is the frequent failure to put new developments into any kind of reasonable context for readers or viewers. In this environment, reporters… conduct interviews that amount to a "hit and run" version of journalism (17).*

In addition, the public now uses media more for entertainment than for news. This helps explain why astrology columns and Sudoku, celebrity gossip, television reality shows, lifestyle features, and other "infotainment" offerings are on the rise, while the amount of "real" news—which costs far more to gather and produce—is on the wane.

Moreover, news is accessed in different ways, including online sites (such as Yahoo! News, MSNBC, Google News, and AOL News), cable television networks, cell phones, Twitter, and podcasts—all communication vehicles that didn't exist 25 years ago. More than 50 million people in the United States get their news online everyday, and the trend is accelerating. The number of Americans surveyed who said they got most of their national and international news online has increased 67% in the last 4 years (41). Meanwhile, newspaper readership and television news viewership continue to decline, and television ratings are flat or falling in the United States (41). And since people can select which information they are exposed to through news aggregators and RSS feeds that deliver a made-to-order news digest to their email inbox, they can avoid topics in which they lack interest.

As a result, newspapers and magazines have become a lot slimmer and newsroom resources and travel budgets have shriveled. The average number of stories produced per reporter has climbed 30%, which may impact quality (13). Journalists are also increasingly required to produce the same story for multiple news platforms, leaving less time to develop the original version. For example, a newspaper reporter may also have to produce a podcast or write a blog post on the same topic for the newspaper's website; a television reporter may also have to write a story for the station's website.

Some newspapers and magazines are in bankruptcy and others have ceased publication. Although nearly 150 US newspapers had a dedicated science section or page two decades ago, that number has dwindled to fewer than 20 today *(42)*. Meanwhile, health and science stories must compete with other stories to be included in the shrinking main section of newspapers. There is also less coverage of pure science and medicine and more consumer health "news you can use" and lifestyle coverage *(42,43)*.

Fewer Journalists, Less Coverage

By the end of 2009, the newsrooms of US daily newspapers employed 20% to 25% fewer people than in 2001 (41). Many experienced health and science reporters have been among the journalists being laid off or taking buyouts (13,*43,44*).

> *There is a greater need than ever before for journalists who are skilled in reporting both the underlying complexity of the science as well as the legal, ethical, and political ramifications of its uses. Unfortunately, jobs for full-time science writers at major print and electronic outlets are declining, while the number of important science and science policy developments is increasing (43).*

Natalie Angier, a science reporter for *The New York Times*, contends that science reporting in newspapers is "basically going out of existence" *(45)* while coverage on television has been greatly reduced. CNN eliminated its entire science and technology team in 2008. In 2009, *The Boston Globe* closed its science section, an action the *San Francisco Chronicle* had taken several years earlier *(42)*. According to Cristine Russell, a former *Washington Post* reporter who is president of the Council for the Advancement of Science Writing:

> *It's ironic that we have fewer writers in our major media focusing on science, while we have ever more issues that have a science base—from climate change to the health care debate, stem cells, evolution and swine flu—many of which are very controversial (42).*

It's a similar situation in Canada. Peter Calamai, a former science reporter for *The Toronto Star*, says most science news is no longer covered by a knowledgeable or discerning science journalist but by a general-assignment reporter who is probably expected to churn out several stories that day (46). He noted that when the Canadian Science Writers' Association was founded in 1971, there were at least 30 full-time staff reporters covering science and medicine for major Canadian newspapers and television and radio networks. That number has since dwindled to about six (46).

In Britain, science reporters are not immune to the pressures facing their peers in other countries, but the state of science journalism is healthier, according to a study by an expert group convened by the British government. The group's report noted that "… reports of a major crisis in science news reporting in the UK are exaggerated." The study noted that there has been a "dramatic increase in the number of science reporters," "an ever-expanding appetite for science stories within news rooms," and "a marked increase in the status of science specialist reporters in the news room" (47). For example, the BBC has gone from two science specialists to 30 in the last two decades (47).

Media Fragmentation

Fragmentation is another trend affecting the media landscape. The public has more choices for information than ever before, including online sites, niche magazines, and cable television networks that cater to specific political and cultural viewpoints. As a result, any single news media organization is less dominant.

Furthermore, journalists are no longer the only gatekeepers of information. Members of the public are increasingly assuming that role by creating their own content, commenting on information, and passing it along via cell phone photos, "tweets," blog posts, and YouTube videos. More than 57 million Americans read blogs regularly (41). There are 70 million blogs and about 900,000 new blog posts are created every day. As a result, the blogosphere continues to double in size about every 5.5 months. While many bloggers comment on and pass along news rather than report and write it, they nonetheless have a growing impact on public communication. But questions remain as to whether bloggers are journalists and whether they should follow the same professional code of ethics.

Credibility of the News Media

Meanwhile, public trust in the news media continues to erode. Public perceptions of media accuracy are at a two-decade low in the United States *(48)*. According to the Pew Research Center for the People & the Press, "The public continues to express skepticism about what they see, hear and read in the media. No major news outlet—whether broadcast or cable, print or online—stands out as particularly credible" *(49)*. Just 29% of Americans surveyed said news organizations get the facts straight while 63% said news stories were often inaccurate *(48)*. Nonetheless, the public continues to view media stories (or "earned media") as more credible than "paid media" (advertising). And most Americans surveyed said they believed it would be an important loss if major news sources shut down *(48)*.

What's Next?

It is impossible to predict whether newspapers will survive in printed form or whether television will increasingly proliferate into niche networks in which "news" will be defined in narrower and more partisan terms. There will always be new mass communication vehicles, but they are unlikely to supplant their predecessors—television did not replace radio and the Internet has not replaced television. Rather, new mass communication vehicles are likely to compete with, influence, complement, and change older ones. New communication techniques that allow people to bypass the news media and communicate directly with one another are also growing. But whether podcasts, wikis, Twitter, and text messaging will continue to flourish, or fade away like Friendster and instant messaging, the basics of effective communication will remain the same: know the objectives, the audiences you are trying to reach, and the messages you want to deliver before doing any communicating. We'll address those topics in the pages ahead.

WHEN A REPORTER CALLS

When you get a call from a reporter, it may seem as though it is coming out of the blue. While that may sometimes be the case, public health professionals, healthcare epidemiologists, and infection preventionists can often anticipate why a reporter is calling by knowing what is in the news. Media monitoring can provide a head's up on emerging issues beginning to capture the news media's interest, hot-button issues that are the subject of significant coverage, and once-hot issues beginning to recede from media and public attention. Keeping on top of the news can provide additional time to prepare when a reporter calls.

There are several ways to monitor relevant media coverage. First, there is no substitute for being an active news consumer. Second, the public relations team at your institution, organization, or agency probably already monitors relevant media coverage; you can request to have the stories or links sent to you. In addition, if the public relations team produces and distributes a daily or weekly email roundup of news stories, you can ask to be included on the distribution list. Third, you can use a news aggregator such as iCurrent or Google Alerts to create your own media monitoring function. News aggregators "crawl" the Internet looking for all stories and blog posts containing the keywords you specify and deliver them your email inbox daily.

Playing Reporter

When a reporter calls, you should politely turn tables and play reporter first. It is your only real opportunity to screen the request and to gather the information you need to help decide whether or not to do the interview, so it is worth the few extra minutes it takes (13). You shouldn't assume that the reporter is interested in a certain topic, even though it may dominate the news. You should always begin by asking the reporter what topic they are interested in, drilling down to specifics about the "angle" of the story. You should also ask about the type of story (a news story or a feature story?) and its expected length. The type of story will provide insight about its tone (serious and analytical or human interest?), while the expected length may suggest the extent of your role. In addition, you should ask whether the reporter proposes to do the interview by phone or in person, and whether an in-person interview would be done at your workplace, in a television studio, or another location.

Moreover, you should ask when the story will air or will be printed and the reporter's deadline. And finally, asking the reporter who else they have interviewed or plan to interview will give you an indication of where the story is headed. For example, if the reporter says they have interviewed several vaccination opponents, you may anticipate being called on to defend the safety of vaccines.

In addition, if you do not already know the reporter, you should always ask them to spell their first and last names and to tell you a little about their background and what they cover. The same goes for the media organization for which they work. The purpose is not to interrogate the reporter but to have a better understanding of who they are and where they are coming from, as well as the wider

audience you would be addressing (8). Quite simply, you need to know what you would be walking into if you decide to do the interview.

You should also ask for the reporter's phone number at work. The unspoken reason is that you will call the reporter back at their office to verify their identity. There have been cases of people in other professions masquerading as reporters to gain access to information. While verification is more difficult in these days of cell phones and freelance journalists who may work from home, try to get the reporter's office number.

After you finish the call, it can be helpful to gather more background information on the reporter and their media organization. One way is to Google the reporter and look at the website of the media organization if you are unfamiliar with it. You should also ask the public relations team at your institution, organization, or agency what they know about the reporter and media organization. In addition, you can do a quick search of the online archives of media organization's website or use a database such as Factiva or LexisNexis to read other stories by the reporter.

Never Doing an Interview Cold

How will you be able to do all this when the reporter is pressing you for "just one quote" and they emphasize how much of a hurry they are in? The worst thing is to succumb to the reporter's pleas or pressure and agree to do an interview "cold"—on the spot. You need to politely buy yourself time to gather and verify information and to prepare for the interview without making it appear as though you are stonewalling or being unhelpful. So after screening the reporter and their request during the initial call, tell the reporter graciously but firmly that you're in the middle of something and will call them back *before* their deadline.

If the reporter says their deadline is tomorrow or next week, you will have plenty of time to prepare, but even a reporter on the tightest of deadlines can spare 5 or 10 minutes in which you can verify their identify, decide whether to do the interview, get your head around the topic, and think about how best to respond to likely questions. Telling the reporter you're in the middle of something is not a lie because you *were* in the middle of something when they called. It's arrogant to assume you can flawlessly switch gears from meeting with colleagues or working on a technical report to answering a reporter's questions. Failing to take the time to compose yourself and get your head around the interview topic can have calamitous results. As Dr. William R. Jarvis, who did many media interviews during his 23 years at the CDC, notes: "You can't just 'wing it,' because if you do you're going to get burned."

After finishing the call with the reporter, it's a good idea to touch base with the public relations team at your institution, organization, or agency. Have they worked with the reporter and media organization before? Do they think you should talk with them? Why or why not? The public relations team may also be able to help you answer the three questions you should always ask yourself before accepting any media opportunity:

1. *Why are you giving an interview?* What are your objectives and those of your institution, organization, or agency? It's not enough to say that you are being helpful or nice. Is your objective to inform or educate? Explain or reassure? Dispel myths or put risks in context?
2. *Who are you trying to reach?* Who are the media organization's audiences? And do the two match up? While the "general public" may be an overly broad target, employees, neighbors, parents, community and civic leaders, and government officials—to name a few groups—may be among the audience for the story.
3. *What do you want to say?* What do you want people to take away from reading or hearing what you said?

Only if you can answer all three questions should you proceed with the media opportunity. If it's a "go," what background can the public relations team at your institution or organization's public relations team provide? What are the watch-outs, if any? Can they help you prepare for the interview? Can they provide communication materials, such as a fact sheet on the topic, to give the reporter?

When Can You Say "No"?

While it's a good idea to be as cooperative as possible with the news media, you shouldn't feel compelled to say "yes" to every interview request (8). Some requests will be easy to turn down; for example, if you lack expertise on the topic or there's someone better to recommend. Dr. Michael T. Osterholm, Director of the Center for Infectious Disease Research and Policy at the University of Minnesota, says he turns down about two-thirds of interview requests for that reason. "It's all about my expertise," he says. "If I don't believe I'm the best source or there's someone with more experience to provide greater credibility, I'll suggest another source."

There may also be media requests that raise your antennae or those of the public relations team where you work. Perhaps the request is from a reporter or blogger known to have a bias or agenda. Perhaps the media organization is not viewed as legitimate. Or perhaps you suspect, based on what the reporter told you about who else they have interviewed, that you will be positioned awkwardly in the story, such as the lone expert criticizing (or defending) a controversial issue, practice, or policy or while a bevy of experts take the other side.

In addition, some media opportunities simply may not measure up as worthwhile. For example, does it make sense for you to carve a half hour out of your schedule to explain flu-prevention tips to a reporter when that information is readily available online or in a brochure your institution, organization, or agency could provide? Or is the media organization so small, such as a local public-access cable television channel, that the audience is likely to be tiny or nonexistent?

Another reason to consider turning down a media request is when there isn't enough time to adequately prepare and practice. You may simply be too busy with pressing duties, such as dealing with an emergency (one that isn't the topic of the reporter's call). Sometimes, it can seem easy to say "yes" until you consider the time requirements involved: it can take a 20-minute interview to produce 15 seconds of quotes for a radio story (8).

WHAT TO EXPECT IN AN INTERVIEW

Reporters' individual style does not matter; the story they produce does. Reporters may come across as friendly and professional, demanding or standoffish. But they are likely to be genuinely interested in the information you provide.

Types of Interviews

There are some similarities between print, television, radio, and online interviews. All reporters, regardless of the type of media organization for which they work, look for accurate, clear, and interesting information and comment that is provided quickly, succinctly, and dependably. But there are numerous differences between print, television, radio, and online interviews. In-person, phone, and email interviews differ as well.

In-Person, Phone, and E-Mail Interviews

The primary advantage of an in-person interview is being able to "read" the reporter's body language (Is there a point on which they seem confused? Do they stop taking notes? Why are they frowning?). On the other hand, the primary advantage of a phone interview is that you can have your notes in front of you, which may make the experience less stressful. Notes are not meant to be a crutch, however, and reading them verbatim will sound stilted and unnatural. For phone interviews, pick a quiet location where you will not be interrupted. Close the door, put a sign on the door asking not to be interrupted, and stop incoming calls (8).

While reporters typically type notes on their computers during phone interviews, most take notes during in-person interviews. For most reporters, writing takes longer than typing, so speak slowly and clearly. Take a moment to collect your thoughts before beginning your answer. If needed, you can pause from time to time and let the reporter catch up with their note taking. Many reporters use tape recorders to supplement written notes. Tape recorders have pros and cons from the standpoint of the person being interviewed. Reporters can go back and check the precise words you said, which may increase accuracy. A tape recording can also help set the record straight if there is a disagreement over whether you were misquoted. Then again, knowing every word is being recorded makes some people more nervous. The best advice is to try to forget the tape recorder and focus on the reporter.

Today, more reporters conduct interviews by email, text messages, and even Twitter, especially when someone they want to interview is not available in person or by phone or when reporters face an imminent deadline. But the informality of a particular communication technology should not influence what you say or how you say it. The same care and precision that should guide you in any media interview should apply here as well. That means writing in full sentences with proper spelling and no slang or use of emoticons.

Print and Radio Interviews

Newspaper and magazine reporters typically do the longest interviews. They may seek considerable background information as well as quotes. The reporter may ask to sit down with you to do the interview, conduct it by phone, or send questions via email.

Radio reporters do interviews by phone or in person. In a radio interview, your voice and inflection can have as much impact as your words, so practicing in front of a mirror can be helpful. Speak slowly (but not too slowly) and clearly and enunciate well. And make a conscious effort to avoid words like "uh," "um," and "like."

Television Interviews

Stand-up television interviews are the type of interview people dread most. There's something about the lights and a microphone in your face that can turn the strongest knees to jelly. But the tips in this chapter can help you overcome these feelings.

Television reporters almost always request in-person interviews so their station or network will have visuals to accompany the story. An exception may occur when it is so close to deadline that a television reporter asks for information or a comment over the phone. Along with a recording of your voice, your quote will likely appear in words on the screen behind the head of the reporter or news anchor as they present the story. Most often, television reporters will want to come to your workplace (or home, if it is an evening or weekend) or suggest another interview location. For example, if the story is about an alleged cancer cluster in a certain community, doing the interview in that neighborhood might make sense (but see the caveats below about interview settings).

Television interviews are almost always taped, not live. The only exception is during a major crisis in which there isn't time or the ability to edit recorded video footage. Taped interviews are more forgiving than live ones, so don't feel compelled to spring to your answer like a racehorse out of the starting gate. Take the time to collect your thoughts after each question. And if you make a mistake, you can stop and ask to do it again. Television stations loathe so-called dead air because air time is a precious commodity. Footage of you pausing, thinking, or doing over an answer will be edited out unless the reporter is deliberately trying to make you look bad. In contrast, there are no "do-overs" in live television interviews.

Setting a Time Limit

Whatever the type of interview, setting a time limit is always recommended. You can tell the reporter something like, "*I have 20 minutes for us to talk before an 11:30 meeting*." Twenty minutes should be sufficient for any reporter to ask you almost anything. Most people are sharpest at the beginning of an interview, a topic we'll discuss in more detail later. Most people being interviewed get run down and tend to become more sloppy as the interview goes on, increasing the likelihood that the information the reporter has to choose from will include some you are displeased with.

Having a preestablished time limit gives you an out, which you can reinforce by arranging for a colleague or assistant to stop by. If reporter still keeps asking questions, you can stand up, thank them, say you're expected elsewhere, and escort them out. However, if you feel the interview is going well and want to extend it for some reason, you have that option as well.

Choosing an Interview Setting

You should not automatically agree to an interview setting the reporter steers you to. Rather, you should take the lead in suggesting—and if necessary, insisting—on a professional, neutral setting. If the interview takes place in your office, make sure all confidential papers are put away and that there is nothing on the walls that would raise a red flag if shown on television. If the interview takes place inside a facility, avoid being near signs that say *warning, danger, hazard, contamination,* or *quarantine*. If the interview takes place outdoors, avoid having the sun in your eyes, making you squint. And check what is behind you. Ask yourself: how would viewers react to what's in the background? Would it detract from what I'm saying or contradict what I'm saying?

PREPARING TO TALK WITH THE NEWS MEDIA

People are not born with good communication skills, they acquire them. Communication skills improve with practice, and, like other skills, get rusty when not used for a long time.

Journalists are often skilled at drawing out the people they interview. Whether it's chatting about the local professional sports team, the weather, upcoming holidays, or other small talk, the goal of reporters is to build rapport with people and help them feel at ease during the interview that will follow. Reporters know that taking a few minutes upfront to do so will help produce a better interview. It's designed to relax you (which is good, up to a point) and to persuade you to let your guard down (which is not). It may lead you to erroneously believe that the interview will be just like the opening chitchat: a friendly conversation.

Reporters have many different interviewing styles. They can be smiling and friendly, asking easy questions at first and nodding their head to show tacit support, then transitioning to tough questions before you realize what is happening. Or a reporter can have the personality of a pit bull, peppering you with difficult questions from the start. What matters, however, is not the reporter's interviewing style, but whether their story is accurate and fair.

Not a Conversation

The biggest peril for anyone talking with the news media is to be drawn into the "just a conversation" mentality. You would never speak at a professional conference with the mindset that it's "just a conversation": you'd be prepared, polished, and buttoned down. Nor would you ask your boss for a raise without knowing exactly what points you want to make to support your case. If you were to ramble, the chances of persuading your boss to increase your salary might be near zero. A media interview needs to be just as polished and put together; it should always be considered a *presentation,* not a *conversation*. After all, the reporter is just the conduit to their audience. And since you have established objectives for the interview, you need to focus on achieving them.

Why Key Messages are Needed

The way to achieve your objectives in an interview is clear and concise key messages: developing them, practicing them, using them, and repeating them. Messages cannot be developed "on the fly" once you are already talking with a reporter; they must be prepared in advance (13). And messages are not "spin"; rather, they are merely a way to break down the information you want to get across and help the audience focus on, understand, and remember what you say (13). After all, the world is inundated with information. There are more messages bombarding us—from billboards to text messages to cable TV and the Internet—than ever before, all competing for our increasingly fragmented attention. People forget approximately two-thirds of what they hear in 1 day and 98% in 30 days.

This "message clutter" has been exacerbated by the fact that while the number of media messages has proliferated, the amount of space or time available for individual messages has dwindled. This has led to an increased reliance on *sound bites*, snippets of information or comment that have become the building blocks of interviews, especially television interviews: "Journalists want the whole story in a few sound bites—their readers or viewers are not experts and need the information in a handful of pithy sentences" (8).

Sound bites have continued to shrink over time. In 1968, when television producers coined the term, a US presidential candidate spoke for about 43 uninterrupted seconds on television newscasts. But with each campaign sound bites got shorter, and by 1988 the average was only 9 seconds *(50)*. The most famous sound bite of that campaign was six words from former US President George H. W. Bush: "Read my lips: no new taxes." Since then, there has been some political pushback against sound bites. When Barack Obama ran for US president in 2008, he used YouTube and other websites to present lengthy policy speeches directly to viewers. But while presidential candidates can try to circumvent the news media and take their case directly to the public, others may lack that opportunity. As a result, the ability to condense what you have to say remains paramount.

Developing Effective Key Messages

Key messages are the three or four most important points you want to make during the interview. Yet scientists, physicians, and public health professionals sometimes think that the more points they can get across, the better, especially when the topic is complex. They may reason that the very next point will be the one that will help the reporter or their audience finally understand the situation or issue. Yet communicating too many messages is counterproductive. If you emphasized six or eight points rather than three or four, the reporter—not you—would determine your main message, and the story may not read or sound like you want it to. Focusing on only three or four key messages helps ensure that the reporter knows what's truly important (13).

Key messages should be concise and straightforward. Using short words and short sentences will help keep what you say simple, but you shouldn't dumb down the information to such an extent that the essence is lost (13). For example, substituting simpler terms for *comparative data,*

uniform baseline, and *environmental niche* in the following quotes could have aided public understanding without losing meaning:

> *"In terms of comparative data, I think we are probably several years off from having a uniform baseline," said Jerry Zuckerman, Head of Infection Prevention and Control at Albert Einstein Medical Center (51).*

> *"Only one bacterium out of a population has to survive in order to replenish that environmental niche with a complete new population of resistant organisms," Levy said (52).*

Key messages should use positive words whenever possible ("tests have shown that residents can drink the water" rather than "there is no documented evidence of health risks that would prevent people from drinking the water") and memorable phrases likely to capture the audience's attention:

> *Dr. Michael Osterholm, head of the University of Minnesota's Center for Infectious Disease Research and Policy, has called for a "Manhattan Project" to find a flu vaccine that does not need to be reformulated every year (53).*

Effective key messages can also help paint a mental picture for the audience, as shown by the following quote from Dr. Danuta Skowronski, an epidemiologist with the British Columbia Centre for Disease Control, in a story about the H1N1 virus:

> *"It is the nature of influenza outbreaks that they have that explosive upswing and then it's going to have to come down. But we're still at levels above the expected range, which means there is still sustained community transmission out there" (34).*

Key messages are not facts; they are value statements. They aim to *aspire* rather than to merely report or *describe*. "Our hospital reported 24 cases of infection during the past three months compared to 46 cases during the same period last year" is not a key message. It is a fact that could be used to help support a key message about the hospital's renewed commitment to reducing infection rates and to demonstrate that it is credible. Because key messages are value statements, one or two supporting points (or *proof points*) are needed to reinforce each key message. Proof points can be facts, statistics (used sparingly), analogies, and personal examples or anecdotes.

Using Key Messages

Why are key messages needed if the purpose of talking with a reporter is answering their questions? If you merely answer the reporter's questions, you will be helping them achieve their objectives for the interview but probably not your own. Instead, think about using the questions you are asked as a springboard to the messages you want to deliver. Key messages provide structure for the interview and help you maintain confidence and control. If you have good key messages and know them well, you can avoid becoming "lost" during the interview and saying things you wish you had not. Key messages can be a road map to guide you "home," back to the terra firma of what you want to say.

Limiting the Reporter's Choices

It's not only okay for you to repeat your key messages during an interview, it's desirable to reinforce them. Of course, you cannot keep repeating a message verbatim or you will sound like an automaton, but you can stick to the main point and change a few words here and there. Your goal is to limit the information choices a reporter has available for their story. You'd prefer they use one of your key messages rather than something that might be off the wall. That's why it's important to reiterate and reinforce your key messages. Think of it as a laying out an information smorgasbord for the reporter. Instead of offering a variety of main courses made of chicken, pork, fish, beef, and lamb, invite the reporter to the Chicken Buffet: offer only baked chicken, fried chicken, chicken fricassee, chicken kabobs, tandoori chicken, and chicken salad, to name a few dishes. All of them have the same main ingredient—your key messages—yet each has its own flavor and flair.

Using Visuals

Before talking with the media, it is important to decide whether you will use visuals to help illustrate what you plan to say. Using photos, charts, diagrams, and timelines during an interview may have both potential benefits and drawbacks. The best reason for using visuals is to provide information that is easier to understand or more compelling visually than verbally. If a visual doesn't add anything to what you have to say, complicates or contradicts your information, is outdated, difficult to read, or has poor-quality photos, you are better off not using it. Sometimes, people being interviewed use visuals as a crutch; they spend too much time going over the visuals and not enough time delivering their key messages. One suggestion is to ask a nontechnical colleague to look at the visual and decide whether it helps or hinders what you have to say.

Journalists at all types of media organizations may also request to post a copy of the visual on their websites. If this is possible, be prepared to tell reporters the source of the visual (or have it printed on the copy) so it can be attributed properly.

Getting Ready

Once you have developed key messages and decided whether to use visuals, the last major task before a media interview is to practice. Part of this task is rehearsing to deliver your key messages and proof points smoothly and professionally. The other part is to anticipate likely questions and practice answering them. Most people rightly worry about answering the tough questions. But sometimes it is simple questions that trip up someone being interviewed. For example, would you be able to give a simple, clear, and succinct answer if a reporter asked, "*Why do so many infections occur in hospitals*?" or even "*What do you do in the Department of Public Health?*"

You can ask a colleague, a member of the public relations team at your institution or organization, or a family member to role play as a reporter and ask you

some possible questions. Formal media training can also be very useful (resources provided at the end of the chapter). While anticipating questions and practicing answers will increase your self-confidence, you should not lose sleep worrying about every possible question. The single best piece of advice for preparing for an interview is to be well rested.

TALKING WITH THE NEWS MEDIA

When you have gathered background on the reporter and media organization, tapped the resources of the public relations team at your institution or organization, developed key messages, anticipated likely questions, and practiced answering them, it's time to talk with the news media. Using key messages reduces the chance of the reporter having to decipher what you said, guessing what your point is, or inaccurately describing your position (13). However, since you are not giving a speech but responding to questions, creating the opportunity to deliver your key messages can be challenging.

Staying on Course

You and the reporter have different game plans for the interview: the reporter has specific—sometimes very specific—information, comment, or opinion in mind that they would like you to say. You have key messages you want to deliver. It may sound as though a battle of wills may be brewing. But two key communication techniques, blocking and bridging and headlining, can help you stay on track during the interview without appearing to be nonresponsive.

Blocking and Bridging

Blocking and bridging is the technique used to take the questions you are asked and use them as a springboard to the messages you want to deliver. Blocking and bridging will seem unnatural and complicated at first and requires practice to do well. But done artfully, it is effective—and can look seamless. National political officials are often masters of blocking and bridging. Reporters may want to ask them about the economy, but if the officials prefer to talk that day about new education initiatives, they will use reporters' questions about economic issues to hammer home the importance of education to strengthening the economy.

Blocking and bridging is not about manipulating the news media or avoiding reporters' questions. But it is about taking full advantage of the interview to deliver the messages you have decided are important to your institution, organization, or agency—and to the public. To be successful, blocking and bridging requires both parts: the block and the bridge. The block is politely stopping the reporter's question in its tracks. The bridge is reframing the question so you take can the answer in a direction that aligns with one of your key messages. A block without a bridge looks as though you are being unresponsive. A bridge without a block may leave the reporter puzzled as to why you are talking about one subject when you were asked about another.

You must first acknowledge the reporter's question; never ignore it. But that doesn't mean you have to answer the question exactly the way it was posed. You can address the topic or the category of the question instead. For example, if you were asked: "*Isn't it true that thousands of otherwise healthy people go into hospitals every year for surgeries and become seriously ill or die from infections they acquire in the hospital?*" Answering that question precisely the way it was asked—"*Yes, but…*"—will immediately put you on the defensive and may lead to a series of equally negative follow-up questions. You recognize that what the reporter is asking about is patient safety. So using blocking and bridging, you can respond this way: "*I think what you're really asking me is what Northfield Medical Center does to protect the health of its patients. We have an excellent track record of ….*" and then continue with a clear, succinct explanation of one or two programs that have been implemented to help control infection.

You can also broaden or narrow the topic of the question. If you are asked about a problem, you can talk about a solution. And if you are asked about something you cannot talk about (such as a lawsuit involving your institution or organization), explain why.

A reporter may ask you to comment on behalf of another individual, institution, organization, or agency. For example, if you are an epidemiologist at County Hospital, you may be asked to comment on a recent outbreak at another hospital: "*What do you think caused the outbreak last week at Johnson Hospital? Does it signal a serious problem there*?" Since you cannot speak for anyone other than your own organization, institution, or agency, the "block" becomes a simple matter of saying, "*I can't speak for Johnson Hospital*." Your bridge might be: "*But as far as County Hospital is concerned ….*" and then talk about something County Hospital is doing or has planned to do to prevent outbreaks. In this way, you're taking a negative question about another institution and turning it around to say something positive about your own.

Reporters will sometimes ask hypothetical or speculative questions, such as: "*What will happen if the H1N1 flu virus mutates and becomes much more deadly to humans?"* While people being interviewed typically fear hypothetical questions, they are one of the easiest types of questions to block and bridge. Since you don't have a crystal ball, you can't answer hypothetical questions. Your answer might be: "*I can't speculate on what may or may not happen to the H1N1 virus in the months ahead. But what I can tell you is…*" and then talk about what your institution, organization, or agency is doing in terms of H1N1 preparedness.

Examples of Blocking and Bridging

"That's an interesting question. However, the real issue here is…"

"What you're asking me is…"

"I can't speak for ____. But as far as (my organization or institution) is concerned…"

"I can't speculate on what may or may not happen. But what I <u>can</u> tell you is…"

Headlining

Headlining is a communication technique to help you communicate successfully in today's sound bite-driven media environment. It means stating your conclusion first, just like a headline sums up the most important point in a story. This may seem alien to the way in which public health professionals and epidemiologists are trained to communicate: laying out the evidence piece by piece, summing up, and then presenting the conclusion. But if you use that approach during an interview, your conclusion may never see the light of day. The way in which you communicate with the news media needs to be the exact opposite: conclusion first, following by supporting material.

For example, if you are asked: "*If hospitals are so focused on cleanliness, why do so many patients get infections every year?*" you should resist the temptation to begin your response with a litany of infection-control measures the hospital has taken or plans to take and to conclude by saying that these measures have made patients and employees considerably safer. Instead, begin with the conclusion: "*The most important thing to know about Dandridge Medical Center is that it has become an increasingly safer place for patients and employees alike*." Then say: "*Here are just a few of the steps we've taken to reduce infection…*" and continue with a few clear, concise, understandable examples of specific actions and the results they have achieved. Adding these proof points will support your key message and help demonstrate that it is true.

Headlining also encourages the use of short, simple, bold words to make your messages meaningful and memorable. This helps audiences remember what you have to say.

Examples of Headlining

"The most important takeaway from this situation is…"

"Let me make one thing perfectly clear…."

"The real issue is…."

"It boils down to these three things…."

Avoiding Jargon

It's essential to avoid jargon when talking with reporters. Every field or profession has jargon—technical words, stock phrases, and acronyms you use every day as "verbal shorthand" with your peers. Often, people being interviewed cling to jargon as they would a life preserver, but it provides a false sense of security. The drawback is that neither the reporter nor the audience will understand. At best, using jargon will minimize the likelihood that your messages will be received clearly; at worst, it will make you come across as patronizing or condescending. This may prompt the audience to tune you out.

To strip jargon from your media vocabulary, you first need to be aware of what jargon you use and how often you use it. This includes acronyms such as *MRSA* and *C diff*., words like *pathogen* and *bacteremia*, and technical terms such as *nosocomial infections* and *symptomatic case-fatality ratio*. Jargon also includes terms laypeople have heard but may have difficulty deciphering: what is the difference between an *epidemic* and a *pandemic*, *contagious* and *communicable*, and *morbidity* and *mortality*? The audience may also think that *colonization* is a term from history books and that a *prion* is part of an atom. To be sure, run a "jargon check" on a friend outside your field, a family member, or neighbor.

As Dr. Michael T. Osterholm of the University of Minnesota notes, "Scientists feel the need to speak to the world in the same way they speak to try to impress their colleagues." But boiling down terms into everyday English and substituting simpler words for technical ones can boost clarity. Aiming for words that can be understood by a high school student— or, as Osterholm suggests, by your mother—is not a slight to the intelligence of the audience; rather, it reflects the fact that while you are an expert on the topic, your audience is not. And you cannot rely on reporters to signal when your words are too complex and ask you to translate. Sometimes, reporters will stop and ask what something means, but other times they may be too intimidated or embarrassed to acknowledge they don't understand and will let you continue, hoping—often futilely—that they can figure it out afterward.

Not Falling for Trap Questions

Most reporters don't deliberately set out to ask trap questions. Rather, it reflects the fact that their story is almost written by the time of your interview and the angle is most likely already decided. Reporters would like your information or opinion to fit neatly within those preconceived boundaries.

Of the four common types of trap questions, two have already been discussed in connection with blocking and bridging. The first is the hypothetical or speculative question. The second is the absent-party trap, in which the reporter asks you to put on the hat of another individual or organization and comment or explain on their behalf.

Another type of trap question is A or B dilemma, in which you are presented with two choices, both unappealing: "*Do employees at this hospital spread infection because they are careless about hygiene or because they aren't given adequate training?*" Pick either of the choices—perhaps the one you think is a lesser evil—and the reporter will likely ask a series of follow-up questions, while you have the potential to dig yourself deeper and deeper into a hole. But you don't have to pick either answer. Using blocking and bridging, you can steer the interview back to firmer ground: "*On the contrary, one of the top priorities at Mercy General is protecting the health of our patients, employees, and visitors. We do this by…*" and then cite two simple, concise examples of concrete actions to improve infection control.

The final type of trap question is the leading or loaded question, which is based on an erroneous assumption or faulty premise: "*Isn't it true that infection rates at Wellington Hospital have skyrocketed recently?*" or "*Since the government has been undercounting cases of H1N1, has it become more difficult to…?"* Since your answer will be built off that assumption or premise, you first need to politely but firmly correct the error: "*Before answering your question, I need to correct what you said about… In fact, …*"

Avoiding the Negative

Reporters often ask questions framed in a negative way. To buy themselves time to think of an answer, many people being interviewed tend to repeat reporters' negative

words and then negate them. It's the quickest and easiest response: "*No, this isn't a public health emergency*," or "*I wouldn't characterize this incident as a case of a rogue healthcare worker deliberately infecting patients*." But the audience tends to pick up on the negative words (*emergency*, *rogue, deliberately*, *infecting*) while mentally skipping over the "no," "not," or "wouldn't."

For example, when Joy Wells, director for health assessment at Cobb and Douglas Public Health in Georgia, told the *Atlanta Journal-Constitution*, "It doesn't mean that Cobb County is a hotbed of MRSA," she was likely repeating part of a reporter's negative question about reporting serious cases of community-associated MRSA *(54)*. But what is apt to stick in readers' minds is a single word: *hotbed*. And when Dr. Tim Brewer, an epidemiologist at McGill University, was quoted as saying, "This is not to engender fear or panic," in an *Ottawa Citizen* story about the government's response to a tripling in H1N1 cases, he was probably playing back the reporter's negative words *(55)*. While spreading fear and panic was the opposite of Dr. Brewer's aim, *fear* and *panic* may be the words readers most remember.

People being interviewed may also use negative words on their own, without prompting from a reporter, with equally damaging results:

> *"There are people who are thinking we're sweeping it (HIV) under the rug," said Jennifer Sizemore, a public affairs official with the health district. "But that's not the case at all" (56).*

Negative words to avoid include such seemingly innocuous words as "no," "not," "can't," "don't, "won't," and "never." They also include emotionally charged words, some obvious (*flesh-eating bacteria*) and others less so (*risk*, *danger*, *emergency*, *crisis*, *catastrophe*, and *problem*). There is a neutral word that can replace almost all these words, such as *incident* instead of *crisis* and *issue* or *challenge* rather than *problem*.

You can avoid repeating a reporter's negative words by beginning your response with a firm block that turns the direction of your response 180 degrees, such as: "*On the contrary…*" And you can circumvent using negative words of your own by pausing after the question to give yourself time to carefully craft your response.

When You Don't Understand the Question

If you do not understand a question, ask the reporter to repeat it. If you still don't understand, ask them to rephrase it. You can even play the question back to the reporter to make sure you are both on the same page: "*So is your question whether…?"* or "*If I understand you correctly, what you'd like to know is…*" The goal is not to make the reporter look foolish, but to prevent misunderstanding (8). Lack of understanding may also occur when a reporter asks a long, convoluted question with multiple clauses. There may even be multiple questions embedded within the question. Take the questions one at a time, and choose the question you want to respond to first.

Why You Should Avoid "No Comment"

It may seem that the easiest answer to a question you can't—or don't want to—answer is a simple "no comment." But you should strongly resist doing so. According to Dr. Vincent T. Covello, a risk communication expert, saying "no comment" makes it appear as though you are stonewalling or hiding something (57). And it is exactly the opposite of how you want to look in the news media, which is truthful, honest, frank, and open. If you can't answer the exact question, say why. For example: "*It is our hospital's policy not to comment on…*" or "*Government privacy regulations prevent me from talking about…*" But then try to follow up with something related that you are able to say: "*But I can tell you that…"*

When You Don't Know the Answer

Always be correct. If you don't know the answer to a question, don't guess or speculate. If it is possible to get the answer, offer to get the information for the reporter and call them back before their deadline—and then be sure to do so. If it is impossible to come up with an answer at this time, focus on what you do know and tell the reporter what actions you will take to get an answer.

Why You Should Not Go "Off the Record"

Reporters may ask you to go "off the record" and provide some information or comment you would be unwilling or unable to provide "on the record." Avoid going "off the record" because the term means different things to different reporters. Does "off the record" mean the information is for "background only" and cannot be print or broadcast at all? Or that the information can be used without attributing it to you? Either way, it's possible for a reporter to take what you say, shop it around to another source for confirmation or denial, and include the information in the story anyway.

Reporters seeking information "off the record" may appear to get chummy and make promises about how the information will and will not be used. Former CBS television reporter Connie Chung did that in 1995 when she interviewed the parents of Newt Gingrich, the new speaker of the U.S. House of Representatives. When Chung asked Kathleen Gingrich what her son thought of Hillary Clinton, wife of incoming US President Bill Clinton, Gingrich said she couldn't say. Chung leaned forward and said softly: "Just whisper it to me—just between you and me." Gingrich responded, "She's a bitch." The comment aired on national television and the video still circulates in cyberspace 15 years later. Rather than agree to a reporter's request to go "off the record," offer information you feel comfortable providing on the record.

Using Body Language to Your Advantage

Studies have shown that 80% of what viewers absorb from television newscasts is not the words of the person being interviewed but their body language. Even in an in-person newspaper or magazine interview, the reporter may pick up on your body language and reflect it in the story. Body language can hurt you (if it makes you look dishonest or stubborn) or help you (if you come across as credible, trustworthy, and authoritative). Since your goal is to come across as knowledgeable and sincere, following these few basic tips can help:

Body Language Tips for Television Interviews

- Watch your hands to avoid overgesturing with them. Letting your hands rest lightly in your lap (if sitting) or by your sides (if standing) is best.

- Don't jingle keys or coins in your pockets because it makes you look nervous.
- Don't cross your arms because it makes you look defensive.
- Don't put your hand over face because it makes you look as though you are hiding something.
- Don't look up at ceiling because it makes you look evasive or nervous.
- Keep your eyes on the reporter and don't look into the television camera; the camera person will frame your face.
- Don't smile inappropriately (for example, if you are talking about injuries).
- Don't rock back and forth when standing; plant one foot slightly in front of the other.
- If sitting, don't swivel in your chair.

What to Wear and What Not to Wear on Television

Dressing for a television interview is all about looking appropriate and professional, so your appearance will imbue credibility. Since you want people to pay attention to your words, anything about your appearance that distracts from what you have to say is a drawback. Small, busy patterns, such as checks and loudly patterned ties, do not come across well on television. The same goes for oversized, dangling, or noisy jewelry. If you are being interviewed outdoors, do not wear sunglasses. If it is a sit-down interview in a television studio and you are offered makeup by a professional makeup person, accept it. The combination of nervousness and the bright lights can make anyone perspire.

Ending the Interview

Near the end of the interview, you may feel that the reporter has neglected an important question or there is something you'd really like to say—or believe the audience should know. It's perfectly fine to point this out, and chances are the reporter will be only too happy to let you say it (8).

Talking with a reporter, whether it's a 5-minute stand-up interview with a television reporter or half an hour sitting across the table from a newspaper reporter, can be a tiring experience. You will be freshest and most likely to stay "on message" at the beginning of the interview; by the end, you may be getting tired. This is when mistakes are most likely to occur. As noted earlier, to prevent a situation in which a reporter can wear you down, set a time limit in advance for the interview and arrange to have a colleague or assistant stop in at that time to reinforce that you have other commitments.

Very few media interviews should require more than about 20 minutes. Dr. William R. Jarvis, the former CDC official, says he talked with a hospital official about her experience being interviewed about an outbreak for the CBS television news program "60 Minutes": "I asked her how long she talked with the reporter and she said, "45 minutes. It was great." I thought to myself that she was probably rambling forever and ever" and would ultimately be disappointed with the way she came across on television. Jarvis adds that he if he had been interviewed, would have set a strict time limit and ground rules, which he would have gone over in advance with the reporter.

You may notice that the reporter asks you the same question, perhaps worded slightly differently, multiple times. This reflects the fact that the reporter has a specific quote or comment in mind for the story. Being asked the same question over and over indicates you have done a good job sticking to your key messages and not a poor job answering the question. There was nothing wrong with your answer; it just didn't align with the reporter's preconceived notions. Don't let it make you stray from your key message. "If you don't keep drilling your sound bite—despite what the reporter wants to hear, which is not your sound bite—you could end up with a story that is very inflammatory," Jarvis says.

By the third time a reporter asks the same or similar question, it's perfectly okay to respond politely, "*I believe I've answered that question already to the best of my ability. Do you have another question?*"

It's Not Over Until…

It can seem a relief when the reporter finally closes their notebook or you see the light on the television camera being turned off. It's a great feeling to be done with the interview—except you're not. It's important to note that you are "on the record" with a reporter the entire time you are in their physical presence, whether it's riding in an elevator, having coffee, or walking them to their car. Even without a notebook, a reporter can make mental notes; even without camera lights, your voice may still be recorded by a microphone. Some reporters attempt to take advantage of the relief people feel when they think the interview is over and then ask the toughest question of all.

COMMUNICATING ABOUT RISK

Virtually every topic that public health professionals, healthcare epidemiologists, and infection preventionists deal with involves risk. Communicating with the public through the news media involves acknowledging and addressing those risks. But the situation may be fluid, the cause unknown, the outcome uncertain, misinformation rampant, and trust in short supply. What is the best way to talk with the news media in those types of situations?

What Kinds of Risks Do the Media Cover?

Mass communication researchers note that "there is an inherent conflict between the business of news and what social scientists and others call risk communication" (25). The news media communicate risk information "by the prominence and space accorded the account of a hazard, but these indirect signals need not correspond to the actual probability of its occurrence or the likelihood of its causing harm." Journalists have been criticized as "risk junkies" who seek out "ever more fantastic and doom-laden scenarios with which to titillate and terrify their audience" *(58)*. But studies show that the news media is just as likely to downplay the potential dangers of particular crises as it is to play them up *(58)*.

What the news media define as a hazard changes over time: nuclear energy and second-hand smoke are

but two examples of hazards whose perceived risks have fluctuated in media coverage. Moreover, there is no relationship between the amount of news coverage a hazard receives and the number of deaths it causes. There is an emphasis on catastrophic accidents rather than the "cumulatively greater but less spectacular risks" reflected in annual mortality figures (25). And patterns of media coverage do not necessarily parallel the actual trajectory of a particular threat (58). For example, coverage of *Salmonella* poisoning dramatically decreased in the British news media at the same time cases actually increased *(59)*.

The news media also emphasizes novel risks rather than chronic ones. This helps explain why avian flu and SARS make headlines, but seasonal flu does not. Risks are also perceived as more serious when there is someone to blame (for example, *E. coli* poisoning from a restaurant meal rather than exposure to radon gas from naturally occurring radioactive rock). And since "most existing information about risks is partial and contingent," risks can be simplified and distorted in news stories (25).

Different Interpretations of Risk

Research has found that members of the public look at risk very differently than do scientists, physicians, and public health professionals. Dr. Peter Sandman, a pioneer of risk communication, developed the classic equation:

Risk = Hazard + Outrage

While scientists and other technical people equate the level of risk with the technical degree of hazard, the public does not. For the public, outrage is the "wild card" in the equation: when feelings of outrage go up, perceptions of risk increase; when outrage is reduced, perceptions of risk diminish (60).

According to Sandman, factors involved in determining the level of public outrage include whether the risk is voluntary or involuntary, whether the risk is exotic or familiar, whether the risk is focused or diffused, whether there is a perception of trust or secrecy, and whether the risk is perceived as fair or unfair (for example, residents may be willing to put up with pollution from a nearby factory because they benefit from the jobs and taxes the facility provides, but once the factory's closing is announced the environmental risks may spark substantial community concern).

Communicating in a Crisis

The fundamentals of effective communication become even more important during a crisis. Simplicity, honesty, clarity, and brevity are the hallmarks of good crisis communication. According to Sandman, "Audiences are less tolerant of complexity when they're upset. Apathetic people just stop listening when they can't understand what's being said; interested people ask for clarification. But frightened or angry people decide you're trying to con them, and therefore become more frightened and more angry" *(61)*.

Dick Thompson, who manages outbreak communications for the World Health Organization, notes that every time you communicate during a crisis, you are either building trust or eroding it. "There are a lot of special things about outbreaks, but most important is that they're unfolding events," he says. "Nobody really knows where they're going and, especially in the beginning, there's high outrage and high concern in the absence of knowing what the hazard is" (24).

Ineffective communication—or the failure to communicate—can help a crisis grow and fester. Four excellent crisis communication tips from billionaire US investor and philanthropist Warren Buffett are as follows:

- Get it right
- Get it quick
- Get it out
- Get it over with

Speed is the essence of crisis communication. Try to get your key messages out first, because it will maximize the likelihood of balanced news stories. Otherwise, someone with less knowledge or no knowledge will attempt to fill the communication void. Your instinct may be to want to postpone talking to the news media because of lack of information, but it is okay to acknowledge that you don't have all the facts. It's important to communicate only what you know for sure and not to place blame. According to Covello, when in doubt, however, lean toward sharing more information, not less, so people do not think that something significant is being covered up or withheld (57).

Although it may seem like having to walk a verbal tightrope, do not minimize or exaggerate the level of risk, dismiss people's concerns, or overreassure (57). Keep your vocabulary simple and nontechnical and your messages short and clear. Sandman asserts there are a number of "risk words you can't use" during a crisis because of the possibility of misunderstanding, including *conservative*, *significant/insignificant, positive/negative, safe, prepared, confident*, and even the word *risk* itself *(62)*.

At the same time, use numbers carefully and sparingly. Do they make sense to laypeople? Are the numbers so big (billions of colonies of bacteria) or so small (parts per trillion of a toxin) that they are difficult to conceptualize? Making risk comparisons can also be tricky. Comparing the relative risks of something that is involuntary (such as a hospital-acquired infection) to things that are voluntary (such as smoking) can be perceived as callous, nonsensical, patronizing, or an attempt to belittle the risk at hand.

Caring and concern should be communicated during a crisis by expressing empathy. Empathy is putting yourself in other people's shoes and acknowledging the validity of their emotions and positions (57). An example is this quote in a story about a doubling in child deaths in Iowa from respiratory illnesses:

> *"What we're trying to do is see if there is a particular respiratory virus in some of these deaths," said Dr. Patricia Quinlisk, the state epidemiologist. "Any child's death is a tragedy and most of these children were otherwise healthy" (63).*

AFTER THE INTERVIEW

After talking with a reporter, it's a good idea to invite them to call if they have questions and provide contact information where you can be reached while the story is being written or produced. You can also offer to review the

technical points in the story before it airs, is published, or appears online. Some reporters will accept your invitation; others won't. A reporter may not have enough time before their deadline or believe they understand the information you provided. On the other hand, a reporter may appreciate the opportunity to run complicated parts of the story by you.

However, you should not insist on previewing the entire story before it is broadcast, published, or posted online. While prepublication review may be part of health and science, it is not part of journalism. Many reporters and their editors would consider it precensorship and bristle at the suggestion. In addition, numerous media organizations have policies forbidding sharing stories with sources prior to publication or broadcast. And if the reporter doesn't call you back, you shouldn't contact them again because it appears as though you are checking up on them (8). The exceptions are if you are following up with the answer to a question or believe you left out a crucial piece of information.

Evaluating Errors

After the story comes out, you may wonder why you spent so much time with the reporter just to have a sentence in a lengthy magazine article or a single sound bite in a television story. You may also have concerns about the content or tone of the story. Despite good intentions and hard work, reporters sometimes make mistakes. Reporters want people they have interviewed to let them know about factual mistakes in their stories but not to overreact. If you believe there are problems, evaluate them before you pick up the phone or click on the mouse to complain. You may also want to ask the opinion of the public relations team at your institution, organization, or agency.

Is there an egregious factual error? If so, be courteous and professional in requesting a correction. Sometimes, however, your concern is that the story was not written like you would have. Of course, if it was written as an academic piece, no one but your peers would read it. Perhaps you believe that the reporter "got it wrong" because of information that was excluded. But brevity is a constant characteristic of journalism; stories don't have room for all details, qualifications, and nuances scientists and public health professionals would like. Or perhaps you object because opposing views were included that challenge or undercut the information or comments you provided. But journalists are supposed to write balanced stories, which can mean providing equal time or space to opposing views.

Ultimately, you may have to balance what you believe to be weaknesses in the story versus the benefits of getting the coverage—and getting the information out to the readers, viewers, or listeners. Remember that the final audience is not the journalist or even other public health professionals, but the public.

OTHER MEDIA COMMUNICATION TOOLS

Interviews are only one way in which public health professionals can communicate with the public through the news media. Several other tools are described below.

News Releases

News releases are frequently used to communicate information to the news media. While the public relations team at your organization or institution will draft the release and decide how and where to distribute it, you may be asked to contribute information or be quoted. News releases can be distributed to specific types of reporters (such as health reporters) or to the editors who decide which stories will be covered by their media organizations (city editors at newspapers and assignment editors or news editors at television stations). They can also be customized for media organizations in specific geographic locations (for example, your state or province) or for certain kinds of media organizations (such as hospital industry publications).

The information in most news releases is available to be used as soon as the media organization receives it. Some news releases are embargoed, however. That means that the information cannot be used until a specific date and time. The goal is to allow equal access to information, but sometimes embargoes are broken by media organizations that want to get a jump on their competitions. Video news releases are like print news releases except they are accompanied by video and photos that can be used on air by television stations.

News Conferences

A news conference is another vehicle to get information to the public through the news media. During a news conference, one or more speakers provide information using a script or key messages. Afterward, reporters are allowed to ask questions.

An advantage of a news conference is that all reporters can be accommodated together, using the speakers' time efficiently. In addition, all media organizations get the same information, resulting in a level playing field. There are several potential drawbacks to news conferences, however. Competing "breaking" local news may limit attendance. Speakers need to be extremely well prepared; a gaffe made during an interview with a single reporter will be magnified when said to a roomful of journalists. A skeptical or critical reporter may turn the questioning hostile and other reporters may chime in. And reporters may still want individual interviews afterward to try to get unique information.

The Internet can extend the geographic reach and longevity of a news conference in two ways. In some instances, reporters who cannot attend a news conference can watch streaming video of the event online. They can then use a toll-free phone number to ask questions just like reporters there in person. A second type of news conference is conducted entirely online: reporters call a toll-free phone number while also calling up a PowerPoint presentation. The speaker or speakers walk through the presentation over the phone and the reporters then ask questions by phone. The presentation materials remain online for viewing and downloading, along with an audio file of the news conference.

If you are participating in a news conference, you need to develop key messages just like you would for an interview. Other tips include checking out the location beforehand and rehearsing your remarks until you can deliver

them smoothly and confidently. If there will be other speakers, it's a good idea to rehearse together to avoid duplication and inconsistencies. Give yourself plenty of time to practice answering likely questions. Before the news conference begins, remember to turn off your cell phone. And when others are speaking, it's important to remain engaged and not look bored.

Op-Eds, Guest Columns, and Letters to the Editor

Another way to provide information to the public through the news media—but unfiltered by a reporter—is to write it yourself. Letters to the editor are brief and may reflect a personal viewpoint on an issue or topic covered in the newspaper or magazine. Op-eds, so called because they appear on the page opposite of the editorial page in newspapers, provide a longer format. Guest columns in magazines or online news sites provide similar opportunities. Both enable you to demonstrate expertise by explaining a situation or issue, helping to put an issue or development into context, presenting or expounding on findings, or providing perspective and opinion. Both are edited by the publication for length. Once you publish an op-ed or guest column, you can extend its reach by turning it into a blog post or newsletter item.

Desk-Side Briefings

Desk-side briefings are a great way to get to know reporters who cover health issues in your community. You can offer to meet with them at their office to provide background on an issue, explain what you do, put a human face on your institution or organization, and provide your contact information (alternatively, you can invite the reporter to your facility). This can be especially helpful for a reporter new to the beat. Like other situations in which you talk with the news media, however, you should establish ground rules upfront: will everything you say be on the record? A desk-side briefing typically does not result in immediate news coverage, but it helps establish you as a "go-to" resource for future stories.

KEYS TO A SUCCESSFUL WORKING RELATIONSHIP

Some public health professionals, healthcare epidemiologists, and infection preventionists not only survive the experience of talking with the news media, they realize that continuing to do so can provide ongoing benefits to the public, to their institution or organization, and/or to their own reputation. They may make the transition from once-reluctant interview subject to trusted news source.

Being a news source is a reciprocal relationship. The reporter contacts you for opinion or information; at the same time, you proactively contact the reporter with story ideas and information or views you believe should be communicated to the media organization's audience.

What Reporters Look for in Sources

In addition to expertise, reporters typically look for three other characteristics in potential sources. The first is accessibility and responsiveness. Willingness to talk to a reporter and having the most fascinating information to share won't suffice if it takes days to return their call or to gather promised information. Recognizing that reporters face frequent deadlines and, often, fierce competition, this may mean taking or returning calls on nights, weekends, or holidays. In this era of a 24-hour news cycle, responding promptly to a reporter can make the difference between their story being "the first" or an "also ran."

Another valued attribute in an expert source is truthfulness. Beyond not lying or stretching the truth, it means being upfront when you don't know an answer. And your expertise only goes so far: if someone else would be a better expert for a story, let the reporter know.

While reliability and truthfulness may be easy to acquire, pithiness—the third prized attribute—may seem more like an art form. It's the ability to get to the heart of an issue, to say something worthwhile and interesting in a simple, concise, and sometimes unexpected way, using colorful but down-to-earth metaphors and analogies rather than abstract concepts. An example is the following story about a measles outbreak linked to an increase in the number of parents rejecting childhood vaccinations:

> *"The very success of immunizations has turned out to be an Achilles' heel," said Dr. Mark Sawyer, a pediatrician and infectious disease specialist at Rady Children's Hospital in San Diego. "Most of these parents have never seen measles, and don't realize it could be a bad disease so they turn their concerns to unfounded risks. They do not perceive risk of the disease but perceive risk of the vaccine" (64).*

Over time, mutual trust will hopefully develop between the reporter and source. Dr. Michael T. Osterholm of the University of Minnesota says he has been a source for some reporters for 15 to 20 years. "They trust me and I trust them," he says. Sources and reporters also need to negotiate boundaries: Is it okay to call on weekends? Are you willing to do stand-up television interviews on a half-hour notice? Are there topics that are off limits? Don't be surprised that once you become a source to one reporter, you are contacted by other reporters who see you quoted in stories and think you may make a good source for them as well.

A Friendly Relationship, but Not Friends

Reporters may act in a friendly way, but they are not your friend. While you share the broad goal of serving the public, there may be an inherent conflict in your respective missions. As a representative of an institution, organization, or agency, you want a story that will support your position, issue, colleagues, or organization—that will hopefully promote it, defend it, justify it, and put it in the best possible light. On the other hand, reporters want a story, period, and the more controversial or sensational, the better. As long as the two of you understand and accept each other's motives and missions, you can have a positive professional relationship. But becoming friends blurs the lines between the professional and the personal and raises potential pitfalls, including troublesome questions about when and where you are "on" and "off" the record.

RESOURCES

Many resources are available to help you become more skilled at communicating with the public through the news media. Following are some suggestions:

Books

- *A Scientist's Guide to Talking with the Media* (2006)—This book is detailed and thorough yet accessible and easy to read. Richard Hayes, media director for the Union of Concerned Scientists, and Daniel Grossman, a science journalist, team up to share practical advice based on their considerable professional experience.
- *Am I Making Myself Clear? A Scientist's Guide to Talking to the Public* (2009)—Cornelia Dean, a science reporter and former science editor at *The New York Times*, wrote this book to encourage scientists to take a more active role in communicating with the public. In addition to explaining how journalists cover science, she provides tips on how to tell science stories on radio, TV, and online.
- *Don't be Such a Scientist: Talking Substance in an Age of Style* (2009)—Randy Olson, a former marine biologist turned filmmaker ("Flock of Dodos"), authored this book to spread the message that scientists have to loosen up, be likable, and learn how to tell stories if they want to have a greater impact on society.
- *Handbook of Science Communication* (1998)—This book, compiled by Anthony Wilson, is broader than *A Scientist's Guide to Talking with the Media* and includes how to give presentations and write up research. Chapter 4, "Working with the Media," is especially relevant.

Online Resources

- The Science Media Centre in the UK has three concise guides available for downloading to help scientists talk with the news media. "Top Tips for Media Work," is a useful overview for scientists who are new to talking with reporters; it is available at: http://www.sciencemediacentre.org/uploadDir/admintop_tips.pdf. "Communicating Risk in a Sound Bite" and "Communicating Uncertainty in a Sound Bite" can help scientists prepare for broadcast interviews. They are available at: http://www.sciencemediacentre.org/uploadDir/admincommunicating_risk.pdf and http://www.sciencemediacentre.org/uploadDir/adminuncertainty_in_a_sound bite.pdf
- "Why Scientists Should Talk to the News Media"—A video of a panel discussion at the Yale University School of Medicine about the importance of communicating with the public. Practical advice is offered by Denise Grady, health reporter for *The New York Times;* Ron Winslow, a reporter for *The Wall Street Journal;* and Mariette DiChristina, editor in chief of *Scientific American*. You can watch the video on the website of the Council for the Advancement of Science Writing: http://casw.org/videos-october-2009-brown-bag-event-yale

Training

There is no substitute for hands-on media training. A half-day or daylong media training session can help you feel confident and prepared when you talk with reporters. Media training involves hands-on practice, in which you are videotaped doing mock media interviews on realistic topics. Afterward, the interviews are played back and critiqued.

If you are interested in media training, ask the public relations team at your institution, organization, or agency if they have media training experience and capability. If not, they may be able to arrange a session conducted by an outside public relations professional who specializes in media training or a member of the public relations faculty at a local university. Other media training resources include:

- APIC has offered a media training workshop at annual conferences. While the 1-hour workshop does not provide hands-on training and critique, it covers basic points in how to prepare for and conduct interviews. To find out if a similar workshop will be offered at an upcoming annual conference, go to www.apic.org and click on the conference link on the home page.
- Research! America offers communication training for scientists. Contact Karen Goralewski at: kgoraleski@researchamerica.org.
- Media training opportunities for scientists in the United Kingdom are described on a government-sponsored website, Science So What? So Everything: http://sciencesowhat.direct.gov.uk/get-involved-in-science/get-involved/media-training-for-scientists
- The Aldo Leopold Leadership Program at the Woods Institute for the Environment at Stanford University provides media training for environmental researchers. Pam Matson, the leadership institute's scientific director, gave an overview of the training program on National Public Radio's "On the Media" program. It can be accessed at: http://www.onthemedia.org/transcripts/2009/02/13/05

Other

- Both the American Association for the Advancement of Science and the British Science Association offer fellowships for scientists to work for short periods at media organizations to experience what it is like to communicate with the public. More information is available at: http://www.aaas.org/programs/education/MassMedia/ and at http://www.britishscienceassociation.org/web/ScienceinSociety/MediaFellowships/index.htm

SECTION III
Informatics in Healthcare Epidemiology

CHAPTER 15

Using the Personal Computer for Healthcare Epidemiology

John A. Sellick, Jr., Keith F. Woeltje, and Rebecca Wurtz

We live in the information age. The effective and comprehensive use of digital information in healthcare epidemiology and infection control is both desirable and necessary. This chapter discusses computer systems, networks, and the Internet from a high-level perspective. Because of space limitations, it is not possible to discuss each computer system, software package, network configuration, or troubleshooting program or to refer to specific products. Rather, this chapter provides a conceptual framework for discussing information services (ISs) in a healthcare setting.

THE ROLE OF THE HEALTHCARE EPIDEMIOLOGIST IN HEALTH INFORMATION MANAGEMENT

For the purposes of this chapter, health information management will be defined as the storage, exchange, and analysis of data generated by healthcare. The term "health information system" encompasses the digital hardware and software applications, architecture and network structure, interoperability standards, and policies governing the generation and use of health data.

The healthcare epidemiologist (HE) and quality officer obviously have a fundamental need for the data generated in electronic health systems. Almost no one else in the hospital and ambulatory setting routinely and systematically analyzes aggregated clinical data and data patterns. A common complaint following the implementation of enterprise-wide health information systems is that "data goes in, but I can't get anything out." It is essential for the HE to be knowledgeable about and involved in discussions about data elements, extraction, analysis, and visualization during the implementation and updating of information systems. Ideally, the HE develops the skills and permissions necessary for querying databases and extracting data without requiring a middleman. Healthcare organization IT departments are often overburdened and may not respond in a timely way to requests for query construction and data.

COMPUTER SYSTEMS AND NETWORKS

Historical Perspective

The Era of the Mainframe Historically, electronic data processing in large organizations, including hospitals, was done on mainframe computer systems. These monolithic systems were developed to support the fiscal and demographic data needs of healthcare organizations and became known as management information systems (MISs). Healthcare MISs have matured to include clinical components such as laboratory, pharmacy, and radiology information systems and clinician order entry, making important patient data more readily available to care providers. Data management systems for a myriad of other discrete purposes, such as surgical, obstetrical, and emergency department resource and inventory management, are available. Data input generally is from a keyboard terminal or directly from laboratory equipment. Printing may be done at central, high-speed printers or distributed network printers.

Mainframe computer software operating systems (OSs) and applications software typically were cryptic and complicated, requiring extensive expertise and time for setup and maintenance. Access for end users usually was through a hard-wired (directly connected) dumb terminal, essentially a monitor with an attached keyboard. User interaction was restricted to a set of defined keyboard commands and functions, often in the setting of predesigned menus or screens.

Attempts were made to develop customized mainframe infection control software to capture relevant demographic and clinical data, and then merge them with surveillance data collected and entered for individual healthcare-associated events (1,2). Standard reporting templates allowed the production of a wide variety of summary reports at set intervals, and provisions were made for the retrieval of data via *ad hoc* queries when the standard reports were insufficient (3). These custom-developed mainframe infection control data management systems typically were developed through cooperative efforts between infection control and the IS departments of a few larger hospitals. They were usually computer OS specific and thus difficult to adapt to other institutions with different computing configurations. Their high development (1) and maintenance costs and their lack of adaptability to other computing environments made them impractical.

The Rise of Personal Computers In the 1970s and 1980s, desktop microcomputers, often called personal computers (PCs), were developed by Apple, Inc. (Cupertino, CA) and International Business Machines Corp. (Armonk, NY). They have become so ubiquitous that most people associate the term computer with desktop microcomputers. The terms personal computer, desktop computer, and microcomputer all describe the same machine and are used interchangeably. These user-friendly machines sport a graphical user interface (GUI) and a control device such as a mouse or trackpad along with the ability to connect to a network and local printer. External input devices such as scanners and bar-code readers are inexpensive and easily attached, as are removable media (hard drive, disk, cartridge, or tape) storage and backup devices. (The standards for such connections are set by the Information Technology Working Group of the Institute of Electrical and Electronics Engineers [IEEE] and often are referred to by number.)

Stand-alone desktop computer hardware and software tools allow for a large measure of autonomy in developing and maintaining data management systems independent of the hospital's information system. As a result, they have significantly altered the practice of surveillance, data management, and data analysis in healthcare epidemiology. Both infection control-specific software programs and generic database management programs are available to develop customized infection control databases. Word processing, statistical analysis, charting, communications, and presentation programs fulfill the remaining needs for most healthcare epidemiology and infection control providers.

Unfortunately, the learning curve for computers and software may be steep, and even software designed specifically for infection control may be difficult to use (4,5). Data often must be manually entered, which is time-consuming and leads to errors. Moreover, the distributed nature of personal computing has resulted in both duplicative and fragmented data sets throughout organizations. Similarly, the keepers of individual databases may be unwilling to share data with others and may not take the necessary steps to ensure the integrity and safety of their data.

The Advent of Client/Server Computing The desire for both the flexibility of a microcomputer and access to the data archives and computing power of a mainframe computer system led to the development of client/server computing. In this system, the desktop computer is a "client" that can connect to a "server" of data and software applications via a network. A network is a series of hardware devices and wiring that connect any number of client or server computers, printers, storage devices, etc. The network also requires its own software or protocol in order for the various devices to communicate and function with one another. Ethernet is the commonest network hardware specification and communications protocol for local area networks (LANs) in use today. There are a variety of network operating system (NOS) software products available to control the services, for example, access to files and printers, provided by the LAN.

A server may simply store files, deliver messages, and queue print jobs, or, in the true sense of client/server computing, it may provide for interaction and shared computing capability between the client and the server. The potential benefits for healthcare epidemiology and infection control services of having a computer attached to an information-laden server on a LAN are readily apparent. With proper client software, the organization's demographic, clinical, laboratory, and financial databases can be searched, data analyzed, and items of interest moved to the client computer for further use or analysis. Other tasks such as providing backup copies of files or sharing documents and mail with other clients on the network are easily accomplished.

The appeal and potential benefits for client/server networks is considerable, but so are the potential problems of implementation. The databases on large servers generally are built using proprietary systems that require additional software and training for appropriate use. Intermediary programs, collectively called middleware, may be needed to create an interface between the client and the database to extract the information desired by the healthcare epidemiology service. However, if this can be accomplished, the rewards can be great once the desired data are identified, collected, and analyzed.

Recommendations for Personal Computer Systems

It is not possible to recommend a "one-size-fits-all" approach to computerizing a healthcare epidemiology or infection control service. As with purchasing a car, the users must evaluate their requirements and budget. Most organizations have moved to a client/server model of computing, making it feasible for healthcare epidemiology team members to have PCs that may fill several roles and satisfy multiple needs. The selection of hardware and software should take into consideration the requirements of connecting to a LAN and accessing a mainframe or other server(s). Consultation with the appropriate university, hospital, or other organization's IS department can provide guidance in these areas.

Hardware If choosing a PC, the first decision to be made is whether to purchase a desktop/minitower or a laptop. The former traditionally have offered the potential of greater power and expandability; however, current laptop models have more than adequate power for almost all healthcare epidemiology functions, plus the advantage and potential problems of portability. Likewise, the availability of universal serial bus, IEEE 1394 ("Firewire"), and ExpressCard or CardBus ports make laptops widely expandable as well. Laptops typically come with active matrix (thin film transistor) liquid crystal diode displays, but a display is a separate item for desktop units. The ultimate decision regarding the choice of desktop vs. laptop often will be a financial one, but the issues of ergonomics and security of the equipment also must be considered.

Regardless of whether a desktop or laptop unit is chosen, it is important that it have adequate random access memory (RAM) for anticipated tasks, an adequate size hard disk drive, and an optical drive. The latter may be a CD-ROM reader or a drive that both reads and writes CD-ROM media (CD-RW). Drives that combine CD-RW with the ability to read and write DVD-ROM (digital versatile disk) media also are widely available as either internal drives or external drives. These will accommodate the use of the many software titles, educational programs, and databases available on optical media. Appropriate networking connections such as Ethernet cable ports or adapters or wireless networking receivers (see below) also are necessary. If not connected to a network, a telephone modem will be needed to connect to the Internet.

Information "output" is a critical part of healthcare epidemiology and infection control and a variety of options are available. Often, a printer will be used and the two types in widespread use are the laser and inkjet varieties. The laser printer fuses microscopic plastic toner particles to a page (paper or transparency) the same way a photocopier does, while inkjet printers deposit droplets of ink on the pages. Laser printers usually are monochrome/grayscale, while almost all inkjet printers produce a full spectrum of colors, including the ability to produce photographic quality prints. Laser printers generally cost more to purchase, but inkjet printers usually have a higher cost of "consumables," namely, ink cartridges and specially coated photographic paper and transparencies. It is important to compare per page costs and also individual needs, that is, frequent presentations might argue for an inkjet printer that can produce color transparencies while predominantly paper reports might favor a laser. It is worthwhile to investigate if a workgroup printer, available to several individuals or departments, is available since it may allow costs to be shared or even avoided.

Presentations may be sent directly to electronic multimedia projectors, but these devices generally are too expensive for individual or even departmental purchase. Most hospitals and universities have them installed in conference/lecture rooms or available for use and/or loan. Information also can be "published" on an intranet or the Internet (see below) using one of the many simple software programs available.

A method to provide backup or duplicate copies of important data must be provided, whether through a local device (such as an external hard drive) or a network file server, so that important or unique information may be retrieved in the event of equipment failure or theft. Many organizations provide each user with "space" on a network file server for copying important files, though this may not be large enough to copy an entire hard disk drive. A DVD-RW with appropriate software is a convenient and inexpensive way to make duplicate copies of important files or even an entire hard disk drive. External hard disk drives now are very inexpensive and much faster than optical drives. They may be disconnected and stored in a safe place.

Operating Systems An OS is the core software that enables computers to function, communicate with the hard disk drive and other devices. Several such systems are in widespread use. Microsoft Windows (Microsoft Corporation, Redmond, WA) is most widely used. However, Apple MacOS and a number of UNIX variants such as the freeware Linux also are popular. OS software often is hardware specific in either type or speed, sometimes both. Other than applications written in Sun's Java programming language, software written for one OS does not run on computers that use a different OS. Also, application software may be specific for different versions of the same OS. For example, documents created using Windows 7 may not open on prior Windows versions. It is important to thoroughly understand the processor, memory, and hard disk space requirements of any OS or application software prior to purchasing it.

Basic Software Aside from the OS software, application software programs (often called applications, software or programs for short) are needed to make a PC more than an expensive Tetris machine. Basic software tools include a word processor for making reports and writing correspondence; a spreadsheet for making calculations and graphing data; a database for storing information, such as surveillance data; and a presentation program for making electronic slideshows and other visual reports. These basic tools often come as part of an "office" suite of software, which may be proprietary (e.g., Microsoft Office) or open source (e.g., OpenOffice.) Price, required RAM, hard drive storage space and the expertise required for efficient use are variable. Before purchasing software, attempt to evaluate it with a demonstration version (often available from publisher Web sites) or on a colleague's PC. Software user reviews are widely available online. Universities, hospitals, and other large organizations often have site license agreements with software publishers that will provide basic software at little or no cost to employees or affiliated professionals.

Basic software also may include statistical analysis software, which no longer requires a mainframe computer to use. Many commercial packages as well as the freeware Epi Info from the Centers for Disease Control and Prevention (http://www.cdc.gov/epiinfo) are available for PCs.

Modern software, running on a GUI-based computer, has the ability to change typefaces (fonts), manipulate typeface styles, organize materials, and add tables, charts, or images to a document. A report of epidemiologic activity, therefore, could include text with bold headings, a table of key data, and several salient charts that result in a clear, concise, and compelling document. However, the very features that allow for this flexibility also can make the report

garishly unattractive if used in excess. In general, multiple typefaces should not be used in a single document, and script or other specialty typefaces should be avoided since they are difficult to read. Likewise, underlining and ALL CAPITALS are distracting and difficult to read in a body of text; emphasis may be added with boldface or italics. Some of the most egregious violations of publishing taste occur with newsletters and information sheets which, along with excessive typeface manipulation, often contain excessive amounts of clip art and other nontext items. Many publications are available to provide guidance for creating attractive documents and compelling visual displays of quantitative information (6,7).

Personal Digital Assistants and Smartphones

The last decade has witnessed the explosive growth of shirt-pocket–size devices known as personal digital assistants (PDAs). Originally developed to be date books and a place to store names and contact information, these small computers have increased in speed and memory and now can provide data retrieval, basic word processing, statistical and database functions. Newer models include wireless access to the Internet or to local networks using the IEEE 802.11 standard. As with PCs, there are competing product platforms available: the original PDAs were produced to run the Palm computing platform (Palm, Inc., Sunnyvale, CA) or a "mobile" version of Microsoft Windows.

Many popular cellular telephone network devices, such as the BlackBerry devices of Research In Motion (RIM, Waterloo, ON, Canada), have emerged in the past few years. Dubbed "smartphones," they offer PDA functions along with Internet/electronic mail access as well as voice telephony. Palm also has transitioned completely away from standalone PDAs to smartphones.

In early 2007, Apple, Inc., introduced the first iPhone and has released several updated versions. Along with PDA, audio playback and telephone functions, this device runs small applications, now commonly called "apps," which gives it computer-like functionality. A nearly identical device, the iPod Touch, and the recently released iPad tablet have the same functions without cellular telephone capability. These devices offer 802.11 wireless Internet communications as well.

Apps for the iPhone, iPod Touch, and iPad have been developed for many purposes including medical applications and can be purchased and/or downloaded from the iTunes store. These include drug databases, medical calculators, and a hand hygiene assistant called iScrub that was developed at the University of Iowa *(8)*. Through the use of third-party software, it also is possible to read Microsoft Office and Adobe portable document format (pdf; Adobe Systems, San Jose, CA) documents. Audio programs called "podcasts" also may be downloaded, and there are many medical lectures, news summaries, journal commentaries, etc., available. In response, some smartphone device manufacturers such as RIM have updated their OSs to offer similar apps and services.

In a recurring theme, the software made for one platform will not run on another and not all titles are available for all platforms. The potential user must evaluate these devices based on intended use, availability of apps and cellular network. Note that the iPhone and smartphone cellular contracts mandate an additional network data service charge beyond cellular voice service charges. Since PDAs and smartphones do not have built-in hard disk drives, it may be necessary to "synchronize" them with a PC to ensure data retention, availability, and security.

This group of devices holds promise in the healthcare setting though there are few data describing specific uses in healthcare epidemiology and infection control (*8*,9). Most uses appear to be for schedules, calculators *(10)*, and pharmaceutical databases, so cost, personal preference, etc., will determine purchasing decisions. One theoretical "downside" of these devices is the potential to be fomites (11,12).

CONVERTING DATA TO INFORMATION

Data

Data for infection prevention can come from a wide variety of sources. Manually collected data (e.g., device days) can be entered by hand. Many data can be obtained electronically from hospital systems. Chapter 16 discusses the use of the electronic medical record for infection prevention and enterprise-level surveillance support. But even those who use their desktop PCs for supporting infection prevention activities can benefit greatly by receiving reports electronically in formats that can be imported into the analytic software they use. Many hospital departments may be able to generate reports (e.g., lists of surgical patients, patient days by ward) in standardized formats (see below) that many PC programs can import. This is certainly faster than reentering the data, but more importantly, avoids the possibility of transcription errors.

When trying to use data from multiple sources, it is important to ensure that the same terminology is used consistently. A wide variety of standardized terminologies exist for medical purposes (e.g., ICD-9, SNOMED). While each terminology is usually used for specific purposes—such as ICD-9 for billing—these often overlap, and even within a single institution different departments or computer systems may use different terms for the same fundamental concept. In such cases, there will be a need to settle on a standard terminology for infection prevention, and translate or "normalize" other codes or terms when necessary.

Once systems are in place to obtain data, provisions should be made for ensuring data integrity and completeness: that all relevant data are transmitted intact, that missing data are detected and replaced, and that new systems and terms are handled appropriately.

Spreadsheets

Even more so than word processing software, spreadsheet software ushered in the PC era. Spreadsheet software remains one of the most versatile tools at the disposal of the HE. Spreadsheet software is any application that allows data to be stored in the familiar row and column layout; Excel (Microsoft, Redmond, WA) is one example. All infection control personnel should know how to use an electronic spreadsheet.

Flat-file Database The column and row design of computer spreadsheets lends itself well to use as a "flat-file"

database. This is a database where all of the information can be contained on a single page (see the discussion of databases below for other types of databases). Typically, the first row is used to enter headings for the information to be collected (i.e., the database "field"; e.g., Name, Age, etc.). Each subsequent row is then used to store information for one subject (i.e., a database "record").

Although database programs can also be used for such flat-file databases, using a spreadsheet for this purpose has a number of advantages. For many users, a spreadsheet is almost always included with their office suite of software, whereas a database program will probably have to be purchased separately. Some users familiar with the use of a spreadsheet for calculations can extend that familiarity more easily than learning an entirely new program. Some statistical software may be able to import data from a spreadsheet table, making the spreadsheet file format a "common denominator" for sharing data between programs.

One of the handiest features of spreadsheets is the "filtering" function. This allows the user to see only records that meet a certain criterion. Although the same information may be obtained from a true database program, it typically involves more work. For example, an ICU may want to keep track of the intravenous devices used on various patients. In a spreadsheet, there may be a column for patient name, and others for medical record number, date of admission to the ICU, etc. A column could then be made for "IV device used." Then, "peripheral catheter" or peripherally inserted central catheter (PICC) or "triple-lumen catheter" could be entered into this column. By using the filter function, one could readily see all of the patients that had a PICC line. But typically, an ICU patient will have multiple types of IV catheters. One could have a column "IV catheter 1" and another column "IV catheter 2," and so on. But consider what would be necessary to find all of the patients who had a triple lumen catheter. First one would have to filter for "triple-lumen catheter" in the "IV catheter 1" column, then in the "IV catheter 2" column, etc. One way to get around this is to have only one column for device and then enter a new row for each type of catheter the patient had. However, this would mean duplicating the patient demographic data for each row and would make a simple count of the patients or calculations like the mean patient age difficult. A more effective option would be to have a column for "triple-lumen catheter" with either "Yes" or "No" listed for each patient. A search for patients with such a catheter would only require that "Yes" be filtered for in that column. Obviously, such a system would become unwieldy if there were a large number of options, but for limited numbers of choices, looking up data can be very efficient. Many spreadsheets will filter on multiple columns, so that, for example, patients with both a PICC line and a triple-lumen would require only filtering for "Yes" in both of these columns.

Simple Calculations Although spreadsheets can be used for simple database functions, they were designed primarily to do mathematical calculations. Spreadsheet software can easily handle nonstatistical data needs of an HE. Users can enter very complex formulas, although for most purposes only relatively simple formulas are necessary. Rates, the fundamental calculation of the epidemiologist, are trivial calculations for these programs. Tables can be created to show rates over time such as monthly. As we'll see, such time series also lend themselves to graphing the data.

A great deal of the power of spreadsheets comes from the ability to program formulas that refer to other cells, even cells that are on sheets other than the one with the formulas. This can be used to great advantage. A user can, for example, use one sheet for entering National Healthcare Safety Network (NHSN) rates into designated cells. That way all other pages are automatically updated for the latest rates without having to enter them into each page or formula separately.

Another powerful capability of spreadsheets is the ability to copy formulas from one cell to another. Thus, once a formula is written, say for a rate calculation, it need not be reentered from scratch over and over again, but can simply be copied. One must be careful to ensure that formulas are copied correctly. Each cell in a spreadsheet has a unique "address," typically formed by the column letter and row number of that particular cell. Thus, the cell in column "C" on row "22" is designated "C22." Sometimes, when copying formulas, the user wants the column or row number to change. Consider a column D with January surgical site infection data. Row 8 has the number of infections and row 9 the number of procedures. Row 10 is designed to have the rates. The user can enter a formula like (D8/D9)*100 to calculate the SSI rate per 100 surgeries in cell D10 (the exact method to designate that there is a formula within in a cell, as opposed to just text, will vary depending on the spreadsheet software used). Column E then will represent February data. Rather than retyping the formula in cell E10, the user can copy the formula from row D10. But the formula must read (E8/E9)*100—the February, not the January data must be used. In other cases, for example, when calculating standardized infection ratios, the user will likely want to use the NHSN rate in multiple calculations. If the spreadsheet is set up as previously mentioned, with NHSN rates entered into designated cells, then the user must be sure that that cell reference stays the same even when formulas are copied. Spreadsheet software has different ways to designate whether the cell references can be changed when a formula is copied.

Although users can enter formulas to calculate summary data (e.g., adding up monthly numbers of VAP cases to get annual numbers of VAP cases), most spreadsheet software allows for more automated ways of doing this. These summary tables go by different names depending on the software; Microsoft Excel (Microsoft Corp., Redmond, WA) calls them "Pivot Tables," whereas OpenOffice Calc (OpenOffice.Org, www.openoffice.org) uses the term "DataPilot." They can be used to quickly aggregate data into a variety of formats (e.g., number of positive blood cultures by patient care unit by month) that would be tedious to program by hand.

ADVANCED STATISTICS

Spreadsheet software programs can readily handle the calculations needed for most statistics, providing simple built-in statistical formulas in which to enter data. The user must select the appropriate statistical test, but the

software does the calculation. Devising and entering very complicated formulas, however, is often tedious and error prone. In addition, these programs typically allow for "add-ins." These add-ins are additional pieces of software that extend the functionality of the base program. Statistical add-ins may come with the spreadsheet software itself (but not installed with the basic program) or are available from commercial software houses. As an example, Microsoft Excel comes with additional tools in what is called the "Analysis ToolPak." This allows more advanced statistics, such as analysis of variance (ANOVA), to be run. These add-ins can certainly extend the capabilities of spreadsheets to do fairly advanced statistics; however, even with these functions, there is still a need for a significant amount of formula entry by the user (frequently along with some programming using the macro language available in the software).

Besides add-ins, spreadsheet templates may be available. These are typically spreadsheets with column or row labels that indicate where data should go. Formulas are already entered in, so that all the user needs to do is fill in the blanks. These are typically much easier to use than add-ins, but one must be sure that the context for which the template was designed actually fits the user's situation.

For users who are very familiar with their spreadsheet software and who are comfortable modifying formulas in templates that may have been written by others, or writing complicated formulas themselves, add-ins and templates may provide a good solution for their needs. For most HEs, however, a specific statistical software program may be easier to use.

Database Software

Although spreadsheets are often used for data storage, they have distinct drawbacks. Databases made in spreadsheets are often termed "flat-file" databases—with their column and row layout they are like a flat sheet of paper. Although many times data collected for epidemiology can easily be fitted to this flat-file model, all too often data are forced to fit this model in an awkward manner. This was somewhat apparent in the previous discussion on using a spreadsheet to capture ICU patient catheter data. One can imagine that if there are multiple variables to be captured, such as microorganisms cultured or which healthcare workers saw a given patient, then any of the options for using a flat-file database would be unmanageable. In such circumstances, a true database program is called for.

True database programs were designed specifically for the task of organizing complicated data. There are a variety of types of databases. Some inexpensive "database" software provides essentially the functionality of electronic index cards. While such software may be adequate for keeping addresses or recipes, for research purposes these are functionally flat-file databases, and thus have all of the disadvantages of storing data in spreadsheets. A number of other database types exist, which vary in how they model or represent the data conceptually. The most popular type currently is the relational database model. Relational databases are popular because of their flexibility in storing data and their conceptual simplicity. They use multiple tables to store data, with a mechanism for relating the tables to one another. Thus, in the ICU line study example considered previously, one might have one table containing patient demographics, a second table containing information on IV catheters, and a third table with blood culture results. Each item would have associated with it some piece of unique information (such as a medical record number) that could be used to determine which data on one table were related to data on the other table. This relational database model is incredibly powerful, and most large hospital systems are built around relational database systems, such as Oracle (Oracle Corp., Redwood City, CA) or PostgreSQL (www.postgresql.org) that run on mainframe computers or high-end database servers. However, very functional relational database software is available for desktop PCs. This would include programs such as FileMaker Pro (FileMaker, Inc., Santa Clara, CA), OpenOffice.org Base (www.openoffice.org), and Microsoft Access (Microsoft Corp., Redmond, WA). Such database software may not be included in typical software "office" suites and must be purchased separately.

Using relational databases properly is somewhat more complicated than using spreadsheets. This is to be expected, given the more complicated structure of the information. Most PC-based database software packages have tools that dramatically simplify the use of the program. These tools also make it possible to generate attractive reports from the databases. Because their purpose is different, database programs do not have the broad range of calculating functions present in spreadsheets. Nevertheless, most of these programs can provide some simple information like tallies or means. To design databases optimally, it is useful to have an understanding of the relational database model. There are large numbers of online tutorials and books available, some of which are general (13) and some of which are specific to a particular database program. Although tools and "wizards" are typically used to elicit results from the programs, advance users can frequently get results not available otherwise by querying the database directly. Structured query language (SQL) is a relatively simple language designed specifically to extract information from relational databases (14). Although used more frequently on large-scale databases, PC-based programs typically provide an option for querying the database directly for advance users. As with spreadsheets, PC-based databases typically allow advanced users to write programs to extend the functionality of the database.

Epi Info

Epi Info is a program available for free from the US Centers for Disease Control and Prevention (CDC). Originally designed for Epidemiology Intelligence Service officers to perform outbreak investigations, it has grown into an extensive data management and analysis tool. Initially written to run on early DOS-based PCs, the software was extensively rewritten in 2000 to run on MS Windows.

Epi Info consists of several major components. These components were designed to facilitate epidemiological analysis from start to finish. MakeView allows the epidemiologist to design data entry screens for collecting pertinent data and automatically creates a database to hold the data. Data entry screens can be made more attractive and functional by allowing related data items to be gathered into a group, which may have a distinct back-

ground to aid the person entering the data. Since Epi Info is built on a true relational database, MakeView allows for the collection of data and of related data in separate tables. Unlike most database programs, Epi Info automatically maintains the proper relationship between the tables. To generate data collection forms, it is possible to print the data entry forms from MakeView. However, using a word processing program to design the forms will yield more control over the printed version and allow for a more aesthetic data collection tool.

The Enter program allows users to enter data into the questionnaire previously designed in MakeView. Enter will also allow for searching of entered data.

The Analysis program provides multiple options for statistical analysis of data. Besides reading data entered using MakeView and Enter, Analysis can import data from other database and spreadsheet formats, and from older versions of Epi Info. Analysis provides a full range of data manipulation and analysis tools. Basic statistics include simple frequency tabulations, contingency tables (which can be stratified), and analysis of variance (ANOVA, both parametric and nonparametric). Advanced statistical functions include linear and logistic regression, Kaplan–Meier survival, Cox proportional hazards, and complex sample statistics (contingency tables and ANOVA). Users can also create new variables within Analysis and can use fairly complicated rules to assign values to these new variables based on the values of existing data. Short programs for automating analyses that are done repeatedly can be written and stored in Analysis.

Epi Report facilitates gathering output from Analysis, Enter, as well as data from Microsoft Access or Microsoft SQL Server databases and formatting them into professional looking reports. These reports can also be saved as hypertext markup language (HTML) files for easy Web publication.

Overall, Epi Info provides the HE with essentially all of the statistical analysis tools he or she will need. Like any complicated program, learning to use the entire package well takes studying and practice. However, the program is simple enough that users who are familiar with the fundamentals of statistics used in healthcare epidemiology (see Chapters 2 and 3), and who have data in a compatible format will be able to run fairly complicated analyses shortly after installing the program. The program comes with extensive online help. The same content can be downloaded as manuals in both Microsoft Word and Adobe Acrobat (.pdf) formats. A tutorial and exercises are included to get users up to speed with the various components of the software. A quick Internet search will turn up other tutorials and educational materials to assist new users.

Specialized Infection Control Software

In addition to general-purpose statistical software, software developed specifically for infection control purposes is available. AICE (ICPA, Austin, TX) and EpiQuest (EpiQuest LLC, Key Largo, FL) are two such packages. Specialized programs guide users in selecting and analyzing data. This is especially useful for those just starting out in infection control or in using computers (or both). The trade-off is that, by nature, these programs are less flexible than general-purpose tools, and thus, may be difficult to tailor to any particular circumstances or *ad hoc* studies. However, over the years, many of these programs have become quite sophisticated. Some allow for automated entry of electronically available data. Such programs may also be used to efficiently generate reports that are mandatory in some states. Some can even send these reports electronically. Another example of reports that some systems can generate is health department reports for certain conditions (e.g., a positive RPR) drawing on the laboratory system as well as the admission system for demographic information.

Some specialized software can be relatively expensive. However, rather than just considering the purchase cost alone, the cost in time and effort to set up general-purpose tools to do the same thing that the specific programs can do must be accounted for. Unless someone locally is facile at setting up spreadsheets and databases, or specific research needs are not met, then specialized infection control software may be a very cost-effective purchase.

Spatially Enabled Data (GIS)

Geographic information and geographic information systems (GISs) are terms that invoke community-wide maps of disease incidence. The use of location data to aid in understanding the geographic correlates of health and disease is not new to the electronic era, as John Snow's well-known map of London's 1854 cholera outbreak attests. However, GIS, more accurately described as spatially enabled data, has many applications for the HE, including illustrating healthcare-associated transmission within a hospital unit, interpreting air movement patterns in operating rooms, and understanding community contributions to drug-resistance patterns in the in-patient setting. Visualization of data using location can aid in understanding many problems in healthcare epidemiology as well as communicate the nature of the problem to other healthcare stakeholders.

There are a number of relatively inexpensive desktop GIS software applications with the features needed by an HE. The most widely used commercial GIS software is produced by ESRI (Redlands, CA). In addition, there are several free applications. EpiMap, an Epi Info component, allows the user to link data contained in Epi Info files to maps. EpiMap uses maps in the popular ESRI SHAPE file format. GIS software applications are somewhat complex, and often the user needs assistance to use the program effectively. Free tutorials are widely available on the Internet, and most academic institutions offer educational sessions for faculty and staff. In addition, courses and certificate programs in GIS are becoming more available.

Free geographic information data for many locations, such as all US states and counties and many countries, are freely available on the Internet. Tools are available to create custom maps. The data to create more localized maps, such as of a hospital unit or building, are more difficult to generate but can be obtained by working with facility engineers and architects.

Visualization of Quantitative Data

The visual display of quantitative information is a critical part of communicating infection control information. Besides performing extensive calculations, most spreadsheet applications provide simple graphing tools. For the epidemiologist, bar and line graphs will be most

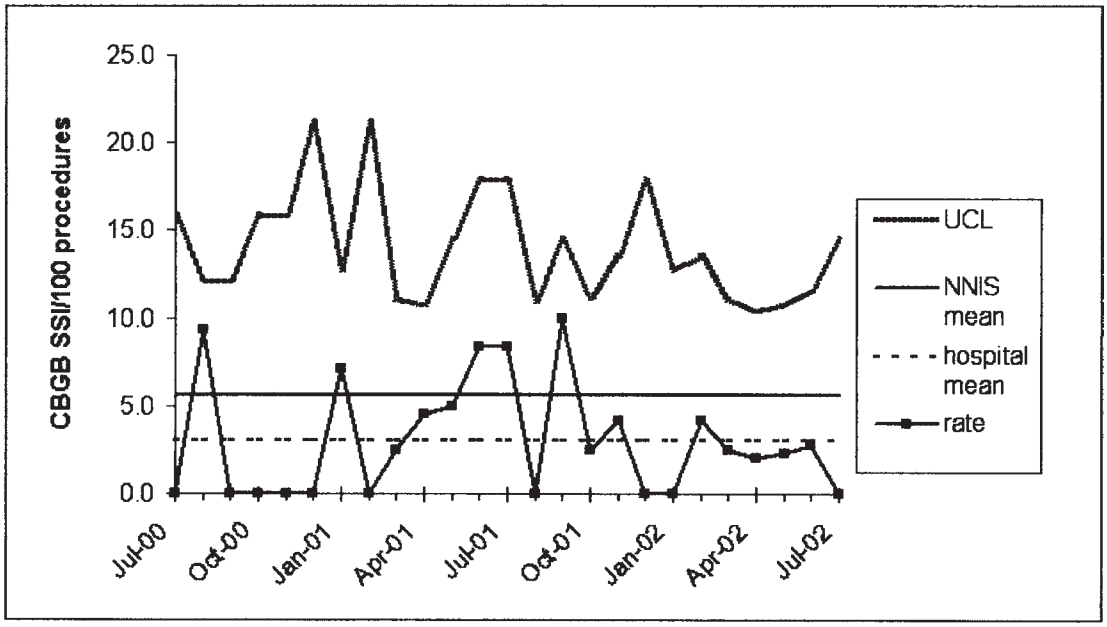

FIGURE 15-1 Control chart for coronary artery bypass surgery (risk category 2) produced on a PC with spreadsheet software. UCL, upper control limit.

frequently used. Bar graphs can be used to show epidemic curves. Line graphs are especially useful for showing trends, such as surgical site infection rates, over time. Other relevant data can be shown on the graph, such as the NHSN mean rate and the mean of the local rates, as well as upper control limits for process control charting (Fig. 15-1). It is important for infection control personnel to learn to use the graphing tools that accompany spreadsheet programs.

Beyond spreadsheets, many advanced statistical programs, including Epi Info Analysis, can produce graphics that are helpful in visualizing epidemiological data.

THE INTERNET

The Internet has become synonymous with the information superhighway, and many of the tools and techniques of accessing and navigating the Internet have been adapted for use on intranets and LANs. Therefore, a discussion of the Internet is an appropriate prelude to a discussion of information management.

Internet Structure and Function

The Internet arose from a network of government and university computer systems that was used to exchange files and information starting in the 1970s (*15*,16,17). With the wider availability of network connections and user-friendly software tools, the number of computers attached to and accessing the Internet has grown astronomically. Much of this growth has been in commercial areas, and commercial carriers now provide most of the pipelines that connect to and constitute the Internet. However, education and healthcare resources continue to thrive as well. A high-speed next-generation Internet or Internet2 has been developed for education and research institutions to rapidly exchange information (http://www.internet2.edu).

Analogous to the telecommunications system that preceded it, the Internet is composed of many computers that are attached to LANs. The LANs are in turn attached to larger networks that eventually become attached to the backbone of the Internet. Most of the computers that access the Internet are on the client side, that is, seeking information, while the minority are servers that provide the information. Like telephones and facsimile machines, each computer on the Internet must have a unique designation in order to send and receive data. These are called Internet protocol addresses (IP addresses for short) and have both numeric and name equivalents. IP addresses are organized by domain, and particular computers or servers within the domain; for example, wings.buffalo.edu designates the central campus Web server in the University at Buffalo second-level domain, within the education top-level domain. The numerical equivalent address for this server is 128.205.4.174. Other common top-level domains are .com for commercial sites, .gov for government sponsored sites, and .org for noncommercial sites. Country or state designations occasionally may supersede the traditional top-level domains at the far right of the IP address, for example, www.health.state.ny.us is the New York State Health Department home page.

While there is no central control agency for the Internet, IP addresses are assigned under the direction of an agency called the Internet Corporation for Assigned Names and Numbers (ICANN; www.internic.net). This maintains order and assures that all computers on the Internet are reliably able to be located.

Also analogous to the telephone system, computers on the Internet must use a common set of instructions in order for communications to move appropriately from source to destination. Most of the servers on the Internet use one of the variants of the UNIX OS, but most of the PC clients are MacOS or Windows based; smartphone devices also are able to access the Internet. To allow these diverse OSs to

communicate with one another, the Internet uses a set of platform-independent protocols that are determined by an international body of experts. The most important of these standards is the networking scheme called transmission control protocol/internet protocol (TCP/IP), which determines how the computers on the Internet connect and communicate with one another. Any computer running any OS can access the Internet if it has an appropriate network connection and is TCP/IP compliant. LANs that utilize proprietary networking protocols still can connect to the Internet through an appropriate router or bridge. TCP/IP also can coexist with Ethernet and the NOS on a LAN, which is important in allowing connectivity and compatibility.

Unlike the telephone system, Internet transmission utilizes packets of digital information rather than a continuous stream of analog data. Each file or message is converted into properly addressed packets before being sent. The address in the packet header instructs the servers on the Internet to relay the packet in a process called packet switching. This allows for many client/server connections to use the same Internet lines simultaneously, rather than keeping a line tied up as happens with telephone circuit switching. The downside of packet switching is that lost or misdirected packets, which increase with heavy Internet usage, can slow the user experience to maddening levels.

Connecting to the Internet

The best connection to the Internet is from a network where a PC is actually a node or a connection point on the Internet with its own IP address. Due to the nature of wiring and routing systems, network broadband connections are capable of very fast and high-capacity transmission compliant with Internet standards. Some networks do not permanently assign a separate IP address to each computer but rather reserve a range of addresses that are assigned electronically to computers as needed, using the dynamic host configuration protocol. Most universities, large hospitals, and other large organizations are able to provide direct LAN access for staff computers. Cable television and telephone companies in many areas provide individual users with broadband connections via fiberoptic cable modems that may approach the speed of traditional Internet network connections.

The development of wireless LAN and Internet connections referred to as Wi-Fi (wireless fidelity) allows a desktop or laptop computer, smartphone, or PDA-type device, with appropriate networking hardware based on the IEEE 802.11 standard to "connect" with network signals provided by an antenna connected to the Internet or a LAN. The antenna may be in the "open" or within a building or even a home. In a hospital, this would allow for real-time entry or retrieval of patient-related information at the bedside. Many issues, such as signal strength (which determines effective range for service), service interruptions and security of confidential information, need to be addressed for successful implementation.

If not directly connected to a network, as might be the case in a small facility or private office, using a telephone modem to dial into a host computer using the point-to-point protocol (PPP) is the next best option. The PPP server of an Internet service provider (ISP) temporarily makes a desktop computer a node on the Internet with its own dynamically assigned IP address. The bandwidth of this service is dependent on the speed of the client and server computers' modems. The development of integrated services digital network and asymmetric digital subscriber line telephone line protocols offers much higher bandwidth than even the fastest current telephone modem connection speeds. These, like fiber optic cable connections, require special modems that are more expensive than standard modems, and the monthly service charge also will be significant. Bandwidth is expensive!

Some organizations, including hospitals, may provide employees with remote access to the corporate network using a virtual private network (VPN). VPN client and server software uses a tunneling protocol to securely transmit information over the Internet using cable or telephone modems. This could allow professionals at remote sites to access electronic mail, databases, and other network-based resources.

Internet Tools

As noted above, the Internet originally was developed to allow scientists to exchange messages and files electronically. This was done with text-based software tools or clients that resided on the large Internet servers and required knowledge of the locations of files as well as the commands to retrieve them. While the use of newer software tools has supplanted the older tools, descendants of the original file transfer and terminal connection tools still are valuable and will be discussed further. The reader is directed to other sources for information about the other tools such as Gopher, Veronica, and Archie (16,17,*18*).

Files can be moved from one computer to another using the Internet file transfer protocol (FTP), and the software program that does this is referred to as an FTP client. (Client may refer to the software application or to the computer on which it resides.) If one knows the IP address of the server that contains a file of interest, this can be entered into the FTP client and a list of the folders (directories) on the server will be returned. This is useful for uploading large files or the pages of an Internet Web site.

Many files on Internet servers are compressed by special software to make the file size smaller for transfer and encoded into American Standard Code for Information Interchange (ASCII) text format to ensure safe passage over the network. This requires that the client computer have appropriate software for decoding and decompression. Compression formats vary among computer platforms. Disk image (.dmg) for Macintosh, Zip (.zip) for Macintosh and Windows, and tape archive (.tar) for UNIX are common. There are freeware, shareware, and commercial products available to decode and expand these files.

Telnet is the other important descendant tool though it too has shown its age. A Telnet software client application allows a client computer to connect to a server or mainframe computer. This in essence re-creates the dumb terminal situation described above, giving the client access to the software programs and files on the host computer. This will be in a text-only mode, generally with keyboard-only commands as defined by the host computer, and printing may be restricted to printers attached to the

mainframe. Since Telnet gives access to the functioning parts of the host (server), password access is generally required, as it would be when logging on from a hardwired terminal. Telnet may be the only means of gaining access to mainframe computers or other servers, so having a Telnet client is essential for anyone who wishes to obtain information from these machines.

Perhaps the most significant nonhardware milestones related to the Internet have been the development of the hypertext transfer protocol (HTTP), HTML, and browsers *(19)*. Together, they have transformed the client/server interface on the Internet from a cryptic, command line, text-based system to a "point and click," visually rich environment known as the World Wide Web (WWW or Web). Hypertext and HTML make it possible to include stylized text, tables, and images as well as hyperlinks (links for short), which, when clicked, move the user from the current location on the Web to another. Browsers are software client applications that understand HTTP as well as FTP and other Internet protocols and make it possible to view (browse), save, or print HTML pages, and to download files from HTTP or FTP sites. The user combines the desired protocol and IP address into the uniform resource locator, which then instructs the browser client to attach to the desired Web server. The Web server must run appropriate software to complete the interaction and deliver the appropriate file or page.

Graphic images such as pictures, scanned images, copies of graphs and other nontext artwork commonly appear in one of several formats on the Web: graphics interchange format (GIF; .gif), which is good for nonphotographic images since it displays only 256 colors but keeps sharp edges, portable network graphics (PNG; .png), a nonproprietary image format that was created as an alternative to GIF, and joint photographic experts group (JPEG; .jpg), which can display millions of colors and is better for photographs and other complex images. Charts, scanned images of electrophoresis gels, and other items of interest to HEs can be saved in one of these formats and placed on a Web page. Browsers can display these image types, as can most word processor, graphic, and page layout software programs.

Java, JavaScript, and Plug-Ins Web pages can be enhanced further with Java, JavaScript, and plug-ins *(20)*. Java is a platform-independent computer programming language developed by Sun Microsystems (now a subsidiary of Oracle Corporation, Redwood Shores, CA). It is used to operate thin client computers and program middleware for database systems, but small Java applications known as applets provide a variety of enhancements to Web sites, such as animation, forms, and messages. Recent versions of popular browsers can run Java applets though the appearance may not be consistent on different products. Java applications also can operate on any computer, smartphone, or other device platform that has a Java Virtual Machine.

JavaScript is a scripting language, unrelated to Java, originally developed by Netscape Communications Corp. (now part of AOL, New York, NY) to provide enhancements such as pull-down menus and scrolling messages for Web pages. It is less complex and less capable than Java, but exists totally within the HTML code of a Web page rather than as a separate applet.

Plug-ins are small pieces of software that can add functions to larger software programs. They are popular for use with Web browsers as a way to add capabilities that are not part of the intrinsic browser repertoire. Plug-ins have proliferated and now are necessary to view the full content of many Web pages. Examples are the Adobe Reader plug-in, which allows the user to view a PDF file (see below) within the browser, and the Adobe Flash plug-in that plays static or streaming (continuous) audio or video. The latter can be used for Web-based transmission of lectures or conferences.

Desktop Widgets Desktop widgets are "one trick ponies" that allow for a specific type of data or function to be seen on a computer desktop, such as weather, CDC alerts, and a calculator. Most are designed to continuously update information when the computer is connected to the Internet. Common widget engines are Macintosh Dashboard, Microsoft Gadgets, Yahoo (Yahoo! Inc., Sunnyvale, CA) widgets, and Google (Google Inc., Mountainview, CA) desktop portlets.

Internet Electronic Mail Electronic mail, or e-mail, is a way to rapidly send messages across the Internet or other networks *(21,22)*. The sending and delivery end points of e-mail transmission are mail servers, so messages are delivered continuously and near instantaneously, rather than slowly and episodically as with postal or "snail" mail. Internet e-mail is governed by standards like all other Internet transmissions. An e-mail software client on a PC or other computer is linked to a mail server that utilizes simple mail transport protocol for sending mail. There are two different client/server relationships for receiving Internet e-mail: post office protocol (POP) and Internet message access protocol (IMAP). POP creates a simple relationship when the client logs into the server, whereby received messages are transferred to the client's computer e-mail program. The e-mail messages then can be sorted into folders and address books can be maintained. IMAP maintains the e-mail and address book on the server, and the client software manipulates the mailboxes and address books. The advantage of IMAP is that stored mail messages and address books can be accessed from any computer that has IMAP-compliant mail client software. Many e-mail systems also can be set up to allow Internet access through the use of a Web browser (Web mail) that allows one to remain "in contact" when traveling.

Along with sending messages via e-mail, appropriately encoded documents or files can be attached to the messages. E-mail clients that are multipurpose Internet mail extension (MIME) compliant can manage messages with files and graphics embedded in them, thereby eliminating the need for encoding. When sending documents or files as attachments, remember that along with incompatibilities among computer OSs, there are incompatibilities among the file formats used by application software programs or even different versions of the same program. There are several approaches to this problem: (a) Have everyone with whom you share a document use the same software, preferably in the same version. This may be possible

within an organization, but is highly problematic when exchanging data in an educational institution or across the Internet. (b) Use one of the file interchange formats that can be accessed through the open, import, save as, or export commands in most software programs. Common formats are rich text format (.rtf) for word processors and dbase (.dbf), and data interchange format (.dif) or symbolic link (.slk) for spreadsheets and databases. Special formatting often is lost in these formats. (c) Transmit the document as an ASCII text document, which will be devoid of formatting but will contain all of the data. (d) Convert the document to platform and software independent Adobe portable document format (PDF; .pdf) using Adobe Acrobat or other software (MacOS has this function built into the print driver). The PDF file, when viewed or printed, provides a document that appears identical to the original. A free Adobe Reader application is available (http://www.adobe. com) for most computer platforms and as a browser plug-in.

Many LANs in hospitals and other organizations use proprietary e-mail software systems. These often have the advantages of having a central post office for both sending and receiving mail and a master address book for everyone who has access to the LAN. Most are IP compliant and communicate well with POP/IMAP servers though there may be some incompatibilities.

Network News Network News can be thought of as a large bulletin board on the Internet where messages and responses can be posted to newsgroups, each of which is devoted to a particular topic *(15)*. The newsgroups may be part of the established Usenet (users network) or may be restricted to a part of the Internet, such as a university. Postings to newsgroups are transmitted over the Internet by the network news transport protocol (NNTP) and posted on NNTP servers, which then make the postings available to clients who subscribe. The postings are read with a newsreader software client, which may be a standalone product or part of a browser or e-mail package. Like the cork bulletin board at the student center, newsgroups generally are not moderated. Caveat lector!

RSS Really simple syndication (RSS) is a Web feed format used to publish frequently updated information such as news headlines in a standardized format. Many news sources such as Reuters Health, CDC, and many professional societies have RSS feeds. An RSS reader, which may be a separate RSS client software program or part of a current browser, is used to continuously retrieve and view selected feeds.

Cloud Computing

The only "constant" in the Internet is constant change. As the complexity and cost of computer infrastructure and software have risen, the concept of providing those services over the Web arose (23). The cloud metaphor draws from the common depiction of the Internet as a cloud in network drawings. A variety of services may be available—enterprise collaboration, software, storage, hardware leasing—in a variety of fee formats. The simplicity lies in the fact that only a Web browser or another "front-end" software solution is needed to access these services.

Personal use of cloud computing ranges from online banking to "office" software suites to epidemiologic statistics. They require only a Web browser (see below) rather than specific banking, office, or statistical software and are provided at no cost to the user. A simple and appropriate example of this is OpenEpi (http://www.openepi.com), which is a subset of EpiInfo statistical software. It does not require any particular OS or software other than a JavaScript-enabled browser.

Despite the attractiveness and potential cost savings, it remains to be seen to what extent healthcare organizations will adopt this model, largely because of concerns over security and confidentiality of patient information (24). However, organizations already use Web interfaces for a variety of functions when patient and other confidential data are protected by a firewall (25). The latter is hardware and/or software that prevent external access to unapproved users.

Information from the Internet

The Internet contains a wealth of information and data that may be important or useful to the HE or infection preventionist. Most of it is contained on the Web or may be obtained by e-mail, so these areas will be highlighted. As noted above, along with commercial growth on the Web, there is a vibrant education presence as well. This is due to the general availability of Web server space at universities and other organizations and the ease with which Web pages can be constructed.

Medical Web sites may be found in several general categories: government, bibliographic databases, professional societies and organizations, educational institutions, publications, and commercial interests. Among the government Web sites, the CDC (http://www.cdc.gov/) has extensive information available including the Morbidity and Mortality Weekly Report (MMWR), Emerging Infectious Diseases, guidelines, course/program announcements, and surveillance reports. Many of these are available as Adobe PDFs, which provide printed copy identical to the offset printed version available by snail-mail subscription. Included in this group are the reports of the NHSN; the tabular data can be printed or cut and pasted to a spreadsheet for use in internal benchmarking. The CDC Wide-ranging Online Data for Epidemiologic Research (WONDER) site (http://wonder.cdc.gov) contains a search engine that can locate documents and data from CDC databases. Other government sites with information or data of potential use to HEs include the CDC Emergency Preparedness and Response page (http://www.bt.cdc.gov/), the Occupational Safety and Health Administration (OSHA; http://www.osha.gov/), and the Food and Drug Administration (FDA; http://www.fda.gov/). Many state health departments similarly post policies, notices, and statistics.

The key medical database of the National Library of Medicine (NLM), Medical Literature Analysis and Retrieval System (MEDLARS), has been available in electronic format for many years through MEDLINE (MEDlars on-LINE). This often has been through telephone modem access or in CD-ROM format, both of which have entailed subscription charges. NLM now provides free Web access to MEDLINE with a number of enhancements, including access to other NLM resources, through PubMed (http://www.pubmed.gov).

Links are provided to full-text journal articles, some of which are free, often after a set period of time from print publication. There also are commercial MEDLINE-based products that may include additional databases and search capabilities available for university or other organization servers. Some may include access to a select number of full-text journals. The latter products usually are licensed on a number-of-seats basis, so access is restricted to the members of the university or organization that has purchased the product or service. Nonetheless, access to the literature of medicine, healthcare epidemiology, and infection control never before has been easier or less expensive.

The Web has provided a tremendous opportunity for many professional societies and similar organizations to interact with a global audience. These organizations can provide news, membership applications, meeting and course brochures, and links to other sources of information. Professional society Web sites of interest to HEs and infection control team members include the Society for Healthcare Epidemiology of America (SHEA; http://www.shea-online.org/), the Association of Professionals in Infection Control and Epidemiology (APIC; http://www.apic.org/), the Healthcare Infection Society (HIS; http://www.his.org.uk/), and the Joint Commission (JCAHO; http://www.jointcommission.org/). The SHEA Web pages include an extensive set of links to other healthcare epidemiology and quality improvement resources, and the APIC site includes a searchable index of topics discussed in their Internet e-mail discussion list.

The healthcare epidemiology and infection control services of several academic institutions have Web sites that contain results of outbreak investigations or ongoing surveillance activities. Information databases, such as the Health Information Research Unit (http://hiru.mcmaster.ca/) of McMaster University and the National Guideline Clearinghouse (http://www.guideline.gov/), add to the diverse sources of critical evaluation of data. In a similar context are the sites of peer-reviewed publications that often are associated with professional societies. These sites may offer the table of contents of journal issues, article abstracts, or full text of articles. The latter usually require society membership or a subscription, and access is password controlled. Finally, it should be noted that most providers of medical products and services have Web sites for self-promotion. Some of these may include data that may be helpful in purchasing or usage decisions. Many of these can be found by using an Internet search engine such as Google (http://www.google.com/) or Ask (http://www.ask.com).

Along with exchanging messages and files with individual colleagues, Internet e-mail can be an important source of information for the HE via mail lists. Automated e-mail list servers send a message to everyone subscribed to the list in a manner analogous to broadcast facsimile, though much more rapidly and inexpensively. Lists can be used to send notices to members of an association, announce availability of products or publications, provide breaking news, or allow list members to ask questions and read/post responses. Individuals interested in the service(s) or topic(s) covered by a mail list subscribe to it by sending an e-mail message to the list administrator or to an automatic subscription program on the list server. Subscribers then receive an e-mail message whenever that message is sent to the posting address for the list. Lists may be one way, where a designated person is the only one who can post a message to the list, or two way, where any message that is posted is sent automatically to all list subscribers. One-way lists may be used as a means of notification; the CDC has e-mail lists by which subscribers are notified of the availability of each edition of the MMWR (http://www.cdc.gov/mmwr/mmwrsubscribe.html) and the occurrence of important healthcare events and publications (http://www2.cdc.gov/ncidod/hip/rns/hip_rns_ subscribe.html). Moderated discussion lists usually are one way as well; all postings must be reviewed and approved by the list moderator prior to being posted. Though this is not peer review, it does control the content and tone of the list. Two-way lists, along with network news groups, do not require any approval for posting messages and tend to become cluttered with redundant, unnecessary, or inappropriate postings. As a result, the volume of e-mail subscribers receive becomes large and the quality of the mail tends to suffer. Again, caveat lector!

Security

The widespread use of the Internet has raised many questions about the security, safety, and confidentiality of the information that is transmitted over it (17). While the topic is too complex for detailed discussion here, some general recommendations can be made. User identification and passwords must not be shared or divulged and proper logoff procedures should be followed; this will protect users and their system by not allowing unauthorized use. E-mail is the least secure form of transmission, and sensitive data such as confidential correspondence or credit card numbers should not be sent this way unless encrypted. Web browsing, online purchasing, or completing surveys may be done with higher levels of security that probably make it safe to undertake these transactions at reputable sites. However, be aware that the server to which you attach may acquire information about you and your computer through bits of information, called cookies, exchanged with your browser. Other information you provide may place you on a mailing list or be shared or sold to other parties.

Downloaded software programs or some e-mail messages may be infected with small programs called viruses, macroviruses, worms, or Trojan horses. Many of these are malicious or destructive to other files on the client computer, and some may send personal information from the infected computer to another source. Others send multiple copies of themselves to all of the addresses in an e-mail account, clogging mail servers. Software programs sent by e-mail or obtained from uncertain sources never should be opened, and unsolicited messages such as these should be deleted. Many organizations require the use of an antiviral utility program by all users who download or exchange files, and incoming mail often will be scanned for malicious programs.

Analogous to junk mail, junk faxes, and recorded telemarketing calls, unsolicited e-mail has burgeoned in the past several years. Often referred to as “spam,” much to the chagrin of the manufacturer of the processed meat product, such mail has ranged from nuisance to disruptive. “Spammers” utilize net robots to seek e-mail addresses from newsgroups, outgoing mail servers, and other sources to

develop a database of target addresses. Some organizations will sell e-mail addresses obtained at the time of a Web interaction (such as opening a free mail account) to others, eventually resulting in addition to a spam list. Responding to spam messages to attempt removal of an e-mail address from a list may actually verify that an account is real and result in even more unsolicited e-mail. Some browsers have antispam filters, and there are a number of third-party software packages that promise to remove spam messages. None of these are perfect, but they often decrease the volume of unwanted mail. Unfortunately, the spammers often are a step ahead of the attempts to foil them. A number of Web sites, including http://www.junkbusters.org/, have more information on avoiding and fighting spam.

Internet chain letters and hoaxes, often threatening the user or user's computer with dire consequences, also have proliferated, and these are best ignored and deleted. More information on security issues and hoaxes is available at the United States Department of Homeland Security Computer Emergency Readiness Team Web site: http://www.us-cert.gov.

Recommendations for Internet Connectivity and Software

It is necessary for healthcare epidemiology and infection control program staff to have access to the Internet using one of the methods described above, preferably from a desktop microcomputer directly connected to a network. An Internet e-mail account likewise is desirable, but a LAN e-mail account that is bridged to the Internet is acceptable. The basic software tools for Internet use include a browser, an e-mail client, and software for decoding/expanding files. No recommendations are made for specific products, and many open source (http://sourceforge.net/) or low-cost shareware products are sufficiently capable to preclude the purchase of more expensive commercial products. The freeware Adobe Reader software also is recommended. If software is available from a university or organization IS department, this should be considered for use since it is likely to be compliant with Internet or LAN standards. Training and support are likely to be available as well.

Currently, three browsers account for the majority of WWW clients: Firefox (Mozilla.org, the open source descendant of the original Netscape browser), Safari (Apple Inc.), and Internet Explorer (Microsoft Corp.). All are freely available: Firefox for Macintosh/Windows/Linux, Safari for Macintosh/Windows, and Internet Explorer for Windows. All have many features—some would say too many features—beyond basic HTTP and FTP functions. All have a closely associated Internet e-mail client: Thunderbird for Firefox, Mail for Safari (Macintosh only), and Outlook for Internet Explorer (part of Microsoft Office for Windows). There are several other browsers and e-mail clients available, each with particular features and proponents; the choice is like the choice of any computer software—very dependent on individual needs and preferences. Note that some content may not display properly in a particular browser or e-mail client, but may be rendered appropriately in another. This is due to ever-evolving standards and the willingness (or unwillingness) of a software company to follow the standards.

As noted in the beginning of this section, the same tools used for accessing data from the Internet also can be used to obtain information on many university or hospital intranets/LANs *(20)*.

DATA SECURITY

One obvious and real danger of using local or mobile computing devices to store and manipulate healthcare epidemiology data is the potential privacy breaches for named or individually identifiable health data. Considerable attention has been directed by healthcare organizations to ensure the safety of identifiable personal health information (PHI), following the well-publicized loss of laptop computers and external hard disk drives containing large volumes of PHI.

Even when housed in a monitored or locked infection control office, files on a table-top computer should be password protected. The general policy for access to infection control data should be a need-to-know basis, which may mean different levels of access (e.g., password-protected files, with the password known only to those with a need to know).

Anyone who uses mobile information storage devices, including laptops, PDAs, and smart phones, must be mindful of the potentially severe consequences of lost or stolen data. If PHI does reside on a portable device, steps must be taken to keep it physically secure when in use and during transit. Regardless of this, all computers, handhelds, smart phones, flash drives, external hard drives, or readable media containing PHI (including e-mail messages) should be at least password-protected and preferably encrypted (26). Most healthcare organizations have policies about security requirements for portable computing devices. Once obsolete or no longer used, any storage devices such as hard drives must be physically rendered unreadable by crushing or degaussing. Other media such as CDs/DVDs/tapes should be shredded or otherwise destroyed, as should any printed versions of the data.

Ideally, all identifiable PHI should be stored on a secure server rather than on the local or portable device. System security technology and practices will help ensure the confidentiality of data stored in this manner, but ultimately, data security and integrity depend on the system users.

Data transmission by electronic mail or other electronic means likewise must be encrypted if it includes PHI. Most hospitals and other healthcare organizations have the necessary software and tools to accomplish this, and some do it automatically. The user's information technology service should be consulted for details. A good reference framework for data security is available at the CDC's National Program of Cancer Registries *(27)*.

"Publishing" Infection Control Policies

It is easy to "publish" infection control policies and procedures to the hospital's intranet. Web enabling the infection control manual makes it more accessible, and perhaps more used, by hospital personnel. The simplest approach to this is to make an index page, similar to a

printed index page, of the manual using a word processor, text editor, or dedicated Web-authoring software (e.g., the freeware NVU, http://www.nvu.com/). Each of the chapters or policies in the index then link to the appropriate document that can be either in Adobe PDF format or that of the word processor used to create it. The more industrious user could use Web-authoring software to develop a truly interactive manual with links between chapters, to other references, etc.

RESOURCES

Many users enter the world of computing and the Internet with trepidation, and this is understandable. However, the potential benefits to HEs and infection preventionists should serve as impetus to overcome fear and ignorance to take advantage of the resources that are and will become available. Introductory courses are offered at educational institutions, libraries, and in healthcare organizations, and are a good starting point for the newcomer. Advanced and specific topic courses also are available.

Books about general and specific computing topics have proliferated and provide additional resources for beginners and more experienced users. Particularly useful for general audiences are the "For Dummies" (Wiley Publishing, Inc., Hoboken, NJ; http://www.dummies.com) and the O'Reilly (O'Reilly Media, Inc., Sebastopol, CA; http://www.oreilly.com) book series. These are readable, are inexpensive, cover a variety of basic and advanced topics, and are widely available. There are magazines for essentially every computer topic, platform, and use area, and many also have some or all of their content posted on the Web. Finally, local computer user groups and educational Web sites provide additional or more detailed information for more advanced users or on specific topics. A useful encyclopedia resource for computer technology is at: http://www.whatis.com/.

CHAPTER 16

The Electronic Health Record: An Essential Technology for Healthcare Epidemiology

Andreas M. Kogelnik, Justin V. Graham, and David C. Classen

Healthcare is an information-intensive industry. Information management is integral to clinical practice, and little occurs in the complex matrix of healthcare that does not involve information management (1,*2–9*,10,11,*12*,13, *14–19*,20,21,*22–32*,33,*34–49*). Clinicians, among their other unique duties, are information managers. In the day-to-day practice of medicine, they must acquire, process, store, retrieve, and apply information. This ability is paramount to the delivery of efficient and optimal healthcare and is becoming increasingly important with the fractionation of healthcare delivery. During the last 50 years, information management has risen to a pivotal role in modern healthcare (1,*2,25–28,34*,*42*). There has been an explosion of information in healthcare. In 2009, Medline indexed over 850,000 new articles from those published in the biomedical literature with over 20 million articles in the database compared with just over 485,000 in 1999. Reports on genetic, genomic, and proteomic data are on the rise, and most providers have little background in such areas. These are areas where information technology (IT) is increasingly important for finding relevant knowledge.

In addition to more knowledge, there has been a corollary growth in patient-specific information. The volume and complexity of patient information has increased dramatically. This increase is due to multiple factors that have occurred in healthcare, such as the greater number of patient visits; higher patient acuity; a proliferation of new data elements arising from new diagnostic techniques; developments in the delivery system that result in many patients receiving care at multiple sites and in multiple systems; and the maturation of high-throughput genomic biotechnology, some of which is now marketed directly to consumers. This dramatic growth has resulted in a situation where effective clinical information management has exceeded the cognitive capabilities of the human mind. Some authors have referred to this phenomenon as "information pollution" *(44)*. In fact, in modern healthcare we are drowning in data while starving for information, and each year this gap widens.

Providing high-quality, cost-effective healthcare is an information-dependent process. Each provider and class of providers in healthcare has developed a unique set of information requirements that have become ever more task/specialty focused. However, in order to deliver truly comprehensive care, at some point in the healthcare delivery process, other providers need access to those information sets. The medical record is the repository of information concerning the patient's health. Virtually everyone involved in providing, receiving, and reimbursing for healthcare needs to interact with it.

It has been estimated that as many as 22 different people need access to a hospital patient's medical record at any given time *(17)*. An estimated 35% to 39% of total hospital operating costs has been associated with provider and patient information activities. Physicians spend an estimated 38% and nurses and estimated 50% of their time documenting in the patient's medical record. Furthermore, 70% of hospital patients' paper medical records are incomplete. This lack of detail is reflected in the fact that 40% of the time the paper medical record does not contain the patient's diagnosis and 27% of the time the patient's chief complaint is not documented *(50)*. This lack of completeness also results in 11% of laboratory tests that have to be reordered, because the results are not in the patient's paper medical record, which leads to significant manual effort to review the patient chart for source data.

Despite the many technologic advances in healthcare over the last 50 years and the plethora of associated problems with the typical patient record, the record has not changed much. Many institutions that have adopted a variety of health information technology (HIT) modalities still rely on paper-based physician documentation. The failure of the modern patient record to have evolved with the other technologic advances in healthcare is now creating additional stress within the already burdened US healthcare system. Because of this failure, the information needs of providers, patients, administrators, third-party payers, researchers, and policy makers, not to mention infection control specialists, are often unmet.

The electronic health record (EHR) seeks to overcome the failures of the traditional paper record (1,*14,15,17,34*). The EHR can make a major contribution to improving the information management problems of healthcare. A 1991 General Accounting Office (GAO) report on automated patient records, still valid today, identified three major ways in which improved patient records can benefit healthcare (1). First, an automated patient record can improve healthcare delivery through its direct impact on

the delivery of care. It can provide easy access to multiple parties simultaneously, faster data retrieval, and, potentially, higher-quality data. The EHR can also enhance decision support capabilities, present clinical reminders to assist patient care, and support quality improvement activities, although implementation successes may vary widely. Second, computerized medical records have the potential to enhance outcomes research by automatically capturing clinical information for evaluation. Third, automated patient records can increase hospital efficiency by reducing costs and improving staff productivity. The GAO reported that an automated patient record system reduced hospital costs by $600 per patient in a Department of Veterans Affairs hospital because of shorter lengths of stay *(51)*.

Ideally, the EHR provides patient-specific, integrated information that is collected during the provision of care and is available among all caregivers in an organized, comprehensive, accurate, timely, and accessible form. Uncontrolled and unorganized information (as available in the paper record) leads to "information pollution" and is a counterproductive force in an information-oriented industry *(44)*. Information collected, presented, and available in an electronic form becomes a valuable resource when properly structured.

OVERVIEW OF ELECTRONIC HEALTH RECORDS

With any endeavor in healthcare, there are definitions and acronyms that one has to be familiar with to effectively communicate. This is particularly true in the area of healthcare information management. The glossary at the end of this chapter lists many of these terms. With respect to information systems, Ledley and Lusted (52) in 1960 defined an information system as consisting of three essential components: a system for organizing or documenting the information in a file; a method or a routine for accessing the information in the file; and a method to ensure that the information was current. Lindberg *(53)* took the definition a step further and concluded that a medical information system (MIS) (or what we now would call an EHR) contained a set of formal arrangements by which health-related facts, those concerning the individual health of the patient as well as the care of that patient, were stored and processed in computers *(27–29)*. Based on this conception, an MIS is a complex hierarchical integration of multiple systems that include an inpatient hospital information system (HIS); an outpatient information system; and clinical support systems, such as pharmacy, radiology, and laboratory information systems. In most current configurations, this can include an inpatient EHR, an outpatient EHR (sometimes integrated with inpatient), as well as ancillary departmental systems for laboratory and pharmacy. A true EHR would contain a longitudinal patient record that contains the complete health status and healthcare delivery of an individual patient from birth to death. Only a few, mostly closed, healthcare systems have even approached such an integrated information system (e.g., Kaiser Permanente), even so, patients often venture outside of such systems for some of their care over the course of their lives.

Both ambulatory and inpatient information systems usually include administrative and financial (or practice management) components and clinical components, all of which are usually separate systems. Administrative information systems (AISs) include data elements such as patient demographic, eligibility, and payer data; patient identification, registration, and appointment schedules; hospital admission, discharge, and transfer (ADT) data; bed census or occupancy data; cost accounting; resource utilization; employee records; and inventory. Generally, AISs are the first computer applications implemented in a hospital or outpatient setting.

Clinical information systems (CISs) are designed to manage information concerning the direct care of the patient and are the foundation of the EHR. The CIS contains both objective and subjective clinical data. Because the practice of medicine and the delivery of healthcare is a dynamic process, the functional requirements of a CIS are continually changing as new treatments, procedures, and diagnostics evolve. However, any CIS has some essential core functions. Some of these functions include an electronic medical record (EMR) that can communicate and manage patient data from multiple sources (e.g., pharmacy, radiology, surgery, laboratory) within the healthcare delivery system; provide healthcare workers with decision support tools; provide a clinical database for epidemiologic research; support medical education; maintain patient confidentiality; and satisfy the requirement for the integrity, reliability, and security of patient data.

In the United States, the hospital has been recognized since the 1960s as the natural laboratory for automation and computerization in healthcare. This realization was partly due to the complexity and scope of the information available within the bounds of a single organization, and the fact that the hospital represented the largest segment of the healthcare industry, commanding over 50% of all healthcare spending *(54)*. Economies of scale dictate that a hospital would have access to much greater IT resources than, say, a small independent physician practice. Additionally, hospitals have regulatory requirements for collecting information and developing rates for defined outcomes such as mortality, length of stay, and costs for various diagnoses and surgical procedures *(55–57)*. Indeed, the hospital setting is probably the most sophisticated segment of the healthcare market with respect to information management. However, to date, less than 10% of US hospitals can truly call themselves "paperless" across all disciplines, departments, and functions, and 85% of the outpatient record remains paper based. The US government's 2009 HITECH stimulus program supporting "meaningful use" of EHRs (discussed below) hopes to rapidly stimulate much greater adoption.

The basic kinds of information that hospitals require and manage have changed little since the early 1960s. What has changed is the volume of that information and the recognition that numerous providers need simultaneous access to the information. Because of these factors and healthcare's insatiable demand for information, the EHR has become a key emerging technology in US hospitals. What differentiates an EHR from a compilation

of departmental information systems within a hospital is the integrated database *(18,58–60)*. Friedman and Dieterle *(18)* have called integration the "holy grail of hospital computing." To effectively use patient care data to improve outcomes and manage care, hospitals need access to fully integrated information. The primary function of an EHR is to communicate data *(58)*. To perform this function, an EHR must have software and hardware components that allow the computer to acquire, process, store, retrieve, and rearrange data, and then display that data throughout the institution. The premise that underlies this design strategy is that many providers, including the medical staff, nurses, pharmacists, radiology, laboratory, respiratory therapy, physical therapy, occupational therapy, dietary, and so on, create patient care data, and those providers need access at almost all times to a variety of patient care data. The key is that the provider-created data must be inclusive. Within an integrated EHR, the design should allow for patient data to be entered once and then be available for all users. Ideally, data should be entered at the point of care. For example, the temperature of a patient should be entered into the database at the bedside, once the healthcare provider has obtained the temperature. This allows for maximum use of patient data, since clinical data are now temporally related to the course of hospitalization. This temporal relationship allows providers to analyze the patient's clinical progress and to relate outcomes to specific events during hospitalization. Point-of-care data entry goes beyond the human provider and is equally applicable to automated devices and analyzers, for example, ventilators or blood chemistries. The technology to accomplish this automated point of care data capture is readily available *(61)*.

Regional/National Health Information Exchange

Electronic patient data, both clinical and administrative, is too often imprisoned in institutional silos due to technical incompatibilities, financial disincentives, and interinstitutional politics. There has been a recent groundswell of support for inter-institutional data exchange (of both identified and de-identified data) to support patient continuity of care and healthcare quality improvement activities. Such data exchange can occur on a peer-to-peer institutional level, on a regional level, and on a state or federal level. Regional Health Information Organizations (RHIOs) and Health Information Exchange (HIE) organizations are two types of collaborative organizations that have formed to enable such exchanges and have met with varying success (and failure). Many RHIOs formed since the late 1990s have struggled with financial, political, and technical barriers. Notable successes on a large scale include the Indiana Health Information Exchange, the New England Healthcare Exchange Network, and the New York Clinical Information Exchange. The recent HITECH funding (see below) has catalyzed the formation of numerous HIE efforts nationally, prompted by the rationale that healthcare data exchange is necessary for healthcare reform and improving health outcomes. However, there remain many challenges ahead for large-scale regional data sharing, including data selection, legal/ethical discussions, privacy standards, and technical/implementation hurdles.

EHRS AND HEALTHCARE OPERATIONS

The inefficiencies of the paper medical record absorb large amounts of a hospital's budget and are directly responsible for many of the failures in the quality of care delivered, including medication errors, misdiagnosis, and poor record keeping. Over the years, HISs and current EHRs have demonstrated many benefits, but perhaps the three that will have the greatest impact on healthcare delivery and cost are (a) improved logistics and organization of the medical record to speed care, prevent duplication of data and procedures, and improve the caregiver's efficiency; (b) automatic computer review of the medical record to aid decision support, limit errors, identify exceptions in care, and identify those in need of care; and (c) systematic analysis of present and past clinical experiences and outcomes to guide future practice and policies (1,*14,30*).

Improved Logistics and Organization of Patient Data

The EHR, with the patient as the central information unit, provides large clinical databases allowing for more comprehensive and accurate patient data collection, more complete data integration and interpretation, and greater facilitation of data analysis (1,*2,17,30,34*). Multiple providers can gain simultaneous access to computer-based data, and data duplications across multiple systems are eliminated. Once stored in the EHR, data can be displayed in numerous different ways, providing for cost-effective utilization of services. A past investigation has demonstrated that in an emergency department with computer-displayed data, physicians ordered 15% fewer tests than when computer display of data was not available *(62)*. Another investigation has shown that when the EHR displayed previous test results to physicians when they were ordering new tests, there was a reduction in test ordering *(63)*. An EHR provides a cohesive, integrated, accurate, and up-to-date record that encourages and enables providers to make informed cost-conscious decisions (*62–67,*68). Computers also serve the information needs of medical, pharmacy, and nursing students *(16,22,47,48,69,70)* as well as the patient *(71)*. The use of an HIS to present clinical guidelines for management of personnel with occupational exposure to body fluids was shown to improve documentation, compliance with guidelines, and percentage of charges spent on indicated activities, while decreasing overall charges *(72)*.

Clinical Decision Support

Humans are prone to a number of inherent cognitive biases and predictably make frequent errors, including overlooking rare and uncommon events *(73)*. An integrated EHR with an intelligent rules engine can monitor patient data for unusual patterns in care and alert healthcare providers; this is commonly referred to as clinical decision support (CDS). Computer-generated reminders have been shown to dramatically affect the outcomes of many different aspects of care (*62–67,73–75*,76,77). Recent investigations into the use of HISs and computerized CDS have demonstrated the potential of remarkable cost savings and improved patient outcomes (68,*78,*79,*80–87,*88,89,*90–95,*96,*97–99*), although there have also been some notable failures.

The EHR can promote a healthcare system that emphasizes prevention, early diagnosis and treatment, and effective management *(100)*. These aspects of healthcare delivery are further facilitated by the advent of computerized decision support (10,13,*101–122*). Six major use cases of decision support that now exist in hospitals with integrated information systems and attendant EHRs are alerting, interpretation, assisting, critiquing, diagnostic, and management.

Alerting decision support is defined as the automatic notification of appropriate providers of time critical decisions. Drug–drug interactions, drug–laboratory interactions, drug–disease interactions, adverse drug reactions, and drug allergy alerts are common clinical examples of this type of decision support *(83,85,86,90)*. These types of alerts are generated at the time of either a medication order or laboratory results reporting if alerting criteria are met. Furthermore, an EHR with this alerting function can monitor patient data continuously; if appropriate criteria are met anytime in the course of hospitalization, specific personnel (such as the ordering physician, the patient's nurse, the pharmacy, and so on) can be notified. Notification can be escalated based on the urgency of the alert. Alerts requiring immediate attention may be sent by a pager or text message. Less urgent alerts can be sent by email or placed in an inbox to be viewed when the user logs on to the EHR.

Interpreting decision support refers to the gathering, arranging, and analyzing of patient data, resulting in a conceptual understanding of that data, usually in relationship to a specific test. One of the earliest applications of interpretive decision support in hospitals was computer analysis and interpretation of electrocardiograms (*7*,11,*36*). Mammograms and Pap smear reading have also seen improved interpretation demonstrated through automated decision support.

Assisting decision support is used to maximize and simplify human interaction with an EHR. This model of decision support usually consists of predictive knowledge about a particular problem or task. Computer-assisted physician ordering is an example of this type of decision support *(66,67,111,117–120,123,124)*. Assisting decision support can be as simple as fixed standing order lists or as sophisticated as computer-assisted antibiotic ordering *(97,99)*.

Critiquing decision support is defined as computer-assisted analysis or review of human decisions for appropriateness. This type of decision support uses the EHR knowledge base to evaluate human decisions and to report to the user the result of the computer analysis. Critiquing decision support has been used by investigators to develop protocols for ventilator management in the intensive care unit (ICU) setting *(115)* and to determine the appropriateness of ordering various laboratory tests *(84,121)*.

Diagnostic decision support is defined as decision support that provides a computer-assisted diagnosis of patient medical problems such as the identification of patients with a healthcare-associated pneumonia. This type of decision support has been the most widely studied of all decision support techniques in medical informatics *(78,103,106,108,109,112,118)*. Today, these tools are generally found in standalone software products, such as VisualDX, Theradoc, or Isabel, used to generate differential diagnoses for patients with complex presentations.

Management decision support is the automatic generation of decisions that are oriented to the therapeutic care of the patient. Management decision support differs from critiquing decision support in that, in the former, the computer manages patient care and suggests treatments; whereas in the latter, the computer reacts to treatment plans or orders initiated by the physician. In clinical management decision support, the physician critiques the computer rather than the computer critiquing the physician. Computerized clinical practice guidelines or "best practice" alerts are examples of this model of decision support. Management decision support techniques are currently being investigated in the ICU setting to assist in the management of patients with adult respiratory distress syndrome *(116,125)*.

The utility of these various modes of decision support is highly dependent on the context in which they function. Without appropriately structured patient data, many of the rule functions underlying these decision support tools may fail to function properly. Furthermore, the presentations of the alerts to the end user can be quite varied, ranging from pop-up windows to cell phone text messages, from hard stops during order entry to reports generated on a weekly basis.

Systematic Analysis of Clinical Data

Another benefit of an automated patient record is access to large amounts of archived clinical data to provide information on past clinical experience. Computers have the capability to examine large amounts of data and statistically summarize various aspects of care to answer administrative and management or clinical research questions. The ability to systematically analyze large numbers of clinical events and correlate these to different outcomes is one of the functions of clinical business intelligence tools, such as a clinical data warehouse. Modern quality management techniques rely on these types of analysis. Many modern clinical practices, however, distribute these data over a disconnected series of systems. Investigators have realized since the late 1970s that there exists a wide variability in the patterns of clinical practice in the United States *(126,127)*. The net results of this variability in clinical practice are the inflating of the healthcare dollar and less than optimal patient care. The EHR provides the necessary tool to identify variation in various aspects of care, where it may exist (1,*4,43,81,98*). Once identified, corrective measures can be developed to reduce the variation or manage exceptions more appropriately.

The computerized medical record has become one of the "agenda items" of the federal government in its attempt to control healthcare costs and improve the quality of care (see below). This is evidenced by recent reports from the Institute of Medicine (IOM) (1) and the Centers for Medicare and Medicaid Services (CMS), as well as Congress's commitment of financial and political support for this initiative. Certainly, the EHR will not, in and of itself, be the sole answer to the US healthcare dilemma, but it has the potential to have major impact by providing superior information to the market.

ELECTRONIC HEALTH RECORDS AND THE INTERNET

Perhaps no technologic advance since the personal computer has had a more profound impact than the rise of the Internet and its most popular usage, the World Wide Web. The Internet has revolutionized communication and provided a unique forum for the exchange of information. This forum has changed the way commerce is conducted and has significantly altered the approach to building and using information systems in all industries. Healthcare has not been immune to this rising tide, but as always in the area of information systems, healthcare organizations have been slower to adapt this new technology *(128)*. Because the Internet and use in healthcare is still developing, it is hard to predict exactly how an Internet-based healthcare system will evolve.

We have already seen the integration of platform-independent graphical user interfaces to EHRs using the Internet *(129,130)*. These types of Web-enabled interfaces have allowed clinicians to access patient data from remote locations, thus expanding the caregiver's ability to provide continuity of care from outside of the hospital setting and helping expand data collected for healthcare epidemiology. Web-based interface tools can also expand the functionality of legacy clinical databases by providing a more user-friendly front end. An added advantage of these interfaces is that they provide a portal of access to the latest scientific information (e.g., treatment guidelines) available either on the local internal servers ("intranet") or supplied by Internet tools such as electronic journals, Micromedex, or UpToDate. An Internet application has already been developed that performs global surveillance on influenza and can be used by clinicians to guide the diagnosis of influenza in their community *(131)*.

The evolution of the Internet's potential to connect individual EHRs is evident in the Centers for Disease Control and Prevention's (CDC) drive to automate its data reporting process. The National Nosocomial Infections Surveillance (NNIS) system is a cooperative effort that began in 1970 between CDC and participating hospitals to create a national nosocomial infections database. In 2005, the CDC established the National Healthcare Safety Network (NHSN) to integrate and expand NNIS along with the Dialysis Surveillance Network and the National Surveillance System for Healthcare Workers. Data from participating healthcare providers are collected uniformly by trained infection control personnel and are reported routinely to the CDC where they are aggregated into a central database. In addition, many facilities use the same data to electronically comply with state reporting mandates. Over 2,600 facilities currently report data directly into NHSN.

The promise of healthcare interconnectivity is the seamless linkage of textual information, aggregated data, and video and audio images all on the same screen through the use of browser technology *(132–134)*. Because of the pervasiveness of the Internet, the improved access to information can bring the patient data directly into the healthcare organizations' computing systems. Additionally, patients will have greater access to their own healthcare information via personal health records. The Internet dramatically increases the boundaries of what constitute a CIS or an EHR by making this information much more broadly available.

Electronic Health Records and Application Service Providers

Application service providers (ASPs) can be thought of as computer applications that are provided on demand via the Internet. These are typically subscriber-based models where a user or institution is provided with accounts (e.g., via the Web) to a remote application. The application is operated and maintained in a remote data center, and users access it with a unique login and password. No local software need be installed. These ASP models are gaining popularity under a new term: "cloud computing," which refers to a very large super-aggregated version of ASP models. This phrase will likely replace the ASP term over the next several years.

One advantage of the ASP model is that there are greatly decreased installation and support costs. Users can leverage the work of others with the same problem(s). ASP disadvantages include an institution becoming wholly reliant on the ASP vendor and their Internet connectivity. Some vendors' applications lack customizability and flexibility. ASP applications can draw data from other HIS systems (e.g., where the ASP may be epidemiologic analytics tools), or they may serve as the EHR itself. Nonetheless, this type of approach is very popular with small physician offices that often lack the capability of making large capital expenditures for EHRs.

MOBILE COMPUTING

In recent years, the growth of mobile computing has mirrored the growth of the Internet and may be on pace to exceed it. The demand for mobile devices, from smart phones to personal digital assistants (PDAs), and now wireless tablets, continues to explode. Witness:

- The number of wireless Internet users in the United States will reach 136 million by the end of 2010, or 59% *(135)*.
- By the end of 2010, there will be 205 million browser-enabled smart phones *(136)*.
- The wireless LAN market was expected to reach $2.5 billion in 2010.
- Over 50 million iPhones sold within 3 years of release, and over 2 million iPads sold within 3 months of release.

An increasing number of healthcare mobile computing applications today access data via the Internet. *Mobile computing* or *wireless* refers to the underlying technology that supports the transport of data between the mobile handheld computing device and a networked main computer system without a wired connection between them. Mobile computing includes a range of solutions that enable end-user mobility by providing access to data anytime, from any location. Hospital-based mobile computing has three main components:

- Underlying hospital, clinic, or central CIS (EHR)
- Connecting technology that allows information to pass between the site's information system and the handheld device
- Handheld computing devices (aka mobile computing devices, mobile devices, handheld devices, handhelds, smart phones, tablets)

It is helpful to see how these work together in a clinical example. The end user enters or accesses data—such as vital signs, charge information, clinical notes, and medication orders—using a software application on the handheld computing device. Using one of several connecting technologies, the new data are transmitted from the handheld to the site's information system where system files are updated and the new data are accessible to other system users—the billing department, for example. Now both systems (the handheld and the site's computer) have the same information and are synchronized. The process works the same way starting from the other direction. For example, a physician may want to have access to all new laboratory results for today's clinic patients. This information is stored in the site's EHR and now needs to be transmitted to the handheld device. Again, the connecting technology delivers the data to the handheld device, and the physician can move from room to room, accessing the appropriate information from the handheld device. The process is similar to the way a desktop PC accesses the organization's applications, except that the end-user device is not physically connected to the organization's systems. The communication between the end-user device and the site's information system can use different methods for transferring and synchronizing data. Some common data transfer approaches include:

- Wireless local area network (WLAN)
- Wireless Internet or wireless Web over cellular networks
- Hot synching or data synching using docking cradles or docking stations that are connected directly to the organization's information system via the wired local area network (LAN)

Wireless LAN

WLAN is a flexible data and communications system used in addition to, or instead of, a wired LAN. Using radio frequency (RF) technology, WLANs transmit and receive data over the air, minimizing the need for wired connections and enabling user mobility. In a WLAN, the caregiver enters data into a handheld device such as a PDA or a laptop computer that has a special WLAN card. This card has an antenna that transmits the data in real time using RF technology to an access terminal, usually connected to a ceiling or wall. The access terminal is connected to the wired LAN and sends the data received—or requests for data—from the handheld device to the patient care information system. Conversely, data from the site's information system can be sent to the handheld device using the same technology. PDAs, popularly used by physicians, have a very small screen size that is best suited to only limited data viewing and data collection functions such as laboratory order entry, single results display, and very limited clinical notes entry. Laptops and tablets provide improved processing capabilities, more data storage, better keyboards, and larger displays, so end users can make more extensive use of entire patient records and view results in a number or graphical formats. Complex applications whether inpatient or outpatient work best in a wireless LAN environment that uses these larger devices.

The Wireless Web

Wireless Internet, also known as the wireless web, provides mobile computing access to data using the Internet and specially equipped handheld devices. For example, using a Web-enabled smart phone, the end user can display data accessible from the Internet. Technically speaking, the mobile device connected to the cellular system sends the request to a computer link server. This server acts as a gateway that translates signals from the handheld device into language the Web can understand, using an access and communication protocol. One of the leading protocols is called Wireless Access Protocol. The server also forwards the request over the Internet to a Web site, such as Yahoo or Google or the organization's own Web servers, connected to the CIS. The Web site responds to the request and sends the information back through the link server. The response is translated into a wireless markup language, so it is viewable on a small cell phone screen. This translated response is then sent to the cellular system and finally to the Web-enabled mobile computing device. Examples of the current uses of the wireless Internet include accessing short emails, quick lookup capabilities (stocks, weather, flights, directions, movies, and restaurants), retailing transactions (e.g., Amazon.com), and alert messaging in healthcare. Newer faster technologies are steadily moving these portable devices closer to full workstation functionality over a wireless connection.

Synchronization Synchronization or hot synching provides many of the benefits of mobile computing without the necessity of installing wireless LAN equipment or needing access to the Internet. Information is periodically downloaded from the EHR to the handheld device and then uploaded from the device to the EHR. The major drawback of data synchronization is that it does not provide real-time access to data. Data synching is not a wireless data transfer method since data are transferred from the mobile computing device to the site's information system through a docking (or synching) cradle wired to the LAN. However, since the end-user device is only physically attached to the LAN during the batch data transfers, it is still considered a mobile device.

Mobile Computing Devices

An ever-increasing number of mobile computing devices are available for use in the healthcare setting *(137)*:

- *Web phones*: cellular phones with Internet access and Internet browser that allow limited email, calendar, appointment scheduling, and directories. There are currently a growing number of healthcare content and vendor-specific healthcare applications on Web-enabled phones.
- *PDA/phone*: combination of a Web phone with PDA functionality with Internet browser functions including email, calendar, appointment scheduling, and directories (e.g., iPhone, Trio, Blackberry). Healthcare functions include charge entry, prescription writing, and Internet access.
- *PDA or pocket PC*: handheld computerized information organizers (e.g., Palm Pilot, Handspring Visor, Compaq iPaq) with email, calendar, appointment scheduling, and directories, including some desktop application functions (e.g., Word and Excel), pen-based system for data entry, and bar-coding functions. Healthcare applications include charge capture, prescription writing, lab results review, and multiple functions using browser technology with wireless LAN.

- *Handheld PC*: small hand size personal computer with a keyboard. Much more powerful than a PDA device with some desktop application functions (e.g., Word and Excel), keyboard for data entry, voice recognition, and recording options. Healthcare functions similar to those cited above.
- *Tablet/laptop*: tablets are flat paneled computing devices, including laptops, tablet computer, and iPads. Tablets use pen or touchscreen technology and allows for multiple integrated functions, for example, full EHR capabilities.

Mobile Computing Applications

Given the new and evolving application market and continually advancing technology components, today's most effective software applications are those focused on tasks that require data access at the point of care but do not require sophisticated infrastructures to transfer data between the device and the organization's computer system. These types of tools currently include the following.

Alert Messaging and Communication These applications go far beyond the pagers long used by on-call physicians, often allowing them to receive test results and send messages. The biggest challenge for these products is the ability to deliver secure, uninterrupted messages. As electronic interactions between ambulatory physicians and patients become more common, devices may be able to deliver messages and alerts to physicians in that setting as well *(138)*.

Clinical Documentation Rapidly increasing regulatory requirements and changing payment documentation needs are increasing the need for point-of-care clinical documentation systems. Tools with a wide range of functionality from basic notes templates on PDAs to images that can be displayed on a laptop help clinicians quickly document clinical activities, as well as organize and track patient information from one encounter to the next. Most mobile software applications supporting inpatient care are focused on nursing documentation; only a few vendors currently support applications for physicians in the ambulatory setting. As more physicians and other providers begin to participate in disease management, which requires increased data collection and monitoring, tools that enable providers to cope with the volume of data at the point of care will become increasingly valuable and will be accessible via mobile computing.

Charge Capture and Coding These popular tools for both inpatient and outpatient care enable caregivers to record information at the point of care instead of after the fact. The handheld computing application replaces the antiquated index card system for recording charges. It includes coding tools for translating increasingly complex payer rules, especially in the ambulatory setting. These applications can have a positive financial impact by capturing more accurate and complete information about diagnoses, procedures, and other care-related services. In the future, charge and coding functions will likely be integrated with other clinical computing tools, thus capturing financial information as part of the automated care documentation process.

Lab Order Entry and Results Reporting Most often found in the inpatient setting, these applications allow users to order laboratory tests and view results at the point of care. Most focus first on one aspect of the process and then move to the other. For example, one vendor decided to start with result viewing because of the limited handheld processing and customization required, and then moved toward a total ordering and result viewing application. Lab order entry streamlines the ordering process; results reporting allows access to often critical patient information anytime and anywhere. Because these functions require real-time interfaces with existing ordering and resulting systems, success so far has been limited to a few vendors who have either partnered with well-known traditional vendors or added integrating tools to their products. As the technology advances, allowing for better integration of applications, laboratory order entry and results reporting tools will likely become common.

Prescription Writing Using a smartphone, tablet, PDA, or pocket PC instead of a prescription pad, physicians can now generate prescriptions by clicking on the patient, medication, and dose. Many e-prescribing tools can also check prescriptions for drug interactions and potential allergic reactions and transmit completed prescriptions directly to the pharmacy. Products on the market today differ in almost every step of the process, from how patient data are obtained, to where processing occurs, to how scripts are sent to the pharmacy, making this a crowded and confusing vendor field. E-prescribing tools are likely to advance rapidly as problems of integration with patient data and data transmission are overcome *(139,140)*.

In many ways, these applications are mobile extensions of the traditional EHR. Some of the most popular inpatient applications are bedside charting, emergency room documentation, and remote access to data for physicians *(141)*. Mobile solutions for inpatient clinical computing are likely to be offered by traditional EHR vendors; these vendors will likely partner with wireless technology providers and mobile computing vendors.

Physician use is the primary focus of mobile computing, and that is in the outpatient setting *(142,143)*. Mobile computing devices are well suited to physician practice since physicians often spend their whole day moving between exam rooms and offices and need continuous access to clinical data. Mobile computing also avoids the cost of hardwiring many physician offices and exam rooms. In the physician office, mobile devices that use batch synchronization of data are most common. In addition to reference tools, handheld applications are focused largely on high-stake individual processes such as charge capture or prescription management *(144,145)*.

Mobile Computing Infectious Diseases Applications

PDAs, smartphones, pocket personal computers, and the like, provide immediate access to clinically relevant infectious diseases information at the point of care. Several infectious diseases applications are available that provide information on pathogens, diagnosis, medication, and treatment.

One well-studied example is ePocrates Rx, a comprehensive drug information guide that is downloadable free from the Internet and designed for multiple mobile computing platforms. A 7-day online survey of 3,000 randomly selected ePocrates Rx users was conducted observing the following parameters: user technology experience, product evaluation, usage patterns, and the effects of the drug reference database on information-seeking behavior, practice efficiency, decision making, and patient care. The survey response rate was 32%; 946 physicians who used the program reported that it saved time during information retrieval, is easily incorporated into their usual workflow, and improves drug-related decision making. They also felt that it reduced the rate of preventable adverse drug events (ADEs). The clinical and practical value of using these devices in clinical settings will clearly grow further as wireless communication becomes more ubiquitous and as more applications become available *(146)*.

In another study, several infectious diseases PDA applications were reviewed *(147)*; these included ePocrates ID (part of ePocrates Rx Pro), the Johns Hopkins Division of Infectious Diseases Antibiotic Guide, the 2002 Sanford Guide to Antimicrobial Therapy, and Infectious Diseases and Antimicrobials Notes. Drug information, including clinical pharmacology, dosing in patients with renal insufficiency, adverse reactions, and drug interactions, was evaluated for completeness and accuracy by comparison of each application with the package insert. Treatment recommendations for six diseases using these programs were compared with current practice guidelines. Each PDA infectious diseases application reviewed was found to have unique advantages and disadvantages. This critical review will help healthcare professionals select the infectious diseases PDA application best tailored to meet their individual information needs *(147)*.

AUTOMATED ELECTRONIC CLINICAL SURVEILLANCE SYSTEMS

Background

Surveillance has been defined as the collection, collation, analysis, and dissemination of data *(148,149)*. Several methods have been developed to perform this task in hospitals and other settings of care. The traditional method includes collection of data through extensive chart review, a time- and labor-intensive process. Computerized methods have been developed for hospital surveillance; several PC-based programs in infection control are available, which are reviewed in Chapter 15. These systems offer added efficiencies in the analysis of data but not in the collection of data. As surveillance in hospitals is expanded from infection control to other areas, more efficient means of data collection will be essential. The development and implementation of comprehensive enterprise HIT offer the potential for improving, enlarging, and more efficiently conducting hospital-wide surveillance. This section reviews hospital surveillance systems that make use of a previously installed EHR.

Data Sources

The creation and adoption of healthcare data standards has been a massive undertaking that has engaged the informatics community for several decades. A detailed discussion of the myriad issues involved in information harmonization is beyond the scope of this chapter. Those interested in a more detailed look at proposed Federal interoperability standards and implementation protocols are referred to the work of the Healthcare Information Technology Standards Panel, a cooperative partnership between the public and private sectors under contract to the U.S. Office of the National Coordinator for HIT (ONC).

Administrative HIT systems

A complete computerized medical record is not necessary before computerized surveillance can begin. Indeed, most institutions build a computerized medical record gradually over several years *(150–152)*. However, certain key areas are essential before beginning hospital-wide surveillance. Virtually all hospitals have established computerized systems for ADT information. These programs are implemented for administrative purposes, but they often collect important demographic information, including admission dates, diagnoses, lengths of stay, and discharge status, that informs the core of the inpatient medical record. Some organizations choose to implement an enterprise master patient index to facilitate administrative and clinical data from disparate systems that may not share patient identifiers. Generally, integrated clinical computer systems will have some kind of patient demographic system as a foundation to which other information is added.

Most American administrative healthcare computer systems index healthcare data using the International Classification of Diseases (ICD). ICD was originally developed by the World Health Organization for reporting morbidity and mortality statistics, but has been adapted for billing and administrative purposes. Healthcare facilities in the United States generally make use of a clinically modified version of the 9th edition (ICD-9-CM), although the CMS has announced it will begin using ICD-10 exclusively beginning October 2013.

Recent work (153) has highlighted the advantages and limitations of using administrative coding data for healthcare-associated infection surveillance. Notably, diagnosis code lists may be artificially abbreviated; codes may not correspond directly to clinical syndromes; and codes may be optimized for billing, rather than clinical, purposes.

Clinical Documentation in HIT Systems

As EHRs become more widespread, electronic clinical documentation has become increasingly available to infection preventionists (IPs). And, while free text documentation cannot readily be analyzed by automated surveillance systems, there are relevant clinical observations (such as temperature, presence of a urinary catheter, and so on) that are valuable for surveillance activities. Additionally, clinical problem lists may adhere to a standardized nomenclature. Traditionally, structured problem lists have utilized ICD-9-CM, but, as described above, the ICD classification system has been optimized as a billing and administrative tool.

The Systematized Nomenclature of Medicine—Clinical Terms (SNOMED CT) offers better promise for descriptive terminology that is relevant to both clinical practice and epidemiology. SNOMED, which was developed by the College of American Pathologists and is made freely available

by the National Library of Medicine, utilizes 11 axes (or components) that can be combined into useful clinical concepts. For instance, components enumerating anatomical structures, microorganisms, findings, and procedures might be combined to describe "a chest tube inserted to drain a left lower lobe pneumococcal pneumonia and associated empyema."

SNOMED's strength as a descriptive clinical terminology has also been its limitation, as its complexity has limited its adoption and implementation. However, it is widely understood that CMS will require providers to report clinical observations and problem lists in SNOMED CT format in order to receive HITECH incentive funding under future definitions of the "meaningful use" of EHRs.

Laboratory HIT Systems

Clinical laboratory systems, a rich source of clinical data, are ubiquitous within healthcare and are increasingly interfaced with a variety of external systems, including EHRs and clinical data repositories *(154–157)*. Legacy lab systems may not adhere to data standards, but more modern systems (and, increasingly, those belonging to large reference laboratories like Quest or LabCorp) will utilize several key standardized terminologies. The Logical Observation Identifiers Names and Codes (LOINC) nomenclature provides a set of universal names and ID codes for identifying laboratory and clinical test results facilitating the exchange and pooling of results for clinical care, outcomes management, and research. The EHR-Lab Interoperability and Connectivity Specification (ELINCS) can be used to define interfaces for results reporting from external laboratories.

Unfortunately, the least standardized aspect of laboratory systems is the microbiology laboratory. Microbiology data are often represented in free text form with frequent updates as culture data evolve, which frustrates automated analysis. Furthermore, heterogeneity in reporting susceptibility profiles complicates the usage of standardized tools. Ideally, microbiology reporting systems can utilize a combination of LOINC and SNOMED to reduce the reliance on free text, although this is rarely done in practice. Nevertheless, because of their great relevance to infection control surveillance, customized interfaces and extraction of microbiology reports are usually worthwhile endeavors for implementers of infection control systems.

Pharmacy HIT Systems

Many hospitals have computerized pharmacy systems, both for automation of pharmacy operations and for drug ordering (e-prescribing) or drug administration (usually in the form of bedside barcode medication administration). Pharmacy data may help the IP identify patients suspected as having a healthcare-associated infection (e.g., those receiving oral vancomycin may be suspected of having *Clostridium difficile*–associated diarrhea), or those who may have a communicable illness that requires special precautions (e.g., orders for permetherin suggesting treatment of an ectoparasitic infestation). Older CISs have not always adhered to pharmacy data standards, but the ONC regulations for EHRs specify a few key standard nomenclatures for medications that will be the norm for EHRs in the future.

The first is the National Council for Prescription Drug Programs (NCPDP) Script standard for sending prescription messages between pharmacies, prescribers, intermediaries, and payers. The standard supports messages regarding new prescriptions, prescription changes, refill requests, and medication history.

NCPDP Script defines the syntax and message structure between systems; RxNorm provides normalized drug names and links to many proprietary drug vocabularies, such as those provided by First Databank, Micromedex, and others. RxNorm is a product of the National Library of Medicine and is freely available.

Medication allergy terminology has proven particularly resistant to standardization, given the great variation in classifications of drug reactions and intolerances, drug components acting as allergens, and workflow in recording these critical data elements. ONC's current guidance is to use a combination of RxNorm, SNOMED CT, and the Unique Ingredient Identifier codes, which include inactive drug additives (e.g., dyes and fillers). Few existing CISs adhere to these allergy standards today.

Automated Infection Control Surveillance Using HIT Systems

A combined clinical data set, with discrete values as defined by standardized terminologies above, can be stored in a computer database (such as a clinical data warehouse) that is optimized for sophisticated analytical queries. In some cases, manual or *ad hoc* analyses may be sufficient. However, in order to automate surveillance, the IP will require a knowledge base or a rules engine. Rules can be simple ("Send an alert for all new MRSA isolates.") or quite sophisticated (a multistep algorithm to determine automated device-days calculations for device-associated infection). In general, rules should be tested carefully against standard methodologies, such as chart review, to determine their test characteristics (sensitivity and specificity) and limitations before being used routinely (158).

The *American Journal of Infection Control* recently highlighted the value of automated surveillance systems (77), including the ability to generate individual alerts for sentinel events or microorganisms; *ad hoc* data requests and line lists; automated cluster detection; and regular computerized infection reports. IPs have generally been pleased with these tools and their ability to automated rote and mundane data collection, reduce the risk of transcription error, and identify unusual trends in the data that may not have otherwise been identified.

Automated infection surveillance systems in the United States were first developed primarily in academic medical centers, including LDS Hospital in Salt Lake City *(159,160)*, Barnes-Jewish Hospital in Saint Louis (*161*,162), and New York Presbyterian Hospital *(163)*. Public hospitals in the United States and abroad have also had success with implementation of clinical data warehouses *(164)*, automated surveillance for surgical site infections *(165)*, and healthcare-associated ICU infections *(166)*.

Studies of these standalone systems have generally demonstrated substantial potential. The adoption of the LDS surveillance system resulted in the savings of two fulltime equivalent positions in the infection control department *(159,160)*, while identifying significantly more healthcare-associated infections than manual surveyors. The use of this program has also resulted in significantly

more patients being placed on appropriate isolation and better coordination of the infection control isolation program (*159,160*,167). Automated screening for surgical site infections by Saint Joseph Hospital in Paris identified nearly as many cases as manual review, but in 60% less time (*165*). New York Presbyterian Hospital screened radiology reports to identify healthcare-associated pneumonias in the neonatal ICU with a sensitivity of 71% and specificity of 99.8%.

Many infection control systems have become available as commercial software available for purchase and implementation. These products include TheraDoc Infection Control Assistant, Cardinal Health MedMined, Premier SafetySurveillor, rL Solutions Infection MonitorPro, and Sentri7. These systems have not yet been subjected to rigorous comparative evaluation in a peer-reviewed publication, but there have been a number of case reports suggesting their value *(51,168)*. Generally, these tools offer the ability to mine raw surveillance data for unexpected patterns and generate *ad hoc* or routine reports based on infection control queries (77). Some additional features include automated infection control reporting to public health departments and alerts upon detection of clusters of unusual syndromes or microorganisms.

APIC's 2009 position paper on the importance of surveillance technologies in the prevention of HAIs "supports the use of automated surveillance technologies as an essential part of infection prevention and control activities (169)." They highlight the benefits of these systems, including facilitating efficient review of surveillance data; expanding the scope of infection prevention activities; reducing infection prevention time spent on clerical tasks; and improving regulatory compliance and financial performance. APIC also provides an "Infection Prevention and Control Surveillance Technology Assessment Tool" on their Web site to aid IPs in selecting the right product (170).

IPs have generally welcomed the automation of surveillance activities, but the technology has catalyzed a shift in their job duties *(61)*. The time previously spent engaged in manual data collection and aggregation can now be spent on investigations, interventions, and education. Additionally, IPs now have the new responsibility of ensuring that their automated systems remain updated with the latest software, that reports and decision rules stay in sync with the data provided from other clinical systems, and that changes in clinical workflow don't create "blind spots" in automated surveillance reports and consequent falsely assuring negative findings.

Adverse Drug Event Surveillance Programs Using HIT systems An emerging area of healthcare epidemiology is drug-use surveillance. Pharmacy information systems can also be adapted to target and monitor specific drugs. Such a program at LDS Hospital was used to prospectively monitor the use and safety profile of imipenem/cilastatin, a drug associated with seizures *(98)*. Over 1,900 patients were studied and the observed seizure rate was 0.2%, which was markedly less than the 2% rate noted with the use of the drug at other centers. In addition, using creatinine clearances and other indicators of renal function that are automatically collected and stored on every patient, it was determined that all three patients experiencing seizures were receiving significant overdosage based on their renal function, thus associating the observed seizures with improper imipenem/cilastatin dosing. This system was also used for noninfectious adverse events associated with the use of midazolam, a benzodiazepine *(92)*. In this study, respiratory arrests were found to be related to drug overdosage. Both studies allowed for appropriate physician education and improved therapeutic use of both agents.

ADEs from antibiotics are only the tip of the safety iceberg for hospital patients; potentially surveillance can be broadened to include all ADEs in hospital patients. However, the routine method for detecting and reporting ADEs at hospitals involves voluntary reporting by physicians, who are required to complete and sign incident reports and submit documentation to the FDA, but rarely do in practice. Computer methods have been developed to automate the detection of hospital-associated ADEs *(91)*. These programs allow for both voluntary and nonvoluntary detection. Computer programs automatically conduct surveillance on all laboratory values of all patients, looking for certain arbitrary abnormalities such as eosinophilia, leukopenia, increased creatinine, and drug levels. Rule-based algorithms using medical decision logic are also used to detect ADEs.

For example, pharmacy orders are automatically screened for potential antidotes, sudden stop orders, and dose reduction orders. Each day, a report of all potential ADEs detected in the last 24 hours is printed out. A pharmacist reviews the records and interviews healthcare personnel relevant to all patients identified as having a potential ADE. The pharmacist then determines likely ADEs and enters his report into the patient's permanent record and the hospital ADE file. This report includes the time course of the event, pertinent subjective data, and the subsequent clinical course, all of which are stored in the ADE file. In addition, surveillance systems integrated with EHRs can automatically record the drug indication, administration time, duration of therapy, route of administration, and the National Drug Code. Each patient's ADE can be permanently stored in the record, and, if the offending drug is reordered, an alert may be generated to the appropriate clinical personnel.

THE FUTURE OF EHRS—MEANINGFUL USE OF HEALTH INFORMATION TECHNOLOGY

In the landmark report "To Err is Human," the IOM called for the adoption of EHRs as an essential infrastructure for improving the safety and quality of care in the United States (171). During the past decade, many hospitals and ambulatory care sites have begun implementing EHRs, but most care is still delivered without these systems. Furthermore, recent studies reveal that, despite considerable investment in these systems, many organizations have so far made only limited use of the most powerful capabilities of these systems to improve the quality and safety of care *(172)*.

The US government had previously invested relatively little in HIT compared to other nations, and lags far behind many other developed countries with respect to

HIT adoption. This level of investment, however, is about to change radically—the American Recovery and Reinvestment Act (ARRA) of 2009 provides up to $45 billion for the adoption and use of Health Information Technology (commonly called HITECH); prior federal spending on HIT in this area was approximately $50 million per year *(173)*. Most of this funding will go as financial incentives to physicians (individual non-hospital "eligible providers") and hospitals able to demonstrate that they are using "certified EHR technology in a meaningful manner" *(173)*. The ARRA underscores several specific areas of EHR use that fit the overall EHR-enabled improvements called for by the IOM. For both the hospital and the physician delivering ambulatory care, these requirements include "using the EHR to report on designated clinical quality measures, to exchange health information to support continuity of care, and to write orders electronically (Computerized Physician Order Entry [CPOE] or electronic prescribing [e-Rx], respectively) to gain the benefit of clinical decision support (CDS) to improve the safety and quality of patient care."

Tying financial incentives to the concept of meaningful use is essential because merely implementing an EHR does not necessarily mean that providers are using the software in the manner necessary to achieve the desired improvements in care. EHR vendor products are not all the same and cannot be used "out of the box"; local organizational EHR configuration and customization are always required regardless of the setting of care. In one survey, in the 14.8% of US nongovernment hospitals using CPOE, only 70% were using any decision support in CPOE, only 52% had CPOE in use for all inpatient beds, and only 39% had physicians entering at least 75% of orders *(174)*. In the outpatient setting, national data show that simply using an EHR was not associated with improved quality of care across a wide array of quality measures *(175)*.

To receive the financial incentives, eligible providers and hospitals must achieve "meaningful use" of an EHR. Meaningful use requirements are grouped into three stages, but the designations are no longer tied to specific dates as originally proposed (2011, 2013, and 2015). In Stage 1, the focus is on capturing data, in Stage 2 on reporting health information and tracking key clinical conditions, and in Stage 3 on improving performance and health outcomes (176,177). In the rules released in July 2010, hospitals and providers would be able to qualify for their first payment using Stage 1 criteria up until 2014. In the first payment year, only 3 months of meaningful use needs to be demonstrated to receive incentive payments, while in future years, meaningful use must be demonstrated for the entire year. To get the maximum Medicare payments, eligible providers need to qualify by CY 2012 and hospitals by FY 2013. Both physicians and hospitals also need to meet Stage 3 criteria by 2015 to avoid Medicare penalties. Physicians who provide more than 90% of their care in a hospital inpatient, hospital outpatient, or ED (point of service codes 21, 22, and 23) are not eligible for incentives. Eligible hospitals are defined by their unique CMS Certification Number (CCN or OSCAR codes).

The new rules break the criteria down to those to be achieved in 2011 (Stage 1), those to be achieved in 2013 (Stage 2), and those to be achieved in 2015 (Stage 3) (176). Only those criteria for 2011 (Stage 1) are included in the final rule. These criteria are quite specific for both the inpatient and outpatient settings of care and, although they include percentages for some measures such as computerized medication order entry, it is the quality measures themselves that will require the most significant effort on the part of all organizations to collect and report with their EHR. In addition, the infrastructure at the state and federal levels to receive these reports is not yet in place. Thus, quality measure reporting electronically will not be formally required until 2012, but the burden of collecting and reporting these measures through an EHR will still be substantial.

Healthcare organizations and physicians are understandably anxious about meeting these stringent meaningful use requirements in time to achieve the financial incentives by 2011. The Rules on Meaningful Use include both objectives and potential measures for meaningful use; many of these measures are currently reported and collected quality-of-care measures. However, some of these areas of performance are already measured in nearly all inpatient institutions whether they use an EHR or not; and hospitals, most without a comprehensive EHR, have initiated complex, labor-intensive processes to improve performance in these areas.

In terms of infection control, these criteria will require reporting of multiple types of data electronically to both state and federal agencies. The requirements include immunization data, reportable laboratory results of interest to public health, and electronic syndromic surveillance data.

In addition, there is a requirement for reporting nationally endorsed quality measures, many of which touch on infection control. The challenge here is that the requirements for this public reporting will start in 2012, and it will require collection of these data from the EHR and electronic submission to state and federal agencies as well as public health authorities. The meaningful use requirements mandate collection of these data through the EHR rather than through the ancillary systems where most hospitals manually enter their quality measurement data.

Hospitals should begin this journey by selecting an EHR product that includes the functions and features necessary to achieving meaningful use. ARRA is explicit that "the EHR technology used must be certified." At the time of this writing, the CMS is putting the finishing touches on an EHR certification program. At a minimum, these criteria are expected to include data capture and reporting for quality measurement. For both inpatient and ambulatory care settings, certified HIE capabilities will likely be expanded to include the Continuity of Care Document (CCD) (an existing HIT EHR standard vehicle for transmitting patient clinical summaries among providers) and capabilities for medication reconciliation across the continuum of care. EHR certification may also be expanded to address ease of use by providers and additional safeguards to protect patient privacy and information security (176,177).

For meaningful use, certification—though necessary—is alone not sufficient. How certified EHRs are actually implemented by hospitals is probably even more important. First, the manner in which the EHR software is implemented (what features are turned on and applied) must offer providers all of the capabilities needed to use it in a meaningful way. Second, physicians, nurses, and other healthcare workers must incorporate the use of the EHR into their routine workflow. These points require different approaches for the hospital and the physician practice, but can be based on the same principles.

CMS has stated that the threshold for "meaningful use" will be raised over time, incentivizing incremental implementation to meet increasing requirements from 2011 to 2015 or Stages 1, 2, and 3. Hospitals are further incentivized to help providers implement EHR and e-prescribing through exemptions to the Stark laws that allow hospitals and group practices to support providers with nonmonetary donations of hardware, software, and related training.

Because of the urgent call by the IOM and others for improved patient safety for the hospital setting, targeted EHR functionality will include CPOE with CDS, capability for HIE, and electronic clinical documentation for both nurses and physicians. The right implementation must include setup and configuration of CPOE to cover medication orders at a minimum and to leverage the CDS tools to address the common, serious ADEs that still occur in hospitals today. The best practice implementation must also accommodate the electronic clinical information exchanges that will be occurring with increasing frequency at patient admission and discharge as more physician practices and other providers are able to participate in electronic exchanges during patient transitions in care. This will include the ability to exchange structured problem list, labs, or radiology test results. Medication management including administration and dispensing is included, because these care processes, like order writing, can be made significantly safer through the use of such interventions as electronic medication administration record (eMAR) with bar coding *(178)*.

Successful infection control applications within EHR products will benefit from the above requirements being in place. Hospitals should immediately explore their chosen EHR vendor's path to achieving meaningful use of infection control data collection and reporting. Although many hospitals will likely report these data from standalone or ancillary systems initially, the long-term strategy should be to transition this function to the EHR as incentivized by meaningful use requirements.

Approach to Data Analysis: Use of Data Warehouses

HISs offer many advantages to the healthcare epidemiologists and IPs. They provide comprehensive detailed and integrated clinical information in a timely fashion to help with outbreak investigation and design of interventional programs for the prevention and control of healthcare-associated events. Additionally, the healthcare epidemiologist can automate analysis of infection control data on a regular basis to detect trends and changes suggestive of healthcare-associated outbreaks.

Most EHRs, however, are optimized to support individualized patient care, and are not designed to support analysis across cohorts and populations. In addition, complex statistical queries made against an EHR's active patient database may reduce the performance of the clinical system to the extent that it may actually interrupt the clinical workflow at the bedside.

For this reason, the most practical approach to data analysis is not to use the EHR for this task, but to analyze the data in a separate data warehouse. Data warehouses can be complex information systems implemented on an enterprise level, or, in more resource-constrained settings, they can be simple database programs loaded onto personal computers.

This approach allows flexibility, convenience, and computational efficiencies that are not often available on an EHR. In addition, there are many software tools widely available for data analysis such as statistical packages and spreadsheet programs for report generation.

For epidemiologists, this approach is hampered by (a) additional cost for an institution to develop and maintain a data warehouse, (b) the need to separately integrate additional relevant data that may not have been part of the clinical record, and (c) data fields often not structured properly for epidemiological queries (e.g., microbiological data). In practice, creating an epidemiologically complete data warehouse is nontrivial, and proper implementation eludes many sites.

Role of the Healthcare Epidemiologist in Selection and Implementation of EHRs

The healthcare epidemiologist has training and experience in infection control and healthcare epidemiology; these fields require considerable sophistication in data collection, data analysis, statistical interpretation, and experimental study design. The healthcare epidemiologist is also often involved in ongoing programs to improve antibiotic use, prevent healthcare-associated infections, and detect potential healthcare-associated outbreaks. As a physician, the healthcare epidemiologist is intimately involved with direct patient care and in many institutions is viewed by the medical staff as role model. The combination of medical staff credibility and a strong foundation in epidemiology offers the healthcare epidemiologist a natural leadership position in helping lead the selection and implementation of computerized patient information systems. Unfortunately, leadership in acquisition of clinical computing systems often has come from administrators who are more interested in realizing financial benefits without a clear understanding of clinical needs *(179)*, leading to clinicians' frustration with the clinical functionality of computer systems in their institutions.

System selection and implementation requires at least one (and often several) physician champion. The champion role does not require significant computer experience or a background in computer science; in fact, being perceived as the medical staff computer "nerd" can be damaging to one's credibility. A physician leader must be able to see the broad view of clinical computerization, the institutional needs, and the goals and not have this view poisoned by narrow interests in specific computer applications.

However, a physician leader should have experience in data collection and analysis for an understanding of the important role these issues play in EHRs. Clinical epidemiology experience is a great fit, because it encompasses issues related to data collection, structure, and analysis, combined with deep understanding of the workflow of nearly every unit in the medical setting.

A physician leader should have clinical credibility with medical staff in order to facilitate the implementation of an EHR. Because healthcare epidemiologists are often well-regarded opinion leaders, they have a significant leadership potential with the medical staff. They are a natural choice for involvement on a physician task force for selecting and implementing an EHR. Medical staff involvement at all stages of the process is critical; no other group can

effectively customize an EHR. Physician leaders must take a strong role in setting vision and educating medical staff members about the goals of implementation.

Each institution that is considering an EHR needs not only a vision, but also, on a more practical level, a concrete set of institutional goals for information management. These goals are pivotal in setting the requirements for an information system. These goals need to consider the history and tradition as well as the mission of the institution. From this list of goals, a group of needs can be generated, taking into account the existing resources at that institution. Obviously, all the needs cannot be met given limited resources; thus, some form of prioritization of needs is necessary. Based on this analysis, specific criteria for an information system can and must be developed. This is crucial for a rational choice among the multitude of systems available. Once these factors have been delineated, they must be presented and agreed upon by the medical staff and the administration before moving ahead to select a system.

A detailed strategy for EHR system selection is beyond the scope of this chapter; however, there are many points in the process where the healthcare epidemiologist should be at the table.

When the goals, needs, and priorities for information management are established, other clinical leaders and administrative or IT managers may neglect to include the need for capabilities for population or cohort data analysis, or tools for outbreak investigation.

When evaluating possible EHR vendors, the healthcare epidemiologist should understand the system's potential capabilities: Is the system designed for direct physician use? If so, where are sites of use in the institution? Is there evidence that the system meets clinical needs? What are the speed and flexibility of the system? Have physician suggestions been incorporated into the system? What is the scope and design of the EMR and the capability for a longitudinal record? Does it offer inpatient and outpatient applications? Are there a central database and a knowledge base, and who will maintain them? What are the methods for data capture? What are the interfacing capabilities and communication protocols in the system? What standardized terminologies and messaging standards does the system use? Is the system Web enabled, and does it support browser applications in all of its applications? Does this system capture financial data and true cost data? Will there be a clinical data warehouse, and how can it be queried? Does the system allow patients to directly access their own records? Does the system offer order entry, and what provisions are there for electronic signatures and security?

In summary, healthcare epidemiologists of the future will have a much broader mission both in the inpatient and outpatient settings as the healthcare reform process moves forward and as clinical information is computerized. Not only will healthcare epidemiologists be more effective in managing infection control issues in a timely and real-time basis, but their experience and background will make them invaluable in managing outcomes information in all aspects of healthcare delivery, especially as care moves to the outpatient arena. Future healthcare epidemiologists must be computer literate, as they will either adapt to the electronic revolution in healthcare or become a victim of it.

HEALTH INFORMATION TECHNOLOGY GLOSSARY

Admission–discharge–transfer (ADT) The registration data that are the core component of a hospital information system that maintains and updates the hospital census.

Application program A computer program designed to accomplish a user-level task.

ARRA The American Recovery and Reinvestment Act of 2009, federal legislation driving economic stimulus and recovery in the United States that includes a significant focus on health information technology and meaningful use of information by healthcare providers (see HITECH).

Artificial intelligence The branch of computer science concerned with endowing computers with the ability to simulate intelligent human behavior, both cognitive and perceptual.

ASCII American Standard Code for Information Interchange; the world standard code for representing characters (all the upper and lowercase Latin letters, numbers, punctuation, etc.) as binary numbers used on computers, terminals, printers, etc. In addition to printable characters, the ASCII code includes control characters to indicate carriage return, backspace, etc.

Application service provider (ASP) A service delivery model where the application is run on remote computer systems maintained by a vendor and the client/end user accesses the service(s) remotely (usually via the Internet) (see also cloud computing).

Bandwidth The maximum amount of data per second that can be transmitted across a telecommunications line or received by a network interface. T1 speed = 1.544 Megabits per second.

Biomedical computing The use of computers in biology or medicine.

Biomedical engineering An area of engineering concerned primarily with the research and development of medical instrumentation and medical devices and the application of engineering methods and technology to biomedical science.

Bit A digit that can assume the values of either 0 or 1. Shorthand for *b*inary dig*it*.

Browser A client program that is used to look at various kinds of Internet resources. For example, Firefox/Mozilla, Microsoft Internet Explorer, Google Chrome, Opera, etc.

Continuity of Care Document (**CCD**) An XML-based markup standard that defines the encoding, structure, and semantics of a clinical summary document for a patient.

Clinical Document Architecture (CDA) An XML-based markup standard that defines the encoding, structure, and semantics of clinical documents.

Byte A sequence of eight bits. The amount of memory space needed to store one character, which is usually eight bits.

Central processing unit (CPU) The "brain" of the computer. The CPU executes a program stored in main memory by fetching and executing instructions in the program.

Client A computer that receives services from another computer (known as a server), or (on multitasking operating systems) a process that receives services from another process. The system (software running on a piece of hardware) that initiates the process or requests services in a client/server architecture (see Server).

Client/server A style of distributed computing that enables several local area network–based PCs or workstations (known as clients) to share access to a more powerful server computer. With this approach, processes are divided between two systems that work together to perform a task, such as retrieving information from a database.
Clinical data repository A database containing information from numerous sources, optimized for review of individual patient data (see Clinical data warehouse).
Clinical data warehouse A data repository that encompasses enterprise-wide data on many topics with data often drawn from multiple source systems in the institution that has been optimized for display and analysis of aggregate data, reporting, and data mining.
Clinical decision support system A computer-based system that assists physicians in making decisions about patient care.
Clinical prediction rule A rule, derived from statistical analysis of clinical observations, that is used to assign a patient to a clinical subgroup with a known probability of disease.
Cloud computing A type of distributed client-server computing generally via the Internet where applications and data reside in a remote data center (or cloud) often via the ASP model.
Cognitive science Area of research concerned with studying the processes by which people think and behave.
Consulting system A computer-based system that develops and suggests problem-specific recommendations based on user input (see Critiquing system).
Computerized provider order entry (CPOE) The process or system by which healthcare providers have direct computer access to enter and process their clinical orders. This is a core component of most electronic medical record systems.
Critiquing system A computer-based system that evaluates and suggests modifications for plans or data analyses already formed by a user (see Consulting system).
Data mining A technique that uncovers new information and relationships by systematically examining existing information in an existing data set.
Decision support system An information processing system or subsystem designed specifically to address the information needs of decision makers often within a larger application. Decision support systems evolved from database and management information systems.
Distributed computing A collection of independent computers that share data, programs, and other resources.
Domain A named subnetwork of the Internet defined by an institution or its components—for example, idsociety.org
Electronic health record An electronic record of health-related information on an individual that conforms to nationally recognized interoperability standards and that can be created, managed, and consulted by authorized clinicians and staff, across more than one healthcare organization.
Electronic medical record An electronic record of health-related information on an individual that can be created, gathered, managed, and consulted by authorized clinicians and staff within one healthcare organization *(27)*.
Enterprise system A system that spans or is designated for use by an entire institution (usually reserved for larger institutions—e.g., a hospital or corporation).
EHR-Laboratory Interoperability and Connectivity Specification (ELINCS) A standard for defining laboratory and electronic clinical data promoted by the California Healthcare Foundation.
Ethernet A type of local area network originally developed by Xerox Corporation. Communication takes place by means of radio frequency signals carried by a coaxial cable. Most Ethernet systems today use the transport protocol called TCP/IP (see TCP/IP).
Expert system A program that symbolically encodes concepts derived from experts in a field and uses that knowledge to provide the kind of problem analysis and advice that the expert might provide. Specifically, a computer system designed to capture the skills and factual knowledge of one or more individuals. A program that uses a set of rules to construct a reasoning process that can reach conclusions and generate new data.
FAQ Frequently asked question. Documents that contain and answer the most asked questions on a particular subject. A popular heading on many Internet sites.
FTP File transfer protocol. The name of a program that transfers files from one computer to another on the Internet and on other TCP/IP networks (see Internet and TCP/IP).
Gateway A link between two or more computer networks.
GUI Graphical user interface. A way of communicating with the computer by manipulating icons (pictures) and windows with a mouse as opposed to a textual user interface (TUI), which requires typed commands.
Heuristic A rule of thumb; a cognitive process used in learning or problem solving.
Health information exchange (HIE) An organization or system for exchanging healthcare data across a region or set of cooperating institutions.
Health Information Technology for Economic and Clinical Health (HITECH) Act A component of the ARRA of 2009 promoting EHR/EMR adoption and meaningful use.
Health Level Seven (HL7) A standard format for defining clinical data for exchange that is frequently used by commercial applications.
HTML Hypertext markup language. The coding language used to create hypertext documents on the World Wide Web (WWW) (see WWW).
HTTP Hypertext transport protocol. A formal program for moving hypertext files across the Internet (see Internet).
Hypertext A formal way of creating documents so that information can be connected in many different ways rather than in a simple sequential manner as in books. Any text that links to other documents; words or phrases in a document that can be chosen and that cause another document to be retrieved and displayed.
Inference engine A computer program that embodies one or more general-purpose problem-solving algorithms that are largely independent of any specific domain. Inference engines draw conclusions by performing simple logical operations on knowledge bases and the information supplied by users.
Information Organized data or knowledge that provides a basis for decision making.
Information science The field of study concerned with issues related to the management of both paper-based and electronically stored information.

Integrated The state where two or more computer systems or applications have been closely tied together for both data and function sharing.
Interfaced The state where two or more computer systems or applications have direct links established to transfer data.
Internet An immense worldwide network of networks, connecting computers at universities, research labs, hospitals, offices and other commercial settings, private homes, and military sites.
IP Address A network address under the Internet protocol (IP) composed of four numbers (0–255) separated by periods that designates a unique location on the Internet.
Knowledge Relationships, facts, assumptions, heuristics, and models derived through the formal or informal analysis (interpretation) of data.
Knowledge base A collection of stored facts, heuristics, and models that can be used for problem solving.
Knowledge engineering The art of formalizing knowledge. Typically, the term is used in reference to building expert systems.
Laboratory information system (LIS) A computer-based information system that supports laboratory functions for collecting, verifying, and reporting test results.
Local area network (LAN) A network for data communication that connects multiple nodes, all typically owned by a single institution and located within a small geographic area. A system of network software and hardware components used to connect a group of end stations via wire or fiber optic cable. A single LAN segment connects from one to several hundred end stations, usually in the same building. A large organization may have a thousand or more LAN segments and tens of thousands of end stations.
Logical Observation Identifiers Names and Codes (LOINC) A nomenclature system for uniquely identifying laboratory and clinical observations for data exchange.
Mainframe computer A large computer designed to manage large amounts of data and complex computing tasks. A mainframe computer can be utilized by hundreds or even thousands of users. The term also describes the memory storage and computing part of a large computer system, as opposed to input or output devices, such as video monitors, keyboards, or printers.
Meaningful use A term coined with the release of the HITECH Act that encompasses the definition of information utilization for compliance with federal requirements for the use of electronic health information systems and Medicare/Medicaid claims payments.
Medical informatics A field of study concerned with the broad range of issues in the management and use of biomedical information, including medical computing and the study of the nature of medical information.
National Council on Prescription Drug Programs (NCPDP) A national standards organization and their protocols for representing pharmacy and medication data.
Network A set of computers that are connected together using standard communications protocols. A collection of hardware, such as printers, modems, servers, and clients, that enables users to store and retrieve information, share devices, and exchange information (see Local area network and Wide area network).
Nursing information system (NIS) A computer-based information system that supports nurses' professional duties in clinical practice, nursing administration, nursing research, and education.
Open architecture An approach to computing systems that assumes heterogeneous mixture of applications and host computers, systems, and databases, which are minimally interfaced with one another by means of de facto conventions and standards.
Open server A network server that can accommodate multiple operating systems and myriad software products. In addition, an open server can be used in numerous hardware configurations, because it is not dependent on proprietary standards.
Picture archiving and communications system (PACS) An enterprise system for storing, managing, and sharing radiology and other clinical images across a network.
Patient monitor An instrument that collects and displays physiologic data, often for the purpose of watching for and warning against life-threatening changes in physiologic state.
Patient monitoring Repeated or continuous measurement of physiologic parameters for the purpose of guiding therapeutic management.
Personal health record An electronic record of health-related information on an individual that conforms to nationally recognized interoperability standards and that can be drawn from multiple sources while being managed, shared, and controlled by the individual.
Pharmacy information system (PIS) A computer-based information system that supports the medication verification and delivery workflows that take place inside the pharmacy.
RAID Redundant array of inexpensive disks. A method of storing data on multiple hard disk drives for faster access and/or greater reliability. Currently, there are six officially defined levels, each designed for a specific kind of application.
Regional Health Information Organization A health information organization that brings together healthcare stakeholders within a defined geographic area and governs HIE among them for the purpose of improving health and care in that community.
Remote Installation Services (RIS) A system for installing or updating software on remote systems for a given institution or network. This allows centralized administration of remote systems.
Server A computer that provides services to another computer (called the client). On multitasking machines, a process that provides services to another process (see Client).
Service-oriented architecture A methodology/set of design principles for loosely coupling services from various sources into an integrated architecture.
Short message service (SMS) A standard for exchange of short text messages between telecommunications devices such as mobile phones.
Systematized Nomenclature of Medicine—Clinical Terminology (SNOMED CT) A systematic computer-interpretable medical vocabulary defining diseases, diagnoses, and other medical terms.
Standards The creation of common protocols for communication between different computer systems including

electronic communication and data exchange. Examples include ASTM, HL7, ISO, and MEDEX.

Tablet PC A personal computer that has a pen-based or touch interface usually with an optionally available keyboard. Many models are also fully functional laptops.

TCP/IP Transmission control protocol/Internet protocol. A standard format for transmitting data in packets from one computer to another. It is used on the Internet and various other networks (see Internet).

Telnet A command on the Internet and other TCP/IP networks that allows one to use their computer as a terminal on another computer. The command allows a user to log in from one Internet site to another (see Internet and TCP/IP).

Terminal A computer that is dependent on a single host computer for its accessibility and capability.

Three-tier architecture A client/server architecture in which the screen presentation, database, and software programs run separately on the client, host computer, and one or more application servers, respectively. This division of labor allows information to be processed more quickly and facilitates distribution of data across wide area networks.

TUI Textual user interface. A way of communicating with a computer through typed commands. For example, DOS or Unix.

URL Uniform resource location. The standard method to give the address of a resource on the Internet that is part of the WWW (see Internet and WWW).

Vaporware Software promised by a vendor that never materializes (an exceedingly common occurrence).

Wide area network (WAN) A set of widely separated computers connected together. Long-distance telecommunication links and networks that connect local area networks and end stations.

Wireless LAN A local area network in which the computers communicate by radio signals. Also called WiFi.

Workstation A computer that is connected to a network of host and server computers and has enough local processing power to run local applications and to interface with the hosts and servers.

World Wide Web (WWW) A worldwide standard Internet protocol for sharing and interlinking documents and applications using hypertext transmission protocol (http) and other standards.

eXtensible Markup Language (XML) A standard language for defining and encoding structured data for transmission.

SECTION IV
Epidemiology and Prevention of Healthcare-Associated Infections of Organ Systems

CHAPTER 17

Healthcare-Associated Infections Related to the Use of Intravascular Devices Inserted for Short-Term Vascular Access

Angela L. Hewlett and Mark E. Rupp

BACKGROUND AND CLINICAL SIGNIFICANCE

Short-term vascular catheters are vitally important medical devices that are ubiquitously used in acute care settings. Over 150 million intravascular devices are purchased yearly in the United States, including 7 million central venous catheters (CVCs). Unfortunately, despite recent significant reductions in the incidence of IV catheter–related infections (*1*,2), they continue to result in substantial morbidity and excess economic cost. Although most studies that account for severity of illness have not found central line–associated bloodstream infection (CLA-BSI) to be independently associated with mortality (*3*,*4*,5), they do extend hospitalization by approximately 1 week (5) and result in excess attributable cost that ranges from $7,288 to $29,156 per episode *(6)*. However, CLA-BSIs due to more virulent pathogens such as *Staphylococcus aureus* or *Candida albicans* are associated with greater morbidity and mortality than less virulent microbes such as *Staphylococcus epidermidis (7,8)*.

There is a growing recognition that many, if not most, CLA-BSIs are preventable through the use of existing technology and clinical practice techniques, and there is increasing pressure to eliminate preventable CLA-BSI. Many states now require public reporting of hospital-specific CLA-BSI rates *(9)*. The Centers for Medicaid and Medicare Services (CMS) no longer reimburses hospitals for excess costs associated with CLA-BSI *(10)* and the Department of Health and Human Services has recently targeted CLA-BSI for a 75% reduction within 5 years *(11)*. These efforts have focused unprecedented scrutiny on CLA-BSI rates and fueled additional efforts to develop products and clinical techniques to prevent CLA-BSI.

EPIDEMIOLOGY

The National Healthcare Safety Network (NHSN) collects data on the incidence of healthcare-associated infections (HAIs) in the United States, including those related to the use of intravascular devices *(12)*. The NHSN data are expressed as the risk of a CLA-BSI per 1,000 CVC days. The CLA-BSI rates from data collected from 2006 to 2008 are presented in Table 17-1. The risk of infection varied according to the type of ICU or inpatient ward setting, as well as the birth weight of the infant in neonatal ICUs. Burn units were found to have the highest rate of infection (5.5 per 1,000 catheter days) and pediatric medical ICUs had the lowest rate of infection (1.3 per 1,000 catheter days) *(12)*. CLA-BSI rates are influenced by multiple factors including patient-related factors (severity and type of illness), catheter-related factors (catheter type and conditions under which the catheter was placed), and institutional factors including academic affiliation of the institution and bed size (13). It should be noted that the NHSN data may overestimate the true risk of CLA-BSI, because some bloodstream infections may be due to an unrecognized source

TABLE 17-1

National Healthcare Safety Network Central Line–Associated BSI Rates (2006–2008)

Location	*Pooled Mean*[a]
Critical Care Units	
Burn	5.5

of infection that is unrelated to the CVC (13,*14*). In spite of these issues the risk-adjusted rates reported by NHSN are utilized by various types of facilities for benchmarking.

The European Centre for Disease Prevention and Control (ECDC) reported data from 695 hospitals in 12 European countries in 2007, which included 4,718 episodes of ICU-acquired bloodstream infections. These data indicate that ICU-acquired bloodstream infections occurred on average in 3% of patients staying more than 2 days in these ICUs, with 56% of these infections being catheter associated *(15)*. The incidence of CLA-BSI in limited-resource countries has been investigated in a comprehensive review and is reported to range from 1.6 to 44.6 cases per 1,000 central line days in adult and pediatric ICUs *(16)*. The International Infection Control Consortium (INICC) reported a CLA-BSI rate of 7.6 per 1,000 CVC days in INICC ICUs *(17)*. These rates are higher than the rate reported by NHSN for the United States, which may be secondary to the lack of infection control resources in these developing countries. However, one study found the incidence of CLA-BSI in non-US and US hospitals to be similar in an international group of hospitals with similar infection control practices *(18)*.

The type of intravascular device inserted markedly contributes to the risk of catheter-related bloodstream infections. Peripheral venous catheters are rarely associated with bloodstream infections. However, peripheral venous catheters are by far the most commonly used intravascular device, so the burden of bloodstream infections due to peripheral venous catheters may be more substantial than is commonly appreciated (19). Phlebitis is the most common complication associated with peripheral venous catheters and may represent inflammation rather than infection, but when phlebitis is present, the risk of subsequent bloodstream infection may be increased *(20)*.

Studies show that midline catheters are associated with lower rates of infection than CVCs *(21)*. Peripherally inserted central venous catheters (PICCs) have traditionally been utilized to administer medications in the outpatient setting, and have been shown to have a low infection rate *(22)*. However, the use of PICCs is currently becoming more common in the inpatient setting. Infection rates in PICC lines inserted into high-risk hospitalized patients are associated with an infection rate similar to that of CVCs *(23)*.

CVCs account for the vast majority of catheter-related bloodstream infections, causing an estimated 90% of these infections *(20)*. Factors associated with increased risk of CLA-BSI include prolonged hospitalization, prolonged duration of catheterization, heavy microbial colonization at the insertion site or the catheter hub, internal jugular catheterization, neutropenia, prematurity, total parental nutrition, and substantial care (excessive manipulation) of the catheter *(24)*. An increased risk of CLA-BSI has been observed with catheters with multiple lumens in observational studies, but a randomized trial did not observe a difference in infection risk between single lumen and triple lumen catheters *(25)*.

The risk associated with site selection for CVC insertion has received particular attention in the medical literature. It has been suggested that the subclavian site is the preferred site of insertion in order to minimize the CVC infection risk, and femoral catheterization has been shown to be an independent risk factor for CLA-BSI *(14)*. However, data on the optimal insertion site are conflicting, with some studies demonstrating a higher incidence of CLA-BSI when the femoral site is used, while others showing a higher incidence of CLA-BSI when the jugular site is used (*26,27,28*,29). One study showed that infection rates did not differ according to insertion site when experienced operators inserted the catheters, strict sterile technique was utilized, and trained ICU nursing staff performed catheter care *(30)*. Another study involving patients requiring short-term dialysis vascular access demonstrated that the jugular site may be preferred over the femoral site in patients with a high body mass index *(31)*. In contrast, several studies have demonstrated that the femoral site may be preferred in certain patients, especially those with tracheostomy *(32–34)*. Pediatric studies have shown that placement of catheters at the femoral site in children have a low incidence of mechanical complications and that infection rates are equivalent to that of catheters placed at other sites *(35–37)*. Careful consideration of the risks and benefits of placing a CVC at the recommended site should be weighed against the risks of mechanical complications, the experience of the person inserting the catheter, and patient-specific factors like the presence of open wounds, obesity, or anatomic deformity (13).

PATHOGENESIS

A comprehensive discussion of the pathogenesis of CLA-BSI is beyond the scope of this chapter and interested readers are directed to recent reviews *(38,39)*. Briefly, the pathogenesis of intravascular catheter infections includes

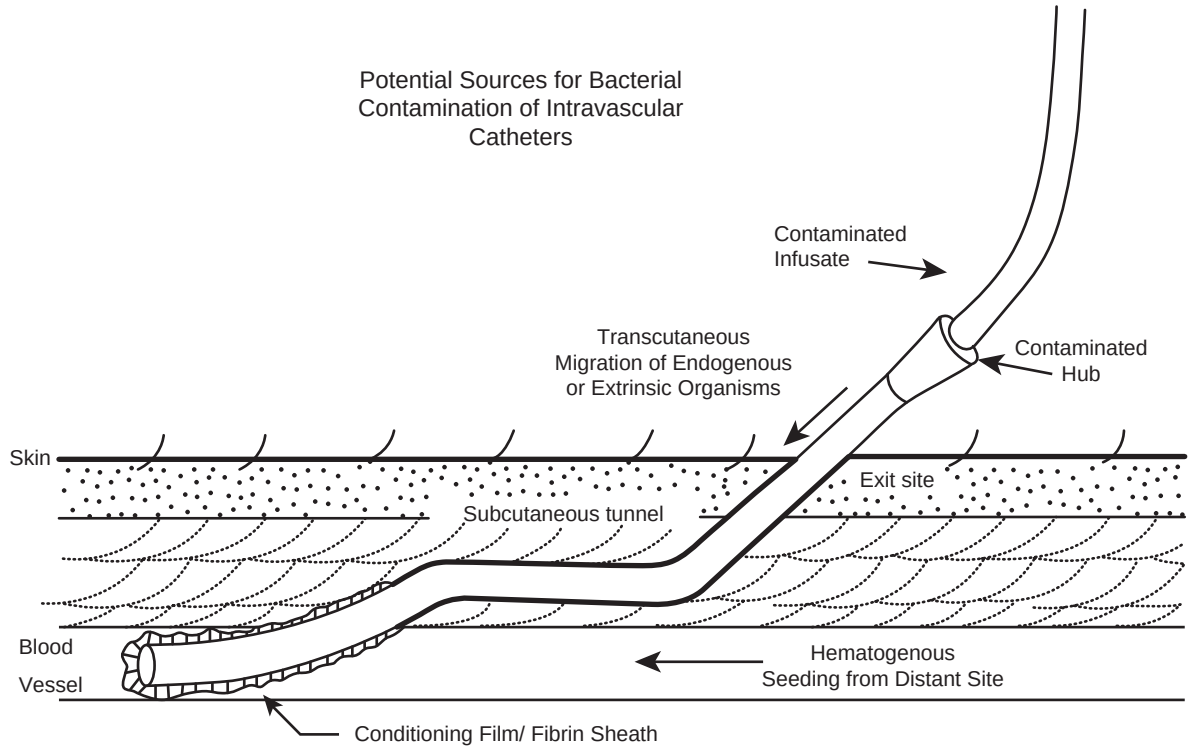

FIGURE 17-1 Pathogenesis of intravascular catheter–related infection. Routes by which microbes gain access to the intravascular catheter and initiate an infection are illustrated. Short-term catheters are most frequently colonized via the transcutaneous route, while longer-term catheters become infected via hub contamination. (From Rupp ME, Infections of intravascular catheters. In: Crossley KB, Archer GL, eds. *The Staphylococci in human disease*. New York, NY: Churchill Livingstone, 1997:381, © Elsevier [1997]).

complex interactions between the microbe, the catheter and what is infused through the catheter, and the host. Microbial factors include the presence of various polysaccharide and proteinaceous adhesions, and the ability to proliferate and elaborate biofilm. Catheter variables involve biomaterial composition, device design, and surface coatings. Host factors include such items as underlying illness, condition of the skin, local commensal flora, and site of catheter insertion.

Figure 17-1 illustrates the routes by which microbes gain access to the catheter. For short-term, nontunneled, CVCs, it appears that most infections are caused by microorganisms from the patient's skin that track via the external surface of the catheter *(40)*. The longer a catheter remains in place, the more likely it is that a break in aseptic practices takes place and microbes gain access to the hub of the catheter and migrate via the luminal surface *(41,42)*. Rarely do catheters become infected via hematogenous seeding or via infusion of intrinsically contaminated infusate *(43)*. Once the microbes gain access to the catheter, they interact with the conditioning film that is comprised of host plasma proteins and blood cellular elements that quickly coat the catheter surface after insertion, and they adhere, proliferate, and elaborate biofilm *(44)*. Figure 17-2 illustrates the appearance of a 1-day old, experimentally induced *S. epidermidis* biofilm-associated catheter infection. Physical and nutritional conditions differ from one portion of the biofilm to another and various populations of microbes are found, including rapidly growing cells at the macrocolony–blood interface as well as metabolically quiescent, antibiotic-resistant, persister cells in deeper portions of the biofilm *(45)*. Because of associated cost and morbidity and because successful treatment of biofilm-associated catheter infections often requires removal of the catheter, it behooves us to apply stringent measures to prevent these infections in the first place.

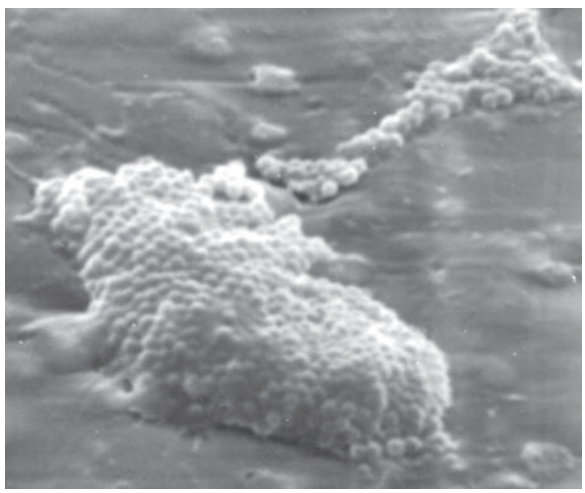

FIGURE 17-2 Intravascular catheter–associated infection. Scanning electron micrograph of the surface of an intravascular catheter demonstrating a *S. epidermidis* biofilm 24 hours after the catheter was experimentally infected *in vitro*. (Reproduced from Rogers KL, Fey PD, Rupp ME. Epidemiology of coagulase-negative staphylococci and infections caused by these microorganisms. In: Crossley KB, Jefferson KK, Archer GL, Fowler VG Jr, eds. *Staphylococci in human disease*. 2nd ed. Oxford, UK: Wiley-Blackwell, 2009:313, with permission).

MICROBIOLOGY

The 2008 NHSN Annual Update report contains data on pathogens associated with HAIs and the associated antimicrobial resistance patterns reported between January 2006 and October 2007 *(46)*. Overall 463 hospitals reported one or more HAIs, resulting in a total of 28,502 HAIs including 10,064 (35.3%) cases of CLA-BSI.

According to the NHSN data, gram-positive cocci remain the most common cause of CLA-BSI. Coagulase-negative staphylococci are the most frequent causative microorganism in both adult and pediatric patients, causing 34.1% of the cases of CLA-BSI in the hospital setting *(46–48)*. Other pathogens that cause CLA-BSI include *Enterococcus* sp. (16%), *Candida* sp. (11.8%), and *S. aureus* (9.9%). Gram-negative bacilli like *Klebsiella* sp., *Escherichia coli*, *Enterobacter* sp., *Pseudomonas* sp., and *Acinetobacter* sp. account for 17.7% of CLA-BSI according to NHSN data.

Antimicrobial resistant microorganisms are commonly implicated in CLA-BSI infections. Data from NHSN indicate that 56.8% of *S. aureus* isolates are resistant to oxacillin (MRSA), and 36.4% of Enterococci are vancomycin resistant (VRE). Resistance amongst gram-negative microorganisms is also emerging, with 27.1% of *Klebsiella pneumoniae* isolates demonstrating resistance to third generation cephalosporins, and 23% of *Pseudomonas aeruginosa* isolates demonstrating resistance to carbapenems such as imipenem and meropenem.

CLINICAL MANIFESTATIONS

Signs and symptoms related to intravascular device infections vary depending on whether the infection is localized or systemic. Local catheter infections include those at the exit site, tunnel infections, and phlebitis. Exit site infections commonly manifest with evidence of localized inflammation including erythema, warmth, tenderness, and purulent discharge. An infected CVC tunnel may demonstrate similar inflammatory signs extending along the tunneled portion of a tunneled catheter. Phlebitis is inflammation of the veins associated with a catheter. It typically involves peripheral catheters, and often presents with signs of local inflammation. Phlebitis may represent a localized infection or a chemical irritation of the vein due to the catheter material or drugs administered. Localized infections may lead to a systemic catheter infection, but are not a reliable predictor of such infections *(49)*.

Systemic catheter infections typically present with signs of systemic infection, including fever, chills, and hemodynamic instability. Other signs may include altered mental status, catheter dysfunction, and complications of bloodstream infections such as endocarditis.

DIAGNOSIS

Initial diagnosis of catheter-related bloodstream infection involves examining the catheter site for local signs of infection and obtaining blood cultures. Since the symptoms and signs of CLA-BSI are nonspecific, microbiologic evidence is necessary to establish that the catheter is the source of the infection. Diagnostic methods to identify CLA-BSI can be divided into methods that require removal of the catheter and methods that do not necessitate removal of the catheter *(50)*.

One diagnostic technique that does not require removal of the catheter involves obtaining paired blood cultures (one from the catheter and one through a peripheral vein) prior to initiation of antimicrobial therapy (*50*,51). When possible, these cultures should be drawn by a phlebotomy team *(52)*. A definitive diagnosis of CLA-BSI can be made if the blood culture drawn through the catheter yields a colony count that is at least threefold greater than that of the culture obtained from the peripheral vein (51,*53*,*54*). If a peripheral blood culture is not possible, two quantitative blood cultures obtained through two catheter lumens in which the colony count for the blood sample drawn through one lumen is at least threefold greater than the colony count for the blood sample obtained from the second lumen is suggestive of CLA-BSI (51). One study demonstrated that obtaining blood samples from all catheter lumens may help to establish a diagnosis of CLA-BSI *(55)*. However, this has not been clearly documented in the literature, and the possible advantages must be weighed against the additional time required, expense, and possibility of contributing to healthcare-associated anemia. If there is purulent material present at the catheter exit site, this should also be sent for Gram stain and culture *(56)*.

Differential time to positivity (DTP) is a method that involves obtaining blood cultures from the catheter and a peripheral vein simultaneously, and comparing the amount of time it takes for the cultures to become positive. Blood cultures should be obtained prior to initiation of antibiotic therapy when DTP is used. CLA-BSI can be diagnosed definitively when the blood culture obtained through the catheter becomes positive at least 2 hours earlier than the culture obtained through the peripheral vein (*57*,*58*,59).

When the catheter is removed for suspected CLA-BSI, catheter tip cultures should be performed. However, catheter tip cultures should not be performed routinely if CLA-BSI is not suspected *(60)*. In order to satisfy the definition of CLA-BSI the same microorganism must be isolated from one percutaneous blood culture and from a culture of the catheter tip (51). If the catheter is a pulmonary artery (PA) catheter, the introducer tip should be cultured *(27)*. If a subcutaneous port is removed for suspected CLA-BSI, the catheter tip and the port reservoir should be cultured *(61)*. Growth of >15 colony-forming units (CFU) from a 5-cm segment of the catheter tip by semiquantitative (roll-plate) culture or growth of $>10^2$ CFU from a catheter by quantitative (sonication) broth culture reflects significant catheter colonization (51,*60*,*62*,63).

PREVENTION

Efforts to prevent infections due to short-term intravascular catheters can be broadly divided into two categories: (a) clinical practice measures associated with insertion and care of catheters and (b) technologic innovations. Guidelines for prevention of intravascular catheter-related infections were recently updated (13) and key recommendations are summarized in Tables 17-2 and 17-3. Table 17-2 summarizes clinical practice measures that are broadly recommended in almost all clinical settings. Table 17-3

TABLE 17-2

Summary of Recommended Clinical Practices for Prevention of Short-Term Intravascular Catheter–Related Infection

1. *Education, Training, and Staffing*
   - Healthcare workers who insert and maintain intravascular catheters should be adequately trained and their knowledge should be periodically assessed regarding the indications for catheter use and proper insertion and care procedures (*81*,*82*,83).
   - Appropriate nursing staffing levels should be maintained in the ICU *(84,85)*.
2. *Catheter Type and Site Selection*
   - Catheters and site of insertion should be selected based on the intended purpose, duration of use, potential complications, and patient specific factors.
   - In general, the femoral vein should be avoided for central venous access, particularly in obese patients *(27,31)*.
3. *Insertion Technique*
   - Perform hand hygiene at appropriate time points (before and after palpating insertion site; before and after inserting, accessing, or dressing an intravascular catheter) *(86)*.
   - Use maximal sterile barrier precautions, including a cap, mask, sterile long-sleeve gown, sterile gloves, and a head-to-toe sterile body drape (87).
   - Prepare the skin with a ≥0.5% concentration chlorhexidine-based preparation before CVC insertion and with catheter dressing changes (88).
   - Do not administer systemic antimicrobial prophylaxis before insertion or during use of an intravascular catheter to prevent catheter infection *(89)*.
4. *Site Care*
   - Use sterile gauze or a sterile, transparent, and semipermeable dressing to cover the catheter site; monitor catheter sites regularly, and change the dressing if it becomes damp, loosened, or visibly soiled *(90,91)*.
   - Do not submerge the catheter or catheter site in water. Showering is permitted if the catheter and catheter connector device can be protected with an impermeable cover *(92)*.
5. *Replacement of CVCs and Administration Sets*
   - Promptly remove an intravascular catheter that is no longer required for patient care (2).
   - Do not routinely replace CVCs or routinely change catheters using guidewire exchanges to prevent infection (*79*,93).
   - Replace continuously used administration sets between 4 and 7 d *(94–96)*.
   - Replace tubing used to administer blood, blood products, or fat emulsions within 24 h of initiating the infusion and replace tubing used to administer propofol infusions every 6–12 h *(97)*.
6. *Needleless Intravascular Catheter Systems*
   - Access ports should be adequately disinfected with an appropriate disinfectant (70% alcohol, chlorhexidine, iodophore, povidone-iodine) that is applied correctly.
   - Needleless, mechanical connector valves should be used with caution as some particular valves or types of valves may be associated with an increased risk of infection *(98,99)*.

covers technologic innovations and devices designed to minimize the incidence of CLA-BSI that should be considered in conjunction with clinical practice. Most authorities believe that it is important to first emphasize clinical practice measures and then introduce technologic innovations if clinical practice measures are not successful in minimizing the incidence of CLA-BSI. New devices and other technologic approaches may be particularly useful in populations that are at high risk of CLA-BSI (e.g., persons receiving long-term parenteral nutrition, burn patients). Comparative effectiveness research to establish which device or technique is most cost effective is particularly needed in this clinical area.

IMPLEMENTATION OF PREVENTIVE AND PERFORMANCE MEASURES

Unfortunately, despite the presence of a good foundation of knowledge in the epidemiology and pathogenesis of intravascular catheter infections and the presence of evidence-based measures to prevent infection, widespread implementation of well-supported preventative measures has been suboptimal *(64,65)*. Recently, substantial success has been observed in prevention of CLA-BSI through a combination of specific insertion and maintenance procedures into a "prevention bundle" (2,*66,67*). In addition, through use of an insertion compliance checklist and ongoing surveillance and reporting, the gains in these programs have been sustainable *(68)*. Compliance with the insertion bundle can be optimized by conveniently providing all necessary equipment in an all-inclusive catheter insertion kit or on an easily accessible cart *(66)* and bedside personnel should be empowered to stop a nonemergent procedure if breaks in aseptic technique are observed.

Oftentimes, CVCs are inserted in the operating room, interventional radiology suite, emergency department, or general patient care ward, and efforts to ensure appropriate insertion and care of CVCs should be performed in all of these settings. In many acute care hospitals and long-term acute care hospitals, 25% to 30% of patients have CVCs *(69)* and therefore it is important to perform surveillance outside the ICU setting. In order to accurately measure institutional performance, standardized definitions of infection should

TABLE 17-3

Summary of Technologic Innovations Recommended to Minimize the Risk of Short-Term CVC-Associated infection

1. *Coated/Impregnated CVCs*
   - Use a chlorhexidine/silver sulfadiazine or minocycline/rifampin-impregnated CVC if the CVC is expected to remain in place at least for 5 d (*100*,*101*,102,*103*).
2. *Dressings*
   - Use a chlorhexidine-impregnated sponge dressing for patients >2 mo of age (*104*,105).
3. *Patient Bathing*
   - Use 2% chlorhexidine-impregnated washcloths or a 2% chlorhexidine solution to bathe patients on a daily basis (106,*107*).
4. *Prophylactic Antimicrobial Lock Solution*
   - A variety of antibiotic and antiseptic solutions can be utilized to flush or lock catheter lumens to prevent CLA-BSI. This technique has primarily been utilized on long-term catheters in patients with a history of recurrent CLA-BSI. The lock solution should not interact with the catheter material *(108–110)*.
5. *Antibiotic/Antiseptic Ointments*
   - Povidone iodine, bacitracin/neomycin/polymyxin B, or mupirocin ointment can be applied at the catheter insertion site to prevent central line–associated bloodstream infection *(111,112)*. This technique has primarily been used on long-term hemodialysis catheters. If this technique is used, the ointment should not interact with the catheter material. Concern regarding catheter material interactions, selection for fungal pathogens, and development of antimicrobial resistance has discouraged wider use of this technique.
6. *Other Promising Technologic Innovations that are in Development or do not Currently have Sufficient Clinical Data to Support a Recommendation*.
   A. Coated catheters:
      - Silver/platinum/carbon (silver iontophoretic) *(103)*
      - Rifampin-miconazole *(103)*
      - Active iontophoresis *(113)*
      - Numerous surface modifications and coatings in laboratory investigation

   B. Dressings and catheter securement devices
      - Chlorhexidine-impregnated gel pad dressing *(114)*
      - Silver-impregnated dressing
      - Sutureless catheter securement device

   C. Caps/connectors
      - Silver-impregnated mechanical connector valve *(115)*
      - Antiseptic barrier cap/hub

be utilized *(70)* and unit-specific infection rates should be expressed as CLA-BSI per 1,000 catheter days. Benchmark rates can be used to measure relative performance *(1,12)*. In addition to outcomes measures, process measures such as compliance with CVC insertion guidelines, checklist completion, documentation of daily catheter assessment, compliance with site care recommendations, and compliance with catheter access procedures should be monitored *(24)*. Up-to-date process and outcomes measures should be reported frequently to both senior hospital leadership as well as bedside clinicians *(24)*.

Pulmonary Artery Catheters

PA catheters are complex intravascular devices that are utilized for hemodynamic monitoring of critically ill patients. A meta-analysis demonstrated a higher rate of catheter-related bloodstream infection with PA catheters (3.7 per 1,000 catheter days) when compared with unmedicated, nontunneled CVCs (2.7 per 1,000 catheter days) (19). One prospective study of 297 Swan–Ganz PA catheters found a high incidence of local catheter-related infection (21.8%) but a low incidence of catheter-related bacteremia (0.7%) *(27)*. Another study of 164 PA catheters in cardiac surgery patients demonstrated an 11.6% incidence of PA catheter colonization and a 0.6% incidence of catheter-related bacteremia *(71)*. The risk of PA catheter-related infection increases with the duration of catheterization, cutaneous colonization of the insertion site, insertion into the internal jugular vein, and insertion in the operating room with less stringent barrier precautions *(27,61,72)*.

Arterial Catheters

Arterial catheters, most frequently inserted in the radial or femoral artery, are frequently used in critical care settings in order to monitor blood pressure and obtain arterial blood for blood gas determinations. Compared to CVCs, there are few data examining the risk of infections associated with arterial catheters and, traditionally, arterial catheters have been regarded as low-risk devices. However, more recently, there is growing recognition that arterial catheters pose a substantial risk for infection (19,*73,74*). In a review of 14 studies of arterial catheters, Maki et al. (19) noted a mean rate of arterial catheter-related bloodstream infection of 1.7 per 1,000 catheter days (95% CI 1.2–2.3). When the femoral site is utilized for arterial catheterization,

catheters are more likely to become colonized and there is a greater risk of bacteremia due to gram-negative bacilli than when the radial site is used *(75)*. However, a meta-analysis did not note a significant difference in the rate of bloodstream infection when comparing catheterization at the femoral, radial, and axillary sites *(76)*. Other factors that have been implicated as increasing the risk of infection include the duration of catheterization and utilization of a cut-down method for catheter placement.

The use of full sterile barrier precautions has not been shown to decrease the risk of arterial catheter related BSI *(77,78)*. Similar to CVCs, most evidence does not favor routinely changing arterial catheters to prevent infection *(79,80)*. In order to prevent arterial catheter–associated infections, the following measures should be followed (13):

- Avoid the femoral artery site for catheter insertion.
- Barrier precautions consisting of a minimum of a cap, mask, sterile gloves, and small sterile fenestrated drape should be utilized.
- Do not routinely replace arterial catheters to prevent infection and remove arterial catheters as soon as they are not needed.
- Use disposable transducer assemblies and replace them at 96-hour intervals.
- Minimize manipulation of the catheter and pressure working system and keep all components of the system sterile.

CHAPTER 18

Healthcare-Associated Infections Related to Use of Intravascular Devices Inserted for Long-Term Vascular Access

Anne-Marie Chaftari and Issam Raad

Long-term intravascular devices (IVDs) have become indispensable in the modern medical care of chronically ill patients such as cancer patients, patients with renal failure requiring chronic hemodialysis, or patients requiring organ or bone marrow transplantation. In the 1960s and 1970s, treatment of cancer patients through a small peripheral venous catheter was often complicated by extravasation of vesicant chemotherapeutic agents and thrombosis of peripheral veins, which limited the use of parenteral anticancer chemotherapy. Long-term silicone central venous catheters (CVCs) allowed the extended, safe use of anticancer chemotherapeutic agents as well as the potential for appropriate use of total parenteral nutrition (TPN) fluids, blood products, and other intravenous therapeutic agents. For patients with short bowel syndrome, long-term CVCs have become the only source for nutritional support through TPN. Similarly, patients requiring hemodialysis who have had prior failure of arteriovenous fistulas or shunts become totally dependent on intravascular catheter–related access for their hemodialysis. In all of these clinical situations, the long-term CVC becomes an essential device for the maintenance of life.

There is no standard agreed-upon definition for long-term catheters in terms of the duration of catheterization. Sherertz defined long-term catheters as those with a duration of placement of an average of >8 days. Rather than using an average duration, we have defined this term in a previous study to signify catheters that remain in place for >30 days. We also defined short-term catheterization by duration of placement of <10 days, and intermediate catheterization by duration of placement ranging between 10 and 30 days *(1)*.

Long-term IVDs can be categorized into one of three groups: (a) nontunneled long-term CVCs (such as peripherally inserted central catheters [PICCs] or subclavian CVCs such as Hohn catheters); (b) cuffed and tunneled catheters (such as Hickman/Broviac, Groshong, and tunneled Uldall catheters); and (c) implanted subcutaneous central venous ports.

NONTUNNELED CATHETERS

Traditionally, it was assumed that the only method of maintaining long-term intravascular access in chronically ill patients was through surgically implantable CVCs such as the tunneled catheters and implantable ports. Over the last decades, nontunneled long-term silicone CVCs (particularly PICCs) have become more accepted as a cost-effective form of intravascular access. In addition, these catheters could be maintained for a long period, up to 400 days, without complications (2). Nontunneled long-term catheters consist of two types: long-term nontunneled subclavian catheters and PICC lines. Nontunneled subclavian catheters are inserted percutaneously via the subclavian vein into the superior vena cava, in the outpatient nonsurgical setting. The advantage of these catheters is that they are associated with low cost, because their insertion does not require the use of an operating room or a special surgical technique *(3)*. In addition, these catheters can be exchanged over a guidewire, and the removed intravascular segment may be cultured if a catheter infection is suspected or if a new catheter needs to be inserted. These catheters are available as single-, double-, or triple-lumen cannulas.

The PICC lines are becoming widely used, particularly for outpatient long-term central venous therapy, such as patients requiring intravenous home antibiotics for osteomyelitis or endocarditis, cancer patients, or patients requiring TPN delivery. These catheters are usually inserted in the antecubital space, via the cephalic or basilic vein, and advanced into the central venous system. These catheters are very cost-effective, because they can be inserted in the outpatient clinic by a trained infusion therapy nurse and do not require a physician for their insertion. These catheters can be maintained for an average of 3 months and are associated with a low infection rate and cost (2). However, their main disadvantage is a high rate of aseptic thrombophlebitis related to mechanical contact *(4)*. Traditionally, many of these catheters were made of silicone, although

over the last decade, most PICCs are power injectable made of polyurethane and hence allow the use of contrast material for diagnostic imaging.

TUNNELED CATHETERS

In 1973, Broviac et al. (5) described the first surgically implanted tunneled catheter to be used in pediatric patients requiring long-term TPN. Later, Hickman et al. (6) described another long-term tunneled catheter for cancer patients requiring bone marrow transplantation. These catheters are usually tunneled under the skin for several inches until they reach the cannulated vein. Tunneled catheters have a Dacron cuff that is located in the proximal subcutaneous segment 5 cm from the exit insertion site. After insertion, the Dacron cuff becomes enmeshed with fibrous tissue, hence anchoring the catheter and creating a tissue interface mechanical barrier against the migration of skin microorganisms along the external intracutaneous pathway. Tunneled catheters usually exit the body midway between the nipple and the sternum. Another vascular access catheter is the Groshong, which, unlike the Hickman/Broviac, is thin walled and has two slit valves adjacent to a rounded closed end that remains closed unless fluids are being infused or blood is being drawn. This decreases the risk of intraluminal blood clotting or infusion of air when the catheter is not in use. Hence, this type of catheter does not require daily heparin flushes, but rather is flushed with saline on a weekly basis.

IMPLANTABLE PORTS

To eliminate the migration of skin microorganisms from the skin insertion site in externalized catheters along the intracutaneous pathway, the surgically implanted subcutaneous central venous ports were developed where the whole catheter, including the metallic port, is placed beneath the skin *(7)*. Hence, implantable ports consist of a metal/titanium or plastic port placed beneath the skin and connected to a catheter that enters the cannulated vein. Ports are usually placed in a subcutaneous pocket on the upper chest or, less often, in the antecubital area of the arm (peripheral port). Ports are available as single- or double-lumen catheters with or without Groshong valves and can be accessed as needed with a steel needle.

EPIDEMIOLOGY

The bloodstream infection (BSI) rates associated with long-term CVCs should be reported using catheter-days as the denominator. The Centers for Disease Control and Prevention (CDC) recommends that rates of central line-associated bloodstream infections (CLABSI) be expressed per 1,000 device-days. This recommendation takes into consideration the varying risks of CLABSI over time for the different types of CVCs. According to Crnich and Maki (8), although the rates of CLABSI per 100 CVCs used are usually higher for long-term devices, the risk per 1,000 catheter-days is usually considerably lower than that for short-term CVCs. Previous studies showed that the average infection rate for long-term CVCs in cancer patients ranged from 1 to 1.5 episodes per 1,000 catheter-days (*9,10*,11,*12*). Assuming this rate and the fact that three million long-term CVCs are inserted annually in the United States (with an average dwell time of 100 days), the estimated annual number of episodes of catheter-associated bacteremia that occur in the United States related to the use of these catheters in cancer patients is between 300,000 and 450,000.

Several studies have compared the efficacy of tunneled catheters (such as Hickman/Broviac catheters) with implantable ports. Mueller et al. *(13)*, in a prospective, randomized study, compared the complications of the two types of long-term catheters and found no significant difference in infection rates between the two types of devices. Similarly, Keung et al. *(14)* conducted a retrospective study of infectious complications in 111 long-term CVCs. Multivariable analysis revealed no significant difference in infection rates between tunneled catheters and implantable ports. On the other hand, there are several studies that suggest that ports may be associated with lower infection rates. Mirro et al. *(15)* evaluated 266 tunneled catheters and 93 implantable ports in children with cancer, and showed that, when all causes of failure were analyzed including infectious complications, ports had a significantly longer duration of use than tunneled catheters. In a prospective observational study conducted at Memorial Sloan-Kettering on 1,630 long-term CVCs (923 tunneled catheters and 707 ports), Groeger et al. *(16)* found that the incidence of infection per device per day was 12 times greater with the tunneled catheter than with ports. Therefore, these data might suggest that ports are associated with a lower infection rate than tunneled catheters, even though they are not conclusive. In addition, the data should be analyzed with caution because there could be confounding variables, such as the various uses of the catheters (including the use of TPN), duration of neutropenia, and thrombotic complications that were not taken into consideration.

There are very few data in the literature comparing tunneled with nontunneled long-term CVCs in terms of infection rates. In a prospective randomized study, Andrivet et al. *(17)* showed that the infection rate associated with nontunneled subclavian silicone CVCs was not different from that related to tunneled silicone catheters. However, the lack of a difference could be related to the small sample size. In a prospective study evaluating nontunneled long-term CVCs at the M. D. Anderson Cancer Center, we determined that the infection rate for PICC lines and nontunneled subclavian CVCs was 1.4 per 1,000 catheter-days, which was comparable to what was described for Hickman catheters in the literature (2). At the M. D. Anderson Cancer Center, the cost of insertion of nontunneled catheters, including the chest x-ray postinsertion and other related fees, is in the range of $1,190 to $1,326 as compared with more than $6,502 for the Hickman tunneled CVC. The cost of placing an implantable port at our institution is about $7,076. Given the comparable durability of all long-term catheters, the potential marginal difference in infection rates might not justify the wide difference in cost between the tunneled catheters and ports on the one hand and the nontunneled CVC (PICC lines and nontunneled subclavian catheters) on the other.

PATHOGENESIS

Microbial adherence and colonization of long-term catheters is the by-product of the interaction of several factors: (a) host-derived proteins, (b) microbial factors, (c) catheter material, and (d) iatrogenic factors.

After insertion, a thrombin sheath covers the internal and external surfaces of the catheter, which is rich in host proteins *(18,19)*. These proteins include fibronectin, fibrinogen, laminin, thrombospondin, and collagen *(20–24)*. *Staphylococcus aureus* binds strongly to fibronectin and fibrinogen, whereas coagulase-negative staphylococci (CNS) bind strongly to fibronectin *(20,21)*. In addition, *Candida albicans* has been shown to bind well to fibrin *(25)*.

Biofilm formation represents the microbial factor involved in the enhancement of adherence of microorganisms to catheter surfaces. Microorganisms, such as CNS, *S. aureus*, and even *Candida parapsilosis*, have the potential of undergoing intrinsic phenotypic changes that result in the expression of several enzymes that lead to the production of an exopolysaccharide, thus causing the biofilm to form *(26–31)*. Microorganisms embed themselves in this layer of biofilm (or microbial slime), and hence protect themselves from antimicrobial agents such as glycopeptides *(32)*. Other microbial factors, such as hydrophobicity and the surface charges of microorganisms, contribute to the adherence to catheter materials such as silicone *(33,34)*. Hydrophobic staphylococcal microorganisms adhere better to silicone surfaces of which most long-term catheters are made than to the polyurethane or Teflon surfaces of short-term catheters.

The material from which the catheters are made plays a role in the adherence of microorganisms to the catheter surface. The physical characteristics of the catheter surfaces, including hydrophobicity, surface charges, irregularities, and defects on the catheter surface and the thrombogenicity of the catheter surface, contribute to the process of microbial adherence *(3,35)*. Several investigators have shown, for example, that *Staphylococcus* and *Candida* species adhere better to polyvinyl chloride catheters than to Teflon catheters *(36,37)*. Sherertz et al. *(38)* have demonstrated in a rabbit model that silicone catheters are easier to infect with *S. aureus* than polyurethane, Teflon, or polyvinyl chloride catheters. This was also shown by Vaudaux et al. *(39)*, who demonstrated that indwelling silicone catheters, after being removed from patients, were more prone to *S. aureus* adherence than were polyurethane or polyvinyl chloride catheters. This was related to the fact that silicone catheters tend to have a direct toxic effect on neutrophils, alter neutrophil chemotaxis, and cause a localized depletion of complement *(40,41)*.

Iatrogenic factors associated with medical interventions in high-risk patients entail a higher risk of colonization of catheter surfaces. These consist of the use of TPN fluids and lipid emulsions, interleukin-2, and long-term hemodialysis *(3,35)*. TPN has been associated with higher rates of infection in tunneled catheters *(42)*. The 25% dextrose and the lipid emulsions have been associated with microbial growth, particularly *Candida* species and *Malassezia furfur* *(35)*. In addition, interleukin-2 has also been shown to predispose to catheter colonization and infection by staphylococcal microorganisms *(43,44)*. It is postulated that interleukin alters neutrophil chemotaxis toward staphylococcal microorganisms, and hence leads to a higher degree of colonization of catheter surfaces with these microbial agents. Finally, chronic hemodialysis patients have a high rate of nasal carriage of *S. aureus*, ranging from 30% to 65% *(45–47)*. Hemodialysis patients who are chronic carriers of *S. aureus* have a threefold higher risk of contracting catheter-related *S. aureus* BSI when compared with noncarriers *(48)*. The majority (more than 90%) of *S. aureus* infections in carriers are caused by the same type as that carried in the nares *(45)*.

The most common microorganisms causing catheter-associated infections in long-term CVCs are CNS, *S. aureus*, and yeasts (49). This is related to the fact that staphylococci are skin microorganisms. In addition, staphylococci and *Candida* adhere well to host proteins found on catheter surfaces and tend to form a microbial biofilm *(25–31)*. This is in contrast to gram-negative microorganisms, such as *Escherichia coli* and *Klebsiella pneumoniae*, that do not adhere well to fibronectin and fibrin and are not known to produce a biofilm. Other microorganisms that have been associated with long-term CVC infections are *Bacillus* species, *Corynebacterium* species, *Pseudomonas aeruginosa*, *Acinetobacter* species, *Stenotrophomonas maltophilia*, micrococcus, Achromobacter, rapidly growing mycobacteria, and various other fungal microorganisms such as *M. furfur* and *Fusarium oxysporum (50)*.

For long-term catheters, the lumen seems to be the major site of colonization and source of CLABSIs. This has been shown for catheters used for long-term hemodialysis and for CVCs used for TPN and cancer treatment *(51–53)*. Previous investigators highlighted the hub as the most common source for long-term catheter–related bloodstream infections (CR-BSIs) *(51,54)*. However, for short-term catheters with an average duration of <8 days, the skin seems to be the major source, followed by the hub/lumen *(55,56)*. The relative contribution of contaminated infusate, hematogenous seeding from a remote infected source, or extension from a contiguous site of infection seems to be low even in long-term catheters. Using semiquantitative scanning electron microscopy studies, we have determined that the extent of biofilm formation and colonization is greater on the external surface of short-term catheters (<10 days of catheterization) than the internal surface *(1)*. However, for catheters that remain in place for >30 days, this phenomenon is reversed with greater biofilm formation and ultrastructural colonization in the lumen of the catheter versus the external surface.

Electron microscopy studies have shown that colonization is universal *(1,57)*. It involves all CVCs within 24 hours of insertion *(57)*. However, although colonization is universal, only a few catheters are associated with infection. There is a quantitative relationship between the number of microorganisms (particularly free-floating microorganisms) on the catheter and the risk of BSIs. Sherertz et al. *(58)* studied 1,610 CVCs and found that the greater the number of microorganisms retrieved from the catheters by sonication, the greater the risk of BSI. Therefore, infection could be a function of whether the microorganisms on the catheter surface, particularly those that are free-floating, exceed a certain quantitative threshold due to various risk factors outlined above.

MANIFESTATIONS AND DEFINITIONS

The clinical manifestations of a CLABSI for long-term catheters consist of systemic manifestations such as fever and chills, which are nonspecific, particularly in the immunocompromised patient. Clinical evidence of a local infection at an exit site, tunnel, or port pocket would be necessary to suggest the catheter as the source of the BSI. However, for PICC lines, local catheter site inflammation consisting of erythema and phlebitis could be aseptic in nature and reflect a local mechanical irritation of the vein due to the insertion of a large catheter in the relatively small basilic or cephalic veins (2). Therefore, local catheter-related infection or systemic CLABSI should be defined in terms of clinical manifestations associated with microbiologic data implicating the catheter as the source of the infection (Tables 18-1 and 18-2). The following definitions were proposed in a recent guideline by the Infectious Diseases Society of America (IDSA) (59):

1. Local catheter infection: Local catheter infection could exist in different forms, depending on the type of catheter (nontunneled or tunneled implantable port). However, in the presence of positive results of a blood culture, it would be classified as CLABSI (59,60).
   a. Exit-site infection: erythema, tenderness, or induration within 2 cm of the catheter exit site, may be associated with other signs and symptoms of infection such as fever or purulent drainage emerging from the exit site.
   b. Pocket infection: purulent exudate in the subcutaneous pocket containing the reservoir of the port or erythema and necrosis of the skin over the reservoir of a totally implantable device.
   c. Tunnel infection: erythema, tenderness, and induration in the tissues overlying the catheter and >2 cm from the exit site.
2. Systemic catheter infection: BSI could either be
   a. Infusate-related: with the concordant growth of a microorganism from infusate and from percutaneously obtained blood cultures with no other identifiable source of infection.
   b. Central line–related:
      i. Bacteremia or fungemia in a patient who has an IVD and >1 positive blood culture result obtained from the peripheral vein, clinical manifestations of infection (e.g., fever, chills, and/or hypotension), and no apparent source for BSI (with the exception of the catheter).
      ii. For the definitive diagnosis of CLABSI or CR-BSI as defined by the IDSA (59), one of the following should be present:
         1. the isolation of the same microorganisms (species) from a semiquantitative (>15 colony-forming units (CFU)/catheter segment) or quantitative (>102 CFU/catheter segment) catheter tip culture and from at least one percutaneous blood culture
         2. simultaneous quantitative cultures of blood drawn, one from a catheter hub and the other from a peripheral vein with a ratio of >3:1 CFU/mL (catheter vs. peripheral blood)
         3. differential time to positivity (DTP) of 2 hours (growth in a culture of blood obtained through a catheter hub is detected by an automated blood culture system at least 2 hours earlier than a culture of simultaneously drawn peripheral blood of equal volume).

TABLE 18-1

Definitions of Colonization, Phlebitis, and Local Central Line–Associated Infections

Type of Central Line–Related Infection	*Definitions*
Catheter colonization	Significant growth of one microorganism by quantitative or semiquantitative culture of the catheter tip, subcutaneous catheter segment, or catheter hub, in the absence of simultaneous clinical symptoms
Phlebitis	Induration or erythema, warmth, and pain or tenderness along the tract of a catheterized or recently catheterized vein
Exit-site infection	Purulent drainage from the catheter exit site, or erythema, tenderness, and induration within 2 cm of the catheter exit site
Tunnel infection	Erythema, tenderness, and induration of the tissues overlying the catheter and more than 2 cm from the exit site
Pocket infection	Purulent exudate in the subcutaneous pocket containing the device or erythema, tenderness, induration, and necrosis of the skin over the pocket

However, quantitative blood cultures are not widely available for a definite diagnosis of CR-BSI. According to the CDC, a CLABSI can be diagnosed in a patient who has a central line that was in place at the time of, or within 48 hours before, onset of bacteremia in the presence of any one of the following:

a. A recognized pathogen cultured from one or more blood cultures and organism cultured from blood is not related to an infection at another site.
b. A common skin contaminant cultured from two or more blood cultures drawn on separate occasions within two days of each other and at least one of the following clinical signs or symptoms: fever (>38°C), chills, or hypotension and signs and symptoms and positive laboratory results are not related to an infection at another site.

Most CR-BSIs are uncomplicated. However, with virulent microorganisms such as *S. aureus*, *C. albicans*, and *P. aeruginosa*, deep-seated infections can occur, particularly catheter-related septic thrombosis, which consists of

TABLE 18-2

Diagnosis of Intravascular Catheter–Related Bloodstream Infection[a]

IDSA 2009 Definition of Intravascular Catheter–Related Bloodstream Infection (CR-BSI)	*CDC Definition of Central Line–Associated Bloodstream Infections (CLABSI)[b]*
A. A definite CR-BSI diagnostic method sparing the catheter requires one of the following to be present: 1. The same organism is cultured from two quantitative blood cultures samples drawn, one from a catheter hub and the other from a peripheral vein with a 3:1 ratio (the catheter hub is at least threefold greater than the colony count from blood obtained from a peripheral vein) 2. The same organism is cultured from two blood cultures samples drawn, one from a catheter hub and the other from a peripheral vein with a differential time to positivity (DTP) of 2 h (same pathogen detected from a blood sample drawn from a catheter hub at least 2 h before it is detected in a blood sample obtained from a peripheral vein) B. A definite CR-BSI diagnostic method implicating catheter removal requires that the same organism is cultured from at least one percutaneous blood culture and from a culture of the catheter tip	Patient has a central line that was in place at the time of, or within 48 h before, onset of bacteremia with any one of the following: 1. A recognized pathogen cultured from one or more blood cultures and organism cultured from blood is not related to an infection at another site 2. A common skin contaminant cultured from two or more blood cultures drawn on separate occasions within 2 d of each other and at least one of the following clinical signs or symptoms: fever (>38°C), chills, or hypotension and signs and symptoms and positive laboratory results are not related to an infection at another site

[a]According to the Infectious Diseases Society of America (IDSA) 2009 guidelines for the diagnosis and management of intravascular catheter–related infections and to the CDC definition for CLABSI.
[b]Centers for Disease Control and Prevention (CDC) definition of CLABSI does not require catheter removal.

CR-BSI with an infected thrombus *(61–63)*. The clinical course of septic thrombosis is characterized by occasional swelling above the site of the thrombotic vein and persistent BSI on antimicrobial therapy even after the removal of the catheter. Other deep-seated infections associated with complicated catheter-related bacteremias and fungemias consist of endocarditis, osteomyelitis, and retinitis in the case of candidemia *(61,62)*.

DIAGNOSIS

Catheter-related infections are often overdiagnosed, resulting in unnecessary antimicrobial therapy and wasteful removal of the CVC. Misdiagnosis is often the result of relying on false-positive microbiologic data, such as positive blood cultures from the CVC or clinical data such as catheter-site inflammation/phlebitis associated with PICC lines in the absence of other confirmatory data. Therefore, the diagnosis of these infections is often difficult and should be the result of integrating clinical and microbiologic findings. A positive nonquantitative blood culture drawn through the CVC with a concurrent negative peripheral blood culture should be interpreted with extreme caution. Bryant and Strand *(64)* demonstrated that 93% of such cultures are often contaminated with microorganisms that colonize the hub or the lumen, and hence do not reflect an infection. This is particularly true for skin microorganisms such as CNS. It has been demonstrated that the positive predictive value of a single positive blood culture for CNS ranges from 4.1% to 26.4% *(65–68)*. Therefore, prior to initiating antimicrobial therapy and considering whether the catheter should be removed, a single positive blood culture yielding a skin microorganism should be interpreted in light of associated clinical and microbiologic data. Because CVCs are universally colonized, a positive blood culture from the CVC could reflect intraluminal or hub colonization. Therefore, attention should be paid to other laboratory findings suggestive of BSI and which consist of (a) multiple positive blood cultures of skin microorganisms (60), (b) quantitative blood cultures revealing a high colony count (>15 CFU/mL of blood) or time to positivity of <20 hours for blood culture growing CNS (69,*70*), and (c) the same microorganisms isolated from the quantitative catheter culture and peripheral blood culture (59). All three of these factors should be considered to reflect a catheter-related infection in the setting of concurrent signs of infection such as fever and chills with no other apparent source for the infection other than the catheter.

Before or after removal of the catheter, the diagnosis should be made based on the interplay of clinical and microbiologic findings. The infection is initially suspected when there is a positive blood culture in a patient with a CVC with clinical signs of infection, such as fever and chills, and no other apparent source for the BSI, such as pneumonia, urinary tract infection, intra-abdominal infection, or surgical site infection (Table 18-2). This type of BSI has been termed primary BSI. In this case, the primary BSI is a probable CLABSI. The diagnosis becomes definitive in the presence of either confirmatory clinical or microbiologic data.

Clinical findings are unreliable for establishing the diagnosis of IVD-related infection because of their poor sensitivity and specificity. However, clinical data consisting of (a) local inflammation, such as catheter exit-site inflammation or tunneled/port inflammatory signs (Tables 18-1 and 18-2)—the presence of purulence at the insertion

site, particularly in patients with *S. aureus* bacteremia, is diagnostic of catheter-related bacteremia—and (b) systemic signs of infection, such as fever and chills, that persist despite appropriate antimicrobial therapy for the BSI but resolve with catheter removal should increase the suspicion for CLABSI *(71)*.

Confirmatory microbiologic data may be available prior to catheter removal. The three best-studied methods to determine the diagnosis prior to catheter removal are simultaneous quantitative blood cultures from the CVC and a peripheral vein, DTP, and, for nontunneled catheters, quantitative cultures of the skin at the exit site (*59*,*68*,69,*70–84*). In the former case, the diagnosis of CR-BSI is often suggested when the number of colonies isolated from a quantitative blood culture obtained from the catheter is at least threefold more than that quantitated from a peripheral venipuncture blood culture *(73–78)*. DTP is a method that was shown in cancer patients to be a simple and reliable tool for *in situ* diagnosis of catheter-related bacteremia. Blot et al. *(81,82)* defined DTP as the difference in time necessary for the blood cultures drawn from a peripheral vein and through the catheter to become positive. When DTP was >120 minutes, this diagnostic method was shown to be highly sensitive (100%) and specific (96.4%) for the diagnosis of CR-BSI *(81)*. Blot et al. *(82)* concluded that using DTP as a diagnostic technique is mainly of value for patients requiring long-term catheterization. Another large prospective study conducted by our group confirmed that DTP of >120 minutes was highly suggestive of CR-BSI associated with the use of both short-term and long-term CVCs *(83)*. Semiquantitative and quantitative catheter cultures are not very helpful in the setting of long-term CVC because they require the removal of the CVC in order to diagnose CR-BSI. The roll-plate semiquantitative culture method is most commonly used for culturing catheters *(85)*. However, this method is limited in that it cultures only the external surface of the catheter and may not retrieve microorganisms that are well embedded in the biofilm on the catheter surface. The fact that this method does not quantitate microorganisms from the lumen of the catheter is important for long-term indwelling catheters where colonization is mostly luminal. In a study of long-term catheters (nontunneled CVC and PICC lines) at the M. D. Anderson Cancer Center, the sensitivity of the roll-plate technique was 45% compared with 72% for the sonication technique for making the diagnosis of catheter colonization or catheter-related infection by culture of the intravascular segment of the catheter *(1)*. Quantitative catheter cultures, particularly sonication, which retrieves microorganisms from the external and internal surfaces, have been shown to be of higher diagnostic value than the roll-plate technique, particularly for long-term CVC with predominantly luminal colonization *(1,86,87)*. If semiquantitative or quantitative catheter cultures are not done, then a clinical response to catheter removal within 24 hours, after failure of antimicrobial therapy to resolve the infection, with the catheter *in situ*, is highly suggestive of CR-BSI *(88)*.

If the bacteremia or fungemia persists after catheter removal in spite of the use of appropriate antimicrobial agents, then one has to determine whether the patient has a deep-seated catheter-related infection, such as right-sided endocarditis or septic thrombosis *(61,62)*. In these situations, a venogram would be useful to rule out septic thrombosis, and a transesophageal echogram might be useful to detect valvular vegetations suggestive of endocarditis.

PREVENTION

Effective preventive strategies for long-term CVC-related infections should be based on an understanding of the pathogenesis of these infections. Because luminal colonization is the major source of BSIs in long-term catheters, preventing colonization of the external surface of the catheter during the early-phase postinsertion will not decrease the overall rate of infection. One such example is the use of the silver-impregnated cuff, which was shown to interrupt the intracutaneous migration of microorganisms and to decrease the risk of short-term catheter colonization and infection *(55)*. However, this silver-impregnated cuff has failed to protect against infections in long-term tunneled Hickman catheters. Measures that decrease the risk of colonization of the lumen of the catheter have been shown to be of benefit in decreasing the risk of catheter-associated infection for long-term CVCs *(89)*. However, some of the preventive measures suggested for prevention of long-term catheter–associated infections have limited data to support their use with respect to this type of catheter (Table 18-3).

Maximal Sterile Barriers

A prospective randomized study was conducted to test the efficacy of maximal sterile barriers in reducing infections associated with long-term nontunneled subclavian silicone catheters with a mean duration of placement of approximately 70 days *(90)*. Maximal sterile barrier precautions (which involve wearing sterile gloves and gown, a cap, and

TABLE 18-3

Measures for the Prevention of Long-Term Catheter–Related Infections

A. Traditional measures:
   a. Education of healthcare workers on vigilant catheter care
   b. Skilled infusion therapy team
   c. Hand hygiene
   d. Chlorhexidine cutaneous antisepsis
   e. Use of maximal sterile barrier precautions during CVC insertion
   f. Use the subclavian vein as the preferred insertion site and avoid femoral insertions
   g. Removal of unnecessary CVCs
B. Novel technology:
   i. Strongly recommended or well supported by evidence:
      a. Antimicrobial coating of catheters
      b. Flush solutions/antimicrobial catheter lock
      c. Chlorhexidine sponges
      d. Topical antibiotics at the insertion site
   ii. With limited supporting evidence:
      a. Antimicrobial hubs and connectors

using a large drape during insertion of the catheter) were compared with routine procedures (which involve wearing only sterile gloves and use of a small drape). Maximal sterile barrier precautions decreased the risk of catheter-related bacteremia from 0.5 per 1,000 catheter-days to 0.02 per 1,000 catheter-days. Long-term catheters consisted of nontunneled subclavian CVCs and PICC lines. A recent multicenter prospective randomized clinical trial conducted in Japan failed to demonstrate better prevention of CLABSI by maximal sterile barrier precautions compared with standard sterile barrier precautions (which involves the use of sterile gloves and a small drape during insertion of CVC) in surgical inpatients; however, this study was underpowered and might not negate the possible benefit of the maximal sterile barrier precautions *(91)*.

Hand washing, maximal sterile barrier precautions, skin cleansing using chlorhexidine, avoiding the femoral site if possible, and removing unnecessary catheters represent the five evidence-based procedures recommended by the CDC for having the greatest effect on the rate of CR-BSI and the lowest barriers to implementation (92,93). Although the five bundle elements remain the mainstay of protection against CLABSI associated with short-term CVC used in critically ill patients, its efficacy has not been studied during the insertion of long-term IVDs. Furthermore, its implementation is not easily enforceable, requires continuous educational training and compliance assessment for sustained efficacy, is usually associated with high cost and poor compliance, and does not completely prevent infection.

Skilled Infusion Therapy Team

In addition to decreasing the catheter-related infection rate by five- to eightfold, an experienced infusion therapy team has been shown to be cost-effective. Most of the studies were done with relatively short-term catheters (94–98). However, we have reported the finding that the duration of placement of nontunneled, noncuffed silicone catheters (mean duration of catheterization of 109 days) could be prolonged to approach that of the tunneled Hickman catheter with a very low infection rate of 1.4 per 1,000 catheter-days at the M. D. Anderson Cancer Center (2). This was attributed, at least in part, to the presence of a skilled infusion therapy team at our institution.

Tunneling

Tunneling of catheters is considered a standard of care for the prevention of long-term CLABSI. Because tunneled catheters have been associated with long durability and low infection rates, it has been assumed that tunneling decreases the risk of catheter-related infections and is the only safe option for the maintenance of long-term externalized silicone catheters. A prospective, randomized study evaluating the effect of tunneling on long-term silicone catheters was conducted by Andrivet et al. *(17)*, wherein the catheters were used in immunocompromised patients. The risk of catheter-related bacteremia associated with tunneled as compared with nontunneled catheters was 2% and 5%, respectively. The difference was not significant, probably due to the relatively small number of patients in each group (107 and 105 patients, respectively). In another study involving short-term polyurethane catheters placed in the internal jugular vein of critically ill patients, tunneled catheters were associated with a statistically significantly lower rate of catheter-related bacteremia than nontunneled catheters, suggesting that tunneling may decrease the risk of infection *(99)*. A prospective randomized multicenter trial showed that BSIs were four times less likely to originate from minocycline and rifampin (M-R)-impregnated, nontunneled, long-term catheters than from tunneled catheters (100). The cost saving related to simple insertion of a nontunneled M-R CVC at M. D. Anderson Cancer Center when compared to a tunneled, uncoated, long-term silicone CVC is at least $2,500. This cost saving is restricted only to insertion cost and does not include the added cost saving associated with the reduction of CLABSI related to the use of M-R CVC versus tunneled, uncoated CVC (100). The use of a M-R-impregnated, long-term CVC may help obviate the need for surgically implantable catheters (100).

Ports

The lowest rate of CR-BSI has been associated with the use of surgically implanted subcutaneous central venous ports. In a review by Crnich and Maki (8), in which they evaluated the results of 13 prospective studies of subcutaneous central venous ports, the pooled mean of CR-BSI rates associated with ports was at a low 0.2 per 1,000 catheter-days (95% confidence interval (CI) 0.1–0.2) (8). Another recent systematic review of 200 published prospective studies on different IVDs showed that all types of IVDs were associated with IVD-related BSI (101). Ports are especially useful for intermittent venous access needed for short durations such as with periodic chemotherapy administrations.

Antiseptic Dressings

A chlorhexidine-impregnated hydrophilic polyurethane foam dressing, which can be pressed firmly onto the skin at the catheter insertion site and then covered with a transparent polyurethane dressing, was shown to reduce site skin colonization as well as epidural catheter colonization *(102)*. It also prevented infection at the site of orthopedic traction pins in an animal model *(103)*. The chlorhexidine-impregnated sponge dressings were evaluated in a multicenter trial involving six neonatal ICU patients, where they were found to be similar to gauze and tape combined with periodic skin disinfection with 10% povidone-iodine, in preventing skin colonization and CR-BSI *(104)*. However, the use of these chlorhexidine dressings was associated with 15% incidence of dermatotoxicity in low birth weight neonates (<1,000 g). Another multicenter, prospective randomized controlled trial, demonstrated that the use of chlorhexidine gluconate–impregnated sponges used for intravascular catheter dressings in critically ill adult patients decreased the risk of major catheter-related infections by 60% despite a low baseline infection rate *(105)*.

A prospective randomized controlled trial showed that the use of chlorhexidine-impregnated wound dressings significantly reduced the incidence of central line–related infections in adult cancer patients with long-term CVC (106).

Intraluminal Antibiotic Locks

This prophylactic measure consists of flushing and filling the lumen of the catheter with antimicrobial agents and leaving the solution to dwell in the lumen of the catheter for 2 to 12 hours. Although heparin has become widely used

as an antithrombotic agent to maintain catheter patency, it has been shown to enhance staphylococcal biofilm formation when used at the relevant concentration of 1,000 U/ml used in catheters lock (107).

Various antimicrobial agents have been used as antimicrobial locks, often following an infection in a surgically implanted catheter in order to treat the infection without removal of the catheter *(108,109)*. Among the antimicrobial agents used were vancomycin, gentamicin, ciprofloxacin, cefazolin, erythromycin, nafcillin, ceftriaxone, clindamycin, fluconazole, and amphotericin B. Vancomycin in combination with heparin has been used as a daily flushing solution of tunneled CVCs and has been reported to significantly decrease the frequency of catheter-related bacteremia caused by vancomycin-susceptible gram-positive microorganisms colonizing the lumen *(110)*.

A meta-analysis of seven prospective randomized controlled trials showed that a vancomycin heparin lock or flush solution reduces the risk of BSI in high-risk patients with long-term CVCs *(111)*. However, with the emergence of resistant microorganisms, it is prudent to avoid using antibiotics that are commonly used in the therapy of BSIs (such as beta-lactam antibiotics, vancomycin, quinolones, and aminoglycosides) for prophylaxis against catheter infections. This is particularly true for vancomycin which has been shown to have little to no antimicrobial activity against microorganisms embedded in biofilm on catheter surfaces *(112–114)*.

Chelating agents such as ethylene diaminetetraacetic acid (EDTA) or citrate possess anticoagulation properties and enhance the activity of antimicrobials in eradicating bacteria and fungi embedded in biofilm *(115–120)*. A novel catheter flush solution consisting of low concentrations of minocycline and ethylenediaminetetraacetic acid (EDTA) has been developed. Minocycline is not commonly used in the treatment of systemic infections and does not have cross-resistance with vancomycin or beta-lactam antibiotics against resistant gram-positive bacteria. A flush solution of minocycline and EDTA (M-EDTA) was shown to have broad-spectrum and often synergistic activity against methicillin-resistant staphylococci, gram-negative bacilli, and *C. albicans*, and was found to prevent CR-BSIs in several complicated, high-risk patients *(121)*. Also, in a rabbit model, M-EDTA lock solution succeeded more than heparin alone and heparin–vancomycin in preventing catheter colonization, CR-BSI, and phlebitis in all of the study animals ($p < .01$) *(122)*. In that study, the M-EDTA lock solution also prevented tricuspid endocarditis, as did the heparin–vancomycin lock solution, more effectively than heparin alone ($p \leq .06$).

In a prospective randomized trial involving patients with long-term hemodialysis CVCs, M-EDTA flush solution significantly reduced rates of catheter colonization ($p = .005$) (123). Also, in another prospective pediatric cohort study, M-EDTA was used as a lock solution in 14 pediatric cancer patients with ports (124). There were no CR-BSIs, thrombotic events, or adverse events associated with the use of M-EDTA flush solution over a total of 2,073 catheter-days in comparison with a rate of 2.23 infections per 1,000 catheter-days in a control group that received heparin flush solution.

C. albicans is the most common fungal pathogen associated with colonization and biofilm formation on the surface of indwelling medical devices *(125,126)*. Ethanol has a potent anticandidal biofilm activity, anticoagulant property, and could be synergistic when combined with other antibiotics in lock solution *(127–129). In vitro* studies have shown the efficacy of ethanol, alone or in combination with other agents in preventing and eradicating biofilm formation *(127–129)*. A recent randomized clinical trial showed a nonsignificant reduction of CLABSI in patients receiving 70% ethanol locks compared to those receiving 0.9% NaCl locks for 15 minutes per day *(130)*. In addition, drug-related toxicities such as feeling of discomfort, facial redness or flushing, drowsiness, and alcohol taste were significantly higher in the patients receiving 70% ethanol lock compared to placebo. Hence, ethanol locks when used alone particularly at high concentrations might not be very useful for the prevention of CLABSIs. Although small clinical trials have shown promising results *(131–133)*, large prospective, randomized, controlled trials are needed to evaluate the role of ethanol (particularly lower concentration of 25%–50%) in combination with other agents such as biofilm-penetrating antimicrobials and chelator agents in the prevention and treatment of CLABSI *(128)*.

Taurolidine, a derivative of the amino acid taurine, is an antimicrobial agent, which in high concentrations (250–2,000 μg/mL) has inhibitory as well as cidal activities against many microorganisms *(134)*. The use of taurolidine lock solution reduced the rate of CR-BSI associated with the use of hemodialysis CVCs *(135)* and other long-term CVCs *(136)*. A combination of taurolidine and citrate-based catheter lock solution (Neutrollin; Biolink Corp., Norwell, MA) reduced bacterial counts in a catheter model by more than 99% *(137)*. The microorganisms affected included *S. aureus*, *S. epidermidis*, *P. aeruginosa*, *E. faecalis*, and *C. albicans*. Taurolidine–citrate significantly reduced biofilm on silicone disks in modified Robbins devices more than heparin treatment (by 4.8 logs vs. 1.7 logs, $p < .01$).

In a multicenter, prospective, randomized controlled trial in adult patients with end-stage renal disease receiving hemodialysis through a cuffed and tunneled CVC, Maki et al. demonstrated that a novel lock solution containing sodium citrate, methylene blue, and parabens significantly reduced the rate of CLABSI when compared to a heparin lock (0.24 vs. 0.82 infections per 1,000 catheter-days, respectively, with a relative risk of 0.29 [95% CI: 0.11–0.70]; $p = .005$) and provided a similar protection against thrombosis compared with heparin (138).

The issue of resistance developing with a wide use of prophylactic antibiotic lock solutions needs to be investigated thoroughly. However, currently, the CDC guidelines for the prevention of intravascular catheter-related infections do not recommend the routine use of prophylactic antibiotic lock solutions. The guidelines recommend the use only in special circumstances, such as in treating a patient with a long-term cuffed or tunneled catheter or port who has a history of multiple CLABSIs despite optimal maximal adherence to aseptic techniques (92).

Antimicrobial Coating of Catheters

Antimicrobial coating of catheters has been shown to be effective in reducing the rate of catheter-related infection in short-term polyurethane catheters. By coating the external surface of catheters with chlorhexidine plus silver

sulfadiazine (CH-SS), Maki et al. *(139)* showed that this combination did decrease the risk of colonization by nearly 50% and decreased the risk of catheter-related bacteremia by at least fourfold. A meta-analysis analyzed the results of 12 studies investigating the efficacy of catheters impregnated with CH-SS *(140)*. According to this analysis, the mean duration of catheterization with CH-SS catheters was between 5.1 and 11.2 days, and hence their efficacy is only proven for short-term catheterization. A second generation of catheters impregnated with CH-SS, in which the catheters are impregnated both externally and internally, significantly reduced catheter colonization more than uncoated catheters, but failed to reduce the risk of CR-BSI in two prospective randomized trials *(141,142)*. In a prospective, randomized multicenter study when CVCs impregnated with M-R on their external and internal surfaces were compared with first-generation CH-SS catheters, they were shown to be 12 times less likely to be associated with CR-BSI and three times less likely to be colonized. It was shown that the risk of catheter colonization was reduced by threefold and the risk of CLABSIs was reduced from 5% to 0%. Among catheters that remained in place for more than 7 days, the rate of CLABSI was significantly higher for catheters impregnated with CH-SS than for catheters impregnated with M-R (6.4% vs. 0.7%, respectively, $p = .01$) *(143)*. Another prospective randomized clinical trial comparing 182 long-term silicone CVCs impregnated with M-R to 174 nonimpregnated catheters showed that M-R catheters were safe and efficacious in preventing CRBSI in cancer patients. In this study, the rate of CLABSI was 0.25 per 1,000 catheter-days with the M-R-impregnated catheters versus 1.28 per 1,000 catheter-days with the nonimpregnated catheters ($p = .003$) (144). As previously mentioned, a randomized controlled trial showed that long-term nontunneled M-R-impregnated CVCs prevented CLABSI more effectively and at a lower cost than tunneled CVCs (100). A recent study conducted over a 7-year period demonstrated that M-R CVCs significantly decrease the rate of CLABSI in critically ill patients *(145)*.

Several meta-analyses demonstrated the effectiveness of antimicrobial catheters impregnated with CH-SS or M-R in preventing CLABSI (*146*,*147*,148). M-R CVCs outperform the antiseptic catheters and are preferred when long periods of catheterization are expected (148). The M-R CVCs were shown to have an antimicrobial activity with a half-life of 25 days against *S. epidermidis* compared to 3 days for CH-SS CVCs (149). In a randomized controlled trial, CH-SS CVCs did not decrease the rate of CLABSIs in patients with hematologic malignancies who had a mean duration of catheterization of 20 days (150).

Despite the significant evidence from multiple randomized controlled trials and several meta-analyses proving the efficacy of M-R-impregnated CVCs in decreasing CLABSI, concerns exist about the potential emergence of resistance to M-R developing with the prolonged use of such devices (151). *In vitro* exposure of gram-positive bacteria to rifampin and minocycline in combination did not lead to the emergence of resistance (152,153). In randomized clinical trials, no evidence of antibiotic resistance bacteria was noted after the use of M-R-impregnated catheters (*143*,144,*154,155*). A 7-year experience of extensive use of M-R CVC exceeding 0.5 million catheter-days demonstrated the lack of emergence of resistance to tetracycline or rifampin among clinical isolates of *S. aureus* and CNS on a hospital-wide level and in the intensive care unit *(145)*.

Currently, the CDC guidelines for the prevention of intravascular catheter-related infections recommend the use of antimicrobial CVC in adults whose catheter is expected to remain in place for more than 5 days, if rates of CR-BSI remain above the goal set by the individual institution after implementing aseptic techniques, including maximal sterile barrier precautions (92).

CHAPTER 19

Healthcare-Associated Bloodstream Infections

Trevor C. VanSchooneveld and Mark E. Rupp

Healthcare-associated bloodstream infections (HA-BSIs) are a significant and continuing problem in our present-day healthcare system. A variety of factors, including central venous catheterization, predispose patients toward development of infections involving the bloodstream. Pathogens causing these infections vary according to the primary site of infection and a variety of patient factors. Preventive efforts are generally directed at the primary site of invasion. This chapter summarizes general issues related to healthcare-associated bacteremia. More specific information can be found in chapters covering specific primary infections and pathogens.

INCIDENCE AND IMPACT

HA-BSIs are increasing in prevalence and result in significant morbidity, mortality, and economic cost. From 1975 to 1998, the proportion of healthcare-associated infections accounted for by BSIs increased from 5% to 17% *(1,2)*. McGowan and Shulman *(3)* noted from 1975 through the early 1990s that the rate of HA-BSI increased dramatically from approximately 2 to 4 episodes/1,000 discharges to 15 to 20 episodes/1,000 discharges. A recent review of data from the US Nationwide Inpatient Sample estimated the rate of HA-BSI at 21.6 episodes/1,000 admissions *(4)*. It is estimated that each year in the United States between 250,000 and 500,000 patients experience a HA-BSI and between 30,000 and 100,000 die from these infections *(4,5)*. A recent encouraging development has been a decrease in methicillin-resistant *Staphylococcus aureus* (MRSA) HA-BSIs *(6)*. The reason for this decline is not clear but possible explanations include changes in *S. aureus* epidemiology, the impact of hospital policies designed to decrease MRSA transmission, and widespread efforts to decrease rates of central venous catheter (CVC) infection.

The crude mortality associated with HA-BSI varies in published reports from 5% to 58% and depends on the microbial etiology and the underlying condition of the patient *(3)*. Over a 7-year observational period from 1995 to 2002, the Surveillance and Control of Pathogens of Epidemiological Importance (SCOPE) investigators analyzed over 24,000 cases of HA-BSI from 49 medical centers, and noted a crude mortality rate of 27%, ranging from 21% for coagulase-negative staphylococci to 40% for *Candida* sp. (7). However, attributable mortality is more difficult to ascertain. In some studies that controlled for confounding variables such as severity of illness, BSI was not noted to increase mortality *(8,9)*, while other investigators noted substantial increased mortality *(10,11)*. HA-BSIs result in dramatic increases in economic cost. The length of hospital stay is extended by 1 to 4 weeks at a cost of up to $40,000 per survivor *(10–14)*. There is no doubt that HA-BSI is a very significant problem associated with the current healthcare system and that efforts to better understand and prevent this problem are well warranted.

CLASSIFICATION AND DEFINITIONS

Although the definition of hospital-acquired BSI appears clear-cut, the application of the definition is, at times, confusing. HA-BSI is typically defined as the demonstration of a recognized pathogen in the bloodstream of a patient who has been hospitalized for >48 hours. BSIs can be further categorized as primary or secondary. When a microorganism isolated from the bloodstream originated from a healthcare-associated infection at another site (urinary tract, surgical site, etc.), the infection is classified as a secondary BSI. Conversely, primary BSIs occur without a recognizable focus of infection elsewhere. It should be noted, that BSIs stemming from intravascular catheters are classified as primary infections.

The Centers for Disease Control and Prevention (CDC) National Healthcare Safety Network (NHSN) previously defined BSI as "laboratory-confirmed BSI" or "clinical sepsis" *(15)*. However, the category of clinical sepsis, which applied to infants and neonates, is no longer considered an NHSN event for BSI (16). NHSN laboratory-confirmed primary BSI must meet at least one of the following criteria:

Criterion 1: Patient has a recognized pathogen cultured from one or more blood cultures *and* microorganism cultured from blood is *not* related to an infection at another site.

Criterion 2: Patient has at least *one* of the following signs or symptoms: fever (>38°C), chills, or hypotension (systolic pressure ≤90 mm Hg) *and* signs and symptoms and positive laboratory results are *not* related to an infection at another site *and* common skin contaminant (e.g., diphtheroids, *Bacillus* sp., *Propionibacterium* sp., coagulase-negative

staphylococci, viridans group streptococci, *Aerococcus* sp., or *Micrococcus* sp.) is cultured from *two* or more blood cultures drawn on *separate* occasions.

Criterion 3: Patient ≤1 year of age has at least *one* of the following signs or symptoms: fever (>38°C rectal), hypothermia (<37°C rectal), apnea, or bradycardia *and* signs and symptoms and positive laboratory results are *not* related to an infection at another site *and* common skin contaminant (e.g., diphtheroids, *Bacillus* sp., *Propionibacterium* sp., coagulase-negative staphylococci, viridans group streptococci, *Aerococcus* sp., or *Micrococcus* sp.) is cultured from *two* or more blood cultures drawn on *separate* occasions.

Although ambiguity is generally not encountered in evaluating patients with positive blood cultures, it is important to note that there is potentially wide practice variation with regard to procurement of blood cultures, and thus bias can be introduced when comparing rates of BSI from institution to institution or unit to unit *(17)*. In general, it is felt that clinicians in the United States are very liberal in their ordering of blood cultures, and it is doubtful that many clinically significant episodes of bacteremia escape detection. However, differentiating true, clinically significant BSI from blood culture contaminants can, at times, offer a challenge to clinicians. This is discussed in greater detail in subsequent sections.

Another issue that has complicated the definition of HA-BSI is the blurring of the distinction between healthcare-associated and community-acquired infections as many therapies traditionally used only in hospitalized patients are now performed routinely in the outpatient setting. Multiple studies have attempted to better define this new category of BSI usually defined as HA-BSI. Friedman et al. *(18)* observed that of 504 consecutive BSIs detected at an academic medical center and two associated community hospitals, 37% were considered healthcare-associated. Likewise, Siegman-Igra et al. *(19)* noted that 39% of 604 BSIs occurring in settings traditionally classified as community-acquired could be more accurately classified as healthcare-associated. An analysis of over 6,600 BSIs from a national database classified 55.3% of these infections as healthcare-associated using the criteria of first positive culture within 2 days of admission and any of the following: transfer from another healthcare facility including nursing home, receiving chronic hemodialysis, prior hospitalization within 30 days, and currently on immunosuppressive medication or with metastatic cancer (20). It has been noted that HA-BSIs have similar mortality rates to HA-BSI and are more likely to be due to drug-resistant pathogens including MRSA and extended-spectrum beta-lactamase (ESBL)-producing *Enterobacteriaceae (19,21)*. Table 19-1 summarizes the characteristics of BSI associated with different patient groups. These findings have significant implications for empiric antimicrobial treatment choices as patients with HA-BSI have been noted to be more likely to receive initially inadequate therapy, likely due to higher rates of resistant pathogens *(22)*. Further research is needed to better delineate this category of patients and their unique risk factors and characteristics.

CLINICAL MICROBIOLOGY AND DIAGNOSTIC TECHNIQUES

The diagnosis of BSI is dependent on the capacity to recover microbes from the blood. Most large laboratories utilize various automated blood culture systems that are reasonably comparable and are often continuously monitored. These automated systems have been reviewed elsewhere *(23)*, and an extensive discussion is beyond the scope of this chapter. In considering the reliability of recovery of nonfastidious microbes, issues with appropriate procurement likely outweigh the type of system used.

Several factors regarding blood culture reliability and contamination should be emphasized:

TABLE 19-1

Classification, Pathogens, and Outcomes from 6,697 Bacteremic Patients

Microorganism/Outcome	*CAB No. (%) (n = 2,524)*	*HCAB No. (%) (n = 3,705)*	*HAB No. (%) (n = 468)*
Gram positive	1,110 (44)	1,810 (48.9)[a]	229 (48.9)
MSSA	354 (14)	672 (18.1)[a]	92 (19.7)[a]
MRSA	95 (3.8)	280 (7.6)[a]	47 (10)[a]

Skin Preparation and Culture Technique

Inadequate skin preparation has been reported to be the most frequent cause of culture contamination *(24)*. A variety of products are available for skin preparation. Several studies have found that use of iodine tincture results in lower rates of contamination when compared to povidone iodine, which is thought to be due to the shorter drying time and rapidity of antimicrobial activity associated with the alcohol containing iodine tincture *(25–27)*. Similarly, a number of trials have observed that skin disinfection with alcoholic chlorhexidine resulted in fewer contaminated blood cultures than povidone iodine *(28,29)*. However, Calfee and Farr (30) observed no significant differences in contamination rates among four different skin antiseptics including povidone iodine, povidone iodine with 70% alcohol, isopropyl alcohol, and tincture of iodine. Studies comparing tincture of iodine and alcoholic chlorhexidine have noted no difference and both have very low rates of contamination *(31,32)*. Based on these studies, guidelines published by both the Infectious Disease Society of America and the American College of Critical Care Medicine recommend using either alcohol alone, chlorhexidine with alcohol, or tincture of iodine for skin decontamination *(33,34)*. Following appropriate skin preparation, if the blood vessel must be palpated, it should be done with a sterile glove. A new needle should be utilized for each attempt at venipuncture *(35)*. Blood should be promptly inoculated into culture bottles following disinfection of culture bottle top septums as they are not sterile. While a meta-analysis suggested the practice of changing needles between procurement of blood and inoculation of blood culture bottles decreased the rate of contamination from 3.7% to 2.0%, it is generally believed the risk of needle stick injury outweighs the benefit of this practice *(34,36)*.

Blood Volume Sampled

To maximize the diagnostic yield from blood cultures, an adequate amount of blood must be sampled. In many cases, the concentration of microorganisms in the bloodstream is ≤1 colony-forming unit (CFU)/mL, and therefore 10 to 20 mL of blood should be sampled to reliably detect bacteremia *(37,38)*. Mermel and Maki *(39)* calculated that the yield from blood cultures in adults increased 3% per milliliter of blood obtained. Unfortunately, the inadequate sampling of blood volume is frequent in many clinical centers *(39)*. Interestingly, inadequate blood volume has also been associated with increased rates of culture contamination *(40)*.

Timing and Number of Blood Cultures

The optimum time to draw blood cultures is when the number of microbes in the bloodstream is greatest, which unfortunately is 1 to 2 hours before the onset of symptoms *(41)*. Therefore, it is recommended to obtain blood cultures as soon as symptoms occur and preferably before antimicrobials are administered. Although it is common to wait 30 to 60 minutes between obtaining culture sets, Li et al. *(42)* found no advantage associated with this practice. The practice of drawing blood cultures with fever spikes does not appear to increase yield either *(43)*. Previous literature suggested that two to three blood cultures obtained over a 24-hour period could detect >99% of all bacteremias *(44,45)*. More recent literature suggests that three to four blood cultures over a 24-hour period may be necessary to detect >99% of bacteremias and recent guidelines have recommended this practice, particularly in the critically ill (*34*,*43*,46,*47*). Issues regarding repetitive blood cultures, the utility of anaerobic cultures, blood-to-broth ratios, and other clinical microbiology issues have been reviewed elsewhere *(48–50)*.

Sites for Obtaining Blood Cultures

Although it is generally recommended to avoid obtaining blood for cultures via intravascular catheters because of concern for contamination, the ease of vascular access, minimization of patient discomfort, and consideration of the catheter as a source of infection has made this a common clinical practice. Multiple studies have evaluated the utility of blood cultures drawn from catheters for the detection of BSI and a recent systematic review summarized their findings (*51*,*52*,53). Obtaining blood cultures from catheters increases the sensitivity for detection of bacteremia but is associated with increased isolation of contaminants and decreased positive predictive values. The sensitivity of a single blood culture from either a CVC or peripheral site is not considered adequate for detection of bacteremia and paired blood cultures from both sites are indicated if a blood stream infection is suspected *(33)*. A variety of new diagnostic techniques have been developed to evaluate the source of fever/bacteremia in patients with CVCs including semiquantitative superficial cultures, differential time to positivity and differential quantitative blood cultures *(54–56)*. These techniques, which are described in greater detail in Chapters 15 and 16, are based on the premise that patients with a catheter-associated infection have a greater burden of bacteria in blood drawn from the intravascular catheter than in blood drawn from the periphery. Recently published guidelines on the diagnosis of CVC infection consider both differential time to positivity and quantitative blood cultures acceptable methods for the diagnosis of CVC-related BSI *(33)*. Therefore, if clinicians are using catheter-drawn blood for culture, it should be paired with a sample drawn peripherally and the sites and times of procurement should be clearly documented.

INDICATIONS FOR BLOOD CULTURES

Indications for blood cultures are not standardized, but should be obtained as a routine study whenever there is a realistic possibility of a HA-BSI. Fever is generally the most common clinical marker for serious healthcare-associated infection, and blood cultures are usually included in the evaluation of fever in hospitalized patients. However, it should be noted that fever may be absent during episodes of bacteremia in certain patient populations such as the elderly, neonates, immunocompromised hosts, and persons with end-stage renal disease. Changes in mental status or functional status may be the most prominent findings associated with bacteremia in elderly patients or patients with renal dysfunction *(35,57)*. Likewise, bacteremia in neonates is often manifested by lethargy, feeding intolerance, apnea, cholestasis, and temperature instability rather than fever *(58,59)*.

If a BSI is identified by blood culture, it is generally not necessary to repeat blood cultures after appropriate treatment has been initiated. Patients who fail to improve despite appropriate antimicrobial therapy should have repeat blood cultures performed to assess for persistence of infection. Also, in the evaluation of *S. aureus* HA-BSI, many authorities would recommend repeating blood cultures to help assess whether a patient has endocarditis or other deep-seated staphylococcal infection. An exception to this practice are BSIs due to *Candida* species that require repeat blood cultures to document clearance and determine length of therapy *(60)*.

MICROBIAL ETIOLOGY OF HEALTHCARE-ASSOCIATED BSI

The microbial profile of HA-BSI has changed markedly over the past several decades in response to changes in patient population and antibiotic use. Throughout the 1970s, Enterobacteriaceae were the most common cause of HA-BSI *(61)*. During the 1980s, a relative decrease in bacteremia due to *Escherichia coli* and *Klebsiella pneumoniae* was observed, whereas the contribution due to coagulase-negative staphylococci, enterococci, and *Candida albicans* increased *(62)*. These changes were attributed to the widespread use of antibiotics with activity against Enterobacteriaceae and the increased utilization of indwelling medical devices, particularly intravascular catheters. Banerjee et al. *(63)*, reporting on secular trends in healthcare-associated primary BSIs during the 1980s, found that, depending on the type of hospital studied (small, ≤200 beds; large, ≥500 beds; teaching vs. nonteaching), the rate of bacteremia due to coagulase-negative staphylococci skyrocketed by 161% to 754% *(63)*. Similarly, enterococcal bacteremia increased by 120% to 197% and *Candida* sp. fungemia increased by 75% to 487% *(63)*. Another trend observed during the 1980s was a shift toward more antibiotic-resistant pathogens. Increased prevalence of antibiotic-resistance was observed in *Pseudomonas aeruginosa* and *Enterobacter cloacae* resistant to third-generation cephalosporins, *S. aureus* and coagulase- negative staphylococci resistant to methicillin, and enterococci resistant to high levels of aminoglycosides *(62)*.

These trends continued in the 1990s. Figure 19-1 illustrates the distribution of over 14,000 bloodstream isolates from the CDC's National Nosocomial Infection Surveillance (NNIS) hospitals from 1990 through 1996 *(64)*. BSI accounted for approximately 14% of healthcare-associated infections with gram-positive cocci including coagulase-negative staphylococci, *S. aureus*, and enterococci responsible for 56% of all HA-BSIs *(64)*. Unfortunately, since the mid-1990s, due to limitations in time and personnel resources, fewer and fewer hospitals participated in the hospital-wide surveillance component of the NNIS system and it was discontinued in 1999. However, the NNIS system continued to track healthcare-associated infections from targeted surveillance in intensive care units (ICUs). There was little change in the relative rank order of bloodstream isolates observed in ICU patients from 1990 to 1999. Table 19-2 summarizes this information (65). Pathogens varied by type of ICU with gram-negative pathogens such as *Enterobacter* sp. or *P. aeruginosa* causing BSI more frequently in burn ICUs than other types of ICUs (11.2% and 9.5%, respectively), whereas BSI due to *S. aureus* and coagulase-negative staphylococci occurred with greater frequency in coronary care and cardiothoracic ICU patients (23.2% and 42.7%, respectively) than in other ICUs (65).

NNIS has transitioned into the NHSN in the last decade and while NHSN includes a much larger number of institutions, it no longer reports HA-BSI data. Data on HA-BSIs has been less frequent as both national surveys and literature reports have focused on the syndromes responsible for HA-BSIs such as intravascular catheter infections, pneumonia, and UTI. Some literature has been published including a nationwide surveillance study (SCOPE) that described over 24,000 HA-BSIs from 1995 to 2002 (7). The gram-positive pathogens coagulase-negative staphylococci, *S. aureus*, and enterococci were most common in both ICU and non-ICU settings (62.5% and 59.3%, respectively). Coagulase-negative staphylococci, *Enterobacter* sp., *Serratia* sp., *Acinetobacter baumannii*, and *Candida* species were more common in the ICU while *S. aureus*, *Klebsiella* sp., and *E. coli* were more common in the general ward ($p < .001$). A notable finding in this study was the high incidence of BSIs due to *Candida* species, accounting for nearly 10% of HA-BSIs and increasing significantly from 8% in 1995 to 12% in 2002 ($p < .001$, trend analysis). *C. albicans* was the most common species isolated (54%) and *C. glabrata* (19%), *C. parapsilosis* (11%), and

E. coli	514 (2.3)
Other	3,774 (17.2)

(Reprinted from National Nosocomial Infections Surveillance (NNIS) System Report, data summary from January 1990–May 1999, issued June 1999. *Am J Infect Control* 1999;27:520–532, with permission from Elsevier.)

C. tropicalis (11%) were also frequently isolated (7). Other centers have noted similar trends with candidal BSIs making up 10% or more of HA-BSIs (66,*67*,*68*). Some institutions have recently described a reemergence of gram-negative pathogens causing HA-BSIs. In a tertiary care center in the US from 1999 to 2003 the number of BSIs caused by gram-negative microorganisms significantly increased from 15.9% to 24.1% ($p < .001$) while infections due to coagulase-negative staphylococci and *S. aureus* decreased over the same time period ($p < .007$) (66). These findings have not been described nationally, but in some centers gram-negative pathogens have eclipsed gram-positives as the most common microorganisms causing HA-BSIs *(69,70)*. Factors possibly contributing to the increase in gram-negative pathogens include improved practices in the placement and maintenance of CVCs leading to decreased line-related gram-positive infections, increasing resistance in gram-negative isolates, and the emergence of microorganisms such as *A. baumannii* as major pathogens in the ICU. These trends in the etiology of HA-BSIs are described in Table 19-3.

As previously mentioned, during the 1980s a trend was observed indicating that HA-BSIs were increasingly being caused by antibiotic-resistant pathogens. This trend continued in the 1990s and worsened in the first decade of the 21st century. Klevens et al. *(71)* compared NNIS microbiologic data for the period 1990–1994 to 2000–2004 and noted significant increases in MRSA BSIs (27.0–54.1%), ceftazidime-resistant *P. aeruginosa* pneumonias (16.6–22.7%), and ciprofloxacin-resistant *E. coli* urinary tract infections (UTIs) (0.9–9.8%). The most recently published data from the NNIS system, summarizing bacterial isolates from ICU and non-ICU inpatient areas from January 1998 to June 2004, indicate an alarming prevalence of antimicrobial resistance *(72)*. These data are shown in Table 19-4. Using data from the SCOPE study that included HA-BSI from 49 hospitals from 1995 to 2002, Wisplinghoff et al. (7) described significant increases in the isolation of MRSA (22–57%), ceftazidime-resistant *P. aeruginosa* (12–29%), and vancomycin-resistant *Enterococcus faecium* (47–70%). The rise of resistant pathogens is a global phenomenon as a survey of over 81,000 BSI from three continents noted 2- to 3-fold higher rates of MRSA (38.5%), vancomycin-resistant enterococci (13.3%), ESBL *Klebsiella* sp. (24.6%), and multidrug-resistant *P. aeruginosa* (9.0%) in HA-BSIs compared to community BSIs *(73)*.

SOURCES OF BACTEREMIA

Most episodes of primary or laboratory-confirmed HA-BSI without an obvious source are thought to be due to intravascular catheters. These infections are discussed in depth in Chapters 17 and 18. Prior to the widespread use of intravascular catheters, HA-BSIs were largely secondary to infections at other sites. During the 1960s and 1970s, approximately 75% of HA-BSIs were secondary to surgical site infections, intra-abdominal infections, infections of the urinary tract, pneumonia, or skin and soft tissue infections *(74,75)*. Approximately two-thirds of these infections were due to aerobic, gram-negative bacilli *(74)*. As previously mentioned, in more recent years primary BSI has become more prevalent and staphylococci and enterococci have become more prominent pathogens. Pittet and Wenzel (76) noted that from 1981 to 1992 the proportion of HA-BSIs classified as primary BSIs increased from 51% to 71%. Over the same time period, the proportion of HA-BSIs due to coagulase-negative staphylococci increased from 12% to 30% and those due to aerobic gram-negative rods fell from 52% to 29%. SCOPE study data from 1995 to 2002 classified 77% of HA-BSIs as primary with 31% of primary BSI attributed to infections of intravenous catheters (7). UTIs and lower respiratory tract infections were other common sources of BSI (6.5% and 6%, respectively). Corona et al. (77) described HA-BSIs in 26 different countries and classified 58.3% as primary with 45% of primary BSIs being catheter-related. Other frequent sources of BSI included the respiratory tract (15.4%), gastrointestinal tract (8.9%), and wound infections (5.7%). While infections of intravenous catheters are the most common source of device-related HA-BSI other sources may be more common in specific populations. In the elderly and those undergoing urologic procedures, infections due to urinary catheters are the most common source of BSIs *(78)*.

Rates of bacteremia vary due to the pathogen and site of infection. For example, although healthcare-associated UTIs are common and account for 30% to 40% of healthcare-associated infections, they result in secondary bacteremia in only 0.4% to 4% of cases *(79–81)*. The rate of bacteremia secondary to healthcare-associated UTI appears to be higher with pathogens such as *Serratia marcescens* (16%) and is lowest in low virulence microorganisms such as coagulase-negative staphylococci (1.8%) *(82)*. Allen et al. *(61)* found that bacteremia was associated with 3.3% of healthcare-associated UTIs, 6.2% of surgical site infections, and 8.6% of lower respiratory tract infections. Petti et al. *(83)* recently noted in a community hospital setting that 9.1% of surgical site infections were associated with bacteremia. *S. aureus* surgical site infection was associated with an almost 3-fold increased rate of bacteremia compared to other microbes *(83)*. Table 19-5 characterizes the relative contribution of various sites to overall rates of secondary bacteremia (7,76,77,*84*).

Two additional trends in the microbiology of HA-BSI should be noted. First, a significant proportion of BSIs are due to multiple microorganisms with up to 15% to 20% of HA-BSIs being polymicrobic *(85,86)*. Pittet and Wenzel (76) observed from 1980 to 1992 that polymicrobic HA-BSIs increased from 8 episodes/10,000 patient-days to approximately 20 episodes/10,000 patient-days, which equated to a rise from 11% to 14%. Polymicrobic infections are more common in elderly patients *(87)*, neonates *(88)*, patients with underlying gastrointestinal disorders or on parenteral nutrition *(89,90)*, and patients with underlying malignancies *(91)*. Polymicrobial BSIs are also frequent in patients with candidemia. Klotz et al. *(92)* found 24% of patients with candidemia also had synchronous bacteremia and 3% had more than one species of *Candida* present *(92)*. In addition, polymicrobic infections are more likely to be associated with mortality than monomicrobic infections *(93)*. A second trend is that along with an increase in HA-BSIs due to yeast, a shift in the microbiology of yeast has occurred. Increasingly, non-albicans *Candida* sp. are being recovered from blood cultures. Edmond et al. *(94)* noted that half of *Candida* BSIs were due to species other than *C. albicans*, and in 34 medical centers throughout North America and Latin America, 46% of 306 episodes of candidemia were due to non-albicans species of *Candida* (95). Similar trends were seen in NNIS system hospitals and a large multicenter database (PATH Alliance database) *(96,97)*. The increasing prevalence of non-albicans

species as a cause of HA-BSI has been attributed to the increased use of imidazole antifungal agents and CVCs *(67,98)*.

HEALTHCARE-ASSOCIATED BSI IN SPECIFIC PATIENT POPULATIONS AND CIRCUMSTANCES

HA-BSIs are more common in certain patient populations. Healthcare-associated infections in many of these specific groups of patients (elderly, neonates, ICU patients, burn patients, etc.) are discussed more thoroughly in other chapters of this text. The following is a concise summary of issues related more specifically to HA-BSIs.

Elderly and Long-Term Care

Older age (>65 years old) has been noted as a predisposing factor for healthcare-associated bacteremia and an indicator for worse outcome (99,*100–102*). Some authors have reported that the rates of BSIs per hospitalization in the elderly appear to be increasing, but others noted no change in ICU BSI incidence over 18 years *(102,103)*. Incidence rates of BSI increase with age and are highest in the most aged population *(104)*. Mortality rates also increase with age and hospital mortality has been reported to exceed 50% in patients over 75 years *(102)*. Mylotte et al. (99) reviewed the literature on BSIs in nursing home residents and estimated the incidence of BSI to be approximately 0.3 episodes/1,000 patient-days with mortality ranging from 18% to 35%. Staphylococcal species including *S. aureus* (12–24%) and coagulase-negative staphylococci (10–24%) are the most common cause of HA-BSI in the elderly, but *E. coli* is the single most common pathogen (9–32%) *(102,104,105)*. MRSA BSIs are more common among those older than 65 but other forms of resistance (vancomycin-resistant enterococci and ESBL-producing pathogens) have not been associated with increasing age *(73)*. Intravascular devices are the most common source of BSIs (14–41%) followed by the urinary tract (8–25%), lung (8–14%), and abdominal sources (7–11%) *(102,105,106)*.

Neonates and Pediatrics

General considerations regarding healthcare-associated infections in neonates and pediatric patients are discussed thoroughly in Section VI (Chapters 48–52). Previously BSI rates in these patients were generally higher than the adult population, but more recent data suggest a decrease in the rate of HA-BSI among children and neonates to near adult levels *(107)*. Neonatal BSI, during the initial period after birth, is most often a result of infection of the birth canal or maternally acquired microbes. Late-onset BSIs are usually due to healthcare-associated microorganisms. BSI is the most commonly observed healthcare-associated infection in neonates in the NHSN system and is estimated to account for 40% of infections depending on birth weight category *(5,107)*. Low birth weight is a major risk factor for HA-BSI with each 100 g decrease in birth weight conferring an additional 9% risk of BSI *(108)*. The U.S. National Institute of Child Health and Human Development documented that late-onset BSI was commonly due to the healthcare-associated pathogens coagulase-negative staphylococci (55%), *S. aureus* (9%), enterococci (5%), and *Candida* sp. (7%) *(109,110)*. A recent development has been the spread of MRSA to neonates. NNIS data from 1995 to 2004 showed a 308% increase in MRSA infections in neonatal ICUs *(111)*. Primary BSI is the most common source of HA-BSI in neonates with up to 85% of BSIs considered primary (*108*,112). Intravascular catheter use is the major risk factor for primary BSI in neonates, and data from the NHSN system from 2006 to 2008 documented BSI rates ranging from 1.9/1,000 CVC days to 3.9/1,000 CVC days, depending on birth weight classification *(107)*. Lastly, administration of certain therapies strongly increases the risk of bacteremia due to specific pathogens. For example, fungemia due to *Malassezia furfur* is seen almost exclusively in infants receiving intravenous lipids *(113)*.

Among nonneonatal pediatric patients BSIs were responsible for 21% to 34% of healthcare-associated infections depending on the age of the patient *(114,115)*. Risk factors for HA-BSI among children are similar to adults and include the use of CVCs and other invasive devices, but more unusual risk factors such as the presence of a genetic syndrome have also been reported to increase the

TABLE 19-6

Pathogens Isolated from Healthcare-Associated BSI in Neonates and Children ≤16 Years, 1995–2001, *n* = 3558

	Percentage of Isolates		
Pathogen	***Age <1 y***	***Age 1–5 y***	***Age >5 y***

(From Wisplinghoff H, Seifert H, Tallent SM, et al. Nosocomial bloodstream infections in pediatric patients in United States hospitals: epidemiology, clinical features and susceptibilities. *Pediatr Infect Dis J* 2003;22:686–691, with permission.)

risk of a BSI *(114,116)*. Similar to the experience observed in adult patients, the most frequently recovered pathogens are coagulase-negative staphylococci, enterococci, and *S. aureus*; *Enterobacter* sp. and *P. aeruginosa* are the most commonly observed gram-negative pathogens, and *C. albicans* is responsible for around 10% of pediatric HA-BSIs (112,*115*,*117*). Table 19-6 summarizes the pathogens found most commonly in neonatal and pediatric HA-BSIs (112).

ICU Patients

ICU patients account for a disproportional share of healthcare-associated infections compared to other patients. Despite only making up 5% to 10% of all hospital beds, a national survey of 49 institutions found 51% of all HA-BSIs occurred in the ICU (7). A large multicenter study in France, noted the risk of HA-BSI was 12-fold greater in ICU patients than in ward patients *(118)*. (For an extensive description of ICU-associated HA-BSI, see several recent reviews and studies that will be briefly discussed herein (119,*120–123*)). Table 19-7 summarizes observations from several studies concerning ICU BSI. The rate of HA-BSI in ICU patients has been increasing and is primarily due to intravascular catheters, lower respiratory tract infections, and intra-abdominal infections. A multicenter trial matched ICU HA-BSI cases on severity of underlying illness and risk-exposure time and noted that HA-BSIs were associated with a 3-fold increase in mortality *(123)*. Overall mortality is approximately estimated at 40%. Similar to HA-BSI throughout the hospital, the gram-positive cocci are the most frequent etiology and most often associated with line-associated or primary BSI. Gram-negative pathogens are more frequently present in lower respiratory tract, urinary tract, and surgical infections *(123)*. In a surgical ICU population Mainous et al. *(124)* noted that enterococci were the most common cause of HA-BSI. Polymicrobic infections are observed in 10% to 20% of bacteremic patients. The prevalence of polymicrobic infections depends on the ICU setting and is most common in surgical ICUs that care for a larger number of patients with intra-abdominal infections *(10,118,121)*.

Multidrug-resistant pathogens, particularly gram-negative microorganisms are an increasing problem in hospitals and resistance rates are higher in the ICU than the general ward *(73)*. These microorganisms are important not only for their infection control implications, but their presence impacts empiric therapy choices and patient outcomes. MRSA and multidrug-resistant *P. aeruginosa* were associated with increased mortality in primary BSI and hospital-acquired pneumonia, respectively, when compared to sensitive microorganisms of the same species *(125)*. The reason for increased mortality from resistant microorganisms may be inadequate initial therapy. A retrospective review of over 5,700 patients with septic shock, including 2,300 with BSI, noted inappropriate therapy (i.e., therapy not active against the pathogen) was given in 19.9% of cases and was associated with a 5-fold reduction in survival *(126)*. In contrast, Corona et al. (77) prospectively evaluated >1,700 ICU patients with BSI and found that initial receipt of ineffective therapy did not alter patient outcomes, but increasing age, severity of illness and immunosuppression were associated with increased mortality. Blot et al. *(127)* reviewed their experience in ICU patients with HA-BSI due to gram-negative bacteria and noted no increased association with mortality in relation to antimicrobial resistance. Similarly, no increase in mortality was observed in patients with HA-BSI due to ESBL-producing Enterobacteriaceae in comparison to those with bacteremia due to non–ESBL-producing strains *(128)*. Similar findings have been noted in patients with resistant gram positive infections such as VRE suggesting that underlying patient factors have the dominant effect on patient outcomes *(129)*. Determining the clinical significance of antimicrobial resistance is difficult as severely ill patients who are more likely to be colonized with resistant pathogens, and many studies that evaluate resistance have not controlled for the severity of underlying disease and further more definitive studies are still needed.

A. baumannii is an increasingly important gram-negative pathogen in the ICU. Healthcare-associated infections due to *A. baumannii* occur late in hospitalization (16–26 days after admission on average), most often involve the respiratory tract and intravascular catheters, and are typically multi-drug resistant (7,*130*,*131*). Risk factors independently associated with *A. baumannii* BSI have included immunosuppression, prior antibiotic therapy, unscheduled hospital admission, respiratory failure, prior ICU sepsis, previous *A. baumannii* colonization, cardiovascular failure, and the invasive procedure index *(130,131)*.

Neutropenia/Oncology Patients

It has long been known that patients with underlying oncologic diseases and/or neutropenia are more likely to experience HA-BSI *(132–134)*. These conditions are discussed more fully in Chapters 57 and 59. Rates of BSI vary based on the type of malignancy and the intensity of chemotherapy with patients with hematologic malignancies at a greater risk of HA-BSI than patients with solid tumors *(135)*. Gram-positive pathogens, most commonly coagulase-negative staphylococci, have

TABLE 19-7

Healthcare-Associated Bloodstream Infections in ICU Patients

Author/Reference/ Year(s)	*No. BSI*	*Rate of BSI (per 1,000 ICU admissions)*	*Source of BSI (%)*	*Mortality (%)*	*Comment*
Crowe et al. *(121)*, 1985–1996	315	Increased from 17.7 (1985) to 80.3 (1996)	IVC 24.5, LRTI 39.7, GI 7.3, UTI 4.1, SSI 2.2, CNS 5.1, Unk 8.9	44.4	Single ICU
Valles et al. *(120)*, 1993	590	36	IVC 37.1, LRTI 17.5, GI 6.1, UTI 5.9, SSI 2.4, Unk 28.1, Other 2.9	41.6	Multicenter study, length of ICU stay for patients with BSI 28.5 days
Edgeworth et al. *(122)*, 1971–1995	486	Increased from 17.4 (1971–1975) to 38 (1991–1995)	IVC 62, LRTI 3, GI 6.9, UTI 2.4, SSI 3, Unk 22.5, Other 2.9	Decreased from 44% (1971–1975) to 31% (1991–1995)	Single ICU

IVC, intravenous catheter; LRTI, lower respiratory tract infection; GI, gastrointestinal/intra-abdominal; UTI, urinary tract infection; SSI, surgical site/skin, soft tissue infection; CNS, central nervous system; Unk, unknown.

replaced gram-negative pathogens as the most frequently isolated etiologic agents *(136,137)*. This is likely due to the increased use of intravascular catheters and widespread use of prophylactic agents directed at gram-negative microorganisms for patients with neutropenia *(136,138)*. Risk factors for development of BSI in this population include hematologic malignancy, cytotoxic chemotherapy resulting in neutropenia and mucositis, graft versus host disease in bone marrow transplant patients, and the presence of intravascular catheters or other invasive devices (*132*,*134*,*139*,140).

Cirrhosis/Chronic Liver Disease

Patients with cirrhosis are predisposed to a variety of infectious complications including bacterial peritonitis and HA-BSI *(141)*. Campillo et al. *(142)* studied 200 cirrhotic patients in whom 194 episodes of bacterial peritonitis and 119 episodes of BSI were documented over a 5-year period; 93.3% of these infections were healthcare-associated, and *S. aureus*, specifically MRSA, was the most commonly observed pathogen, responsible for 39.5% of cases. The mortality rate was 49.5% for patients with healthcare-associated BSI versus 23.8% for patients with community-acquired BSI *(142)*.

Burn Patients

Thermal injury destroys the barrier function of the skin and is often complicated by burn wound infection and bacteremia *(143)*. *S. aureus*, particularly MRSA is the most frequent pathogen encountered in BSI in burn patients, followed by *P. aeruginosa* and other healthcare-associated gram-negative bacilli *(144–146)*. Enterococci and *Candida* have become more problematic in more recent years *(144–146)*.

Spinal Cord Injury Patients

HA-BSI in spinal cord injury patients is largely secondary to UTI (25–47%), infected pressure sores (19%), and pneumonia (9%) *(147,148)*. Resistance to antibiotics is common in this population with up to 65% of patients having resistant pathogens including MRSA and multidrug-resistant gram-negative bacilli *(149)*. Predisposing conditions include indwelling urinary catheters, ventilator dependency in quadriplegics, and pressure sores. Prevention of BSI requires prevention of the primary infectious complications associated with spinal cord injury. HA-BSIs in patients with spinal cord injuries are discussed more fully in Chapter 56.

Hemodialysis

Over 300,000 persons are maintained on hemodialysis in the United States. These patients experience BSI at a rate of approximately 0.6 BSI/1,000 patient-days, which equates to approximately 65,000 BSIs per year *(150)*. Approximately 80% of BSIs in hemodialysis patients are related to vascular access and 20% are secondary to infections at other sites, most frequently UTI and lower respiratory tract infections *(17)*. Primary BSI is much more likely in patients whose vascular access is achieved through intravascular catheters than those with arteriovenous fistula or synthetic grafts. Klevens et al. *(5)* summarized data reported by 32 dialysis centers to NHSN in 2006 and noted rates of BSI per 100 patient-months based on the type of access is as follows: fistula (0.5), graft (0.9), permanent central line (4.2), and temporary central line (27.1). Primary HA-BSI in hemodialysis patients is described more fully in Chapter 63.

Solid Organ Transplant Patients

Healthcare-associated infections in solid organ transplant recipients are discussed in detail in Chapter 58. A few specific issues regarding HA-BSI are as follows:

Renal Prior to the widespread use of posttransplant antibiotics, 50% to 70% of renal transplant patients developed UTI with a 40% incidence of bacteremia *(151)*. Although prophylactic antibiotics have significantly reduced the incidence of UTI to 5% to 10%, UTI remains responsible for 40% to 60% of episodes of bacteremia in kidney transplant patients *(152,153)*. Gram-negative bacilli are responsible for between 60% and 80% of bloodstream isolates, with *E. coli*, *Pseudomonas* sp., *Klebsiella* sp., and other Enterobacteriaceae most prominently represented *(152,153)*.

Liver HA-BSI occurs in approximately 10% of liver transplant recipients *(153)*. The most common source of BSIs is intravascular catheters and is predominantly due to gram-positive cocci *(153,154)*. HA-BSIs due to gram-negative bacilli have been increasing in frequency and are usually secondary to intra-abdominal or biliary tract infections *(155–157)*. Antibiotic-resistant pathogens including MRSA, VRE, and ESBL-producing gram-negative bacilli are being increasingly described as significant pathogens following liver transplantation and are associated with significant morbidity and mortality *(153,155)*.

Small Bowel Healthcare-associated bacteremia is a common complication of small-bowel transplantation with approximately 80% of small-bowel recipients developing at least one bacterial infection within the first 2 months after transplant *(158)*. Intravascular catheter and intra-abdominal infections are the most common sources in this patient group *(158,159)*. BSIs also occur in patients with organ rejection due to altered permeability of the small-bowel allograft *(160)*.

Lung Approximately 10% to 25% of lung transplant recipients experience a BSI within the year after transplant with pulmonary and line-related BSI being most common *(153,161,162)*. MRSA, *P. aeruginosa*, and *A. baumannii,* and *Candida* species are commonly observed pathogens *(153,161,162)*.

Heart HA-BSI occurs in roughly 10% of heart transplant recipients and most commonly stems from a pulmonary, intravascular catheter, or surgical site source *(153,163)*.

Pancreas HA-BSI occurs in 10% to 20% of pancreatic transplant patients *(153,157,164)*. Surgical site infections, line-related BSI, and UTIs (particularly in kidney-pancreas transplant patients) are the most common identifiable sources for bacteremia.

Transient Bacteremia

A large variety of medical procedures can result in transient bacteremia. Although many of these episodes might not be considered "healthcare-associated" in a strict classification scheme, they would oftentimes qualify as "healthcare-associated" bacteremia. In most instances, transient healthcare-associated bacteremia does not result in significant infection due to efficient host defense mechanisms designed to filter and interdict circulating pathogens. However, in some groups of patients, transient bacteremia can result in infection. Roberts et al. *(86)* noted that 7% of almost 2,000 positive blood cultures were due to transient bacteremia; 71.6% of these episodes were due to gram-positive cocci (39% coagulase-negative staphylococci, 23% viridans streptococci). Transient bacteremia has been well documented to result from dental procedures. Although tooth brushing and tooth flossing cannot usually be considered a healthcare-associated source, they result in transient bacteremia in up to 86% of patients *(165–167)*. Similarly, tooth extraction results in a very high percentage of patients experiencing transient bacteremia *(168,169)*, and antibiotic prophylaxis is recommended to prevent endocarditis in patients at high risk for developing this condition *(170)*. Numerous other procedures have been documented to result in transient bacteremia and occasional infection and include endotracheal intubation *(171,172)*; lachrymal duct probing *(173)*; burn wound manipulation *(174)*; gastrointestinal endoscopy, including gastroscopy, scleral therapy, sigmoidoscopy, colonoscopy, esophageal dilatation, and polypectomy *(175–180)*; chorionic villous sampling *(181)*; nephrostomy tube manipulation *(182)*; minor dermatologic surgery *(183,184)*; urologic endoscopy and transurethral prostatic resection *(185)*; replacement of intrauterine contraceptive devices *(186)*; barium enema *(187)*; and percutaneous liver biopsy *(188)*. The significance of bacteremia in most of these settings is debatable, and the rationale for and benefits of antibiotic prophylaxis is often minimal *(170,189,190)*.

BLOOD CULTURE CONTAMINATION OR PSEUDOBACTEREMIA

Pseudobacteremia, false-positive blood cultures, and blood culture contamination all refer to the problem in which microbes from a site outside the bloodstream are introduced into the sample of blood obtained for culture. This is a widespread phenomenon and occurs in 1% to 5% of cultures even under optimal conditions and up to 50% of positive cultures may represent contamination *(24,48,191,192)*. The implications of blood culture contamination are significant and include increased cost due to additional cultures and tests needed to investigate culture positivity, unnecessary antibiotics, side effects and toxicity due to the antibiotics, increased length of hospital stay and inappropriate admission to the hospital. The total excess cost associated with blood culture contamination was $4,385/patient in one study and $4,100/patient in another *(26,193)*.

Differentiating contamination from true bacteremia must be done clinically by consideration of the microbe recovered from the blood, clinical presentation, number and source of positive cultures (line vs. peripheral), and incubation time to positivity. It should be noted, however, that discounting single positive cultures with skin flora microbes (coagulase-negative staphylococci) may lead to misdiagnosis in up to 25% of clinically significant bacteremic episodes due to these microorganisms, particularly in patients with CVCs (*35*,53). Measures to prevent contamination were discussed in the section on clinical microbiology (see also Chapter 9).

PREVENTION OF HEALTHCARE-ASSOCIATED BACTEREMIA

The prevention of HA-BSI requires prevention of intravascular catheter infections and other sites of infection (pneumonia, UTI, wound infection, etc.). Prevention of infection associated with intravascular catheters is best achieved by having catheters inserted in the least infection prone site (subclavian vein) by trained personnel using appropriate precautions (full sterile barrier precautions) and effective skin antisepsis (chlorhexidine). Additionally, great care must be exercised in accessing the catheters and in routine site care. The combination of these interventions into a standardized protocol has been shown to be highly effective *(194)*. These measures are discussed in detail in Chapters 17 and 18 and both the CDC Hospital Infection Control Practices Advisory Committee (HICPAC) and The Society for Healthcare Epidemiology of America (SHEA) have published guidelines addressing these practices *(195)*.

Similarly, to prevent urinary catheter–associated infection and the potential complication of HA-BSI both CDC HICPAC and SHEA have recently published evidenced based guidelines recommending that urinary catheters should be used only when necessary, inserted with careful attention to aseptic technique, carefully maintained, and removed as soon as possible *(196,197)*. The use of antiseptic-bonded urinary catheters has shown promise in prevention of healthcare-associated UTI, although further research is needed to clarify the role of coated catheters and their routine use is not currently recommended *(80,196–198)*. These preventive measures are discussed in greater detail in Chapter 20.

Prevention of healthcare-associated and hospital-acquired pneumonia requires a multidisciplinary approach designed for the provision of appropriate care to patients receiving mechanical ventilation and other high-risk groups. Both the CDC HICPAC and SHEA have issued guidelines for the prevention of healthcare-associated pneumonia and ventilator-associated pneumonia *(199,200)*. Strategies advocated include minimizing the use and duration of invasive ventilation, minimizing contamination of respiratory equipment, following rigorous hygiene and infection control practices, preventing aerodigestive colonization with pathogens, and taking steps to prevent subsequent aspiration of these pathogens (see also Chapter 22).

Prevention of surgical site infections requires careful attention to preoperative risk factor reduction, timely administration of prophylactic antibiotics, aseptic surgical technique, and appropriate wound care. A more comprehensive discussion can be found in Chapter 21 and the CDC HICPAC and SHEA guidelines *(201,202)*.

Specific recommendations for prevention of healthcare-associated infection and, hence, secondary bacteremia can be found throughout this text in sections detailing specific infections and specific patient populations and care settings.

PREDICTION MODELS FOR HEALTHCARE-ASSOCIATED BSI AND CHALLENGES FOR THE FUTURE

Clinicians tend to make decisions regarding diagnosis and prognosis based on overall clinical judgment and anecdotal experience. Unfortunately, the inability of physicians to accurately predict the presence of bacteremia has been noted *(203)*. Therefore, investigators have attempted to develop quantitative predictive models to assist clinicians in their recognition of bacteremic patients. HA-BSIs are associated with a variety of risk factors, many of which have been previously discussed, such as age, use of intravascular catheters, underlying diseases and conditions, severity of illness, and healthcare worker understaffing. Taking many of these factors into account, a number of investigators have developed predictive models *(204–207)*. In general, these models are not specific for HA-BSI, and their clinical utility remains unknown. Recently, as our understanding of the pathogenesis of sepsis has improved, a number of investigators have attempted to correlate various proinflammatory markers and other factors with bacteremia and outcome in several patient populations *(208,209)*. One of the most promising markers is the molecule procalcitonin. Procalcitonin elevations are predictive of systemic bacterial infection and elevations in procalcitonin have been found useful in the prediction of BSIs *(210–212)*. The combination of clinical predictive models with biomarkers such as procalcitonin, particularly if coupled with electronic decisions support, holds the most promise for predicting BSI. These markers and models have not been specifically applied to patients with healthcare-associated infections, and further validation is required.

HA-BSIs will likely remain a significant medical problem as the number of high-risk patients and the use of invasive devices continues to increase. Increased numbers of outpatient surgical procedures, shorter hospital stay, utilization of outpatient intravenous infusion services, and expanding populations of hemodialysis patients, residents of long-term care facilities, and immunocompromised hosts will influence the occurrence of BSI. Healthcare epidemiologists will continue to be challenged with the question of how to operate surveillance systems to monitor HA-BSI in the rapidly changing healthcare arena. It is encouraging to note that an improved understanding of the pathogenesis, predisposing risk factors, and underlying causes of HA-BSI has led to numerous evidence-based interventions that have had a significant impact on healthcare-associated infection rates. Future work will hopefully lead to further improvement in prevention and detection of this ongoing problem.

CHAPTER 20

Healthcare-Associated Urinary Tract Infections

John P. Burke and David J. Pombo

Urinary tract infections (UTIs) are the most common healthcare-associated infections in both acute care hospitals and long-term care facilities, accounting for about 40% of all healthcare-associated infections and constituting a major source for healthcare-associated septicemia and related mortality. The rates of healthcare-associated UTIs are similar in both adult and pediatric patients *(1)*, and nearly all such infections are associated with urinary tract instrumentation. In acute care hospitals, the vast majority of UTIs occur in patients with temporary indwelling bladder catheters; the remaining ones are usually related to cystoscopy and other urologic procedures. The costs for the prevention, detection, treatment, and complications of these infections add significantly to the nation's healthcare bill.

The catheterized urinary tract is also a model of the growing problem of infections related to the placement of a foreign body in a patient's tissues. So-called device-associated infections are important both because of their high frequency and expanding number of different types of devices, and because they appear to be the most preventable of all healthcare-associated infections *(2)*. Their prevention depends on the oldest and most basic tenets of infection control as well as on the promise of technologic advances to develop safer instruments *(3)*. By virtue of being device-related and the most common healthcare-associated infection, catheter-associated UTIs (CA-UTI) are also increasingly a focus of the patient safety movement.

Urinary catheters are characterized by site of insertion (e.g., urethral, suprapubic, or nephrostomy) and by duration of use (e.g., intermittent or indwelling). Modern catheters are typically manufactured of latex rubber, silicone- or Teflon-coated latex rubber, or solid silicone, and come in a bewildering variety of types and sizes *(4)*. The indwelling Foley catheter with a retention balloon was first developed in 1927 by Frederick E. B. Foley to control bleeding in patients after transurethral prostatectomy *(5,6)* and is still essential to modern medical care. It is used today to drain the functionally or anatomically obstructed urinary tract, to control drainage in incontinent patients, and to obtain precise measurement of urinary output (7). Although the most mundane of invasive devices, it is the single most frequent cause of healthcare-associated infection. Major questions regarding its use and care—not to mention alternatives to its use—remain unanswered.

Infections associated with urinary catheters occur in both endemic and epidemic circumstances; common-source outbreaks are infrequent, although an estimated 15% of endemic infections occur in clusters, presumably from cross-infection *(8)*. Most TIs—whether endemic or epidemic—are asymptomatic, and removal of the catheter is usually curative. The usually benign nature of catheter-associated UTIs and the perception that they are easily treated by antibiotics may inhibit aggressive measures for both their prevention and their recognition.

Nevertheless, today's complacency of clinicians toward the continued high occurrence of UTIs should not diminish recognition of the remarkable achievements of the last several decades in their prevention. Indeed, this is one of the most successful chapters in the history of infection control. In the past, UTIs were generally accepted as an inevitable consequence of indwelling bladder catheterization. However, in the 1950s, the effectiveness of closed sterile urinary drainage, which had first been proposed by Cuthbert Dukes at London's St. Mark's Hospital more than 30 years earlier (9), was finally established. Its introduction proved a landmark in infection control (*10,12*,13). Commercially available systems for closed drainage into sterile plastic bags now enable the prevention of UTIs in 70% to 85% of patients with temporary indwelling catheters (*14*,15,16,*17*).

The benefits of closed drainage systems have not been fully documented because routine surveillance of healthcare-associated infections did not exist before the 1970s. Furthermore, current surveillance methods that focus on catheter days are a recent development. According to a recent National Healthcare Safety Network (NHSN) report, healthcare-associated UTI rates ranged from 0.4 to 6.6 per 1,000 urinary catheter-days for the 10th to 90th percentile in medical/surgical intensive care units at major teaching hospitals *(18)*. Thus, in contrast to the era prior to closed drainage systems, even in severely ill patients the use of closed sterile drainage, when properly maintained, currently prevents infection in the overwhelming majority of patients in whom this device is placed for short-term use.

The challenge of preventing UTIs has multiplied with changes in the character of hospitalized populations. These changes are often enumerated: the increased numbers of patients with advanced age and more severe underlying illnesses, the emergence of specialized units for the care of

critically ill patients, the increased use of multiple invasive devices, the growing population of immunosuppressed patients, and the expanding use of organ transplantation. Such factors may have increased both the use of indwelling catheters and the susceptibility of catheterized patients to infection. Even today, despite significant progress, virtually all patients with chronic indwelling bladder catheters are continuously infected. Moreover, as a result of the extensive use of broad-spectrum antimicrobial agents and the emergence of multiply resistant pathogens, patients with urinary catheter–associated UTIs also harbor an increasingly formidable reservoir of antibiotic-resistant pathogens *(19–22)*.

All urinary catheters may induce UTIs, but indwelling catheters have additional hazards; for example, they may also obstruct the periurethral glands, producing urethritis, epididymitis, or urethral stricture. Paul Beeson (23) was one of the first, in 1958, to advise caution in the use of urinary catheters: "At times, the catheter is indispensable for therapy and there are many good indications for its use. Nevertheless, the decision to use the instrument should be made with the knowledge that it involves the risk of producing serious disease which is often difficult to treat." Many investigators, stimulated by Beeson's admonition and the controversy it aroused, have added to our knowledge of the pathogenesis, epidemiology, and prevention of these infections. Although the remaining problems should not be underestimated, the grounds for optimism have been summarized by Calvin Kunin *(24)*: "In the current era of magnificent biotechnological advances, we should be able to solve the apparently simple but very important problem of draining the urinary bladder without producing infection."

EPIDEMIOLOGY

Catheter Use

The problem of healthcare-associated UTI appears to be deceptively simple: the major extrinsic risk factor is the use of a device that bypasses host defense mechanisms and allows microorganisms to grow in normally sterile body sites. Yet, the pathogenesis is far more complex than is implied by a purely mechanical model, and the epidemiology of the use and complications of urinary catheters is today understood only in its broad outlines.

The relative neglect of this problem by investigators undoubtedly reflects the low importance assigned to UTIs both by clinicians and by infection control programs. Indeed, in 2001, Jarvis *(25)* reported no epidemics of UTIs among 114 healthcare-associated outbreaks that the Centers for Disease Control and Prevention (CDC) investigated on-site in the previous decade *(25)*. Although this could suggest that the CDC did not elect to participate for various reasons or that individual hospitals simply did not request the CDC's help, underreporting or failures of surveillance are also likely explanations.

Healthcare-associated UTIs present unique challenges for epidemiologists. Because endemic UTIs occur throughout the hospital and because healthcare-associated epidemics often involve multiple sites of infection, epidemic rates of catheter-associated UTIs may not be readily apparent unless they involve an unusual microbial species *(26)*. Indwelling urinary catheters are used in nearly all hospital nursing units, unlike ventilators and many other devices. For this reason, healthcare-associated UTIs have complex behavioral and social determinants.

Duration of indwelling catheterization is the most important risk factor for the development of catheter-associated infection. Overall, the mean and median durations of catheterization in acute care hospitals are 2 and 4 days, respectively, and catheters are removed within 7 days in nearly 70% of patients *(27)*. Although the prevalence of infection increases steadily with extended durations of catheterization, the daily incidence of newly acquired infection is relatively constant during closed drainage, at least for the first 10 days, with 2% to 16% of previously uninfected patients acquiring infection each day (28,29). Infection becomes nearly universal by 30 days. Nonetheless, this is a dramatic improvement over open drainage systems, for which universal infection followed just 4 days after insertion *(30)*.

Thus, the principal benefit of closed drainage has been to delay, if not prevent, the onset of infection. True prevention begins by avoiding unnecessary catheter use. Catheters that must be used should be removed at the earliest possible time. Unfortunately, epidemiologists have not fully exploited the potential of these simple principles. Studies in many countries suggest that more restrictive policies for catheter use would be beneficial *(31–45)*. Though patterns of use in other countries may differ from those in the United States, investigators in Denmark and Sweden determined that indwelling catheters were used in 13% of patients and 12% of hospital days, respectively, and there was great variation between hospitals for the same type of nursing service *(32,33)*. Catheter usage is most prevalent in ICUs; data from NHSN that examine utilization of urinary catheters indicate that 54% to 90% of all ICU days in medical/surgical intensive care units at major teaching hospitals involve the use of a urinary catheter, in the lowest 10th percentile to the 90th percentile, respectively, of reporting hospitals *(18)*. A study in Israel suggested that patients with intermediate durations of catheterization (7–30 days) and who are catheterized for the indications of obstruction or incontinence are a high-risk group that may benefit most from intervention *(35)*. Such patients had a higher daily risk (8.6%) of acquiring infection even during the early period of catheterization. In Canada, an investigation of overutilization of indwelling urinary catheters in a large tertiary-care hospital found that 20.3% of patients admitted via the emergency room were catheterized upon admission *(36)*. Furthermore, 50% of catheters were inserted for unjustifiable reasons and 60% of those patients who subsequently developed UTI did not meet the study's criteria for justifiable catheterization. Another study found that 21% of catheterized medical patients did not have any initial indication for placement of the urinary catheter and that continued catheterization was unjustified in 47% of patient-days studied *(37)*.

Other recent studies have produced similar findings. For example, 10.7% of patients on a medical service had an indwelling urinary catheter inserted within the first 24 hours, with 91% having been placed in the emergency room and 38% deemed inappropriate *(38)*. Another study

of emergency department patients found appropriate indication for catheter placement correlated with documentation of a physician order in the chart; only 52% were deemed appropriate in those without orders versus 73% to 82% with orders *(46)*. In a point prevalence study from Spain, only 22% of patients had a correct indication with adequate drainage systems *(39)*.

Lack of awareness of the presence of an indwelling catheter is a further problem. One group found that physicians were not aware of the catheter status in 28% of their patients and in as many as 41% of those whose catheterization was judged inappropriate *(40)*. Thus, physicians appear to discount the importance of the urinary catheter, leading to overuse and misuse, for example, for inappropriate indications such as nursing staff convenience. In a study of patients with urinary incontinence, 37.5% were catheterized even though 55.5% of these were previously incontinent before admission to hospital and had managed this problem by other noninvasive methods. The decision to catheterize was made by physicians in 31.7% and by nursing staff in 37.3% *(41)*. Recent studies directed at prevention of unnecessary catheter use have shown some success of nursing education as a means to reduce the use of urinary catheters. Reinforcing strict adherence to approved indications and use of alternatives to bladder catheterization in non-ICU settings were associated with decreased overall incidence of healthcare-associated UTI through reduction in catheter use. CA-UTI incidence in those with bladder catheters did not change *(44)*. Less comprehensive approaches to reduce duration of urinary catheter use, such as simple reminder systems, have been shown to reduce the median duration of catheter use in an ICU setting from 5 to 4 days *(47)*, without an effect on infection rates. However, a recent meta-analysis of stop orders and reminders for removal of urinary catheters concluded that both approaches appear to reduce rates of infection *(48)*.

All the above studies emphasize that catheter use is frequently inappropriate; inattention to both the proper indications for catheter use and the catheter status in patients appears to be an important factor. Potential solutions include the implementation of hospital-wide protocols for catheter insertion and continued usage, such as allowing removal of a catheter by a nurse without a physician's order, and systems for computer-based order entry of indwelling catheters *(42,43)*.

Magnitude of the Problem

Incidence and Costs From a broad epidemiologic perspective, the problem of catheter-associated infections acquires force from the magnitude of the population affected. Each year, 3 to 6 million of the 33 million patients admitted to acute care hospitals in the United States receive indwelling catheters. It has been estimated that about 15% to 25% of patients in general hospitals have a catheter inserted sometime during their stay *(49)*, and that the prevalence of urinary catheters has increased over recent decades *(50)*. The problem encompasses many different medical specialties, local practice patterns, and geographical differences. For example, in a French urology department, 52.4% of the patients received indwelling catheters and the incidence of catheter-related UTI was 13% *(51)*. By contrast, in a pediatric population, healthcare-associated UTI was the fifth most common healthcare-associated infection and only 50% of patients with healthcare-associated UTIs had urethral instrumentation *(52)*. According to an older estimate performed by the CDC, there were 2.39 healthcare-associated UTIs per 100 hospital admissions in 1975 to 1976 *(53)*. Recent NHSN reports provide data on both catheter-associated UTI and urinary catheter utilization rates for a variety of patient settings. For the category of medical/surgical inpatient wards, the largest single category, the pooled mean data suggest that urinary catheters were utilized in 22% of patient days and infection developed in 5.9 patients per 1,000 catheter days *(18)*. In 1992, the CDC estimated that more than 900,000 healthcare-associated UTIs occurred in the United States, and that the resulting extra charges exceeded $600 million *(54)*. This represented nearly 14% of the total charges for healthcare-associated infections, estimated to be $4.5 billion.

These figures, however, may markedly understate the actual costs of UTIs, since they are based on decades-old estimates of an expected increased length of stay of only 1 day and extra charges of $680 (1992 dollars) for each UTI. Moreover, charges reflect cost shifting, and therefore are an inaccurate measure of true costs. Using attribution methods in a case-referent study of true costs at the Salt Lake City LDS Hospital from 1990 to 1992, the mean attributable difference in length of stay for patients with healthcare-associated UTIs was 3.8 days, and the mean increase in hospital costs was $3,803 *(55)*. If this is representative of all US hospitals, the true national cost of healthcare-associated UTIs is likely to be more than $3 billion.

In the managed care environment, costs are a financial loss to healthcare institutions. Thus, market forces should revive interest in preventing all healthcare-associated infections, including UTIs. Based on a theoretical model, the extra costs were estimated for each symptomatic healthcare-associated UTI to be at least $676 and for each catheter-associated bacteremia to be $2,836 *(56)*. Another study estimated the mean costs of a healthcare-associated UTI to be $589, with the lowest costs associated with infections caused by *Escherichia coli* and higher costs with infections caused by other gram-negative bacilli and yeasts *(57)*. The substantially lower estimates in this study as compared to other earlier retrospective studies were attributed to cost-containment measures implemented in the era of managed care as well as to the availability of newer oral antimicrobials with activity against gram-negative pathogens. Additional economic incentive for hospitals in the United States to reduce rates of healthcare-associated UTI due to urinary catheter use has recently come in the form of a change in reimbursement policy from the federal government *(58)*. Under revised policy, additional payments for certain complications from medical care that are deemed "reasonably preventable" will be curtailed *(59)*.

Mortality The extent of mortality attributed to catheter-associated UTIs is still uncertain since these infections might be effect modifiers or simply markers of high mortality from other causes. The most generally acknowledged cause of death is related to bacteremia, which occurs in 0.3% to 3.9% of patients with healthcare-associated

catheter-associated UTIs *(60–62)*. Secondary bacteremia from a urinary source is generally considered unequivocal evidence of an invasive UTI. However, when a blood culture was obtained immediately after urethral catheterization from patients with sterile bladder urine, 6.5% were positive *(63)*. Therefore, transient bacteremia secondary to urinary tract instrumentation can be a source of a remote infection, perhaps at the site of an implanted prosthetic device.

As many as 35,000 cases of bacteremia secondary to healthcare-associated catheter-associated UTIs occur each year in the United States. Even though the crude case-fatality rate perhaps exceeds 30%, the mortality rate attributed specifically to bacteremic UTI in one large retrospective study was 12.7% *(61)*. According to this estimate of the attributable mortality, as many as 4,500 deaths occur in the United States each year from healthcare-associated UTIs, but most of these deaths may occur in patients with serious underlying disease processes.

The true mortality rate from bacteremic UTIs for the United States in recent years is also undoubtedly lower than such extrapolations from studies in large tertiary care hospitals. In 1992, the CDC estimated that UTIs directly caused only 932 of the 19,027 deaths from healthcare-associated infections but contributed to an additional 6,500 of 58,092 deaths associated with healthcare-associated infections in US hospitals *(54)*. To appreciate recent advances, consider that, before closed drainage systems were used, Martin et al. (64) estimated that 31,000 deaths occurred in US hospitals each year because of urinary catheter-related bacteremia. This study serves as the principal evidence that closed drainage markedly lowered the mortality rate and suggests that further reductions will be achieved only with great difficulty.

Additional mortality may nonetheless occur from causes unrelated to bacteremia. One study, using logistic regression analysis in a large hospital population, suggested that the actual mortality rate of healthcare-associated UTIs is significantly higher than estimates based on the incidence of bacteremia *(65)*. Acquisition of catheter-related UTI predicted a nearly threefold increase in mortality that was not completely explained by clinical sepsis, documented bacteremia, or underlying disease. If this study is representative of all US hospitals, the actual excess mortality associated with catheter-related infections could be as high as 56,000 deaths per year in acute care hospitals. Possible support for this conclusion also came from observations of women with long-term catheters in whom the incidence of death during fevers of suspected urinary origin was 60 times the incidence during afebrile periods *(66)*. A more recent retrospective study of over 25,000 patients with indwelling urinary catheters, and at least 4 days of hospitalization, documented a relative risk, by multivariate logistic regression modeling, of 1.37 for death among those patients who developed UTI *(67)*.

Morbidity Indwelling urinary catheters pose a risk for many infective and noninfective complications. Catheter-related infection can spread to any site in the urinary tract and can predispose patients to perinephric, vesical, and urethral abscesses as well as epididymitis, prostatitis, orchitis, and vesicoureteral reflux. The overall incidence of these complications is unknown, although 20% to 30% of patients with asymptomatic catheter-induced UTIs may develop local or systemic symptoms *(56,60)*.

Infection may also have a role in other complications of catheterization. Bladder and renal stones, hemorrhagic pseudopolyps of the bladder *(68,69)*, and squamous metaplasia and carcinoma of the bladder *(70)* have all been associated with UTIs in patients with long-term or chronic indwelling catheters. Accidental inflation of the catheter balloon in the posterior urethra has caused minor hematuria and subsequent urethral stricture as well as periurethral abscesses, sepsis, and death *(71)*. Neglect of long-term catheters, usually in patients who are discharged from the hospital with an indwelling catheter, can lead to bladder gangrene, perforation, and peritonitis *(72–74)*. Among noninfectious complications of indwelling urethral catheterization, some cardiovascular surgery units have reported that urethral ischemia during cardiopulmonary bypass caused urethral strictures that could be prevented by the use of silicone rather than latex catheters *(75)*.

Healthcare-associated UTIs may also be a source for other healthcare-associated infections. In one large study, 40% of UTIs occurred in patients with multiple healthcare-associated infections, but the incidence of autoinfection secondary to the urinary site was not evaluated *(76)*. In a study of patients in a university hospital in Spain, an indwelling urinary catheter used for more than 3 days more than doubled the risk of developing bacteremia *(77)*. A more recent study from Spain investigating bacteremia occurring within 30 days of solid organ transplantation found UTI was the most common identifiable cause, in 27% of cases, with *E. coli* being the most common bacteria isolated *(78)*. Healthcare-associated UTIs can be the source for 10% to 15% of healthcare-associated bloodstream infections *(61,62,79)*. A recent study identified 350 cases of healthcare-associated UTI-related bloodstream infection over a 9-year period at a large academic medical center, predominantly among patients with immunosuppression, liver, or kidney disease *(80)*. Healthcare-associated *Staphyloccocus aureus* UTI among residents of a long-term care facility was found to be associated with bacteremia in 13%; among the cohort 82% had recent urinary catheterization *(81)*.

Surgical site infection secondary to a healthcare-associated UTI has been documented as a cause of major morbidity with an attack rate of 2.3 secondary surgical site infections per 100 surgical patients with healthcare-associated UTIs *(82)*. Two reports confirm an increased rate of surgical site infections and allograft dysfunction in renal transplant recipients with healthcare-associated UTIs *(83,84)*, whereas others have demonstrated associations between UTIs and infections of prosthetic heart valves *(85,86)*, total hip replacements *(87,88)*, and central venous catheters *(89)*. Rare complications such as gram-negative endocarditis and septic discitis may also complicate urosepsis of healthcare-associated origin *(90,91)*.

Consequences of Antimicrobial Use The indication for antibiotic therapy of healthcare-associated UTIs in acute care settings is a subject of debate and controversy. Nonetheless, treatment of symptomatic UTIs is virtually universal. In one report, among 1,233 patients with healthcare-associated UTIs, only a single patient

was not treated *(92)*. Yet, routine therapy increases not only drug costs but also adverse drug reactions and the emergence of antibiotic-resistant microorganisms. These adverse consequences have not been fully evaluated in epidemiologic studies, although antibiotic use during catheterization influences the patterns of microbial species causing healthcare-associated UTIs. The changing nature of UTIs at one medical center in the last decade was reflected by significant increases in the proportion of certain uropathogens such as yeasts, *Klebsiella pneumoniae,* and group B streptococcus *(93)*. Antibiotic use was probably largely responsible for these changes. Other reports, such as one that tied the emergence of multidrug-resistant *K. pneumoniae* to prophylactic use of trimethoprim–sulfamethoxazole in patients with indwelling catheters *(94)*, serve as further evidence that antibiotic use shapes the character of healthcare-associated UTIs.

In the report from the NNIS system with data from 1992 to 1997 for healthcare-associated infections in medical ICUs, fungi accounted for almost 40% of urinary isolates *(34)*. *Candida albicans* alone accounted for 21% and was the single most frequent microorganism cultured. This was a marked change from a previous report with results from 1986 to 1989 that included all types of ICUs in which all fungi constituted 22.1% and *C. albicans* 12.8%. Extensive use of broad-spectrum antibiotics and antifungal drugs may have contributed to this increase, especially for the increasing prevalence of non-albicans *Candida*.

Epidemics of Healthcare-Associated UTIs Epidemics of healthcare-associated UTIs have garnered national attention when the causative microorganisms displayed unusually high levels of antibiotic resistance. In seven large epidemics investigated by the CDC between 1970 and 1975, asymptomatic catheter-associated UTIs were reservoirs of the epidemic microorganisms *(95)*. The most frequently observed risk factor in these epidemics was prior exposure to broad-spectrum antibiotic therapy.

Only three microorganisms caused the seven outbreaks: *K. pneumoniae, Serratia marcescens,* and *Proteus rettgeri*. Gastrointestinal carriage was especially prominent in outbreaks caused by *K. pneumoniae*, but the epidemic microorganism was thought to be transmitted from patient to patient on the hands of healthcare workers in all seven outbreaks. Healthcare-associated UTIs were also sources for other healthcare-associated infections as the epidemic microorganism was isolated repeatedly from nonurinary sites in five of the outbreaks.

Indwelling urinary catheters and other types of urologic instrumentation have contributed to the emergence of healthcare-associated pathogens highly resistant to antimicrobial agents. The urinary drainage bag is a potential site for extraintestinal transfer of resistance plasmids in Enterobacteriaceae as well as an environmental reservoir for cross-infection *(96)*. For instance, interhospital spread of multiply resistant *S. marcescens* occurred among patients with indwelling catheters in four geographically separate hospitals in one city *(97)*. Hand carriage by personnel rotating among hospitals was the apparent mode of transmission. Indirect contact transmission of highly resistant *P. rettgeri* appeared to be important in two reported outbreaks of healthcare-associated UTIs *(98,99)*.

Contaminated equipment and inadequate disinfectants have also been responsible for epidemics of UTIs. An outbreak of gentamicin-resistant *P. rettgeri* and *Providencia stuartii* UTIs in patients with chronic indwelling catheters in a rehabilitation unit was caused by contaminated urinary leg bags *(100)*. In another hospital, a contaminated drainage pan in a cystoscopy room caused a common-source outbreak of 105 cases of multiple antibiotic-resistant *S. marcescens* UTIs following cystoscopy, and cross-infection of 29 patients on nursing units amplified the magnitude of the epidemic *(101)*. At yet another hospital, inadequate disinfection of urologic instruments with reuse of 2% glutaraldehyde led to a 12-month-long epidemic of antibiotic-resistant *S. marcescens* UTIs after a variety of urologic procedures *(102)*. The use of chlorhexidine for hand washing caused an outbreak due to multiply antibiotic-resistant and chlorhexidine-resistant *S. marcescens* UTIs that lasted over 19 months *(103)*, and use of hexachlorophene solution in preparing patients and cleaning instruments for cystoscopy and transurethral resection of the prostate was associated with *Pseudomonas aeruginosa* UTIs *(104)*. Contaminated urine measuring containers and urometers were the reservoir for *P. aeruginosa* that caused 66 catheter-associated UTIs *(105)*. Clearly, rigorous application of existing infection control principles can prevent such epidemics.

Many of these and other reported epidemics had well-defined sources. Others occurred from previously unsuspected environmental reservoirs. For example, uninfected patients with condom catheters who had contaminated urine drainage bags served as a reservoir for infection of patients with indwelling catheters on the same hospital unit *(106)*. Contaminated drainage bags may also mislead surveillance personnel, as false diagnoses of UTIs made from urine specimens obtained from drainage bags can skew surveillance data. Such errors at one hospital led to a pseudoepidemic of *Trichosporon beigelii* UTIs that, if not recognized, could have subjected patients to the risks of antifungal treatment *(107)* (see also Chapter 9).

ETIOLOGIC AGENTS

The microorganisms usually responsible for catheter-associated UTIs are derived from the fecal flora native to the patient or that originate in the hospital environment. According to 1990–1992 data from the NNIS system, these include *E. coli* (25%); *Enterococcus* species (16%); *P. aeruginosa* (11%); *C. albicans* (8%); *K. pneumoniae* (7%); *Enterobacter* species and *Proteus mirabilis* (5% each); coagulase-negative staphylococci (CoNS) (4%); other fungi (3%); *Citrobacter* species, group D streptococci, other *Candida* species, and *S. aureus* (2% each); *Acinetobacter* species, *S. marcescens*, group B streptococci, other *Klebsiella* species, other streptococcal species, and other Enterobacteriaceae (1% each) *(108)*.

Although anaerobic bacteria have been isolated from catheter urine of patients with long-term catheters, and most secondary suppurative genitourinary infections commonly involve anaerobic bacteria, anaerobic UTIs

are rarely reported *(109,110)*. *S. aureus* is an occasional cause of catheter-associated UTI, with a high rate of secondary bacteremia, but is also frequently found in urine cultures secondary to *S. aureus* bacteremia *(81,111–113)*. In addition, some microorganisms, such as CoNS, have received increased attention in recent years, although their role as uropathogens is still unsettled *(114)*.

A single infecting species is responsible for about 80% of UTIs in patients with short-term catheters, but most patients with long-term catheters have polymicrobial infections with spontaneous turnover of individual species *(115)*. The microbial species causing healthcare-associated UTIs have always differed from those causing community-acquired UTIs. *E. coli,* for example, causes 80% or more of the cases in outpatients *(116)* versus <50% of the healthcare-associated ones. As with other complicated UTIs, recognized virulence factors of *E. coli* are not prevalent among the strains causing catheter-associated UTI *(117,118)*. The frequencies of the various pathogens also differ in chronically catheterized patients who have, for example, a particularly high risk of infection with *P. stuartii (119)*.

The frequency of individual pathogens causing healthcare-associated UTIs has changed markedly in the last two decades. The single most important factor influencing the distribution of infecting species in the hospital is the use of antimicrobial agents. Although reduced rates of healthcare-associated UTIs have been associated with antibiotic use in patients who have indwelling catheters for brief periods, this possible benefit has been offset by increased acquisition of resistant species such as enterococci, *Klebsiella, Pseudomonas, Proteus, Enterobacter*, and yeast (28,*34*).

At Salt Lake City's LDS Hospital, antibiotic use during the period of catheterization has steadily increased: 53% of 405 catheterized patients in 1972 received antibiotics, as compared to 80% of 1,309 in 1990 *(120)*. As a consequence, in 1990, *E. coli* accounted for only 10% to 20%, other gram-negative bacilli for 20% to 30%, enterococci for 20%, coagulase-negative staphylococci for 10%, and yeast for 20% to 30% of all isolates from urine cultures with microbial growth.

The incidence of healthcare-associated UTIs caused by *Candida* species and other yeasts has been increasing in recent years *(34,93)*. The risk for candiduria has been related to duration of catheterization, duration of hospitalization, and antibiotic use *(121)*. It is usually asymptomatic, but complications can include fungus balls in the bladder or renal pelvis, fever, renal and perirenal abscess, and disseminated candidiasis *(122–125)*.

Viral agents have not been systematically studied in patients with indwelling catheters. Cytomegalovirus can be isolated, often intermittently, from the urine of patients infected with this agent, but the risk of transmission to healthcare workers is probably negligible *(126–128)*. Human immunodeficiency virus type 1 (HIV-1), however, could not be detected in the urine of 48 seropositive individuals *(129)*, and no evidence suggests that HIV can be transmitted by urine. Nevertheless, because urine can become contaminated with blood, especially after catheterization, standard precautions should apply to the handling of urine as well as blood. The proper use of gloves, particularly changing gloves between tasks, not only can protect the healthcare worker but also can theoretically prevent transmission of UTIs.

PATHOGENESIS

Role of the Catheter

Microbial colonization of bladder urine precedes most invasive UTIs. Urine is an excellent growth medium for common urinary tract pathogens *(130,131)*. Nonetheless, the urinary tract above the distal urethra is normally free of bacteria, and micturition permits nearly complete cyclic emptying of the bladder, thereby rapidly eliminating the small numbers of microorganisms introduced through minor urethral trauma *(132)*. The indwelling transurethral catheter breaches this normal defense mechanism, distending the urethra, and blocking the ducts of the periurethral glands. The retention balloon prevents the complete emptying of the bladder and creates a small pool of residual urine in which microorganisms can multiply. The resulting increase in susceptibility to infection is shown by observations that low-level bacteriuria progresses very rapidly to levels exceeding 100,000 colony-forming units (CFUs)/mL when any microorganisms appear in the catheterized bladder (28,133).

Since the catheter is a continuously open channel, microorganisms can migrate upstream into the bladder through the lumen of the catheter. As long ago as 1957, Dutton and Ralston (134) showed that nonmotile bacteria could ascend sterile tubing against a flow of sterile urine. In addition, the external surface of the catheter stresses the urethral surface, creating a channel for bacterial colonization and entry outside the catheter *(24)*. It has been reemphasized in recent years that the urethra is not merely a passive conduit but has its own complex defense mechanism *(135)*. Exfoliation of urethral cells with bound uropathogens is one example of an overlooked defense mechanism, and differences in the rates of exfoliation of cells in menstruating women or those on hormone replacement as compared with postmenopausal individuals may account for the different rates of UTIs in these populations. The effect of a foreign body on the rate of exfoliation of urethral cells and its contribution to bacteriuria has not been well defined.

The foreign material of the catheter also may promote infection by a number of other mechanisms. For instance, by blunting the local inflammatory response as shown in other types of implanted foreign bodies *(136)*, the catheter may interfere with the removal of bacteria that gain entry to the bladder. In mouse models, Toll-like receptor 4 (TLR4) on both bladder epithelial cells and leukocytes protects against *E. coli* infection by recruiting inflammatory cells and upregulating chemokine expression needed for an innate immune response *(137,138)*. Although the effect of the urinary catheter on the local innate immune response has not been well studied, a dysfunctional TLR4 may hinder inflammation and bacterial clearance from the urinary tract *(138)*. The possibility that the innate immune response is blunted in catheter-associated UTIs is suggested by observations that, in humans, healthcare-associated UTIs are seldom symptomatic (139) and the sensitivity of detecting catheter-associated UTIs by screening for pyuria is only 37%

(140). Pyuria is also less frequently associated with yeast and gram-positive microorganisms than with gram-negative microorganisms colonizing the catheterized urinary tract.

Recently, the function of defensins, specifically human β-defensin 1, which is produced by renal epithelial cells, and their role in UTI and pyelonephritis have been studied more closely. β-Defensin 1 has activity against *E. coli*, although the concentration required is tenfold higher than is present in the urine. However, it is also possible that defensins could exist on epithelial cells to form an antimicrobial barrier, a process that may be affected by or compromised by the presence of a urinary catheter *(141)*. Studies have shown that the presence of a catheter may enhance the adherence of gram-negative bacteria to uroepithelial cells. For unknown reasons, 2 to 4 days before the onset of bacteriuria, epithelial cells harvested from the catheterized bladder show a transient increase in the adherence of gram-negative bacteria *(142)*.

Bacteria may also adhere to and migrate along the extraluminal surface of the catheter itself. The physical and chemical properties of the catheter material, therefore, are posited as important determinants of UTI *(143)*. In consequence, efforts have been made to develop an adhesion-resistant or colonization-resistant urinary catheter. An *in vitro* study found marked differences in the ability of various gram-positive and gram-negative bacteria to attach to red rubber catheters and those coated with either a hydrophilic substance, silicone, or tetrafluoroethylene (Teflon) *(144)*. Most bacteria are hydrophobic, and none of the tested bacteria adhered to the hydrophilic catheter. However, studies of hydrophilic catheters in patients have demonstrated no clinical benefit *(145–147)*. Regardless of their influence on bacterial adhesion, catheters made of Teflon-coated latex or silicone have been introduced for clinical use with the hope of improved biocompatibility, but in the absence of established infection there is little evidence of less irritation and inflammation in the urethra from these catheters than from those made of latex rubber *(148,149)*.

Bacteria that colonize both the external and the internal surfaces of urinary catheters grow in microcolonies within a biofilm that encases the bacterial cells. When urine cultures reveal a single species, the biofilm often contains a mixed community with up to four species. In recent years, there has been greater understanding of the biology of biofilms, with additional insight into the process by which planktonic or freely suspended microorganisms become surface-associated microorganisms or biofilms *(150–152)*. A biofilm is loosely defined as a collection of microbial cells that is stably associated with a surface and enclosed in a matrix of primary polysaccharide material. The microbial cells in a biofilm are also different from their freely suspended counterparts with respect to gene transcription and growth. The initial step in the process is the formation of a conditioning film by the urine on the catheter surface followed by attachment of the microbial cell to the surface of the urinary catheter or substratum. The surface properties of the catheter appear to play a role, with microorganisms more rapidly attaching to hydrophobic surfaces like Teflon and plastics than to hydrophilic substances like glass *(153)*. It is thought that hydrophobic interactions occur between the cell and the catheter surface and overcome local repulsive forces, thereby enabling attachment. *In vitro* studies have also shown that the nutrient content of the aqueous medium, in this case urine, also affects the number of bacterial cells that attach to the surface. In certain bacteria, differences in bacterial surface hydrophobicity and presence of fimbriae (pili) and flagella also influence the rate and amount of attachment.

The next step in the formation of a biofilm is a change in gene expression by attached cells upon initial adherence *(154)*. Most of these changes are needed for adaptation to living in a new environment and the change from a planktonic to a surface-associated form. After attachment, the bacterial cells produce extracellular polymeric substances (EPS), which will account for 50% to 90% of the total mass of the biofilm *(155)*. The EPS is composed mainly of polysaccharides and is highly hydrated. The overall charge and composition of the polysaccharides and the amount of EPS produced can vary between different microorganisms and may contribute to antimicrobial resistance by decreasing diffusion of antibiotics through the EPS *(156)*. Genetic variation in the pathways controlling polysaccharide biosynthesis has been shown to result in structural differences in biofilm produced by *P. aeruginosa (157)*.

An *in vitro* study has shown that certain cell-to-cell signals are needed for biofilm formation in a process called quorum sensing *(158)*. In a model using *P. aeruginosa*, mutants lacking two signaling genes were only able to produce a biofilm that was flat, undifferentiated, and phenotypically vastly different from the wild type and much less resistant to surfactant treatment. These signaling systems are also thought to play a role in dispersion of microorganisms from the biofilm, although the process is still not fully understood. The final architecture of the biofilm is a heterogeneous mixture of microcolonies of microbial cells surrounded by an EPS matrix with microbial colonies separated by water channels that play a role in transport of nutrients and possibly antimicrobial agents.

Several factors account for the fact that biofilm-associated infections are resistant to treatment without removal of the catheter. The rate of penetration of antimicrobial agents through the biofilm may be reduced to such an extent that they do not reach a sufficient concentration to be effective. Also, even small amounts of bacterial enzymes such as beta-lactamases might be sufficient to hydrolyze the reduced numbers of antimicrobial molecules that manage to reach the microbial cells. Another factor is the reduced metabolism and reproductive rate of the cells living within the biofilm, as some antimicrobial agents act only on rapidly dividing cells *(159,160)*.

These mechanisms, however, do not readily explain the resistance of biofilms to the activity of fluoroquinolones that readily equilibrate across biofilms and kill nongrowing planktonic cells of *P. aeruginosa*. Recently, it has been shown *in vitro* that increased concentrations of a quinolone did not result in further killing after an initial three- to four-log decrease in the bacterial population in biofilms *(161,162)*. This small fraction of persistent cells may account for high-level resistance of biofilm-associated bacteria. In support of this concept, it has been demonstrated that *E. coli* can use indole, produced by proliferating cells, as a diffusible signaling molecule to turn on drug efflux pumps among all bacteria within a population *(163)*. Thus, a few resistant cells in a colony may provide "umbrella" protection to

antibiotic-induced damage. Whether this mechanism is active in biofilms is not established.

Bacterial Factors

Bacterial *virulence factors* (VFs) have been sought to explain each stage of UTI pathogenesis: bacterial adherence to uroepithelial cells and to the catheter surface, intraluminal migration of bacteria within the drainage tubing against the direction of urine flow, ascending infection through the ureters to the upper urinary tract, invasion of the kidney to cause pyelonephritis, invasion of the bloodstream to cause bacteremia, and persistence of bacteriuria in long-term catheterized patients. The swarming motility of *Proteus mirabilis* has been postulated as a VF for ascending infection of the ureters *(164)*. Other virulence factors encoded by genes localized to chromosomal pathogenicity islands, including hemolysin, the siderophore aerobactin, and adhesive organelles (S pili, Dr family adhesins, P pili, and type 1 pili), have been identified in strains of uropathogenic *E. coli* (UPEC) causing urinary infection syndromes in noncatheterized patients *(165)*. In addition, uropathogenic *E. coli* have recently been shown to secrete mimics of the intracellular signaling domain of TLR—thereby blocking activation of the innate immune response and enhancing virulence *(166,167)*. However, *E. coli* is a less common cause of infection in catheterized patients, and many strains causing urosepsis in catheterized patients typically lack these VFs *(117,168)*. Catheterization enables otherwise avirulent microorganisms to persist and initiate infection *(169)*.

The diversity of microorganisms causing catheter-associated UTIs and the relatively greater importance of host compromise make it unlikely that recognition of common virulence properties will lead to strategies capable either of blocking attachment or of predicting strains most likely to cause bacteremia. Type 1 pili that are mannose sensitive and mediate adherence to epithelial cells and polymorphonuclear leukocytes, for example, have been found in 61% of *E. coli*, 55% of *Klebsiella* species, and 11% of *Proteus* species from catheterized patients *(170)*. Moreover, *E. coli* flora of the urethral meatus, when present, has been shown to change frequently from isolates expressing adhesins to those without this property, perhaps resulting from on-off phase variation in phenotype *(117)*.

In contrast, type 1 pili-mediated adherence has been correlated with persistence of *E. coli* in the long-term catheterized urinary tract *(171)*. In an animal model of cystitis, UPEC expressing type 1 pili were able to invade and persist within bladder cells and serve as a reservoir for recurrent infection *(172)*. This is a dynamic, cooperative interaction between the UPEC microorganism and the uroepethelial cells, dependent on actin cytoskeleton reorganization via a microtubule-dependent process *(173)*. Evidence for similar intracellular reservoirs, termed intracellular bacterial communities, has also been demonstrated in humans *(174)*. So-called type 3 pili [mannose-resistant, *Klebsiella*-like (MR/K) hemagglutination] found in *Providencia, Proteus,* and *Morganella* species also may play a role in long-term catheter-associated bacteriuria through adherence to the catheter material *(175)*, and numerous other adhesins continue to be discovered. Further evidence shows that *E. coli* strains lacking the more common virulence factors (P pili and hemolysin) often carry multiple antibiotic resistance and aerobactin plasmids and are associated with bacteremia in patients with urinary tract abnormalities *(176)*.

Urease, a VF of *Proteus* species, is undoubtedly important, since virtually all patients with *Proteus* bacteriuria develop upper tract infection. Urea splitting by microorganisms such as *Proteus* species and *Corynebacterium* group D2 causes alkalinization of the urine that damages the urothelium, and urease inhibitors such as acetohydroxamic acid can prevent invasion of kidney tissue *(177,178)*.

Pathways of Infection

Clinical studies have also contributed to our understanding of the pathogenesis of catheter-related urinary infections (15,28,29,*114,179–184*). Such studies have confirmed the importance of the extraluminal pathway of infection during closed drainage, and they have revealed other problems that complicate the prevention of UTIs. For example, in the hospital, indwelling catheterization may unmask community-acquired asymptomatic bacteriuria *(185)*. The incidence of asymptomatic bacteriuria is higher in hospitalized than in nonhospitalized populations and varies from 10% to 30% in women on medical wards to 70% in men on urology wards *(186)*.

Catheter insertion may also push microorganisms into the previously uninfected bladder, a mode of infection that has not been well studied but may account for a risk of at least 2% based on the incidence of bacteriuria after a straight in-and-out catheterization *(187,188)*. Urethral catheterization following use of an external condom catheter system may be associated with an even higher risk of infection that is due to the introduction of a large bacterial inoculum that results from the warm moist conditions inside the condom *(189)*. Finally, infection may be acquired, or become clinically manifest, after the catheter is removed, perhaps in association with straight catheterizations during bladder training. The relative importance of each of these patterns of infection, and, therefore, the effectiveness of prevention, depends on host factors, patient care practices, and environmental influences.

The use of sterile barriers and procedures in insertion of central venous catheters reduce the rates of healthcare-associated bacteremia, but the effectiveness of such maximal sterile procedures during urinary catheter insertion has not been conclusively demonstrated. Patients who had a urinary catheter inserted in an operating room had a lower incidence of early healthcare-associated UTIs *(190)*, but a separate small randomized study showed no difference between sterile and nonsterile urinary catheter insertion *(191)*. Nonetheless, catheter insertion under suboptimal conditions and with poor visualization of the urethral meatus may increase the risks of subsequent UTIs.

Closed systems are designed to block the intraluminal pathway of infection by preventing exogenous contamination from air, dust, and the environment. Modern systems for closed sterile urinary drainage consist of a plastic collection bag fused to the distal end of the collecting tube. But since the system is vented to the air and since the collection bag must be emptied frequently, the system is never truly closed. Improper emptying of the bag or nonsterile disconnection of the junction between the catheter and the collection tube may result in microbial contamination of the

system. Large populations of bacteria can grow in the collection bag and travel upstream against the flow of urine to infect the bladder within a day or two (15,28,134,*179,192*).

After the first week of indwelling catheterization, the extraluminal pathway of infection becomes increasingly important as fecal bacteria migrate and colonize the perineal and meatal-urethral surfaces. The first direct evidence for the existence of this external pathway came many years ago from experimental application of *S. marcescens* (which was then considered a nonpathogenic microorganism) to the periurethral area; the microorganism was then recovered from catheter urine 1 to 3 days later (193). Supporting evidence came from the finding that colonization of the perineum or fossa navicularis with pathogens usually preceded the development of bladder bacteriuria by several days in catheterized urology patients *(194,195)*. Indirect evidence indicated that more than 85% of patients had the onset of bacteriuria and colonization of the drainage bag on the same day, implying that the major pathway of infection during closed drainage is extraluminal (15,28,*196*).

Each pathway is accompanied, to some extent, by a characteristic pattern of infection by different species. In general, exogenous microorganisms more frequently enter through the intraluminal pathway, whereas endogenous microorganisms cause infection through the extraluminal route. Exogenous microorganisms such as *Citrobacter freundii, Pseudomonas* species, *Serratia* species, and nonfermenting gram-negative bacilli that are not part of the normal flora are commonly acquired from transient carriage on the hands of personnel or from collection containers and may be transmitted by cross-infection (197). In contrast, endogenous microorganisms that enter through the pericatheter space are generally part of the patient's normal fecal and perineal flora.

Exogenous microorganisms may become a part of the perineal flora as a consequence of hospitalization and especially of antibiotic use. Selden et al. *(198)* found that the gastrointestinal tract of hospitalized patients frequently became colonized with multidrug-resistant *Klebsiella,* and that the fecal reservoir then served as a source for endogenous infections, with the urinary tract being the commonest site. Finally, many microorganisms are associated with both exogenous and endogenous infection. Bacteriuria with CoNS has been linked to disconnections of the catheter-drainage tube junction and, perhaps, exogenous sources (29), as well as to endogenous meatal colonization *(114)*.

The effect of the duration of indwelling bladder catheterization and the relative importance of each of the possible mechanisms of bacterial entry were confirmed in a study documenting that 66% of healthcare-associated UTIs were acquired extraluminally and 18% were detected within the first 24 hours *(190)*. After this time, the extraluminal route was also more frequent. Gram-positive microorganisms and yeasts were far more likely to be extraluminally acquired, whereas gram-negative bacilli were associated with both routes equally.

Host Factors

The effective prevention of exogenous intraluminal infection by closed drainage systems has revealed differences in the risk of infection among different categories of patients (15,28). Risk factors that were identified in a study analyzed by a multivariable statistical technique include increasing duration of use, female gender, absence of systemic antibiotics, diabetes mellitus, and renal insufficiency (serum creatinine >2 mg/dL) *(184)*. Advanced age and severe underlying illness also have been identified as risk factors by univariate analysis (28). Thus, biologic differences in the nature of patient populations account for differing rates of catheter-related UTIs. Importantly, these patient variables can distort interhospital comparisons of infection rates.

Colonization of the urethral meatus appears to be a pathogenetic link between host factors and the risk of infection. In one study of 612 patients with meatal colonization by gram-negative bacilli or enterococci, 110 (18%) developed bacteriuria as compared to 28 (5%) of 601 patients not colonized ($p < .001$) (181). Meatal colonization was more frequent for each of the high-risk groups than for their lower-risk comparison groups. For example, 72% of female patients had meatal colonization as compared with 30% of male patients ($p < .0001$). Overall, the same species was isolated from prior meatal and later urine cultures in 94 (68%) of 138 patients with catheter-induced bacteriuria —further evidence that the extraluminal spread of bacteria within the periurethral space is the major route by which bacteria enter the bladder during closed drainage.

The increased risk of bacteriuria for catheterized women has been blamed in part on the short length of the female urethra, a conclusion that is not well founded. For instance, consider the pathogenesis of bacteriuria due to CoNS. The prevalence of meatal colonization with CoNS, according to one study, was similar in both sexes, as were the rates of bacteriuria with these microorganisms; in both sexes, the rates of CoNS bacteriuria were significantly higher in those with a prior meatal culture yielding CoNS (4.5% vs. 1.5%, $p < .05$) *(114)*. These data suggest that meatal colonization is the major risk factor and that urethral length is relatively unimportant in the catheterized patient.

Although the rates of bacteriuria due to gram-negative bacilli and enterococci are generally lower in men than in women, these differences correlated with differences in rates of meatal colonization with these microorganisms (181). For example, the rate of bacteriuria was only slightly higher in women whose meatal cultures showed negative results (12%) than in men whose meatal cultures showed positive results (8%); the extraluminal pathway predominated in both sexes. Therefore, either the intraluminal or the extraluminal pathway may predominate under given conditions, depending on the local environment, the quality of catheter care, and the nature of the catheterized population.

Unfortunately, factors influencing meatal and urethral colonization have not been studied extensively in catheterized patients. One study using serotyping of *E. coli* isolates causing urethral and rectal colonization observed that the same strains were later present in bladder urine. Systemic antibiotics were associated with a lower rate of bacteriuria while having little apparent effect on serial cultures of urethral colonization (183). In catheterized patients with spinal cord injuries or who had undergone renal transplantation, bacteria colonizing the urethral meatus were acquired after admission to the hospital *(182)*. The density of bacterial colonization increased during catheterization,

was associated with increased rates of bacteriuria, and was greater in patients on open wards than in those in reverse isolation.

By sampling the intraurethral flora using cultures of the external surface of catheters after removal, Kunin and Steele *(199)* documented gradually increasing colonization of the urethra with gram-negative bacilli and enterococci with extended durations of catheterization. They further found that predominantly gram-positive species could be grown from removed catheters of patients with sterile urine. Despite high concentrations of antibiotics in the urine, antibacterial activity could not be detected on the catheters, perhaps explaining the lack of effect of antibiotics on the urethral flora.

DIAGNOSIS

The differing needs of clinicians and epidemiologists are responsible for disagreements over terminology, particularly the definition of UTIs in asymptomatic catheterized patients *(200)*. A clinician uses a diagnosis to define an illness that requires treatment and to help form a prognosis. An epidemiologist selects a pragmatic case definition for surveillance that can be proficiently applied. An investigator demands objective data regardless of cost. These considerations lead to disparate criteria for diagnosis of healthcare-associated UTIs.

The term *bacteriuria,* or, in the case of yeasts, *candiduria,* is widely used by authors when there is no clinical, histologic, or immunologic evidence of infection. Bacteriuria literally means the presence of bacteria in urine and therefore is evidence of colonization and a precursor of infection. The only generally accepted criteria for infection of the urinary tract, therefore, require the presence of symptoms or other evidence of tissue invasion in addition to recovery of a pathogen from a source within the urinary tract.

The CDC has recently revised surveillance definitions, as part of the NHSN reporting system. Formulated as algorithms, these aim to distinguish healthcare-associated from community-acquired infections and infection from colonization *(201)*. These definitions exclude infections that are present or incubating at the time of hospital admission. Unavoidable incongruities occur in the use of these definitions, however. For example, unless a urine culture is performed at the time of hospital admission, preexisting asymptomatic bacteriuria may be falsely attributed to later catheterization. On the other hand, the NHSN criteria no longer include the classification of asymptomatic catheter-associated bacteriuria and introduce two new categories: symptomatic UTI and asymptomatic bacteremic UTI. Another important change is that symptomatic patients with bacteriuria of fewer than 100,000 colonies per milliliter will not be classified as UTI unless predefined criteria are demonstrated on urinalysis.

The common goal for diagnostic criteria is to provide a basis for predicting morbidity and mortality. Quantitative bacterial cultures of urine have proven satisfactory for this purpose. Except with very low colony counts (<100 colonies/mL), the problem of contamination and false-positive results is virtually nonexistent when urine is obtained by aseptic needle aspiration from the sampling port on the drainage tube. Evidence indicates that the diagnosis of infection associated with short-term indwelling catheterization is supported with colony counts as low as 100 microorganisms per milliliter *(202)*. Colony counts of this magnitude are reproducibly present in the same or higher numbers, usually more than 100,000 colonies per milliliter, within 1 or 2 days except for those patients receiving antibiotics or who have infection with fastidious slow-growing microorganisms (133).

The epidemiologist must be cautious when interpreting reported infection rates because of the influence of colony counts on comparative data. The infection rates found in clinical trials, for example, are actually rates of bacteriuria and may be markedly different from rates of clinical UTIs (29,*203*). Some investigators have restricted the definition of uropathogens to certain species of bacteria, which also affects the observed rate of bacteriuria. In addition, very low colony counts (100 or 1,000 colonies/mL) are commonly selected as a threshold to define bacteriuria in clinical trials, with the result that rates are higher than those from routine surveillance. This confers greater sensitivity and hence greater power to detect differences between study and control groups. Infection rates may also be higher in hospitals that use protocols for obtaining urine cultures from all patients regardless of symptoms.

From a clinical perspective, secondary bacteremia occasionally occurs in bacteriuric patients with colony counts of fewer than 100,000 microorganisms per milliliter, and some rapid tests for bacteriuria are insensitive to such low colony counts *(204,205)*. Colony counts may also be lower in urine aspirates from replacement catheters than in those from the original catheters, although the differences are seldom large enough to be detected by conventional urine cultures *(206)*. One proposed method of detecting infection, the culturing of the tip of a removed Foley catheter, has proven ineffective *(207)*.

Few studies have carefully examined the relation of bacteriuria to pyuria. Musher et al. *(208)* found that pyuria nearly always accompanied bacteriuria (>100,000 bacteria/mL) in catheterized male patients, but pyuria was also present in nearly 30% of urine specimens from catheterized male patients without bacteriuria. Therefore, the finding of pyuria did not help to discriminate infection from colonization. In a study of patients with spinal cord injury who underwent intermittent catheterization, bacteriuria with more than 100,000 gram-negative bacilli per milliliter, or colonization with yeast regardless of the colony count, resulted in pyuria *(209)*. In patients with long-term indwelling catheters who had chronic pyuria and bacteriuria, neither urinalysis nor urine culture was a reliable test for symptomatic UTI *(210)*. In contrast, in a study of patients with short-term indwelling urinary catheters, Tambyah and Maki (140) found that only 37% of patients with bacteriuria had pyuria, and similarly bacteriuria was present in 37% of patients with pyuria. The authors concluded that the differences between their results and the previous study done by Musher et al. were likely due to different patient populations.

The NHSN surveillance algorithm uses symptoms to define UTI if other supporting evidence is present, and no longer recognizes asymptomatic bacteriuria, even if the urine culture yields more than 100,000 colonies

per milliliter. However, the symptoms of UTI, such as dysuria, urgency, frequency, or suprapubic tenderness, are often obscured by the presence of the catheter and, except for fever, may become evident only when the catheter is removed. Urinary catheters contribute directly to healthcare-associated febrile illnesses *(211)*. However, fever may be absent in elderly, debilitated, or immunosuppressed patients who also may be unable to report other symptoms. In a companion study by Tambyah and Maki (139), more than 90% of patients with catheter-associated UTI were asymptomatic, but 52% were diagnosed by their physicians using the hospital laboratory. Interestingly, symptoms referable to the urinary tract had no predictive value for the diagnosis of infection. As a corollary, no study has demonstrated that symptoms referable to the urinary tract are a reliable indication of the risk of developing a complication from UTI. To the contrary, a study of *S. aureus* bacteriuria in elderly long-term care patients found that only half of those with subsequent bacteremia met criteria for symptomatic UTI *(81)*.

Objective, reproducible, and economical methods for surveillance are obviously needed. One proposal for the surveillance of healthcare-associated UTIs avoids time-consuming reviews of patient records by using concurrent review of microbiology laboratory reports *(212)*. Because evaluation of symptomatic patients usually includes a urine culture, the sensitivity of laboratory-based surveillance approaches 98% when healthcare-associated UTI is defined by positive urine culture on the third hospital day or later.

PREVENTION

Closed Sterile Drainage

An understanding of the major risk factors and pathways of infection should facilitate logical strategies for the prevention of healthcare-associated UTIs. The most successful infection control method, closed sterile drainage, reduces the risk of infection only through the exogenous pathway and requires little additional effort by healthcare workers. Nonetheless, irregularities in catheter care and resulting breaches of closed systems are pervasive problems and are therefore a target for prevention efforts (28,29). Improper hand hygiene—with a nondisinfectant soap, for example *(213)*—is also an important risk factor for exogenous infection. Proper technique depends on healthcare workers and is difficult to monitor and enforce *(214)*.

Infection Control and Surveillance Programs

The CDC's Study on the Efficacy of Nosocomial Infection Control (SENIC) remains today the major source of data regarding the preventability of healthcare-associated infections including UTIs *(215)*. Complicated methodology hindered the understanding and limited the impact of the SENIC study. The multiple factors influencing UTI rates, for example, could not be independently assessed. Nonetheless, the study suggested the yet-unfulfilled potential of existing methods for prevention and the role of surveillance itself as a control measure.

Beginning in 2008, the NHSN became available in the United States as a way for healthcare facilities to report HAI data, including those on healthcare-associated UTI. Although not yet fully implemented, it presents an opportunity for national, risk-adjusted estimates of infection rates. Like the SENIC study however, the success and value of the process will depend on minimizing complexity and burden on individual facility infection preventionists.

The SENIC report estimated that intensive infection surveillance and control programs—those with at least one infection control practitioner (infection preventionist in current terminology) per 250 beds—might have been able to reduce the UTI rate by 33%. Unfortunately, because relatively few hospitals had effective programs in the mid-1970s, only 2% of the number of healthcare-associated UTIs predicted in the absence of such programs were actually prevented. A follow-up survey in 1983 found that the proportion of hospitals with effective programs had increased from 7% to 24%, with potentially 6% of the UTIs prevented *(216)*.

Guidelines

Almost three decades ago, the CDC developed the first guideline for the prevention of catheter-associated UTIs *(217)*. It emphasized principles for maintaining closed sterile drainage but overlooked the role of surveillance *(218)*. These guidelines have recently been revised, based on a systematic review of the literature though 2007, emphasizing prevention measures for a wider variety of patients and specific surveillance recommendations (219).

Additional recent guidelines have been issued by the Infectious Diseases Society of America (IDSA) *(220)*, the Society for Healthcare Epidemiology of America (SHEA) *(221)*, the Association for Professionals in Infection Control and Epidemiology (APIC) *(222)*, and from the European and Asian urological societies *(223)*.

The extent of adherence to these guidelines remains unknown, although evidence points to marked variation among institutions. Catheter care violations, such as accidental junction disconnections, improper closure of the outflow spigot, and improper positioning of the collection bag, are common and are associated with increased rates of bacteriuria. Studies at the Salt Lake City LDS Hospital reported these errors in 11% of catheter-days and overall in 29% of catheterized patients with little change over time despite intensive education of healthcare workers (29). Modifications in the design of drainage systems, such as antireflux valves and seals of the catheter-drainage tubing junction, aimed at reducing the frequency of errors in catheter care by passive means, have proved disappointing.

Adjuncts to Closed Drainage

In the past few decades, many adjuncts to closed drainage have been introduced and aggressively marketed by device manufacturers, often without adequate clinical investigation and evidence of efficacy. These efforts have focused on more effectively preventing infection by both the intraluminal and the extraluminal pathways.

Randomized controlled trials (RCTs) have been useful in the evaluation of preventive measures for healthcare-associated UTIs. Many seemingly logical adjuncts to closed drainage have not been efficacious when evaluated in RCTs. For example, RCTs showed that a costly and once widely used procedure, daily meatal care, is not cost-effective

and, in fact, that meatal care with iodophors is deleterious (224,*225–227*). However, closed sterile urinary drainage has not been evaluated in RCTs, because its efficacy has been evident from nonrandomized studies *(228)*.

RCTs are expensive and susceptible to many limitations, including errors in design and analysis. Because of the varying importance of the different pathways for acquisition of catheter-associated UTIs in different settings and patient populations, the results of a single RCT may be valid only for the time and place a study was conducted. RCTs are also susceptible to exploitation by manufacturers. Accordingly, Kunin *(229)* has suggested that the efficacy of new devices for infection control should be supported with carefully controlled studies by at least three groups working independently.

RCTs relevant to healthcare-associated UTIs are instructive and may help identify productive areas for future investigation. The listing of 52 representative RCTs from 1962 to 2003 is shown in Table 20-1 intentionally omits some studies of prophylactic antibiotic use in surgery, urology, and gynecology in which catheter-related UTI was an outcome measure. It also omits comparative trials that were not randomized, and some of those included were not randomized at the individual patient level. Furthermore, 30 of the 52 RCTs were restricted to certain types of patient populations, and the results, therefore, may not be generally applicable to all catheterized patients.

Judgments of outcomes as positive (+) or negative (–) were based on the presence or absence, respectively, of statistically significant differences ($p < .05$) between the study and control groups. Some outcomes that were otherwise negative were judged to be equivocal (+/–) if a significant difference was found in at least one subset of the population or if the authors believed a trend favored the intervention.

The majority of these RCTs (35 of 53) had either negative or equivocal outcomes. The studies ranged in size from 31 patients to 27,878 patients. Study size was correlated to outcome: 15 positive outcomes occurred in 26 studies with fewer than 200 patients, as compared to only two positive outcomes in 13 studies with more than 500 patients. Smaller studies, therefore, may have erroneous outcomes.

The types of interventions studied in these RCTs can be grouped in four categories: (a) alternative methods of bladder drainage (intermittent straight and suprapubic catheters); (b) methods to prevent extraluminal infection (urethral lubrication, meatal disinfection, and catheters coated with hydrophilic polymers or antimicrobial compounds); (c) methods to prevent intraluminal infection (antireflux valves and vents, instillation of disinfectants into the bag, irrigation of the bladder with disinfectants or antimicrobials, and junction seals); and (d) combined approaches including systemic antibiotic prophylaxis.

With the exception of antibiotic prophylaxis, none of the individual interventions met criteria for efficacy in at least three RCTs. Systemic antibiotic prophylaxis, with six of seven trials having positive outcomes, and methods that included junction seals, with two positive and two equivocal outcomes among seven trials, appeared to be the most promising approaches. Yet only one of these positive outcomes—an RCT of antibiotic prophylaxis—occurred in a study of more than 500 patients. Junction seals are potentially effective, although they do not yet meet Kunin's criteria for efficacy. However, prevention of junction disconnections might reduce the incidence of bacteriuria by only about 10% (29).

An intriguing approach to antibiotic prophylaxis, evaluated in a single small trial, involved the use of ampicillin 1 hour before, at the time of, and 6 hours after catheter insertion *(230)*. This study found significant protection for up to 1 week after use of this regimen. The use of antimicrobials during catheterization, especially fluoroquinolones—effective in two RCTs—merits further investigation but cannot yet be recommended pending large-scale clinical trials.

Methods to prevent UTIs that are effective in one patient group, such as males undergoing prostatectomy, may not be suitable for general use. All of the RCTs of antibiotic prophylaxis were restricted to certain types of patients. All three positive trials of bladder irrigation with antimicrobials involved patients undergoing urologic or gynecologic procedures, and the control group for one trial received open drainage. Ideally, preventive methods should be evaluated in general hospital use among all patient services. The only RCT of antibiotic irrigation that met this criterion showed no benefit, although the authors believed that this failure was due to an increased rate of junction disconnections in the treatment group *(180)*.

Methods found to be efficacious in RCTs should then be evaluated for effectiveness and cost-benefit in routine clinical practice. For example, the routine use of preconnected catheters with junction seals has not been evaluated despite a strong rationale for an expected cost-benefit based on a single RCT *(231)*. In addition, the largest RCT of the use of catheters with presealed junctions showed only a small reduction in the frequency of disconnections *(232)*. A large RCT showed that tape seals applied after catheterization were not effective in reducing either the frequency of junction disconnections or the rate of bacteriuria *(233)*. Thus, the protective effect of the presealed catheter junctions on the rate of bacteriuria is difficult to interpret and may be related to effects of its use other than preventing disconnections or to the fact that factory preconnection may be important.

The results from recent RCTs and a meta-analysis *(234)* of RCTs of silver-coated catheters were inconclusive *(235,236)* or negative *(237)*. In a recent review of all studies of silver-coated catheters including controlled clinical trials, RCTs, systematic reviews, and meta-analyses, only seven studies satisfied the reviewers' selection criteria for adequate quality and only one had a high-quality score *(238)*. The authors concluded that current evidence is insufficient to recommend silver-coated catheters. In contrast, a recent Cochrane review found a benefit to the use of silver alloy and antibiotic-impregnated catheters for reducing asymptomatic bacteriuria during short-term use *(239)*. Moreover, several studies of possible cost-benefit by reducing infection rates with the more expensive silver-coated catheters have estimated cost savings per patient of only $4.09 *(234)* but annual hospital-wide savings from $12,563 to as much as $573,293 *(236,240)*. In another trial of an antibiotic-impregnated urinary catheter (using minocycline and rifampin), a small number of male patients undergoing radical prostatectomy showed a statistically significant reduction in gram-positive bacteriuria

TABLE 20-1

Randomized Controlled Clinical Trials for the Prevention of Catheter-Associated Urinary Tract Infections, 1962–2007

First Author (Reference)	*Year*	*No. of Patients Studied*	*Intervention Studied*	*Outcome of Trial*	*Comments*
Martin *(267)*	1962	40	Constant bladder irrigation with acetic acid or neomycin–polymyxin vs. open drainage	+	Gynecology patients
Butler *(268)*	1968	470	Polymyxin B vs. placebo lubricant	–

but not gram-negative bacteriuria or candiduria *(241)*. More recently, an RCT of nitrofurazone-impregnated catheters used in adult trauma patients showed a significant reduction in the onset of bacteriuria and funguria up to 30 days, as compared to a silicone catheter *(242)*. Despite the conflicting evidence, current HICPAC guidelines (219) recommend institutions consider using antimicrobial- or antiseptic-impregnated catheters if the UTI rate is elevated and does not decrease after implementing a comprehensive approach to reduce infections.

Alternatives to Foley Catheters

Alternatives to the Foley catheter include the condom catheter for male patients and analogous external urine collection devices for female patients, the intraurethral stent, the conformable catheter, and older approaches such as adult diapers and biofeedback training *(243–245)*. None of these devices has been evaluated in RCTs. However, they are applicable to only certain types of patients (e.g., external devices for women with incontinence or intraurethral stent catheters for males with prostatic obstruction). The conformable catheter, a type of balloon catheter with a collapsible intraurethral segment that may cause less trauma to the urethra, has been tested only in women without urethral strictures and is not commercially available.

A newer method to reduce the use of indwelling catheters involves the use of a portable ultrasound device to scan the bladder before catheterization to accurately measure the volume of urine in the bladder. In a nonrandomized study, this device enabled reduced use of intermittent and indwelling urinary catheters with a reduction in the incidence of UTIs *(246)*. Another study using this method in postoperative patients reported that the rate of urinary catheterization decreased from 31% to 16% *(247)*. However, despite some promise as an objective, safe, and noninvasive technology for assessing the need for urinary catheterization, the use of bladder ultrasound remains underutilized.

Secondary Prevention

Secondary prevention of the complications of UTIs is desirable but has not been evaluated in RCTs. In 1968, Butler and Kunin *(248)* first proposed that routine monitoring of urine cultures from patients undergoing short-term catheterization could enable the use of specific antimicrobial therapy in order to reduce the number of patient-days at risk for gram-negative sepsis. Large-scale clinical trials to test this hypothesis have still not been done. Limited observational studies have been underpowered to detect clinical benefit from early treatment *(60,185)*. However, treatment of asymptomatic bacteriuria in long-term catheterized patients has shown no beneficial effects *(249)*.

Guidelines for the management of catheter-associated UTIs focus on decreasing antibiotic use for asymptomatic bacteriuria. The recommendations are, however, based on very few clinical data, despite the great frequency of this problem and the diverse approaches that have been used. There is also a dearth of well-controlled trials that could be a basis for specific recommendations. Many believe that treatment of asymptomatic bacteriuria while the catheter remains in place has little apparent benefit *(202)*. However, even a single dose of an aminoglycoside antibiotic, if combined with a catheter change, can eradicate bacteria from the urine of catheterized patients *(250)*. The efficacy of this approach has not been evaluated in large-scale trials, but one clinical trial found that daily treatment with a fluoroquinolone antibiotic failed more than half the time with or without a catheter change *(251)*. The high rate

of relapse and reinfection, as well as the adverse consequences of antibiotic use, has also discouraged the routine treatment of asymptomatic bacteriuria.

Wide variation by clinicians likely exists in the use of diagnostic urine cultures, in the indications for antimicrobial treatment, and in the duration of treatment. The practice of obtaining urine cultures only in symptomatic patients may prevent unnecessary treatment *(252)*, but it also prevents an aggressive approach to the detection and management of catheter-associated bacteriuria. A common recommendation is that urine cultures should be obtained at the times of insertion and upon removal of the catheter with an appropriate follow-up culture for those who have acquired bacteriuria *(253)*. Other clinicians recommend against routine cultures even at the time of catheter removal *(254)*. At present, there are few studies to assist in resolving these conflicting recommendations but the opinion is growing to discourage intensive monitoring by culture *(255)*, although the logic behind this approach has been questioned by some authorities *(256)*.

Whether to perform routine cultures to identify catheter-associated bacteriuria, especially in high-risk patients, is an important issue for healthcare epidemiologists. The effective use of closed drainage requires ongoing surveillance, or periodic culture monitoring as recommended by Kunin (7), to uncover epidemic rates, evidence of cross-infection, and possible environmental sources of exogenous infection. The prevention of mortality that is not associated with bacteremia or sepsis may also challenge current approaches to asymptomatic bacteriuria *(65)*. A recent report from France documented a 70% reduction of catheter-related UTI in an ICU setting over 10 years with the use of weekly screening and reflex cultures of all patients with indwelling urinary catheters for more than 2 days in the ICU *(257)*.

The generalization that asymptomatic catheter-associated UTIs should not be treated is already outmoded for certain patient populations. Immunocompromised patients and those undergoing a urologic operation or a surgical procedure involving prosthetic material may also be at high risk for complications of untreated asymptomatic bacteriuria. One study found that asymptomatic bacteriuria in women after short-term catheterization also warranted therapy, even though the bacteriuria resolved spontaneously in 36% of patients *(258)*. In addition, asymptomatic *S. marcescens* UTIs, known to cause a high rate of bacteremia with a prolonged lag time between the onset of bacteriuria and the development of bacteremia, may warrant treatment *(62)*. Therefore, as hospital populations change, with increasing numbers of critically ill and immunocompromised patients, treatment should be considered for many patients with asymptomatic bacteriuria.

Routine monitoring of catheter urine cultures could, in theory, promote more restrained and targeted antibiotic use in catheterized patients and could help eliminate environmental reservoirs of antibiotic-resistant microorganisms *(259)*. More than 80% of catheterized patients receive antibiotics for treatment or prophylaxis of nonurinary infections. Selection of resistance can occur when these antibiotics remain in the drainage bag for extended periods. Virtually no studies assess the contribution of UTIs to the overall problem of antibiotic resistance or means to eliminate these reservoirs of resistant microorganisms. Furthermore, concern has been expressed that the use of antimicrobial-coated catheters may select for resistant microorganisms.

Candiduria has emerged as a problem with a still unclear natural history and few controlled trials of the efficacy of treatment with antifungal agents. Catheter-associated candiduria may resolve in 35% to 40% of patients with catheter removal and in 20% with catheter change alone without antifungal therapy *(260,261)*. On the other hand, the clearance of candiduria by treatment with fluconazole was only temporary *(260)*, though largely in the setting of continued catheter use. Consensus guidelines developed by the Infectious Diseases Society of America for the treatment of urinary candidiasis recommend treatment for certain types of patients, including those with symptoms, neutropenia, or renal allografts, those undergoing urologic manipulation, and low birth weight infants *(262)*. Because use of fluconazole is a risk factor for *Candida glabrata* UTI *(263)* and because the benefits of treatment are still unclear, treatment of catheterized patients with this agent should be avoided if possible.

CONCLUSION

In recent years, a patient safety movement has gathered momentum throughout the world, generating broad public interest in and support for efforts to prevent medical mistakes and adverse clinical outcomes. Healthcare-associated infections are the most common complications affecting hospitalized patients *(264,265)*, and catheter-associated UTIs are the most frequent and perhaps most preventable type of healthcare-associated infection. Despite several decades of investigation by clinicians and epidemiologists, advances in the prevention of such infections are disappointing. Strategies for prevention have been evaluated in randomized controlled trials more frequently for infections associated with urinary catheters than for any other type of healthcare-associated infection. Often, these studies were necessary because of the aggressive marketing of newer modifications of closed drainage systems by their manufacturers. Most of the well-designed large trials found no significant benefits of the new devices and saved healthcare costs through avoidance of more costly equipment. However, other trials have reduced healthcare costs by identifying widely used preventive measures that were not cost-effective or were even harmful. This frustrating history now appears to be a recurring theme with the recent marketing of antimicrobial-coated catheters accompanied by enthusiastic initial reports, followed by disappointing large-scale trials.

Despite the research efforts of a small cadre of committed investigators, healthcare epidemiologists have neglected healthcare-associated UTIs because these infections are associated with relatively low mortality and costs. A reappraisal of the status of UTIs is overdue because of the important relation between antibiotic use in patients with urinary drainage systems and the emergence of multiply antibiotic-resistant hospital pathogens. Drug resistance is now a global problem with the threat of bacterial infections that cannot

be treated with any existing antibiotic and limited prospects for the development of more effective antibiotics. Therefore, we can no longer afford to neglect a category of infection that accounts for nearly half of the healthcare-associated infections; nor can we ignore a patient population—those with indwelling urinary catheter systems—in which antibiotic use is so prevalent.

Epidemiologists must more fully examine and assure the appropriate use of urinary drainage, not simply the problem of healthcare-associated UTIs. Kunin (266) has emphasized that the unnecessary and prolonged use of catheters, the most obvious cause of healthcare-associated UTIs, must be addressed rather than waiting for the perfect technology. Epidemiologists must employ the strengths of their own discipline and not rely only on technical advances from industry.

The agenda for hospital epidemiologists is clear: to eliminate unnecessary urethral catheterization, to promote noninvasive alternatives to the Foley catheter, to reduce the duration of catheterization, and to promote aseptic care of closed drainage systems. Quality improvement programs can successfully restrict the initial use and reduce the duration of catheterization *(42)*, and innovative methods such as the ultrasound bladder scan *(246,247)* can also reduce the use of indwelling urinary catheters in some clinical situations. Because marked variation is inherent in the management of urinary drainage, the techniques of quality management and continuous quality improvement may be especially suitable to identify and implement the best practices. These strategies depend on epidemiologists for the definition and measurement of important outcomes. In an era that touts outcomes research and patient safety, managing urinary drainage represents a model in which the outcomes are definable and important (see also Chapters 10–12).

CHAPTER 21

Surgical Site Infections

Sarah Y. Won and Edward S. Wong

Despite advances in operative techniques, better understanding of the pathogenesis of surgical site infections (SSIs), and widespread use of prophylactic antibiotics, SSIs continue to be a major source of morbidity and mortality for patients undergoing operative procedures. It is estimated that SSIs develop in 2% to 5% of the 27 million patients undergoing surgical procedures each year, resulting in 300,000 to 500,000 infections *(1–3)*. They account for approximately 20% of all healthcare-associated infections (HAIs), making the surgical site the second most common site of HAIs, second only to infections of the urinary tract *(3)*. Compared to surgical patients without SSIs, patients with SSIs have a 2 to >12 times increased risk of death, with 77% of deaths in SSI patients related to the infection *(4–7)*. SSIs add, on average, 7.4 additional hospital days, but can add up to an additional 18 inpatient days, at a cost of between $3,000 and $60,000 per SSI (*1–2,4–10,* 11).

In addition, the rising incidence of methicillin-resistant *Stapylococcus aureus* (MRSA), which is responsible for 7.5% of all SSIs, adds considerable morbidity and mortality in the United States (12). MRSA SSIs may triple rates of death and add an additional $14,000 per infection, compared to patients with methicillin-sensitive *S. aureus* (MSSA) SSIs *(4)*. Total cost of SSIs, including indirect expenses related to SSIs, likely exceeds $10 billion annually in the United States *(5)*.

As a consequence of the significant morbidity, mortality, and cost of SSIs, prevention of SSIs has been receiving increased regulatory, third-party payer, and public attention. SSI prevention has become part of a major quality improvement initiative called Surgical Care Improvement Projects (SCIPs) (13). The Centers for Medicare and Medicaid Services (CMS), the primary payer for Medicare and Medicaid patients, are no longer paying additional reimbursements for certain SSIs, like mediastinitis and select orthopedic infections, and require reporting on two SSI prevention process measures advocated by SCIP *(14)* (see Table 21-1). Public reporting of SSI rates is mandated in an increasing number of states. As a result, understanding the epidemiology, implementing evidence-based prevention measures, and surveillance of SSIs have become all the more important for infection preventionists, surgical teams, and hospitals.

DEFINITION OF SURGICAL SITE INFECTIONS

Clinically, a surgical site can be considered infected when purulent drainage is present at the incision site. This may be associated with local swelling, erythema, tenderness, wound dehiscence, or abscess formation. However, local signs and symptoms may not always be present, nor are they necessarily due to infection when they are present. Therefore, the clinical definition of SSI that has been the most widely adopted is the simplest one—that of a surgical site draining a purulent exudate. Clinicians are encouraged to culture all purulent exudates, but neither culture nor a positive microbiologic result is required for diagnosis of an SSI.

However, the definition of an SSI that is to be used for surveillance and epidemiologic purposes must meet additional needs. Such a definition must be simple to use but also unambiguous so that hospitals with varying surveillance resources will be able to apply it and obtain consistent results so that comparisons between hospitals are meaningful. The Centers for Disease Control and Prevention (CDC) has developed and published definitions for the surveillance of SSIs—see below (15), and they are now widely adopted for surveillance and are the *de facto* national standard.

SSIs are classified as incisional or organ/space. Incisional SSIs are divided further into superficial incisional SSI (when they involve the skin and or subcutaneous tissue—see below) or deep superficial SSI (involvement of the fascia and/or muscle—see definitions below). An organ/space SSI involves structures or organs beneath the area of the incision (15). The anatomic location of each site is depicted in Figure 21-1.

Superficial incisional SSIs are the most common, accounting for more than 50% of all SSIs. However, while only one third of all SSIs are organ/space infections, these infections account for over 90% of deaths related to SSIs *(16)*.

Operative sites are followed for 30 days for the development of SSI, unless an implant is involved, in which case the period of surveillance is extended to a year (15).

TABLE 21-1

Six Performance Measures of the CMS' SCIP

1. Delivery of intravenous antimicrobial prophylaxis within 1 h before incision (2 h are allowed for administration of vancomycin or fluoroquinolones)
2. Use of antimicrobial prophylactic agents consistent with published guidelines
3. Discontinuation of use of prophylactic antibiotics within 24 h after surgery (48 h allowable for cardiothoracic procedures in adults)
4. Proper hair removal: no hair removal or hair removal with clippers or depilatory method. Use of razors is not appropriate
5. Controlling blood glucose during immediate postoperative period for patients undergoing cardiac surgery: controlled 6:00 AM blood glucose level (<200 mg/dL) on postoperative days 1 and 2, with procedure day postoperative day 0
6. Maintenance of perioperative normothermia for patients undergoing colorectal surgery

(From Bratzler DW, Hunt DR. The surgical infection prevention and surgical care improvement projects: national initiatives to improve outcomes for patients having surgery. *Clin Infect Dis* 2006;43:322–330 with permission from Oxford University Press.)

Superficial Incisional Surgical Site Infections: Superficial Incisional Primary/Superficial Incisional Secondary

Superficial incisional SSIs (superficial incisional primary [SIP] or superficial incisional secondary [SIS]) must occur within 30 days after the operative procedure *and* must involve only skin and/or subcutaneous tissue of the incision, *and* at least one of the following must be present:

1. Purulent drainage from the superficial incision
2. Microorganisms isolated from an aseptically obtained culture of fluid or tissue from the superficial incision
3. At least one of the following signs or symptoms of infection—pain or tenderness, localized swelling, redness, or heat—*and* the superficial incision is deliberately opened by the surgeon and is culture positive or not cultured. A culture-negative finding does not meet this criterion.
4. Diagnosis of superficial incisional SSI by the surgeon or attending physician

There are two specific types of superficial incisional SSI:

- Superficial incisional primary (SIP): a superficial incisional SSI that is identified in the primary incision in a patient who has had an operation with one or more incisions (e.g., C-section incision or chest incision for coronary artery bypass graft [CAGB] with a donor site)
- Superficial incisional secondary (SIS): a superficial incisional SSI that is identified in the secondary incision in a patient who has had an operation with more than one incision (e.g., donor site [leg] incision for CABG)

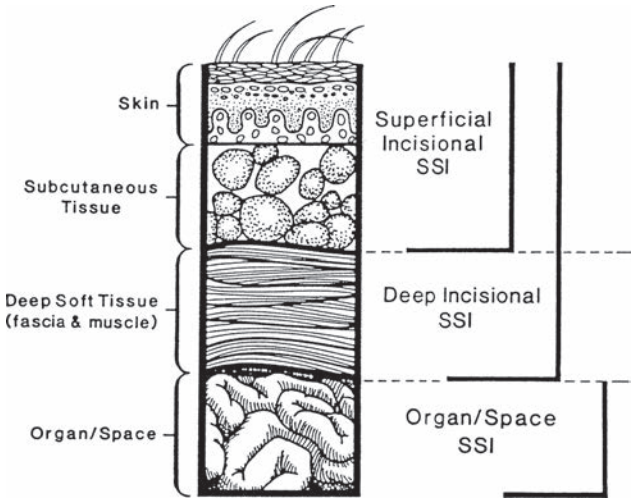

FIGURE 21-1 The anatomy of SSIs and their appropriate classifications.

The following should not be reported as superficial incisional SSIs: (a) stitch abscess (minimal inflammation and discharge confined to the points of suture penetration), (b) localized stab wound infection, (c) infection of a circumcision site in newborns, (d) infected burn wound, (e) incisional SSI that involves or extends into the fascial and muscle layers (should be reported as deep incisional SSI), and (f) involves both superficial and deep incision sites (report as deep incisional SSI).

Deep Incisional Surgical Site Infections: Deep Incisional Primary/Deep Incisional Secondary

Deep incisional SSIs (deep incisional primary [DIP] or deep incisional secondary [DIS]) must occur within 30 days after the operative procedure if no implant is left in place or within 1 year if implant is in place; the infection must appear to be related to the operative procedure; *and* the infection must involve deep soft tissues (fascial and muscle layers) of the incision; *and* at least *one* of the following must be present:

1. Purulent drainage from the deep incision but not from the organ/space component of the surgical site.
2. A deep incision that spontaneously dehisces or is deliberately opened by a surgeon and is culture positive or not cultured when the patient has at least *one* of the following signs or symptoms: fever (>38°C), or localized pain or tenderness. A culture-negative finding does not meet this criteria.
3. An abscess or other evidence of infection involving the deep incision that is found on direct examination, during reoperation, or by histopathologic or radiologic examination.
4. Diagnosis of a deep incisional SSI by a surgeon or attending physician.

There are two specific types of deep incisional SSI:

- Deep incisional primary (DIP): a deep incisional SSI that is identified in the primary incision in a patient

who has had an operation with one or more incisions (e.g., C-section incision or chest incision for CAGB with a donor site)
- Deep incisional secondary (DIS): a deep incisional SSI that is identified in the secondary incision in a patient who has had an operation with more than one incision (e.g., donor site [leg] incision for CABG)

Infection that involves *both* superficial and deep incision sites should be classified as a deep incisional SSI.

Organ/Space Surgical Site Infections

Organ/space SSIs involve any part of the body, excluding the skin incision, fascia, or muscle layers, that is opened or manipulated during the operative procedure. Specific sites are assigned to organ/space SSIs to identify the location of the infection (e.g., intra-abdominal site).

Organ/space SSIs must occur within 30 days after the operative procedure if no implant is left in place or within 1 year if implant is in place and the infection appears related to the operative procedure; *and* the infection involves any part of the body, excluding the skin incision, fascia, or muscle layers, that is opened or manipulated during the operative procedure; *and* at least one of the following must be present:

1. Purulent drainage from a drain that is placed through a stab wound into the organ/space
2. Microorganisms isolated from an aseptically obtained culture of fluid or tissue in the organ/space
3. An abscess or other evidence of infection involving the organ/space that is found on direct examination, during reoperation, or by histopathologic or radiologic examination
4. Diagnosis of an organ/space SSI by a surgeon or attending physician

Occasionally, an organ/space infection drains through the incision. Such infection generally does not involve reoperation and is considered a complication of the incision; therefore, it should be classified as a deep incisional SSI.

INCIDENCE OF SURGICAL SITE INFECTIONS

The true incidence of SSIs across the United States has traditionally been difficult to measure for several reasons: (a) much of the earlier incident data came from the CDC's National Nosocomial Infections Surveillance System (NNIS), which was a voluntary network of 200 larger acute care hospitals that reported HAIs to the CDC, and was not representative of all hospitals; (b) the increasing number of outpatient surgical procedures that were not included in SSI surveillance; (c) and with shorter inpatient stays, SSIs occurring postdischarge with unclear if any or how much postdischarge surveillance was performed.

Since 2005, the National Health Safety Network (NHSN) superseded the NNIS, and unlike the NNIS, the NHSN allows for surveillance of healthcare infections outside the intensive care units, and at other types of healthcare facilities, including ambulatory surgery centers *(14)*. In addition, the NHSN currently includes data from more than 2,000 hospitals across the United States due to two main reasons (a) 21 states' legislative mandates to report surveillance data through the NHSN, and (b) the opening of the NHSN to all hospitals, regardless of size *(16–19)*. Therefore, these SSI rates may be more representative of the true incidence of SSIs. In the most recent NHSN report 2006 to 2008, which includes data from 1,545 hospitals, SSI rates were reported by operative procedure and NNIS risk index (an index used to predict risk of SSIs; see further description below), with lowest risk of SSI designated by NNIS risk index = 0, and highest risk designated by NNIS risk index = 3. Between 2006 and 2008, the pooled mean number of SSI per 100 inpatient operations was as low as 0.2 for gallbladder surgery (NNIS risk index = 0, lowest SSI risk group) and as high as 26.7 for rectal surgery (risk index = 3, highest SSI risk group) *(17)*.

In general, the highest rates of infection occur after abdominal surgeries (reported per 100 surgeries): rectal (3.5–26.7), liver transplant (11.6–20.1), bile/liver/pancreas (8.1–13.7), colon (4.0–9.5), small bowel (3.4–6.8), and kidney transplant (3.7–6.6); however, rates for appendix (1.1–3.5), gallbladder (0.23–1.72), and exploratory abdominal surgery (1.7–2.8) were fairly low. Neck surgeries (NNIS risk index = 2 and 3) also had a high rate of 11.4 SSIs per 100 surgeries. Rates of other high-volume surgeries, therefore with a high absolute number of infections, include all coronary bypass surgery (0.4–8.5), cardiac surgery (1.1–1.8), hip prosthesis (0.7–2.4), knee prosthesis (0.6–1.6), laminectomies (0.7–2.3), spinal fusion (0.7–4.2), cesarean section (1.5–3.8), vaginal hysterectomy (0.7–1.2), and abdominal hysterectomy (1.1–4.0).

For eight outpatient procedures, the rates were between 0.0 and 1.31 per 100 surgeries, but again, it is unclear if any or how postdischarge surveillance was performed *(18)*.

In contrast to SSIs among adults, the rate of SSIs among children has not been studied as extensively. However, medical centers with large pediatric surgical services have published their infection rates. Among these centers, the rate of pediatric SSIs varied from 3.4 per 1,000 admissions at the Children's Hospital in Buffalo *(18)* to 5.5 per 1,000 admissions at the University of Virginia *(20)*. Horwitz reported a rate of 4.4% of all surgeries at three institutions *(21)*. Duque-Estrada reported an overall infection rate of 575 pediatric surgeries to be 6.7%, ranging from 2.7% of clean surgeries to 14.6% of dirty/infected surgeries *(20)*. Both the Horwitz and the Duque-Estrada studies showed increased risk due to the amount of contamination at surgery and duration of surgery, with no difference in risk due to patient-specific factors, length of prior hospitalization, location of operation, or other coexisting diseases, raising the concern that factors at operation, rather than overall physiologic status, contribute to SSIs in children. Another study examining risk factors for sternal wound infection in children undergoing cardiac surgery with sternotomy showed overall SSI rate of 2.7%, with 62% of the infections defined as superficial infections and 38% deep infections. Younger age, cyanotic heart disease, and central venous catheter dwell time increased risk *(22)*. According to CDC estimates based on NNIS, National Health Discharge Service (NHDS), and the American Hospital Association survey, the SSI rates from well-baby nurseries, high-risk nurseries, and intensive care units (both children and adults) were 0.003, 0.2, and 0.95 per 1,000 admission-days, respectively *(3)*.

MICROBIOLOGY

Table 21-2 depicts the most common SSI pathogens and their antibiotic resistance as reported to the NHSN from January 2006 to October 2007 *(14)*. Over the past several decades, the species of microorganisms, and their relative importance, in causing SSI still have not changed considerably. *S. aureus* and coagulase-negative staphylococci continue to be the two most common pathogens isolated largely from clean surgical procedures. When surgery involves entry of the respiratory, gastrointestinal, or gynecologic tracts, pathogens are often polymicrobic, involving aerobic and anaerobic microorganisms endogenous to the organ resected or entered.

In recent years, however, there has been noted in SSIs, as in other sites of HAIs, a shift toward infections with antibiotic-resistant strains of both gram-positive and gram-negative microorganisms. In the NHSN report, from 2006 to 2007, about half of *S. aureus* SSI isolates were methicillin resistant, and 20% of enterococcal infections were vancomycin resistant. Almost a quarter of all *E. coli* were resistant to quinolones, almost 15% of *K. pneumoniae* resistant to third-generation cephalasporins, more than 30% of *A. baumanii* were resistant to carbapenems, and 2% to 5% of *E. coli* and *K. pneumoniae* were carbapenem resistant (12). Infections involving fungi, especially *Candida albicans* and non-albicans *Candida* species, are becoming more common because of the increasing number of immunocompromised patients undergoing operative procedures and use of broad-spectrum antibiotics.

In addition, SSIs caused by unusual microorganisms are also increasingly being recognized; for example, SSIs caused by *Rhizopus rhizopodiformis* due to contaminated adhesive dressings *(23,24)*, multiple outbreaks of infections with rapid growing *Mycobacterium* species *(25–29)*, *Nocardia,* and *Rhodococcus bronchialis* after coronary artery bypass surgery have been reported *(30,31)*. Healthcare-associated SSIs and prosthetic valve endocarditis due to *Legionella pneumophila* after contamination by tap water have been described *(32–34)*. Clusters of infections by such unusual microorganisms clearly warrant investigation to rule out common source exposures.

PATHOPHYSIOLOGY AND RISK FACTORS OF SURGICAL SITE INFECTION

In 1965, Altemeier and Culbertson *(35)* stated that the risk of an infection varies (a) directly in proportion to the dose of bacterial contamination, (b) directly in proportion

TABLE 21-2

SSI Pathogens (NHSN) 2006–2007, *n* = 7,025

Pathogen, Antimicrobial	*% (No.) of Pathogenic Isolates Reported*	*% (No.) of Pathogenic Isolates Resistant*[a]
S. aureus	30.0 (2108)	
Oxacillin		49.2 (1,006)
Coagulase-negative staphylococci	13.7 (965)	Not reported
Enterococcus spp.	11.2 (788)	
Vancomycin		19.7 (136)
Ampicillin		23.8 (151)
Escherichia coli	9.6 (671)	
Ceftriaxone or ceftazidime		5.3 (26)
Fluoroquinolones		22.7 (143)
Carbapenem		2.5 (11)
Pseudomonas aeruginosa	(5.6) 390	
Fluoroquinolone		15.9 (60)
Piperacillin or piperacillin/tazobactam		7.9 (23)
Amikacin		2.0 (4)
Imipenem/meropenem		11.8 (33)
Ceftazidime		5.7 (15)
Enterobacter spp.		
Klebsiella pneumoniae	3.0 (213)	
Ceftriaxone or ceftazidime		8.1 (3)
Carbapenem		5.2 (8)
Candida spp.	2.0 (145)	
Klebsiella oxytoca	0.7 (40)	
Ceftriaxone or ceftazidime		8.1 (3)
Acinetobacter baumanii	0.6 (42)	
Carbapenem		30.16 (11)
Other	19.4 (1,363)	

[a]% (No.) of pathogenic isolates tested that were resistant.
(From Hidron AI, et al. NHSN annual update: Antimicrobial-resistant pathogens associated with healthcare-associated infections: annual summary of data reported to the National Healthcare Safety Network at the Centers for Disease Control and Prevention, 2006–2007. *Infect Control Hosp Epidemiol* 2008;29(11):996–1011, with permission.)

to the virulence of the microorganism, and (c) inversely in proportion to the resistance of the host, that is, the patient's ability to control the microbial contamination.

The host's ability to control the inevitable bacterial contamination of a surgical wound is a complex interaction between overall host characteristics (i.e., age, immunosuppression, obesity, diabetes), appropriate antimicrobial prophylaxis, surgical site conditions during and at the end of the operation (i.e., blood flow, damaged or necrotic tissue, foreign material, including drains and sutures), and operative characteristics (i.e., use of razors for shaving, skill of surgeon, type of surgery). Practically, the surgical site condition may be influenced by perioperative homeostasis, which includes blood glucose levels, normovolemia, oxygenation, and temperature. The condition of the surgical site is also determined by the underlying disease process at the surgical site, that is, severity of trauma or prior radiation.

MICROBIAL RISK FACTORS

Surgical Site Classification

The risk of developing an SSI is affected by the degree of microbial contamination of the operative site. A widely accepted system of classifying operative site contamination was developed by the National Research Council for its cooperative study of the effects of ultraviolet irradiation of operating rooms on SSIs *(36)*, with the least contamination in clean sites and the most in dirty-infected sites. This classification scheme, in a modified form, is as follows:

Clean sites (wounds): These are surgical sites in which no inflammation is encountered and the respiratory, alimentary, genital, and urinary tracts are not entered. In addition, clean wounds are primarily closed and, if necessary, drained with closed drainage. Surgical sites for operations that follow nonpenetrating (blunt) trauma should be included in this category if they meet these criteria.

Clean-contaminated sites (wounds): These are operative sites in which the respiratory, alimentary, genital, or urinary tract is entered under controlled conditions and without unusual contamination. Specifically, operations involving the biliary tract, appendix, vagina, and oropharynx are included in this category, provided no evidence of infection or major break in technique is encountered.

Contaminated sites (wounds): These include open, fresh accidental wounds or operations with major breaks in sterile technique or gross spillage from the gastrointestinal tract. Surgical sites through which there is entry into the genitourinary tract with infected urine or biliary tract with infected bile, and surgical sites in which acute, nonpurulent inflammation is encountered, fall into this category.

Dirty and infected sites (wounds): These include old traumatic wounds with retained devitalized tissue, foreign bodies, or fecal contamination. Surgical sites where a perforated viscus or pus is encountered during the operation fall into this category.

Early studies showed that this surgical site (wound) classification scheme did predict the risk of subsequent SSIs. In Cruse and Foord's *(37)* study, surgery involving clean, clean-contaminated, contaminated, and dirty surgical sites had infection rates of 1.5%, 7.7%, 15.2%, and 40%, respectively. The SSI rates in the National Research Council cooperative study were 3.3% for refined clean sites, 7.4% for other clean sites, 16.4% for contaminated sites, and 28.6% for dirty sites *(36)*.

The correlation of site (wound) class to the risk of SSIs would suggest that intraoperative site contamination should also be linked to the risk of subsequent infections. However, conflicting results were obtained when the microbiology of intraoperative site contamination was examined and attempts were made to correlate microorganisms isolated intraoperatively with pathogens responsible for the SSIs. Barlett et al. *(38)* isolated bacteria from 43 of 91 (47%) intraoperative surgical site irrigation cultures. However, they found no significant difference in the rate of subsequent SSIs between those patients with and those without positive cultures. Further, there was no relationship between the concentration of bacteria in the sites and the subsequent development of infection. A more recent prospective study of neurosurgical patients found no association between total colony-forming unit (CFU) counts of skin flora, either before or after skin preparation, at the operative site and SSIs *(39)*. Therefore, it is clear that degree of microbial contamination is only one risk factor for development of SSIs.

Sources for Pathogens Causing Surgical Site Infections

Pathogens that cause SSIs are predominately acquired endogenously from the patient's own flora or potentially from exogenous contact with operating room personnel or the environment. It is believed that, within 24 hours of an operative procedure, most surgical sites are sufficiently sealed, unless the site was closed secondarily or involved drain placement, making the surgical site resistant to inoculation and infection. Thus, most pathogens, whether endogenously or exogenously acquired, are believed to be implanted at the time of surgery *(40)*. Theoretically, the operative site can be seeded postoperatively by the hematogenous or lymphatic route or by direct inoculation of the closed operative site, but such mechanisms of acquisition are thought to occur infrequently *(40)*. Ehrenkranz and Pfaff *(41)*, however, described a cluster of sternal infections occurring postoperatively that were preceded by infections caused by the same microorganisms at remote sites (pneumonias and bacteremias). In the outbreak of *Legionella* sternal infections reported by Lowry et al. *(34)*, patients were not exposed to contaminated tap water containing *Legionella* during bathing and dressing changes until well after cardiac surgery. Thus, there is evidence to suggest that inoculation (and infection) may occasionally occur postoperatively. Nonetheless, the period of greatest risk for infection remains the time between opening and closing the operative site.

Endogenous Sources of Pathogens The patient's own flora at or contiguous to the site of operation accounts for the majority of SSIs *(42)*. *S. aureus* and coagulase-negative staphylococci, the first and second most frequent causative microorganisms, are residents of skin and mucous membranes, and presumably they are directly inoculated

into the operative site during incision or subsequent manipulations. Between 2006 and 2007, 44% of all SSIs reported to the NHSN were either due to coagulase-negative *Staphylococcus* or *S. aureus*; over 56% of SSIs were due to gram-positive microorganisms and yeast, common skin commensals (12). Unsurprisingly, colonization of the nares and skin with *S. aureus* is a risk factor for developing SSI due to *S. aureus,* and may quadruple the odds of a *S. aureus* SSI compared to those who are not colonized (43). Recently, in a double-blind randomized trial, rapid identification of *S. aureus* colonization by PCR, and subsequent decolonization of the skin and nares of colonized individuals with chlorhexidine showed a 60% reduction in cardiac surgery SSIs due to *S. aureus* (44). However, in order to prevent one *S. aureus* SSI, the number needed to screen and treat was 250 and 23, respectively, making screening and decolonization not cost-effective.

Skin antisepsis during preparation of the operative site for surgery is routinely performed and reduces the surface population of all skin microorganisms, therefore reducing risk of SSIs. Darouiche et al. (45) recently published a prospective randomized study of patients undergoing clean-contaminated surgery (70% abdominal, 30% nonabdominal), which demonstrated a >40% reduction in total SSIs among patients randomized to preoperative chlorhexidine-alcohol skin preparation compared to providine-iodine scrub. This decrease was due to a significant decline in incidence of superficial and deep incision infections caused by gram-positive bacteria and *Candida,* demonstrating the importance of skin flora on incisional SSI pathogenesis, even among clean-contaminated surgeries.

However, if the skin became heavily colonized—for example, as a result of dermatitis—resident flora may persist and be carried into the operative site. In addition, even optimal skin antisepsis may not be able to eradicate all skin bacteria, as up to 20% of these bacteria live beneath the skin's surface along the hair follicles and sebaceous glands *(40)*.

During nonclean surgery, besides the significant role of skin flora that can contaminate the incision, normal flora of the gastrointestinal, respiratory, genital, and urinary tracts can directly contaminate the operative site when these tracts are opened or when injury has occurred to one of these tracts prior to surgery.

The patient's endogenous flora at distant sites may also be a source of SSI. Wiley and Ha'eri *(46)* noted that human albumin microspheres (HAMs) were like human skin squames and could be used as tracer particles. When they applied HAM to the patient's skin outside the area of the incision, they demonstrated that the tracer particles could be easily recovered from the operative site (in 40 of 40 orthopedic operations), suggesting that surface microflora can migrate from distant sites and gain entrance to the operative site despite distance and the use of cloth and adhesive drapes as barriers. Finally, microorganisms causing infections at remote sites may gain access to operative sites by hematogenous or lymphogenous seeding, which is most commonly associated with bacteremia after implantation of prosthetic material (47). Untreated urinary tract, skin, and respiratory tract infections have also been associated with an increase in the rate of SSIs *(48,49)*.

Exogenous Sources of Pathogens

Personnel The hands and nails of the operative team harbor microorganisms that can contaminate the surgical site by direct inoculation during the operative procedure *(50–52)*. This has led to the use of surgical gloves as a barrier to the transfer of microorganisms and to the surgical hand scrub to reduce the microbial population on the skin of the hands. Initially introduced as a way of protecting operating room personnel against dermatitis from Listerian antisepsis, surgical gloving has became a standard of practice as a method to prevent the passage of microorganisms from the surgeon's hands to the patient's surgical site. Whether surgical gloves are an effective barrier has been questioned, since studies have demonstrated that glove perforations occur frequently; this occurs in up to a third or more of operations *(37,52)*. Nonetheless, with appropriate preoperative scrubbing to reduce the burden of microorganisms on the surgeon's hands, there is no evidence that such perforations of surgical gloves are of any clinical significance. Dodds et al. *(53)* found no difference in the rate of SSIs among 100 hernia repairs that were or were not associated with glove perforations.

However, despite standard hand hygiene and gloving, outbreaks due to artificial nails have been reported, due to sequestered microorganisms trapped between the natural and artificial nail *(54)*.

In addition to the hands, other body sites in the operative team may be sources for exogenous contamination of the operative site. The hair and scalp of hospital staff (as well as of patients themselves), nares and oropharynges have been shown to harbor potentially pathogenic bacteria, including *S. aureus* and gram-negative bacteria *(55)*. Despite those observations, however, only a few outbreaks of SSIs have been traced to the hair/scalp or nasopharynx of the operative team *(50,56)*. However, outbreaks of group A *Streptococcus* SSI have been traced to anal or vaginal carriage by operating room personnel *(57–60)*.

Environment The microorganisms that are isolated from the operating room environment are usually considered nonpathogens or commensals that are rarely associated with infections (61). Atypical mycobacteria are ubiquitous and can be recovered from hospital dust but are rarely incriminated in SSIs. In the clusters of infections due to Mycobacterium fortuitum and M. chelonae that followed valve replacement surgery and augmentation mammoplasty (27–29), it was bone wax or gentian violet marking solution that was incriminated rather than the general operating room environment. Spores of Clostridium perfringens have been isolated from the ventilation system and floors of operating rooms (62), but when investigators looked for potential sources for these microorganisms that cause devastating SSIs, they concluded that *C. perfringens* was either endogenously acquired from the patient's own gastrointestinal flora (63) or acquired from contaminated surgical instruments that had been inadequately sterilized between cases (64).

In those rare instances when inanimate sources in the operating room have been incriminated, the sources have been contaminated solutions, antiseptics, or dressings. Contaminated elastic dressings have been implicated

in SSIs caused by *Rhizopus (24,25,65)* and *C. perfringens (66)*. Contaminated solutions have been the source for SSIs caused by *P. aeruginosa, P. multivorans,* and *Serratia marcescens (67–69)*.

It is currently standard practice to wet mop the floor of the operating room with a disinfectant between cases. Coupled with a more thorough wet vacuuming of the rooms and corridors at night, this routine is believed to provide a sufficiently clean environment that minimizes the risk of the operating room environmental surfaces and floors as a source of infection.

Air The role of the operating room air as a source of infection and the need for special ventilation systems in the operating room have long been subjects of debate. The largest source of airborne microbial contamination is the staff in the operating room (61,62). It is presumed that microorganisms become airborne as a result of conversation, which creates droplet nuclei from the respiratory tract, or as a result of shedding from hair or exposed skin. Tracer particle studies using HAMs suggest that airborne microorganisms from the respiratory tract or the head and neck area of operating room personnel can settle on the operative site (46,70,71). Despite this possibility, there is little evidence that the airborne route of transmission contributes significantly to SSIs. Evidence that SSI resulting from airborne contamination occurs at all is based on outbreaks of group A b-hemolytic streptococcal infections that have been reported in the literature (57–60). In these outbreaks, the evidence for airborne transmission was as follows. First, streptococci with the same serotype as the isolates from infected surgical sites were isolated from sites of colonization (anal, vaginal, or pharyngeal) in operating room personnel. Second, the sites of carriage (anal or vaginal) had no possibility of direct contact with the operative site. Moreover, some of these carriers were ancillary personnel who, while they were in the same room, did not work directly in the operative field. Finally, when settling plates were used during these investigations, the epidemic microorganism could be recovered from the air of a room during exercise by the carrier.

Additional evidence for the role of airborne transmission comes from studies on the use of laminar flow air systems and ultraviolet irradiation to provide ultraclean air. Early studies appeared to show a reduction in SSIs when special air-handling systems were used to reduce airborne microbial contamination *(72–75)*. However, many of these studies were flawed, because they were not comparative, had inadequate sample sizes, were not randomized or blinded, or included other interventions that could affect the rate of SSIs. A well-designed multicenter European study compared infection rates among total hip and knee replacement procedures that were performed in rooms with ultraclean air provided by special ventilation systems, antimicrobial prophylaxis alone, or ultraclean air plus antimicrobial prophylaxis (76). In rooms with ultraclean air, the frequency of SSIs decreased from 3.6% to 1.6%; however, when antimicrobial prophylaxis alone was used, the rates dropped from 3.4% to 0.8%. The combination of interventions decreased rates from 3.4% to 0.7%. These results helped demonstrate antimicrobial prophylaxis to be more beneficial in prevention of SSIs than ultraclean air, with no additional benefit of ultraclean air when antibiotics were used.

HOST RISK FACTORS

It is clear that degree of microbial contamination is only one of several variables that determine SSI outcome. Intuitively, host susceptibility, that is, the host's intrinsic ability to defend itself against microbial invasion, should be an important determinant of the risk of infection following surgery. Over the years, studies have demonstrated that such factors as age, obesity, current smoking, prior irradiation at the site of the procedure, malignancy, immunosuppressives, the presence of certain underlying diseases such as diabetes (and hyperglycemia), and *S. aureus* nasal colonization can all increase risk of SSI (*36*,43,*77–82*).

Age

Of these host factors, advanced age has consistently been found to be a risk factor for SSIs, likely due to increased comorbidities, decreased immune function, increasing frailty, and malnutrition (*36,37,77,83–85*). In contrast, others, like Garibaldi and Cushing *(86)*, did not find age to be a risk factor. In their study, it was suggested that age is a marker for increased comorbidities. In the national nosocomial infection study by Haley et al. *(87)*, the percentage of SSIs after 75 years decreased. Recently, Kaye, using a large cohort of over 70,000 procedures, demonstrated that the risk of SSI increased by 1.1% per year between ages of 17 and 65; however, at ≥65 years, the risk of SSI decreased by 1.2% per year *(88)*. Though unclear why rates of SSI should decrease after 65 years of age, lower rates may be a reflection of a surgical selection bias, that only healthier older patients are taken for surgery, or that very old patients are "hardy survivors," with better genetics that enable them to better handle the stressors of surgery. Nevertheless, other studies have shown that elderly patients with SSIs are at increased risk for death compared to younger patients with SSIs. For instance, elderly patients with *S. aureus* SSI were greater than three times more likely to die than younger patients with *S. aureus* SSIs *(89)*.

Diabetes and Hyperglycemia

One risk factor associated with SSIs is elevated blood glucose levels perioperatively or a history of diabetes. Pathophysiologically, diabetes impairs leukocyte adherence, phagocytosis, and overall ability to kill bacteria. In addition, the extracellular glycosylation of proteins due to high blood glucose levels impairs wound healing *(90)*. Cruse and Foord *(37)* reported higher rates of SSIs in their patients with diabetes, as did Nagachinta et al. (91) in their prospective study of 1,009 cardiac surgery patients. In the latter study's regression analysis, diabetes mellitus and obesity were the two host factors that remained independently associated with sternal or mediastinal SSIs. Since these early studies, diabetes has most consistently been associated with increased SSI, especially deep sternal wound infections, in cardiovascular patients (*90,92,93,*94), but has also been a documented risk factor in patients undergoing mastectomy and hepatobiliary-pancreatic cancer surgeries as well *(95,96)*.

More important than a history of diabetes may be the level of postoperative hyperglycemia. Latham et al. *(93)*

observed that in cardiac surgery patients, the risk of SSIs after cardiovascular surgery correlated with the level of postoperative hyperglycemia. The odds of developing an SSI was >2.5 when blood glucose was 200 or more within 48 hours after surgery, compared to those with levels <200 *(93)*. Other cohort studies *(90,94)* have also demonstrated improved deep sternal SSI rates with improving blood glucose levels to <200 in the 48 hours postoperatively, most effectively achieved with continuous insulin infusion.

However, it is unclear if more aggressive hyperglycemia management, below glucose levels of 200, is associated with decreases in cardiovascular SSI. The Diabetic Portland Project, which was an observational cohort study of diabetic cardiovascular surgery patients, demonstrated, over time, the progressive reduction in sternal wound infections, mortality, and length of stay with the use of progressive lowering of target blood glucose ranges by using continuous insulin pump protocols *(97)*. The lowest rates of deep sternal wound infections were found by targeting blood glucose levels of 100 to 150. However, a meta-analysis of five randomized controlled trials comparing conventional blood glucose control (blood glucose <200, which is the current recommendation by IDSA/CDC) versus strict glucose control did not show any SSI, mortality, or length of stay, benefits to strict glycemic control; however, the studies had multiple limitations of sample size and methodologic quality *(98)*.

In addition to postoperative hyperglycemia, long-term hyperglycemia may be a risk factor for SSIs as well. Dronge et al. *(99)* demonstrated in a retrospective study that patients with good long-term control of blood glucose (hemoglobin A1c <7%) had decreased infectious complications (SSIs, pneumonia, urinary tract infection, or sepsis) across a broad range of surgeries, specifically excluding cardiac cases. In Latham's study *(93)* of cardiac patients, patients with good long-term control of diabetes (hemoglobin A1C <8%) were at less risk of developing postoperative hyperglycemia.

Nutrition

The association between malnutrition and SSIs is not well proven. The National Research Council study showed that the crude rate of SSIs was 22% in severely malnourished patients compared to 7% in well-nourished patients *(36)*. However, subsequent studies have not demonstrated an increased risk of SSIs with malnutrition, after adjusting for other risk factors (91,*100*). Multiple trials have not demonstrated any benefit of preoperative total parenteral nutrition (TPN) or other "nutritional therapies" in prevention of SSIs (101).

On the contrary, studies have repeatedly demonstrated the increased risk of SSIs with obesity (*36*,91,*102,103*). This increased risk is likely multifactorial, including increased amount of tissue necrosis, compromised blood flow, but also may be due to inadequate dosing of prophylactic antibiotics *(104)*. Forse et al. *(104)* demonstrated a decrease in wound infections in morbidly obese patients undergoing gastroplasty surgery from 16.5% to 5.6% (2.5% in normal weight patients) by administration of 2 g of cefazolin, rather than 1 g normally administered perioperatively.

Smoking

Nicotine may increase rates of SSI by reducing blood flow, therefore delaying primary wound healing. Nagachinta et al. (91) demonstrated in a large prospective trial that patients who are current smokers have twice the increased odds of SSI compared to ex-smokers or nonsmokers. Other studies have supported these findings.

PROCEDURAL RISK FACTORS

Prolonged Preoperative Stay

Over the years, studies have consistently demonstrated an adverse effect of prolonged preoperative stay on the rate of SSIs. The National Research Council study found that the rate of SSI rose from 6% for a preoperative stay of 1 day to 14.7% when the preoperative stay was 21 or more days *(36)*. Cruse and Foord *(37)* reported that the overall infection rate was 1.1% for patients whose preoperative stay was 1 day versus 2.1% in patients who remained in the hospital for 1 week before their operation. These early studies might be criticized, because the influence of other risk factors was not specifically taken into account. Other studies, however, have used multivariate analysis methodology to adjust for potentially confounding variables (91,*105,106*). These studies continue to find prolonged preoperative stay to be an important independent risk factor for SSIs.

The mechanism(s) by which prolonged hospital stay brings about an increased risk of infection is unknown. A long preoperative stay may promote proliferation of endogenous microorganisms, which can then more heavily contaminate the surgical site, or such a stay may promote the acquisition of hospital-acquired multidrug-resistant pathogens. Prolonged preoperative stay also permits the performance of procedural interventions that allow microorganisms access into the body (portals of entry) or chemotherapeutic interventions that can adversely affect host resistance (e.g., steroids) or alter normal flora (e.g., through exposure to antibiotics). Researchers have found that patients who are hospitalized for cardiovascular surgery quickly become colonized with methicillin-resistant coagulase-negative staphylococci and that these microorganisms were responsible for surgical site complications including mediastinitis and prosthetic valve endocarditis *(106–109)*, though it is unclear whether these microorganisms were acquired during their admission or whether the perioperative antibiotics selected for drug-resistant strains.

Preoperative Shave

In 1971, Seropian and Reynolds *(110)* compared the SSI rate among 406 surgical patients randomized to hair removal by razor or by depilatory. The rate of infection after shaving was 5.6% compared with 0.6% when hair was removed by a depilatory or not removed at all ($p < .02$). In this study, the timing of hair removal also affected the infection rate. Among patients subjected to the razor, the infection rate was 3.1% when the shaving was done just before surgery versus 7.1% when the patient was shaved within 24 hours of surgery, and >20% when patients were shaved more than 24 hours before surgery. In the study by Cruse and Foord *(37)*, similar results were obtained. Patients who were shaved with a razor had the highest rate of infection at 2.5%, clipping decreased the infection rate to 1.7%, and shaving with an electric razor had a rate of 1.4%. Those who were

neither shaved nor clipped had the lowest infection rate of 0.9%. A recent meta-analysis that evaluated 11 randomized controlled trials concluded that there were no differences in SSI rates among those who had hair removal versus those who did not. If hair was removed by shaving versus clipping, the relative risk of SSI was two times higher (RR: 2.02, 95% confidence interval [CI]: 1.21–3.36) *(111)*.

When a scanning electron microscope was used to examine the skin after removal of hair with a razor, electric clipper, and a depilatory, photographs showed that the razor caused gross skin cuts, the clipper caused less injury, and the depilatory caused no injury *(112)*. Thus, the increase in SSIs may result from disruptions in the skin barrier caused by the razor, permitting an increase in colonization or actual invasion with either resident or exogenous microorganisms at the incision site.

Surgical Hand Antisepsis Surgical hand antisepsis is intended to reduce the number of microorganisms on the surgeon's hands and reduce contamination of the operative site through recognized or unrecognized breaks in surgical gloves. This is achieved through the use of an antiseptic hand scrub preparation or hand rub, which the U.S. Food and Drug Administration defines as "a nonirritating antimicrobial containing preparation that significantly reduces the number of microorganisms on intact skin" *(113)*. The only trial evaluating SSI rates found no difference in SSI rates between surgeons that underwent hand rubbing with alcohol solutions versus traditional surgical hand scrubbing. Five-minute hand rubbing with an alcohol solution, preceded by a 1-minute nonantiseptic hand wash before the surgeon's first procedure of the day or before any procedures if the hands were visibly dirty, was compared to at least 5 minutes of hand scrubbing with solutions containing 4% povidone iodine or 4% chlorhexidine gluconate. Not only were there no difference in rates of SSI, but hand-rubbing protocol was better tolerated and had increased rates of compliance (114). Other studies that evaluated CFU of bacteria as the outcome suggest that aqueous alcohol rubs are as effective, or more effective, in reducing CFUs *(115)*.

When comparing only aqueous scrubs, in a recent meta-analysis *(115)*, using microbiologic data as an end point, solutions containing chlorhexidine gluconate appear to be the most effective in reducing microbial hand flora compared with iodophors or hexachlorophene-containing products. No clinical data indicate that reduction of hand flora with hand scrubs will lead to a reduction in the rate of SSIs.

The wearing of long or artificial nails by operating room personnel may compromise the efficacy of the preoperative hand scrub. Several studies suggested that long or artificial nails enhance hand colonization with bacteria and fungi *(116,117)*. In several investigations, such enhanced colonization was linked to outbreaks of bloodstream infections by *P. aeruginosa* in a neonatal intensive care unit and SSIs with *S. marcescens* among cardiovascular surgery patients *(117,118)*. These reports have prompted the CDC in its latest guideline to recommend that operating room team members keep their nails short and that they not wear artificial nails (category IB) (101).

Preoperative Showers Preoperative bathing or showering with an antimicrobial product has been advocated as a preoperative measure with the goal of reducing skin colonization by bacteria that can contaminate the operative site. Cruse and Foord *(37)* reported that SSI rates for clean sites (wounds) were 2.3% for patients who did not shower, 2.1% for patients who showered with soap, and 1.3% for those who showered with hexachlorophene. Studies by Wihlborg *(119)* and Hayek et al. *(120)* seem to confirm the observations of Cruse and Foord. However, other trials have failed to demonstrate a significant difference in SSI rates when different methods of preoperative bathing were used. Garibaldi et al. *(121)* observed no significant difference in infection rates between surgical patients who showered with chlorhexidine and those who showered with povidone-iodine or bar soap. In a large prospective, randomized, double-blinded trial involving 1,400 patients who bathed preoperatively with or without chlorhexidine *(122)*, and a smaller, more recent study in 2009 *(123)* also were unable to find any significant difference in infection rates. In a recent meta-analysis (124), which included seven studies, there was no significant difference in infection rates between those who showered with chlorhexidine versus placebo or those who showered with chlorhexidine versus soap and water. However, one large study did show decreased SSI rates with chlorhexidine versus no shower *(125)*.

Barrier Devices Experimental studies using tracer particles suggest that microorganisms can be shed from hair, exposed skin, and mucous membranes of operating room personnel and that the patient's endogenous skin flora contiguous to or even distant from the operative site can gain access to the operative site through indirect contact *(46,70)*. The use of masks, hoods, and gowns by operating room personnel is intended to reduce shedding of microorganisms by operative personnel. Similarly, surgical drapes are used to cover the patient except for the operative site and to act as a barrier to contamination from endogenous skin flora by indirect contact. Despite the strong theoretical rationale based on these experimental studies, no clinical studies have proved that the use of the barrier devices discussed below has led to a reduction in the rates of SSI.

Masks A 1991 study found no difference in the numbers of SSIs among patients undergoing operations by surgeons who did or did not wear masks *(126)*. Similarly, Orr *(127)* observed no increase in the infection rate when masks were not worn for 6 months. These studies question the importance of surgical masks as an infection control measure. The most important role of the surgical mask is to prevent contamination of the mucous membranes of the operative team.

Caps Surgical caps are worn to prevent hair and skin squames, potentially laden with microorganisms, from falling into the operative field. As noted previously, with the exception of a few outbreaks traced to the hair as a source *(55,56)*, there is scant evidence that hair is an important source for surgical site contamination or that caps are effective in preventing such contamination.

Gowns and Drapes Overall, the use of gowns and drapes to prevent surgical site contamination and infection is logical, and their value is implied but not proven

in clinical studies *(128)*. One of the most important roles for surgical gowns is protection of the operative team from contamination by blood and body fluids.

In addition to drapes that simply cover the skin, adhesive plastic drapes are available that are applied to the skin at the operative site. The belief is that adherent coverage of skin up to the margin of the incision would more effectively prevent surgical site contamination from contiguous sites. Paradoxically, Cruse and Foord *(37)* noted a higher infection rate when plastic drapes were used. Other studies, including the findings of a recent meta-analysis, found no difference in infection rates when adhesive plastic drapes were compared to conventional drapes *(129–131)*.

Shoe Covers The use of shoe covers has been a standard practice in operating rooms. However, no studies demonstrate that their use affects SSIs. The American Hospital Association recommends shoe covers only when laundry facilities permit. The principal utility of shoe covers may be protection of the operative team's shoes from contamination by blood and other body fluids.

Preoperative Antibiotics Contamination of operative sites, even clean ones, is unavoidable despite the best preparation and operative technique. Studies by Culbertson et al. *(132)*, Howe and Marston *(133)*, and Burke *(134)* have shown that potentially pathogenic bacteria, including *S. aureus*, can be recovered from up to 90% of surgical sites just before closure. The goal of prophylactic antibiotics, therefore, is to eradicate or retard the growth of contaminant microorganisms such that SSI can be avoided. The practice began with Lister and his carbolic acid wound antisepsis. The advent of antibiotics saw their use as a means of preventing SSIs. Over the past 40 years, numerous animal and clinical trials have demonstrated the importance of appropriate perioperative antibiotics in preventing SSI. Based on these studies, CMS, the Joint Commission, and other organizations have created performance measures in the SCIP that emphasize the importance of using the appropriate antibiotics, appropriate timing of antibiotics, and prompt discontinuation of antibiotics in SSI prevention (13).

There are five main principles in the use of prophylactic antibiotics:

1. Use of antibiotics for appropriate procedures. The consensus among experts, including the CDC, is that antibiotic prophylaxis is appropriate when the operation is associated with a high risk of infection or when the consequences of an SSI are disastrous, even if the risk of infection may not be high—for example, in operations involving any prosthetic implant or cardiothoracic surgeries where mediastinal infections have catastrophic consequences (13,101,*135*). According to this principle, surgical prophylaxis is indicated for all clean-contaminated and contaminated operative procedures, and certain clean surgeries. Prophylactic antibiotics are not indicated for most clean surgery, which have low rates of infection and in which the risks of antibiotics may outweigh the benefits, or dirty/infected surgical sites for which the use of antibiotics are therapeutic and not prophylactic.
2. The antibiotic chosen should be effective against the most likely pathogen(s) encountered, taking into account their antibiotic susceptibilities, drug pharmacokinetics and concentrations, and patient allergies. All surgical procedures that require an incision through the skin are at risk for developing infections with staphylococcal species; therefore, all prophylactic antibiotics should have good staphylococcal coverage. Gastrointestinal, gynecological, and urologic procedures need additional gram-negative Enterobacteriaceae and anaerobic coverage. First (e.g., cefazolin)- and second-generation cephalosporins (e.g., cefoxitin) are the drugs of choice for most surgical procedures due to their activity against the most commonly isolated microorganisms, bactericidal activity, safety profile, and cost (101,*135*,136).

However, the rising incidences of methicillin-resistant *S. aureus* (MRSA), both community-associated and healthcare-associated, and methicillin-resistant *Staphylococcus epidermidis* challenge the empiric use of cephalosporins as prophylaxis. Currently, the CDC and most experts continue to recommend cephalosporins as empiric antibiotics of choice, unless the local prevalence of MRSA is high. However, "high" MRSA rates are not well defined. In addition, vancomycin use in place of cefazolin has not been shown to decrease overall rates of SSIs, as demonstrated in a randomized study of cardiac surgery patients. Those who received cefazolin for prophylaxis had higher rates of MRSA infections, while those who received vancomycin had higher rates of MSSA infections, with no difference in the overall rate of SSI *(137)*. In a meta-analysis of seven randomized trials that compared SSI in patients receiving glycopeptides prophylaxis (i.e., vancomycin) versus those who received β-lactams, neither agent was superior for the prevention of SSIs though glycopeptides were superior in the prevention of SSIs caused by methicillin-resistant gram-positive microorganisms (138). However, many of the studies included in the meta-analysis were performed over 10 years ago, when the incidence of MRSA was lower than present. In a more recent interrupted time series analysis (139), CABG patients were compared before and after an institutional switch from cefuroxime to vancomycin. The monthly SSI rates of CABG decreased by 2.1 cases per 100 surgeries when compared to control patients who had received vancomycin for valve replacement surgery during the entire time period. This study suggests that the decline in SSI rates in CABG patients was due to the change to vancomycin and decrease in infections caused by methicillin-resistant microorganisms, and not by other confounders (139).

Yet, the routine use of vancomycin in prophylaxis raises concerns of increasing the rates of vancomycin-resistant staphylococcal and enterococcal species *(140)*. In addition, vancomycin has a narrow spectrum of activity (no gram-negative coverage) compared to cephalosporins, slower bactericidal killing, long infusion times, and poorer tissue and bone penetration. Thus, routine use of vancomycin in place of cefazolin raises concerns for decreased efficacy against methicillin-susceptible microorganisms, poor drug levels in tissues, increased risk of vancomycin-resistant microorganisms, and a rise in gram-negative microorganisms as causes of SSI or other postsurgical infections (138,*140*).

Currently, the Society of Thoracic Surgeons recommends both vancomycin and cefazolin to be administered perioperatively in cardiac surgery patients if (a) in the setting of either a presumed or a known staphylococcal

colonization, (b) high incidence of MRSA, (c) patients susceptible to colonization (hospitalized >3 days, transfer from another inpatient facility, already receiving antibiotics), (d) or an operation for a patient receiving a prosthetic valve or a vascular graft insertion *(141)*. Certainly, surgical patients who need prophylaxis, and have been identified as MRSA carriers either by preoperative screening or during other healthcare exposures, should receive vancomycin in place of, or perhaps, in addition to a cephalosporin.

3. The timing of antibiotic administration should be such that there are adequate concentrations of the antibiotic in the tissue at the time contamination is likely to occur (as soon as the incision is made).

The classic work of Burke *(142)* in 1961 provided the experimental basis for the scientific study of antibiotic prophylaxis. He showed how critically important timing was in the administration of the antibiotic. Burke administered penicillin at various times before and after intradermal inoculation of *S. aureus* into the skin of guinea pigs and found that, when the antibiotic was administered before or shortly after the inoculation, there was a marked reduction in the severity of inflammation and infection. If administration of the antibiotic was delayed for more than 3 or 4 hours after inoculation, there was no appreciable difference in the size of the dermal lesion or infection compared with animals who received no prophylaxis. The clinical importance of the timing of preoperative antibiotics was reaffirmed by Classen et al. (143). These authors prospectively monitored the effect of the timing of administration of prophylactic antibiotics on the occurrence of SSIs in 2,847 elective clean and clean-contaminated procedures. When prophylactic antibiotics were administered during the 2 hours before incision, the SSI rate was the lowest, at 0.6%, with the rate more than doubling to 1.4% when given during the 3 hours after the incision. The highest rates of infection occurred when antibiotics were administered either early (2–24 hours before incision) at 3.8% or postoperatively (3–24 hours after incision) at 3.3%.

While guidelines differ on the exact ideal timing of antibiotics, ranging from 30 minutes up to 120 minutes prior to incision, the CMS and The Joint Commission have advocated infusion of antibiotics within 60 minutes prior to incision for antibiotics, except for vancomycin and fluoroquinolones that can be infused up to 2 hours prior to incision due to their long infusion times and risk for reactions (13). Currently, the timing of antibiotics within 60 minutes has become a national standard performance measure that is being collected and increasingly publically reported.

Since these early landmark studies, the recently published Trial to Reduce Antimicrobial Prophylaxis Errors (TRAPE) (144), which prospectively collected data from 29 hospitals and 4,472 randomly selected cardiac, hip/knee arthroplasty, and hysterectomy cases, demonstrated that the risk of SSIs was lowest in patients who received prophylaxis 0 minutes to 30 minutes (for cephalasporins) prior to incision (or within 1 hour for vancomycin or a fluoroquinolone). When vancomycin and fluoroquinolones were excluded, the risk of infection was 1.6% when antibiotics were administered 0 to 30 minutes before incision, compared to 2.4% when the antibiotics were administered 31 to 60 minutes prior incision, with a conditional OR 1.74 (95% CI: 0.98–3.08). The risk of infection increased as the time before antibiotic administration and incision increased or if the antibiotic was infused after the incision (144). Nevertheless, their data do not warrant changing the guidelines from 60 minutes to 30 minutes prior to incision, as the differences in infection rates may be due to chance. Certainly, though, there is no risk and likely benefit in giving short-infusing antibiotics, like cephalosporins, within 0 to 30 minutes of incision.

4. It is important to maintain therapeutic levels of the drug in tissue and blood throughout the entire procedure, which may require redosing of antibiotics during longer procedures and/or higher dosages of antibiotics in obese patients. During prolonged procedures, the open wound is at ongoing risk for bacterial inoculation, and so, adequate concentrations of antibiotics should be maintained for the entire surgical procedure. Therefore, for procedures that are prolonged and have received antibiotics with short-half lives (most cephalosporins), redosing of antibiotics is recommended (11,101,*145*). The TRAPE study observed that the intraoperative lack of redosing with cephalosporins increased the odds of infection (OR: 3.08, 95% CI: 0.74–12.9) in procedures lasting more than 4 hours, as long as the initial dose of antibiotic was timed correctly (144).

In obese patients, traditional dosing of antibiotics may not be adequate to achieve therapeutic levels above the mean inhibitory concentration (MIC) of most microorganisms. In one study of morbidly obese individuals, a 2-g dose of cefazolin rather than 1-g dose was needed to have cefazolin levels greater than the MIC for most bacteria; in addition, this study showed that the use of the 2-g dose dramatically decreased rates of SSI from 26.5% to 5.6% *(104)*. However, in another study, authors found that, even after a 2-g perioperative dose of cefazolin, therapeutic tissue levels were achieved in only 48% of patients with a body mass index (BMI) between 40 and 49, and were achieved only in 10% of patients with a BMI ≥ 60 *(146)*, raising the issue of whether continuous cefazolin infusions are preferable in the morbidly obese.

5. Antibiotics should be discontinued to prevent rise of resistant microorganisms and *Clostridium difficile*. A review of 28 randomized trials comparing one dose versus multiple doses of perioperative antibiotics has not shown any difference in the rates of SSIs across multiple surgical procedures, as antibiotic prophylaxis is limited in efficacy once the wound is closed *(147)*. Even in cardiovascular surgery patients with drains left in place, studies have documented no improvement in SSI rates with antibiotics longer than 48 hours *(148)*. In addition, the prolonged courses of antibiotics have been associated with increased rates of antibiotic-resistant microorganisms and *C. difficile* infections *(148)*. Therefore, most guidelines, including SCIP, recommend discontinuation of prophylactic antibiotics within 24 hours, and within 48 hours after cardiac surgery (11,101,*149*).

The surgical procedures for which antibiotic prophylaxis is currently recommended are shown in Table 21-3.

Intraoperative Measures

Preparation of the Incisional Site

Since SSIs are primarily caused by the skin flora of patients undergoing surgeries, optimal skin antisepsis prior to incision is an important part of SSI prevention. Traditionally,

TABLE 21-3

Antibiotic Prophylaxis for Surgical Procedures to Prevent SSI

Procedure	*Expected Pathogens*	*Antibiotic of Choice*[a]
Cardiac (coronary artery bypass, valve replacement, pacemaker insertion)	*S. aureus, S. epidermidis*, GNB[b]	Cefazolin, cefuroxime, or vancomycin[c]
Vascular surgery	*S. aureus, S. epidermidis*, GNB	Cefazolin or vancomycin[b]
Neurosurgery		
CSF shunt procedures	*S. aureus, S. epidermidis*	Cefazolin or vancomycin[b]
Craniotomy	*S. aureus, S. epidermidis*	Cefazolin or vancomycin[b]
Thoracic (lung resection)	*S. aureus*	Cefazolin
Ophthalmic (lens extraction)	*S. aureus, S. epidermidis,* streptococci, GNB	Topical gentamicin, or tobramycin or neomycin-gramicidin-polymyxin B or subconjunctival cefazolin
Orthopedic		
Joint replacement	*S. aureus, S. epidermidis*	Cefazolin, or vancomycin[b]
Amputation of lower limb	*S. aureus*, GNB	Cefoxitin
General surgery		
Gastric resection	GNB	Cefazolin
Cholecystectomy	GNB, enterococci, clostridia	Cefazolin
Colon surgery	GNB, anaerobes	Oral neomycin and erythromycin base or cefoxitin
Appendectomy	GNB, anaerobes	Cefoxitin or cefotetan
Penetrating abdominal trauma	GNB, anaerobes, enterococci	Cefoxitin or cefotetan
Head and neck		
Procedures with incision through oral or pharyngeal mucosa	*S. aureus*, streptococci, anaerobes	Cefazolin or clindamycin
Gynecologic		
Hysterectomy	GNB, anaerobes, streptococci, enterococci	Cefazolin
Cesarean section	GNB, anaerobes, streptococci, enterococci	Cefazolin[c]
Abortion	GNB, anaerobes, streptococci, enterococci	Cefazolin[d]

[a]Unless indicated, route of administration is intravenous.
[b]To be used when methicillin-resistant *S. aureus* or *S. epidermidis* may be encountered or if patient is allergic to β-lactam antibiotics.
[c]Not to be used in uncomplicated elective procedures.
[d]To be used in uncomplicated abortions unless patient has history of previous pelvic inflammatory disease.
GNB, gram-negative bacilli.

the operative site is prepared first by cleaning to remove superficial bacteria and organic debris and then by application of an antimicrobial solution to reduce the deeply resident skin flora. The most commonly used preoperative skin preparation agents include iodine, chlorhexidine and iodine, or chlorhexidine-containing compounds. Both chlorhexidine and iodophors have a broad spectrum of activity and are effective in reducing the number of microorganisms on intact skin *(150–152)*. Chlorhexidine has a broad spectrum of activity and a substantive action after a single application; unlike the iodophors, it is not inactivated by blood and serum proteins. Chlorhexidine-alcohol has been recommended as the antiseptic of choice to prevent catheter-associated blood stream infections *(153)*.

Darouiche et al. (45) recently published the first multicentered prospective randomized study comparing efficacy of chlorhexidine-alcohol versus povidone-iodine in preventing SSIs in patients undergoing clean-contaminated surgery (70% abdominal, 30% nonabdominal). Patients were randomly assigned to have the operative skin site scrubbed with either 2% chlorhexidine gluconate and 70% isopropyl alcohol or preoperatively scrubbed and then painted with 10% povidone-iodine. Among the total 849 patients in this study, the chlorhexidine-alcohol group had a 41% reduction in risk of all SSIs (RR: 0.51, 95% CI: 0.41–0.85, $p = .0.004$), a 52% reduction in superficial SSIs (RR: 0.48, 95% CI: 0.28–0.84), and a 67% reduction in deep SSIs (RR: 0.33, 95% CI: 0.11–1.01, $p = .05$) compared to the povidone-iodine group. There was no significant difference in organ-space infections between the two groups. Seventeen patients were needed to be treated with chlorhexidine-alcohol versus povidone-iodine to prevent one SSI (45).

While the CDC has not recommended chlorhexidine-alcohol as the antiseptic of choice, this study strongly advocates for the routine use of chlorhexidine-alcohol over povidone-iodine for surgical site preparation (11).

Reduction of Airborne Contamination in the Operating Room Traffic and activity of operating room personnel, including talking and movement, are responsible for increasing the bacterial count in the air (70,71). These airborne microorganisms are usually attached to

dust particles, squames shed by operating room personnel from uncovered skin areas, or respiratory secretions generated by conversation. Attached to particles, these microorganisms settle quickly but can contaminate operative sites located a short distance from the source of the microorganisms. Because of the relationship between the number of operating room personnel and bacterial air count, one method of reducing airborne contamination would be to control the number of people allowed in the operating room and their activity ("traffic control"). Traditionally, this included restricting the number of people allowed in the operating room, closing the doors to the operating room to prevent in and out traffic, and limiting unnecessary movement and talking once in the operating room. The use of proper operating room attire should also serve to decrease the amount of airborne contamination by decreasing the amount of shedding from exposed body areas.

Airborne contamination may be further reduced through dilution by high-volume exchanges with clean, filtered air and introduction of outside air. The standard set by the Public Health Service for the minimum number of air exchanges for the operating room is 15 air changes per hour with three exchanges of outside air *(154)*. However, the value of such a standard requiring high air exchanges is unproven *(155)*. Maki et al. *(156)* compared the results of microbiologic sampling in the operating room and SSI rates in an old and a new hospital. The mean number of microorganisms was lower in the new hospital with 25 air exchanges per hour, compared with 16 air exchanges per hour in the old building. However, they observed no difference in the SSI rates.

Laminar flow ventilation systems and ultraviolet irradiation further decrease airborne contamination to very low levels (ultraclean air). As noted, such ultraclean air would only be expected to lower the SSI rate for clean surgery; specifically, ultraclean air might be of benefit in orthopedic surgery involving the insertion of prosthetic devices, but not for procedures in the other surgical site classes (*36*,76). Even then, the same benefits may be achieved through the use of prophylactic antibiotics. Indeed, a follow-up study by the British National Health Service suggested that, for total joint replacement surgery, antimicrobial prophylaxis was more cost effective than an ultraclean air system *(157)*. Modern rates of organ/space (deep) SSIs following total hip arthroplasty using conventional air-handling systems, standard barrier techniques, and prophylactic antibiotics are comparable with rates reported with ultraclean air-handling systems *(158,159)*.

Length of Operation

The length of surgery has long been established as an important risk factor for SSI. Cruse and Foord *(37)* found a direct relationship between duration of surgery and the infection rate. Among clean wounds, the infection rates for operations lasting 1, 2, and 3 hours were 1.3%, 2.7%, and 3.6%, respectively. The SENIC study found that having an operation lasting more than 2 hours was one of four risk factors for SSI that remained significant when logistic regression techniques were applied to the SENIC database *(160)*. In refining the SENIC risk index for NNIS, Culver et al. *(161)* noted that the 75th percentile of the distributions of duration of surgery for each procedure was a better predictor of infection than the common cut point of 2 hours used for all procedures in the SENIC index. Garibaldi and Cushing *(86)* applied stepwise logistic regression to the analysis of 1,852 procedures and found that the duration of surgery >2 hours was associated with a relative risk of 3 (CI: 1.6–3.6) for SSIs.

Exactly how lengthening duration of surgery increases the risk for SSI remains speculative. Cruse and Foord *(37)* listed four possible explanations: (a) an increase in the contamination of the wound with longer operations; (b) an increase in tissue damage from drying, prolonged retraction, and manipulations; (c) an increase in the amount of suture and electrocoagulation, which may reduce the local resistance of the wound; and (d) greater suppression of host defenses from blood loss and shock. Garibaldi and Cushing *(86)* added that the duration of surgery may be a marker for factors that are difficult to incorporate in multivariate modeling such as the skill of the surgeon and complexity of surgery. Shapiro et al. *(162)* suggested that increased infections after prolonged hysterectomy may be the result of decreasing effects of antibiotic prophylaxis with lengthy procedures. This is the rationale for repeat dosing of antibiotics in operations lasting for more than 2 to 3 hours.

Surgical Technique

The skill of the surgeon has a central role in SSIs. Technique directly affects the degree of contamination of the surgical site through breaks in technique or inadvertent entry into a viscus. The skill of the surgeon also affects the condition of the surgical site and therefore its resistance to infection. The risk of infection is minimized by control of bleeding, gentle traction and handling of tissue, removal of necrotic tissue, and eradication of dead space. Finally, the skilled surgeon can reduce the duration of surgery, which affects the risk of SSI (see above).

The quality of a surgeon's operative technique cannot be easily assessed without direct observation, and thus the impact of a surgeon's technical skill on SSIs has not been evaluated except indirectly. Farber et al. *(163)* used a statewide surveillance program to examine the relationship between surgical volume and the incidence of SSIs. They noted a highly significant relationship between a lower number of procedures performed by surgeons and a higher rate of infection for appendectomies, herniorrhaphies, cholecystectomies, colon resections, and abdominal hysterectomies. One explanation put forth was that higher volume meant more experience, and surgeons with more experience generally acquire better technique. In a follow-up study by the same group, Miller et al. *(164)* examined the relationship of the level of physician training and incidence of endometritis after cesarean section. Among 15 variables examined by stepwise logistic regression analysis, only the presence of a resident as the lead surgeon was associated with a higher risk for endometritis. Surgical residents presumably would have less experience and skill than attending physicians.

Presence of Remote Infections

The presence of a remote infection at the time of surgery has been shown to affect the rate of SSIs. In the National Research Council study, the presence of a remote infection

increased the rate of SSI 2.7 times (18.4% vs. 6.7%) *(37)*. Edwards (*48*) observed that, among 383 patients who had cultures taken from SSIs and remote sites, 55% of the wound infections were preceded by infections of the urinary tract or lower respiratory tract with the same microorganisms. In the study by Garibaldi and Cushing *(86)*, the presence of a remote infection was significantly associated with an increased rate of infection on univariate analysis (odds ratio: 2.8; CI: 1.5–5.3). However, when the authors used logistic regression analysis to adjust for the influence of other variables, the presence of remote infection was no longer significantly associated with SSI.

Foreign Material

Early observational studies suggested that surgical drains contributed to the development of SSIs *(36,37,78)*. Experimental studies seemed to support these clinical observations. Nora et al. *(165)* were able to produce wound infections in dogs with drains placed before abdominal closure but not in dogs without drains. In the clinical phase of this study, the investigators observed that 17 of 50 patients with abdominal drains placed had *S. aureus* and *S. epidermidis* cultured from the interior surfaces of their drains and suggested that these microorganisms may migrate retrograde from overlying skin flora. The work of Magee et al. *(166)* suggested that the drains may also potentiate the risk of infection by acting as a foreign body and suppressing local tissue defenses.

Subsequent studies on the effect of drains on the risk of SSIs have produced conflicting results. Several prospective, randomized trials have also been published *(85,167–169)*. Three studies found no difference in infection rates when drains were used *(85,167,168)*. In the fourth study, Monson et al. *(169)* noted that patients randomized to receive high-pressure suction drainage after cholecystectomy had a significantly higher rate of SSI (15 of 239 with drains vs. 5 of 240 without, $p < .05$). A task force of experts from the Society for Hospital Epidemiology of America (SHEA), the Association of Practitioners in Infection Control, the CDC, and the Surgical Infection Society concluded, after review of the evidence, that the use of drains was only a possible contributor to SSIs. This was the weakest of three categories of risk factors, which included definitive and likely risk factors *(170)*.

In addition to drains, any foreign material, including sutures and prosthetic material, decreases the microbial burden necessary to induce infection. Elek and Conen *(171)* demonstrated that while 10^6 microorganisms of *Staphylococcus* per gram of tissue was required to cause an SSI in healthy normal tissue, if silk suture was introduced, only 10^2 microorganisms were required. Similarly, animal models have shown that the median infective dose (ID_{50}) to establish a wound infection was as low as one CFU in the presence of dextran microbeads *(172)*.

Perioperative Hypothermia

Perioperative hypothermia, which is <37°C, is a serious but common complication during surgery. Normally, body temperature is tightly regulated to within 0.2°C by thermoregulatory mechanisms. However, within 1 hour of administration of regional or general anesthesia, core body temperature rapidly declines between 1.0°C and 1.5°C, due to drug-induced vasodilation and redistribution of blood from the core to the periphery. Over the next several hours, body temperature more slowly continues to decline due to imbalance of heat generation and loss of heat into the cold surgical room environment. Once core body temperature reaches about 35°C, the body temperature begins to plateau with the reemergence of vasoconstriction *(173)*.

Multiple studies have documented the severe consequences of hypothermia, which include increased myocardial infarctions, increased risk of perioperative bleeding, and increased risk of SSI. Frank et al. *(174)*, in a randomized controlled study, documented a tripled risk of myocardial events with a decrease in core body temperature of 1.5°C. Schmied et al. *(175)*, in another randomized prospective clinical trial, demonstrated a 500 mL increased loss of blood in patients undergoing hip arthoplasties in patients with a decrease in body temperature of 1.5°C.

Perioperative hypothermia is thought to increase rates of SSIs by triggering vasoconstriction at the surgical site, during the critical first few hours after bacterial contamination. However, this thermoregulatory vasoconstriction due to hypothermia decreases concentration of oxygen into the tissues, causing tissue hypoxemia. Oxygen is critical for effective neutrophil killing of microorganisms at the surgical site *(176)*. Thus, hypothermia impairs optimal neutrophil function and allows establishment of bacterial infection. In addition, vasoconstriction may impair wound healing since scar formation is also oxygen dependent *(176)*. Kurz et al. (177), in a randomized, double-blind, prospective trial of patients undergoing colorectal surgery, demonstrated that patients who had a decrease of 1.9°C in core body temperature had triple the risk of SSIs, compared to those whose body temperature was maintained at about 37°C; and those infected remained hospitalized for an additional week compared to those who were not infected. Even among those who were not infected, hypothermic patients had a 20% increased duration of hospitalization, thought to be due to impaired healing.

Supplemental Oxygen

The use of a high inspired oxygen faction (FiO_2) during surgery has been advocated as one way to decrease SSIs. As stated above, optimizing the oxygen concentration at the surgical site in the first hours after bacterial contamination is critical in preventing SSIs, as oxygen is necessary to optimize wound healing and in eradication of bacteria by neutrophils. However, wound oxygen concentration is decreased in surgical wounds due to a combination of vasoconstriction caused by hypothermia, hypovolemia, and pain, or due to injury, inflammation, or coagulation *(178)*.

Therefore, in addition to decreasing hypothermia, ensuring adequate hydration and minimizing tissue injury are important in maintaining adequate blood flow and oxygen to the surgical tissues. In theory, increasing the inspired oxygen fraction should also increase wound oxygen, and, as a result, decrease SSIs. However, the randomized studies of increasing inspired oxygen from 30% to 80% have had contradictory results. Two trials by Grief (179) and Belda *(180)* demonstrated a 40% to 50% decrease in SSIs rates when 80% FiO_2 was administered, compared to 30% FiO_2, during surgery and the first hours postoperatively. However, two trials found no difference in rates of SSI, including the most recent PROXI trial (*181*,182). In contrast, Pryor in a smaller study found that the high FiO_2 group had double the rate of SSIs compared to the normal FiO_2 group *(183)*.

The editorial *(178)* accompanying the PROXI trial notes key differences in the trial designs, which may account for different effects of increasing FIO_2. In the trials by Grief and Belda (179,*180*), liberal fluid management and maintenance of euthermia were mandatory. However, in the PROXI trial (182), fluid management and euthermia were not standardized, with PROXI patients receiving less fluid and being more hypothermic compared to the trials by Grief and Belda. Pryor et al.'s study *(183)*, (the study that showed an increase in rates of SSI with increasing FiO_2), has been criticized for small sample size, nonhomogeneous groups, and failure to control for fluids and antibiotics. Overall, these findings suggest that inspired FiO_2 can increase wound oxygen and may prevent SSIs when vasoconstriction is minimized by minimizing hypothermia and by ensuring adequate fluid hydration.

Currently, it is still unclear whether the routine use of high FiO_2 prevents SSIs. Therefore, other measures to prevent SSIs as listed above should be rigorously followed.

GUIDELINES FOR THE PREVENTION OF SURGICAL SITE INFECTIONS

The CDC has published guidelines for prevention of SSIs *(184)*. In 1999, the Hospital Infection Control Practices Advisory Committee (HICPAC) of the CDC published revised guidelines (101). The guidelines contain 72 recommendations, and as in previous CDC guidelines, each recommendation is ranked by a revised scheme that takes into consideration the strength of the recommendation's scientific backing, the opinion of experts in the field, and the practicality and cost of implementation (Table 21-4). In the revised scheme, category IA and IB measures are strongly recommended for adoption by all hospitals. Category IA measures are supported by well-designed experimental or epidemiologic studies; category IB measures are not supported by definitive scientific studies, but they are backed by highly suggestive studies and are viewed as effective by experts in the field and by consensus of HICPAC. Category II recommendations are suggested for implementation by many but not necessarily all hospitals. These recommendations are backed by a strong theoretical rationale or suggestive clinical or epidemiologic studies. In the 1999 guideline, practices for which there is insufficient supportive evidence or for which no consensus could be reached are identified as unresolved issues for which no recommendations could be made.

More recently, SHEA has published guidelines that highlight practical recommendations for acute care hospitals (11).

ISSUES IN SSI PREVENTION

Surgical Infection Prevention Collaborative/ Surgical Care Improvement Project

In 2002, the CMS together with the CDC created the Surgical Infection Prevention Collaborative to prevent SSIs, by targeting three performance measures associated with antibiotic prophylaxis:

1. Delivery of intravenous antimicrobial prophylaxis within 1 hour before incision (within 2 hours for vancomycin or fluoroquinolones)
2. Use of a prophylactic antimicrobial consistent with published guidelines
3. Discontinuation of prophylactic antibiotic within 24 hours after surgery (discontinuation within 48 hours allowable for cardiothoracic procedures in adults) *(185)*

The first two, timing and selection, were selected as measures, because they have been well documented to decrease rates of SSI (see section above on antibiotic prophylaxis); the third was chosen to prevent excessive use of antibiotics, which drive antimicrobial resistance with no benefit on SSI rates *(185)*. However, despite the evidence supporting these practices, in a 2001 national survey of Medicare patients undergoing five major surgeries (cardiac, vascular, general abdominal colorectal, hip/knee total arthroplasty, and hysterectomies), antibiotics were given within 1 hour in only 55.7% of cases, appropriate antibiotics were given in 92.6% of cases, and antibiotics were discontinued within 24 hours after surgery in only 40.7% of cases *(186)*.

A national collaborative (56 hospitals and 43 Medicare Quality Improvement Organizations) instituted a 1-year study in order to study the effectiveness of a multidisciplinary systems-based approach to decrease rates of SSIs by specifically targeting these three performance measures *(187)*. This study reported improvement with these antimicrobial prophylaxis measures: antibiotics within 1 hour (median 72% at baseline to 92% at the end of the study), appropriate antibiotics (90% to 95%), and discontinuation with 24 hours (67% to 95%). They also noted improvement with other SSI-reducing performance measures, including normothermia in the operative room, use of supplemental oxygen, avoidance of shaving surgical site with razors, and glucose control. Combined, this collaborative demonstrated a median 27% reduction in SSI rates *(187)*.

In 2003, the SCIP, an extension of the Surgical Infection Prevention Collaborative, was created as a multiagency national quality partnership of over 40 organizations, steered by 10 organizations which includes CMS, CDC, the Veterans Association, American College of Surgeons, American Society of Anesthesiologists, the Agency for Healthcare Research and Quality, the American Hospital Association, and the Institute for Healthcare Improvement (15). The goal of SCIP was to reduce preventable surgical morbidity and mortality by 25% by 2010. Specifically, SCIP wanted to reduce postoperative complications, which includes preventing SSIs, venous thromboembolism, cardiac events, respiratory complications, and monitor global measures (risk-adjusted patient mortality and readmission) (15).

In the realm of SSI prevention, SCIP added three process measures beyond the three Surgical Infection Prevention antibiotic prophylaxis measures, which are:

1. Control blood glucose postoperatively in cardiac surgery patients (6:00 AM blood glucose level <200 mg/dL on postoperative days 1 and 2)
2. Proper hair removal (no hair removal or removal with clippers or depilatory method; razors not appropriate)
3. Maintenance of perioperative normothermia in patients undergoing colorectal surgery

While participation in SCIP is voluntary, in order to comply with the Deficit Reduction Act of 2005, hospitals

TABLE 21-4

Centers for Disease Control and Prevention (CDC) Guideline for the Prevention of SSI, 1999: Part II—Recommendations for the Prevention of SSI

1. Preoperative preparation of the patient
   a. Adequately control serum blood glucose level in all diabetic patients before elective operation and maintain blood glucose level <200 mg/dL during the operation and in the immediate postoperative period (48 h). Category IB.
   b. Always encourage tobacco cessation. At minimum, instruct patients to abstain for at least 30 d before elective operation from smoking cigarettes, cigars, pipes, or any other form of tobacco consumption (e.g., chewing/dipping). Category IB.
   c. No recommendation to taper or discontinue steroid use (when medically permissible) before elective operation. Unresolved issue.
   d. Consider delaying an elective operation in a severely malnourished patient. A good predictor of nutritional status is serum albumin. Category II.
   e. Attempt weight reduction in obese patients before elective operation. Category II.
   f. Identify and treat all infections remote to the surgical site before elective operation. Do not perform elective operations in patients with remote site infections. Category IA.
   g. Keep preoperative hospital stay as short as possible. Category IA.
   h. Prescribe preoperative showers/baths with an antiseptic agent the night before and the morning of the operation. Category IB.
   i. Do not remove hair preoperatively unless the hair at or around the incision site will interfere with the operation. Category IA.
   j. If hair is removed, it should be removed immediately before the operation using electric clippers rather than razors or depilatories. Category IA.
   k. Thoroughly wash and clean at and around the incision site to remove gross contamination before performing antiseptic skin preparation. Category IB.
   l. Use an acceptable antiseptic agent for skin preparation, such as alcohol (usually 70%–92%), chlorhexidine (4%, 2%, or 0.5% in alcohol base), or iodine/iodophors (usually 10% aqueous with 1% iodine or formulation with 7.5%). Category IB.
   m. Apply preoperative antiseptic skin preparation in concentric circles moving out toward the periphery. The prepped area must be large enough to extend the incision or create new incisions or drain sites, if necessary. Category IB.
2. Preoperative hand/forearm antisepsis

All members of the surgical team:
   a. Keep nails short and do not wear artificial nails. Category IB.
   b. No recommendations on wearing nail polish. Unresolved issue.
   c. Do not wear hand/arm jewelry. Category II.
   d. Perform a preoperative surgical scrub that includes hands and forearms up to the elbows before the sterile field, sterile instruments, or the patient's prepped skin is touched. Category IB.
   e. Clean underneath each fingernail prior to performing the surgical scrub. Category IB.
   f. Perform the surgical scrub for a duration of 3–5 min with an appropriate antiseptic. Category IB.
   g. After performing the surgical scrub, keep hands up and away from the body (elbows in flexed position) so that water runs from the tips of the fingers toward the elbows. Dry hands with a sterile towel and don a sterile gown and gloves. Category IB.
3. Antimicrobial prophylaxis
   a. Select a prophylactic antimicrobial agent based on its efficacy against the most common pathogens causing SSI for a specific operation. Category IA.
   b. Administer the antimicrobial prophylactic agent by the intravenous route except for colorectal operations. In colorectal operations, the antimicrobial agent is administered orally or a combination of oral and intravenous route is used. Category IA.
   c. Administer the antimicrobial agent before the operation starts to assure adequate microbial tissue levels before the skin incision is made. Ideally, antimicrobial prophylaxis should be administered within 30 min before, but not longer than 2 h before the initial incision. Category IA.
   d. For cesarean section, administer prophylaxis immediately after the umbilical cord is clamped. Category IA.[a]
   e. Administer prophylactic antimicrobial agent as close as possible to the time of induction of anesthesia. Category II.
   f. Do not extend prophylaxis postoperatively. Category IB.
   g. Consider additional intraoperative doses under the following circumstances: (a) operations whose duration exceeds the estimated serum half-life of the agent, (b) operations with major intraoperative blood loss, and (c) operations on morbidly obese patients. Category IB.
   h. Do not routinely use vancomycin for prophylaxis. Category IB.
4. Intraoperative issues

   4.1. Operating room environment

   A. Ventilation
   a. Maintain positive-pressure ventilation in the operating room with respect to the corridors and adjacent areas. Category IB.
   b. Maintain a minimum of 15 air changes per hour, of which at least three should be fresh air. Category IB.
   c. Filter all air, recirculated and fresh, through the appropriate filters per the American Institute of Architects recommendations. Category IB.
   d. Introduce all air at the ceiling and exhaust near the floor. Category IB.

(*Continued*)

TABLE 21-4

Centers for Disease Control and Prevention (CDC) Guideline for the Prevention of SSI, 1999: Part II—Recommendations for the Prevention of SSI (*Continued*)

e. No recommendation for the use of laminar flow ventilation or ultraviolet lights in the operating room to prevent SSI. Unresolved issue.
f. Keep operating room doors closed except as needed for passage of equipment, personnel, and the patient. Category IB.
g. Limit the number of personnel entering the operating room to necessary personnel. Category IB.

B. Cleaning and disinfection of environmental surfaces
a. No recommendation on disinfecting operating rooms between operations in the absence of visible soiling of surfaces or equipment. Unresolved issue.
b. When visible soiling or contamination, with blood or other body fluids, of surfaces or equipment occurs during an operation, use an EPA-approved hospital disinfectant to clean the affected areas before the next operation. Category IB.[b]
c. Wet vacuum the operating room floor after the last operation of the day or night with an EPA-approved hospital disinfectant. Category IB.
d. Do not perform special cleaning or disinfection of operating rooms after contaminated or dirty operations. Category IA.
e. Do not use tacky mats at the entrance to the operating room suite for infection control; this is not proven to decrease SSI risk. Category IA.

C. Microbiologic sampling
Do not perform routine environmental sampling of the operating room. Perform microbiologic sampling of operating room environmental surfaces or air only as part of an epidemiologic investigation. Category IB.

D. Sterilization of surgical instruments
a. Sterilize all surgical instruments according to published guidelines. Category IB.
b. Perform flash sterilization only in emergency situations. Category IB.
c. Do not use flash sterilization for routine reprocessing of surgical instruments. Category IB.

4.2. Surgical attire and drapes
a. No recommendations on how or where to launder scrub suits, or on restricting use of scrub suits to the operating suite or for covering scrub suits when out of the operating suite. Unresolved issue.
b. Change scrub suits when visibly soiled, contaminated, and/or penetrated by blood or other potentially infectious materials. Category IB.
c. Wear a surgical mask that fully covers the mouth and nose when entering the operating room if sterile instruments are exposed, or if an operation is about to begin or already under way. Wear the mask throughout the entire operation. Category IB.[b]
d. Wear a cap or hood to fully cover hair on the head and face when entering the operating room suite. Category IB.[b]
e. Do not wear shoe covers for the prevention of SSI. Category IA.
f. Wear shoe covers when gross contamination can reasonably be anticipated. Category II.[b]
g. The surgical team must wear sterile gloves, which are put on after donning a sterile gown. Category IB.[b]
h. Use materials for surgical gowns and drapes that are effective barriers when wet. Category IB.

4.3. Practice of anesthesiology
Anesthesia team members must adhere to recommended infection control practices during operations. Category IA.

4.4. Surgical technique
a. Handle tissue gently, maintain effective hemostasis, minimize devitalized tissue and foreign bodies (e.g., sutures, charred tissues, necrotic debris), and eradicate dead space at the surgical site. Category IB.
b. Use delayed primary closure or leave incision open to close by secondary intention, if the surgical site is heavily contaminated (e.g., class III and class IV). Category IB.
c. If drainage is deemed necessary, use a closed suction drain. Place the drain through a separate incision, rather than the main surgical incision. Remove the drain as soon as possible. Category IB.

5. Postoperative surgical incision care
a. Protect an incision closed primarily with a sterile dressing for 24–48 h postoperatively. Also ensure that the dressing remains dry and that it is not removed during bathing. Category IA.
b. No recommendation on whether or not to cover an incision closed primarily beyond 48 h, or on the appropriate time to shower/bathe with an uncovered incision. Unresolved issue.
c. Wash hands with an antiseptic agent before and after dressing changes, or any contact with the surgical site. Category IA.
d. For incisions left open postoperatively, no recommendation for dressing changes using a sterile technique vs. clean technique. Unresolved issue.
e. Educate the patient and family using a coordinated team approach on how to perform proper incision care, identify signs and symptoms of infection, and where to report any signs and symptoms of infection. Category II.

6. Surveillance
a. Use CDC definitions of SSI without modifications for identifying SSI among surgical inpatients and outpatients. Category IB.
b. For inpatient case finding, use direct prospective observation, indirect prospective detection, or a combination of both direct and indirect methods for the duration of the patient's hospitalization, and include a method of postdischarge surveillance that accommodates available resources and data needs. Category IB.

(*Continued*)

TABLE 21-4

Centers for Disease Control and Prevention (CDC) Guideline for the Prevention of SSI, 1999: Part II—Recommendations for the Prevention of SSI (*Continued*)

c. For outpatient case finding, use a method that accommodates available resources and data needs. Category IB.
d. For each patient undergoing an operation chosen for surveillance, record those variables shown to be associated with increased SSI risk (e.g., surgical wound class, ASA class, and duration or operation). Category IB.
e. Upon completion of the operation, a surgical team member assigns the surgical wound classification. Category IB.
f. Periodically calculate operation-specific SSI rates stratified by variables shown to be predictive of SSI risk. Category IB.
g. Report appropriately stratified, operation-specific SSI rates to surgical team members. The optimum frequency and format for such rate computations will be determined by stratified case-load sizes and the objectives of local, continuous, quality improvement initiatives. Category IB.
h. No recommendations to make available to the infection control committee coded surgeon-specific data. Uresolved issue.

[a]The Committee on Obstetric Practice of the American College of Obstetricians and Gynecologists now recommends that antimicrobial prophylaxis for cesarean deliveries be administered within 60 minutes of the start of the cesarean delivery unless the patient is already receiving appropriate antibiotics (e.g., for chorioamnionitis). *Obstet Gynecol* 2010;116:791–792.

ASA, American Society of Anesthesiologists; EPA, Environmental Protection Agency.

that provide acute inpatient care to Medicare patients must submit information on required quality measures to the CMS, in order to receive their full annual payment update. These measures are now posted on the U.S. Health and Human Services Web site, http://www.hospitalcompare.hhs.gov. Two SCIP measures—antimicrobial prophylaxis within 1 hour and discontinuation within 24 hours after surgery—are part of the required quality measures. In the near future, CMS may require the additional four SCIP SSI prevention measures as well (13,*188*).

Since October 2008, beyond mandating reporting of quality measurements, CMS is no longer paying additional reimbursements for certain conditions acquired during the hospitalization stay, which includes the following SSIs *(189)*:

1. CABG—mediastinitis
2. Bariatric surgery laparoscopic
   - Gastric bypass gastroenterostomy
   - Laparoscopic gastric restrictive surgery
3. Orthopedic procedures
   - Spine
   - Neck
   - Shoulder
   - Elbow

Risk Adjustment

As clinical outcomes have been increasingly emphasized as one way to measure and improve quality of care, an important obstacle to the use of SSIs as a quality assurance outcome indicator has been failure to adjust for differences in types of patients undergoing operations by different surgeons or admitted by different hospitals (differences in case mix of patients). The surgical site classification scheme of the National Research Council attempted to capture the risk of subsequent infection brought on by the degree of microbial contamination of the operative site *(57)*. However, as mentioned previously, this scheme fails to account for the patient's susceptibility to infection that is the result of underlying host conditions (the patient's intrinsic risk to infection).

The CDC developed, as part of its SENIC project, a risk index system that was an improvement over the traditional surgical site classification system *(158)*. By subjecting multiple variables to analysis by regression modeling, it found four risk factors that predicted 90% of SSIs among the SENIC database: (a) an operation that involved the abdomen, (b) an operation lasting longer than 2 hours, (c) an operation classified as either contaminated or dirty infected, and (d) a patient having three or more diagnoses at discharge. The last factor, having multiple diagnoses, was, in effect, a proxy variable for a patient's intrinsic risk to infection. When tested, the SENIC index predicted SSI risk for all surgical patients twice as well as traditional surgical site classifications.

Despite the improved performance over the traditional surgical site (wound) classification scheme, limitations in the SENIC index were noted. First, the SENIC index stratified the length of operation in a dichotomous fashion—that is, either <2 hours or 2 hours or greater. Intuitively, since the technical difficulty of operative procedures varies—for example, a coronary artery bypass procedure would take more operating time than a simple hernia repair—the appropriate cut point for what would be deemed an excessive length of operation should also vary to reflect the complexity of surgery. Second, the SENIC index required the number of discharge diagnoses, information that could only be gotten retrospectively after the patient has been discharged. Its use would thus seem problematic in infection control programs conducting ongoing, prospective surgical site surveillance.

To overcome these limitations, the NNIS system modified the SENIC patient risk index so that it was based on data easily obtainable at the time of surgery *(159)*. In the NNIS risk index, each operation is scored by the presence or absence of three risk factors: (a) a patient having an American Society of Anesthesiologists (ASA) preoperative assessment score of 3, 4, or 5; (b) an operation classified as either contaminated or dirty infected; and (c) an operation with duration of surgery more than *T* hours, where *T* depends on the operative procedure being performed. In the NNIS index, the ASA score becomes the

proxy variable for the patient's intrinsic risk and is more easily obtainable than the discharge diagnoses used for the SENIC index. The *T* cut point for each surgical procedure was derived from the NNIS database and was chosen to be the 75th percentile of the distribution of durations of surgery for that procedure. Unlike the SENIC risk index, where the risk factor of duration of operation is fixed at >2 hours, NNIS's cutoff for excessive length of operation is variable and indexed to a specific operative procedure. The NNIS risk index ranges from 0 (low-risk procedure) to 3 (high-risk procedure).

In validation studies, the basic NNIS risk index generally has performed well in predicting the risk of SSIs *(190)*. For the majority of operative procedures (30 of 40 procedures), a higher NNIS risk index score predicted a higher infection rate. For example, among the 35,293 cardiac surgeries reported to NNIS between 1992 and 2001, the SSI rate was 0.66% for risk index category 0, 1.63% for risk index 1, and 2.54% for risk index categories 2 and 3. Notable, however, was that in 10 procedures, the NNIS risk index performed poorly, as the infection rate was the same whether patients had a risk index of 0, 1, 2, or 3.

The basic NNIS index assumes that the risk index variables of wound class, ASA score, and operative duration account for the majority of operative risk for infection from various influences and that each variable should have equal importance or weight. It is clear from the poor performance of the basic NNIS risk index among certain operative procedures that these assumptions are not necessarily valid. Analysis of SSIs among cholecystectomies, colon surgery, appendectomies, and gastric surgery suggested that the rates of infections were lower when a laparoscope was used. The finding that use of a laparoscope had a protective effect for these four procedures had prompted the CDC to modify its basic NNIS index by allowing subtraction by 1 to a lower risk category when a laparoscope was used for those four procedures *(190)*. However, from the November 2008 NHSN publication, the CDC has found insufficient evidence to continue to adjust for laparoscopic procedures, and has therefore returned to the basic NNIS index with minor differences—the cut point for the duration of procedure is shown in minutes and is the exact 75th percentile of the distribution, rather than rounding to the nearest whole number of hours *(191)*.

Other modifications to the basic NNIS risk index may be necessary, and indeed the optimal approach may be to develop a specific risk index for each surgical procedure based on multivariate analyses of procedure-related risk factors.

Issues in SSI Prevention

***Staphylococcus* Decolonization** *S. aureus* is the most common pathogen isolated from SSIs, accounting for 20% to 30% of all SSIs (12). This pathogen is thought to be acquired largely from the patient's own flora (endogenous acquisition). Up to 30% of healthy humans are colonized in the nares with this microorganism, and up to 50% of healthcare workers may carry this microorganism (*192*,193). Nasal carriage of *S. aureus* has been shown to be a risk factor for hemodialysis catheter infections and for bacteremias in patients undergoing central venous catheterizations (*193*,194–197). Nasal carriage with *S. aureus* is also a risk factor for SSIs, with about four to nine times increased odds or risk of SSI (193,*198–200*). These findings prompted Klutyman's group to attempt to eradicate nasal colonization as a method to prevent SSIs among cardiothoracic surgery patients *(201)*. The nonrandomized trial using historical controls demonstrated a decrease in deep and incisional rates of SSI among treated versus untreated historical controls.

However, the first two placebo-controlled randomized trials using intranasal mupirocin failed to show a reduction in SSI rates in general surgery and orthopedic surgeries. In the first, Perl et al. (43) enrolled 4,030 patients about to undergo general, gynecologic, neurologic, or cardiothoracic surgery. Patients were randomized to receive mupirocin intranasally or placebo twice a day for up to 5 days before surgery. At the end of the study, mupirocin treatment was found to have no effect in reducing the SSI rate caused by *S. aureus*, though when the analysis was restricted to only those patients with nasal carriage of *S. aureus* before surgery, treatment with mupirocin was effective in preventing HAIs due to *S. aureus*. In the second, Kalmeijer et al. *(202)* randomized orthopedic surgery patients undergoing prosthetic implants. Despite effective nasal eradication of S. *aureus,* mupirocin nasal ointment did not decrease rates of SSI.

In a recent meta-analysis, it was suggested that intranasal mupirocin used in *S. aureus* carriers could reduce the rates of SSI due to *S. aureus* by 45%. However, they recommended further randomized studies to be performed *(203)*.

Two main hypotheses have been proposed to explain the failure of mupirocin in preventing SSIs: First, identification of *S. aureus* carriers by traditional culture methods and then decolonization may be too late in preventing SSIs as infections may already be established; second, *S. aureus* also colonizes the skin, not only the nares. In the most recent multicentered randomized placebo-controlled trial (44), Bode and colleagues conducted a study that allowed for rapid identification of *S. aureus* nasal carriers upon admission or during the week prior to admission, by utilizing a PCR assay. Patients expected to remain in the hospital for at least 4 days in internal medicine, or surgery services (cardiothoracic, vascular, orthopedic, gastrointestinal, or general) were included in the study. Once carriers were identified, carriers were randomized to placebo or to decolonization. The decolonization group was decolonized with application of mupirocin ointment to the nares twice a day for 5 days and daily chlorhexidine gluconate soap to the skin. Overall, 6,771 patients were screened, 1,251 patients identified as carriers. Of the 918 randomized patients, the mupirocin-chlorhexadine group had a highly significant 60% reduction in risk of SSIs due to *S. aureus* (RR: 0.42; 95% CI: 0.23–0.75) compared to the placebo group. However, 250 need to be screened by a rapid method and 23 carriers needed to be treated in order to prevent one hospital-acquired *S. aureus* infection, respectively.

In the editorial following the Bode article *(204)*, if the use of chlorhexadine surgical scrub becomes universal (which decreases rates of all SSIs, not just due to *S. aureus*), Wenzel notes the unclear additional benefit of rapid screening and identification for *S. aureus*. However, for procedures associated with high risk of poor outcomes if *S. aureus* SSI infection develops, like cardiothoracic or in procedures where prosthetic material is implanted, rapid screening and decolonization should be considered.

SURGICAL SITE SURVEILLANCE AS AN INFECTION CONTROL MEASURE

Cruse and Foord *(37)* noted that the rate of SSIs among clean procedures was reduced when the information on rates was reported back to practicing surgeons. In a 5-year prospective study, Condon et al. *(205)* similarly observed a decline in the clean SSI rate from 3% to 1% after the institution of their surgical site surveillance program with direct reporting of the results to surgeons. In the CDC study, Haley et al. *(160)* showed that establishment of a strong infection surveillance program and the feedback of SSI rates to surgeons lowered the overall SSI rate by 35%, and the reduction occurred among contaminated or dirty cases as well as in clean or clean-contaminated cases.

How such feedback brings about changes in surgeons' behavior is not known. The effect may be achieved through an improved general awareness of the problem of SSIs that feedback brings about, through a learning process that surgeons undergo when they review cases of infections and identify probable errors in technique, or because of an anxiety factor as surgeons become aware that their patients' outcomes are being monitored.

These studies, among others, form the basis for the CDC's recommendation that hospitals routinely perform surveillance for SSIs and report the information back to the surgeons (11,101).

SURVEILLANCE METHODOLOGY

For valid comparisons of rates of SSIs among hospitals, the surveillance methods for case finding in these hospitals must be similar. Multiple case-finding methods are currently available, including (a) direct method, through daily observation of the surgical site by infection control personnel or other surveyors and (b) indirect methods such as review of microbiology reports, patient medical records, fever charts, antibiotic use, surgeon or patient surveys, screening for hospital readmissions, operative reports, and/or coded diagnoses.

Direct, prospective observation of all postoperative patients for SSIs by trained personnel is generally viewed as the best method to identify SSIs (*2*,11,*37*). However, direct prospective observation is often not practical or feasible. Therefore, indirect methods are often used, and have demonstrated sensitivity of 84% to 89%, and specificity of 99.8%, compared to direct observation *(206,207)*.

Alternative Methods of Surveillance: Use of Automated Databases

Traditional surveillance for SSIs that rely on review of culture results, fever charts, Kardexes, medical records, or postdischarge telephone or written surveys requires significant expenditure of time and effort from infection control personnel. Hence, hospitals with limited resources are often forced to choose among not performing such surveillance, limiting their surveillance to a certain time periods, for example, 3 months out of a year (sampling), or rotating surveillance among different surgical procedural types. In the past decade, the growth and use of computers in the healthcare industry have resulted in the automated capture of healthcare data, some of which could be useful in the surveillance for SSIs. Computerized medical record systems found in today's hospitals, physicians' offices, and health maintenance organizations (HMOs) vary in their sophistication. These databases all capture administrative and demographic information, such as age, sex, underlying diagnoses, and length of hospitalization. More sophisticated databases often capture microbiology and pharmacy data, including the use of antibiotics. The most sophisticated medical record systems are usually found in tertiary referral hospitals or large HMOs. They often contain more specific operative data such as ASA score, duration of surgery, and codes for procedures like incision and drainage that more directly indicate an infection.

The use of automated healthcare databases holds promise as an alternative method of performing surveillance for SSIs, one that would require less effort than traditional methods. However, investigators continue to refine and improve their methodology. Studies have shown that the addition of certain International Classification of Diseases (ICD-9) codes and procedural codes, such as incision and drainage, to the algorithm improves on the specificity of quantitative antibiotic exposure while maintaining a high sensitivity *(208,209)*. More recently, investigators have explored the use of third-party claims data for measuring institutions' SSI rates. Use of insurers' claims data has several advantages over individual hospital data. Claims are made even when patients are hospitalized at institutions other than the ones that perform the surgical procedures. They are made when patients are seen in clinics, private offices, or emergency rooms. Sands et al. *(210)* found that an automated surveillance system based on health plan administrative and pharmacy data was more sensitive in detecting SSIs following CABG procedures than hospital-based surveillance (72% vs. 50%). This study was based on claims data from the Harvard Pilgrim Health Care providing coverage for patients for five hospitals. However, this approach needs to be validated using claims data from different insurers. In addition, the investigators also point out that variations in SSI indicators are affected by patient case mix and differences in case mix between hospitals may not be adequately captured in the claims data *(211)*.

The availability of such automated databases provides an opportunity to use such data in novel ways to identify SSIs, with increased sensitivity, and that requires less time and personnel.

NEED FOR POSTDISCHARGE SURVEILLANCE

Studies estimate that between 19% and 77% of SSIs do not become manifest until after patients are discharged from the hospital *(212–217)*; thus, a surveillance system based solely on inpatients would greatly underestimate the rate of SSIs. With decreasing postoperative stays and the continuing shift toward same-day procedures or outpatient procedures, the likelihood of missing SSIs will only increase unless postdischarge surveillance is performed.

Although the need for postdischarge surveillance may be clear, the best method to accomplish this remains

unknown. Polk et al. *(212)* surveyed patients by letter at 6 weeks and confirmed the diagnoses of infection with their surgeons. They found that 19% of SSIs had occurred after discharge. Rosendorf et al. *(214)* surveyed surgeons and patients at their follow-up clinic appointments and detected an additional 44% of infections by this method. Reimer et al. *(216)* used a telephone survey to contact patients at 30 days after discharge and found that 77% of their SSIs occurred after discharge. However, use of questionnaires or telephone surveys of patients is still insensitive, as one study demonstrated that patient-derived information underestimated the true number of SSIs occurring after discharge *(218)*.

Another issue is the appropriate length of postdischarge surveillance. The CDC recommends that surveillance for SSIs be performed for 30 days after discharge for procedures that do not involve implanted prosthetic materials *(219)*. This has become the *de facto* standard as most published studies have chosen this length of follow-up time. Weigelt et al. *(217)* found that 65% of SSIs occurred by the day of discharge, 82% were noted by the 7th day after discharge, 93% by the 14th day after discharge, and 97% by the 21st day after discharge. The results of this study support the choice of 30 days after discharge as the appropriate period of follow-up, since virtually 100% of the SSIs were detected within this period.

Currently, there are no standardized or reliable methods established for accurate detection of postdischarge SSIs. Because of this, the Surgical Wound Task Force on Surveillance of SSIs recommended that each institution develop and use a method that works based on considerations of its own resources, circumstances, and locale *(170)*. The National Healthcare Safety Network (NHSN) System of the CDC recommends postdischarge surveillance, using any combination of direct and indirect methods, as long as CDC definitions of SSI are used *(220)*. Nonetheless, the Joint Commission as part of their National Patient Safety Goals for preventing SSIs, mandated that institutions "measure SSI rates for the first 30 days following procedures that do not involve inserting implantable devices and for the first year following procedures involving implantable devices" *(221)*.The caveat is that hospitals may chose their own "measurement strategies" and target only those surgical procedures that carry a high risk based on their institution's own risk assessment.

CHAPTER 22

Healthcare-Associated Pneumonia

Dennis C.J.J. Bergmans and Marc J.M. Bonten

The substantial clinical and financial impact of healthcare-associated pneumonia makes this an important topic for healthcare epidemiologists. According to surveillance data from the National Nosocomial Infections Surveillance system of the Centers for Disease Control and Prevention (CDC), pneumonia is the second most common healthcare-associated infection overall (*1*) and the most common infection in intensive care units (ICUs) (*2*). Additionally, pneumonia is associated with significant mortality and considerable costs of care (*3*). The widespread use of tracheal intubation and mechanical ventilation (MV) to support the critically ill has defined an expanding group of patients who are at particularly high risk for developing healthcare-associated pneumonia. In this group of patients, the infection is usually called ventilator-associated pneumonia (VAP). Unfortunately, both the diagnosis and the prevention of VAP have proven to be difficult (*4*).

HISTORICAL ASPECTS

During the last four decades, much has been learned about the epidemiology of healthcare-associated pneumonia. In the 1960s Pierce, Sanford, and others investigated the relationship of epidemic necrotizing gram-negative pneumonia to contaminated reservoir nebulizers in respiratory therapy devices and described effective disinfection measures (*5–7*). During the 1970s and early 1980s, additional work described the continuing association of healthcare-associated pneumonia with respiratory therapy equipment (*8*), risk factors for postoperative pneumonia (*9*), and the relationship of healthcare-associated pneumonia with oropharyngeal (10) and gastric (*11*) gram-negative bacillary colonization. During the 1980s and 1990s, several preventive strategies were designed and tested with varying success, such as the use of sucralfate for stress ulcer prophylaxis (*12*), selective decontamination of the digestive tract (SDD) (*13*), and continuous subglottic aspiration (*14*). Moreover, controversies developed over the relevance of gastric colonization in the pathogenesis of VAP (*4,15,16*), the usefulness of SDD (*17,18*), and the necessity of bronchoscopic techniques for diagnosing VAP (*19,20*). In the most recent years, more general approaches for patient management, not only directed to VAP, have been applied in ICUs, such as strict control of blood glucose levels, noninvasive ventilation, sedation strategies to reduce duration of ventilation, and bundles of care. This chapter summarizes current knowledge of diagnosis, epidemiology, and prevention of healthcare-associated pneumonia.

DIAGNOSIS

Pneumonia refers to inflammation of the distal lung caused by infection with microorganisms and is characterized histologically by the accumulation of neutrophils in the distal bronchioles, alveoli, and interstitium. Three types of healthcare-associated pneumonia can be distinguished: hospital-acquired pneumonia, early-onset VAP, and late-onset VAP. Pneumonia is defined as VAP when diagnosed in an intubated, mechanically ventilated patient after more than 48 hours of ventilation; early-onset VAP occurs within the first 4 days of MV, and late-onset VAP occurs thereafter (*21*). The relevance of a rapid and accurate diagnosis of healthcare-associated pneumonia is obvious. The goals are to prescribe the optimal antibiotic therapy to only those patients with infection of the lungs. Using a technique with a low sensitivity, patients will remain untreated and may suffer significant morbidity and increased risk for mortality. In contrast, a technique with high sensitivity but low specificity will lead to unnecessary use of antibiotics, resulting in unnecessary exposure of patients to toxicity, a potential delay in diagnosing the real etiology of infection, increased hospital costs, and, most importantly, unnecessary selection and induction of resistant pathogenic microorganisms.

Clinical and Radiographic Findings

Traditionally, clinical and radiographic criteria have been used to identify cases of healthcare-associated pneumonia among patients who are not mechanically ventilated. Patients with healthcare-associated pneumonia are likely to have fever, purulent sputum, signs of pulmonary consolidation, and new or progressive radiographic infiltrates. Although they may complain of dyspnea, cough, and pleuritic chest pain, many patients with healthcare-associated pneumonia are unable to give a helpful history because of neurologic impairment or severity of illness. The CDC definitions of healthcare-associated pneumonia have been widely used for infection control surveillance and rely predominantly

on clinical and radiographic criteria, although the results of other diagnostic tests may also be used (*22*).

Diagnosing VAP is even more problematic than diagnosing healthcare-associated pneumonia in nonventilated patients (*23*). For scientific purposes, VAP is usually diagnosed using a modified version of the CDC's definitions (*24*). These criteria are a new or progressive radiographic infiltrate that has persisted for at least 48 hours plus at least three of the following: a temperature above 38.5°C or below 35.0°C, a leukocyte count of >10,000/mm^3 or <5,000/mm^3, purulent sputum, or isolation of pathogenic bacteria from an endotracheal aspirate. An alternative for the modified CDC criteria is the Clinical Pulmonary Infection Score (CPIS) as defined by Pugin et al. (*25*) (Table 22-1). This scoring system, basically, uses the same criteria as in the modified CDC criteria. The range of the score is from 0 to 12, with VAP defined by a score of 7 or more.

TABLE 22-1

CPIS Used for the Diagnosis of Ventilator-Associated Pneumonia

	Number of Points
1. Temperature (°C)	
≥36.5 and ≤38.4	0
≥38.5 and ≤38.9	1
≥39.0 and ≤36.0	2
2. Blood leukocytes (mm^3)	
≥4,000 and ≤11,000	0
<4,000 or >11,000	1
<4,000 or >11,000 and band forms ≥500	2
3. Tracheal secretions[a]	
<14+ of tracheal secretions	0
≥14+ of tracheal secretions	1
≥14+ of tracheal secretions and purulent secretions	2
4. Oxygenation: PaO_2/FlO_2 (mm Hg)	
>240 or ARDS	0
≤240 and no evidence of ARDS	2
5. Pulmonary radiography	
No infiltrate	0
Diffuse (or patchy) infiltrate	1
Localized infiltrate	2
6. Culture of tracheal aspirate (semiquantitative: 0, 1, 2, or 3+)	
Pathogenic bacteria cultured ≤1+ or no growth	0
Pathogenic bacteria cultured >1+	1
Pathogenic bacteria cultured >1+ and same pathogenic bacteria seen on the Gram stain >1+	2

[a]Quantity of tracheal aspirates per day (for each endotracheal aspiration, the quantity of secretions was estimated from 0 to 4+; estimation of the volume of total secretions per day was calculated by adding all the + values recorded over 24 h together).
Total points = CPIS (varies from 0 to 12 points).
ARDS, adult respiratory distress syndrome.
(Adapted from Pugin J, Auckenthaler R, Mili N, et al. Diagnosis of ventilator-associated pneumonia by bacteriologic analysis of bronchoscopic and nonbronchoscopic "blind" bronchoalveolar lavage fluid. *Am Rev Respir Dis* 1991;143:1121–1129.)

Although each of these criteria may have a reasonable sensitivity for VAP, specificity is poor. Radiographic infiltrates are sensitive indicators of VAP; however, more specific radiographic findings such as single air bronchograms, fissure abutment, or rapid progress to cavitation are infrequently present (*26*). Unfortunately, even the combination of clinical and radiographic criteria (as in the modified CDC criteria and the CPIS) has been unable to reliably diagnose cases of healthcare-associated pneumonia diagnosed by autopsy (*26,27*), histopathology (*28*), or other stringent criteria (*29–32*). In an autopsy study of ventilated patients, no radiographic sign predicted pneumonia more than 68% of the time, and no radiographic signs predicted pneumonia in the subgroup of patients with the adult respiratory distress syndrome (ARDS); when clinical and sputum culture results were added to the model, the diagnostic efficiency rose only to 72% (*26*). Two other reports have documented that fever and pulmonary infiltrates in mechanically ventilated patients were caused by processes other than pneumonia in 49% to 69% of cases (*29,30*). A variety of other conditions (such as drug reactions, atelectasis, chemical aspiration, congestive heart failure), alone or in combination, can mimic the clinical and radiographic presentation of healthcare-associated pneumonia (*33*); these conditions are not uncommon in patients with significant underlying medical illness. Furthermore, cultures of sputum and tracheal aspirate do not reliably identify pathogens causing healthcare-associated pneumonia (*33–36*) although surveillance cultures of sputum seem indicative for the pathogen eventually causing VAP and are superior in terms of choice of empiric antibiotic therapy compared to guidelines (*37*).

Interpretation of the usefulness of diagnostic techniques is seriously hampered, because populations studied varied widely, and the use of antibiotics, which strongly influences the yield of bacteriologic procedures, was not always taken into account. The largest problem, however, is the gold standard used to verify the value of diagnostic procedures. Histologic and bacteriologic examination of lung tissue remains the optimal standard to establish the diagnosis of pneumonia. However, these techniques require an open-lung biopsy or autopsy. Although histology and bacteriology of lung tissue, usually at autopsy, have been used as the gold standard in several studies, one should realize that patients who died form a subgroup of all patients with pneumonia. In addition, in several studies, autopsy findings are compared to diagnostic procedures performed several days earlier. In such circumstances, the physiologic host response to infection, usually in combination with antibiotic therapy, may have influenced the ultimate findings. These considerations also account for the evaluation of newer diagnostic techniques.

Quantitative Bronchoscopic Techniques

Diagnostic techniques have been improved by utilizing quantitative cultures of lower airway samples to more accurately diagnose healthcare-associated pneumonia and identify causative pathogens (*28,35,38–41*). The rationale of bronchoscopy is to avoid contamination of culture samples with material from the upper respiratory tract. Three bronchoscopic techniques have been used to diagnose VAP: protected specimen brush (PSB), bronchoalveolar lavage (BAL), and protected bronchoalveolar lavage (PBAL).

The PSB technique uses a double-lumen bronchoscopic catheter with a telescoping cannula and distal plug (*38*). A bacterial burden of $<10^4$ colony-forming units (CFU)/g in lung tissue has been associated with histologic pneumonia (*42*). Since the sample size with PSB is ±0.001 mL, a quantitative culture of 10^3 CFU/mL reflects about 10^6 CFU/mL at the site of infection and is generally used as a cutoff point for VAP. Quantitative cultures of PSB specimens have been shown to accurately identify pneumonia and its causative pathogens in mechanically ventilated patients undergoing open lung biopsy (*28*) and in mechanically ventilated baboons with diffuse lung injury (*35*). Studies in normal hosts (*43*), patients with chronic bronchitis (*44*), and mechanically ventilated patients with suspected pneumonia (*28,29,36*) indicate that quantitative PSB cultures are considerably more specific than clinical and radiographic criteria for diagnosing healthcare-associated pneumonia. Based on the pooled results of published studies (*28,29,35,45*), one review (*33*) reported PSB to have a sensitivity of 83% and a specificity of 91%. False-negative results have been attributed to sampling error and to antibiotic use (*36,41,45*). In several studies, PSB results were compared to histologic and microbiologic evaluation of lung tissue, with sensitivities ranging from 36% to 100% and specificities ranging from 50% to 95% (*28,46–49*).

Some investigators have also used quantitative cultures of BAL specimens to sample a larger portion of the lung, including alveoli (*39,40,50*). BAL entails sampling of an area of 10^6 alveoli. The tip of the bronchoscope is wedged, under visual control, into a third- or fourth-generation midsize bronchus, according to chest radiograph appearance. Lavage is carried out using at least 120 mL of sterile isotonic saline in several aliquot portions. The dilution of alveolar secretions in the lavage fluid is 10- to 100-fold, so a colony count of 10^4 CFU/mL in lavage fluid represents 10^5 to 10^6 bacteria per milliliter of alveolar secretion (*51*). In mechanically ventilated baboons, this method appears to be sensitive and provides the best correlation with culture of lung tissue (*50*). Like PSB, quantitative culture of BAL specimens appears to be more accurate than clinical and radiographic criteria for diagnosing healthcare-associated pneumonia (*39,40,52*); however, most studies evaluating quantitative BAL have not used rigorous criteria for determining whether pneumonia was actually present. BAL samples can become contaminated with bacterial flora from the upper respiratory tract, and reduced specificity may result (*39*). As with PSB, antibiotic use may diminish the sensitivity of BAL (*40,50*). In studies using histology and microbiologic examination of lung tissue as the gold standard, sensitivities of BAL ranged from 47% to 91%, and specificities ranged from 45% to 100% (*46–49*).

To reduce upper airway contamination while still obtaining a representative sample of affected alveoli, Meduri et al. (*41*) developed a technique to obtain PBAL specimens using a balloon-tipped telescoping catheter. In a study of 46 patients, including 25 with suspected VAP, quantitative PBAL culture proved to have a sensitivity of 92% and a specificity of 97% for diagnosing bacterial pneumonia (*41*). Castella and associates (*53*) applied a similar PBAL technique and found that PBAL displayed improved sensitivity (85%) compared with PSB (62%) and improved specificity (83%) compared with BAL (44%). PBAL appears to be somewhat more demanding and time-consuming than unprotected BAL, and has been studied less frequently than PSB and BAL.

After several years of experience with these bronchoscopic techniques, a consensus conference proposed a new definition for diagnosing VAP, which became known as the Memphis Ventilator-Associated Pneumonia Consensus Conference criteria (Table 22-2) (*42*). Definite VAP is only present with radiographic evidence of abscess and a positive needle aspirate, or if there is histologic proof of pneumonia at biopsy or autopsy. Probable VAP requires either positive quantitative or semiquantitative cultures from PSB or BAL, or blood or pleural fluid cultures of a microorganism found within 48 hours of isolation in the sputum, or abscess formation or consolidation with polymorphonuclear-cell infiltration at histologic examination.

Several technical and safety considerations pertaining to these bronchoscopic techniques warrant comment. The technique of the bronchoscopist may influence the results. The passage of the bronchoscope through the upper airway results in bacterial contamination of the suction channel, and the injection of topical anesthetic agents through the bronchoscope carries contaminants into the distal airways (*38*). Therefore, it is prudent to avoid suctioning or the injection of topical anesthetics prior to obtaining bronchoscopic samples. Other operator-dependent variables may also affect quantitative culture results. Elevated temperature, hypoxemia, increased radiographic infiltrates, bleeding, arrhythmias, and pneumothorax may be related to these bronchoscopic procedures, but serious or lasting complications appear to be rare (*19,20*). The use of a high FiO_2, careful monitoring of exhaled volumes and oxygen saturation, and prebronchoscopy assessment of risk should help prevent serious complications.

The most important question remains whether these bronchoscopic techniques influence (preferably improve) patient care in the ICU. Several studies have suggested that quantitative bronchoscopic sampling of the distal airways by PSB, BAL, or PBAL substantially improves the accuracy of diagnosing healthcare-associated pneumonia when compared to clinical and radiographic criteria. In this way, these techniques may help to distinguish between patients who do and patients who do not need antibiotic therapy. In one study, VAP was simultaneously diagnosed according to the modified CDC criteria, CPIS, and quantitative bronchoscopic sampling (*54*). Incidences of VAP were 22% using the modified CDC criteria, 20% using CPIS, 9% using the Memphis criteria for probable VAP, and 0.4% using the Memphis criteria for definite VAP. In another study, only 50% of all patients fulfilling the modified CDC criteria for VAP met the definition of probable VAP with the Memphis criteria (*55*).

Six studies determined the effects of withholding or withdrawing empiric antibiotic therapy if a clinical suspicion was not confirmed by a diagnostic test. In three Spanish studies and a large Canadian study, patients with a clinical suspicion of VAP were randomized to an invasive or noninvasive strategy (*56–59*). Because empirical therapy was not discontinued in any patient, regardless whether the suspicion was microbiologically confirmed or not, these studies cannot answer the question whether addition of these techniques to the diagnostic workup changes patient outcome, and have, therefore, not been included here.

TABLE 22-2

Recommended Definitions for VAP from the Memphis Ventilator-Associated Pneumonia Consensus Conference

Definite pneumonia. The patient meets the clinical criteria for suspicion of VAP of new (progressive) or persistent infiltrate and purulent tracheal secretions and demonstrates one of the following:

1. There is radiographic evidence, preferably CT evidence, of pulmonary abscess and positive needle aspirate culture from the abscess.
2. There is pathologic evidence of pneumonia on histologic examination of lung tissue obtained by open-lung biopsy or at a postmortem examination immediately after death that demonstrates abscess formation of an area of consolidation with intense polymorphonuclear leukocyte accumulation plus a positive quantitative culture of lung parenchyma (>10^4 microorganisms per gram of lung tissue). When used to confirm the diagnosis of pneumonia made by bronchoscopy, the lung tissue for histologic examination and culture must have been obtained within 3 d of the bronchoscopic procedure.

Probable pneumonia. In the absence of any of the above criteria for pneumonia, the patient meets the clinical criteria for suspicion of VAP of new (progressive) or persistent infiltrate and purulent tracheal secretions and demonstrates one of the following:

1. The presence of positive quantitative culture of a sample of secretions from the lower respiratory tract obtained by a technique that minimizes contamination with upper respiratory tract flora (PSB, BAL, PBAL).
2. The presence of positive blood culture unrelated to another source and obtained within 48 h before or after respiratory sampling. The microorganism(s) recovered should be identical to the microorganism recovered from a culture of lower respiratory tract secretions.
3. The presence of a positive pleural fluid culture in the absence of previous pleural instrumentation. The microorganism(s) recovered should be identical to the microorganism recovered from a culture of lower respiratory tract secretions.
4. The presence of pathologic evidence of pneumonia on histologic examination of lung tissue obtained by open-lung biopsy or at a postmortem examination immediately after death that demonstrates abscess formation of an area of consolidation with intense polymorphonuclear leukocyte accumulation plus a negative quantitative culture of lung parenchyma (<10^4 microorganisms per gram of lung tissue). When used to support the diagnosis of pneumonia made by bronchoscopy, the lung tissue for histologic examination and culture must have been obtained within 3 d of the bronchoscopic procedure.

Definitive absence of pneumonia. In patients not meeting the criteria for definite pneumonia, the absence of pneumonia is definitive if one of the following criteria are met:

1. Postmortem exam within 3 d of the suspicion of pneumonia showing no histologic sign of lung infection.
2. Definitive alternative etiology with no bacterial growth on a reliable respiratory specimen.
3. Cytologic identification of a process other than pneumonia (e.g., lung cancer) without significant bacterial growth on a reliable respiratory specimen.

Probable absence of pneumonia. Indicated by the lack of significant growth on a reliable respiratory specimen with one of the following:

1. Resolution without antibiotic therapy of one of the following: fever, radiographic infiltrate, or radiographic infiltrate and a definitive alternative diagnosis.
2. Persistent fever and radiographic infiltrate, with a definite alternative diagnosis established.

BAL, bronchoalveolar lavage; PBAL, protected BAL; PSB, protected specimen brush.
(Adapted from Pingleton SK, Fagon JY, Leeper KV Jr. Patient selection for clinical investigation of ventilator-associated pneumonia: criteria for evaluating diagnostic techniques. *Chest* 1992;102:553S–556S.)

In a landmark study, Fagon and collaborators randomized 413 mechanically ventilated patients with a clinical suspicion of VAP to a diagnostic strategy based on semiquantitative cultures of endotracheal aspirates (n = 209) or an invasive strategy (n = 204) (60). The invasive strategy consisted of bronchoscopy with direct microscopic examination of specimens (see above) and quantitative cultures. Quantitative cultures (PSB cutoff point ≥10^3 CFU/mL, BAL cutoff point ≥10^4 CFU/mL) were used to adjust or withdraw empirical treatment. In 117 of 204 patients, direct examinations yielded no bacteria. However, 20 of these patients had signs of severe sepsis and received antibiotics, although the suspicion of VAP was not confirmed. Of the remaining 97 patients, seven had significant quantitative cultures and antibiotics were started when culture results were available. So in all, the clinical suspicion of VAP was not confirmed in 90 patients. When comparing antibiotic use between patients randomized to either of the two invasive strategies, patients undergoing bronchoscopy had more antibiotic free days. Twenty-nine patients did not receive antibiotics up to day 28 (compared to four in the clinical management group), and patient survival was better among those randomized to the invasive strategy as well.

A different approach was used by Singh et al. (*61*). They determined CPIS scores of patients with a clinical suspicion of VAP and randomized those with a CPIS score ≤ six to different therapeutic strategies; antibiotics for 10 to 21 days (n = 42) or ciprofloxacin for 3 days (n = 39), which could be compared with withdrawing empirical therapy. Patients randomized to a short course had less antibiotic use, lower antibiotic costs, fewer superinfections with

antibiotic resistant pathogens, and no increase in length of stay or mortality. So, it seems safe to withdraw antibiotics after 3 days in patients with CPIS scores ≤6. However, the question is whether patients with such a low CPIS score should receive antimicrobial treatment in the first place.

Investigational Methods

A number of adjunctive or alternative methods for diagnosing healthcare-associated pneumonia have been proposed. Several reports have evaluated nonbronchoscopic techniques for sampling distal airway secretions, including brush (*36*), BAL (*25,49,62,63*), and endotracheal aspirates (*45*). Although such techniques might reduce costs, they have not been adequately validated or standardized, and sampling error can occur. In one study, however, good diagnostic agreement was demonstrated between quantitative cultures from PSB and mini-BAL done by respiratory therapists in patients with suspected VAP (*64*). And in another study, using postmortem analysis as the gold standard, blind bronchial sampling had a higher sensitivity for VAP than PSB (*49*).

The identification of intracellular microorganisms (ICOs) by Giemsa stain of BAL specimens has been reported to be highly predictive of healthcare-associated pneumonia (*25,41,65*). This technique has been compared to histologic and microbiologic examination of lung tissue at autopsy in two studies, with contradictory results. Specificities were high in both studies, 100% and 89% (*46,47*). However, sensitivity was 91% in one study when >5% of leukocytes containing intracellular bacteria was considered positive for VAP (*46*). In the other study, sensitivity was only 37%, when any leukocyte with intracellular bacteria was considered as a threshold for diagnosis of VAP (*47*). Since the presence of ICOs is indicative for the cellular response of the lung to invading microorganisms, it must have discriminatory value differentiating between infection and colonization. Determination of ICOs as an additional, early, indicator of VAP is being used increasingly, the cutoff value of 2% of cells with ICOs is used most frequently as diagnostic for VAP. An additional advantage of the determination of ICOs is that it is not influenced by recent antibiotic use (60,*66,67*).

Measurement of cytokines or inflammatory mediators may be adjunctive tools for diagnosing VAP in the future. Although blood levels of inflammatory mediators poorly correlated with quantitative results from bronchoscopic samples (*68,69*), elevated concentrations of endotoxin (>5 endotoxin units/mL) in BAL fluid had a sensitivity of 100% and specificity of 75% for diagnosing VAP (*70*). Soluble Triggering Receptor Expressed on Myeloid cells-1 (sTREM-1) has proven to be a biomarker for sepsis; however, for the diagnosis of VAP, the determination of sTREM-1 in BAL fluid showed high sensitivity and specificity in the first study (*71*). Unfortunately, this could not be repeated in several later studies (*72*). Procalcitonin is secreted as part of an inflammatory response but only when triggered by infection as shown in severe sepsis. The value of procalcitonin in pulmonary infection remains unclear and studies aiming to establish a diagnostic cutoff value of procalcitonin in case of VAP show contradictory results; sequential measurements might be more useful (*73*).

Other methods that cannot presently be recommended but that may merit further investigation include the detection of elastin fibers (*25,74*) and antibody-coated bacteria (*75*) in respiratory secretions and high-resolution computed tomography (CT) (*76*).

DESCRIPTIVE EPIDEMIOLOGY

Incidence

Incidence rates of VAP among ICU patients depend on the type of ICU, the severity of illness of patients studied, and the criteria for diagnosis. The overall incidence of pneumonia decreases when the definition of pneumonia becomes more strict. Therefore, whether investigators used bronchoscopic techniques in their diagnosis of VAP or just clinical and radiographic parameters is important with regard to incidence rates of VAP. In a number of studies aiming to ascertain incidences of VAP, or to evaluate modalities to diagnose VAP, or studies in which risk factors for VAP were assessed, the cumulative incidences of VAP range from 8.6% to 64.7%. Moreover, in studies on the effect of preventive measures on the occurrence of VAP, incidences of up to 78% have been reported in the control groups (*77*). In the Extended Prevalence of Infection in Intensive Care study (EPIC II), 13,796 patients in 1,265 ICUs were studied on a single day, 51% of the patients were considered infected, and 64% of them had pneumonia (*78*).

The cumulative risk for developing VAP during ICU stay increases until day 5. In one study, the calculated rates for VAP were 3% per day in the first week, 2% per day in the second week, and 1% per day thereafter (*79*). Two other studies suggest that there is a relatively constant 1% to 3% risk per day for developing VAP while MV continues for medical and surgical ICU patients (equivalent to 10 to 30 cases per 10,000 patient-ventilator-days) (*80,81*).

A number of studies have reported incidence rates for healthcare-associated pneumonia in other patient groups, such as the elderly, trauma patients, or cancer patients. However, these studies have relied primarily on clinical diagnostic criteria (10,*11,80–85*).

RISK FACTORS

The strongest risk factor for healthcare-associated pneumonia appears to be tracheal intubation and MV, which results in a 3- to 21-fold increase in the risk of developing healthcare-associated pneumonia (*8,81,85–88*). Because other pathogenetic factors may be different, it is useful to consider nonventilated and ventilated patients (Table 22-3) separately when discussing risk factors.

When nonventilated or broad hospital populations are considered, factors found by multivariate analysis to significantly increase the risk of healthcare-associated pneumonia include chronic lung disease (*85,119*), severity of illness (*119*), upper abdominal or thoracic surgery (*85,119,120*), duration of surgery (*119*), age (*85*), poor nutritional state (*120,121*), immunosuppressive therapy (*120,122*), depressed level of consciousness (*85,123*), large volume of aspiration (*85*), impaired airway reflexes or difficulty handling secretions (*123*), nasoenteric intubation

TABLE 22-3

Risk Factors for ICU-Acquired and Ventilator-Associated Pneumonia

ICU-Acquired Pneumonia	*Ventilator-Associated Pneumonia*
Identified risk factors with no or only limited possibilities for prevention	
Naso/orotracheal intubation (*85,89*)	Emergent intubation (*90*)
Duration of MV (*85,89,91–93*)	Duration of MV (*94–97*)
Severity of illness (*91,93,98*)	Severity of illness (*90,99*)
History of COPD (*85*)	History of COPD (*94,96,100*)
Reason for admission	Reason for admission

	Accidental extubation (*118*)

MV, mechanical ventilation; COPD, chronic obstructive pulmonary disease; ICU, intensive care unit.

(*123*), neuromuscular disease (*121*), and male gender (*119*). Additional risk factors suggested by univariate analysis include duration of hospitalization (*6,9*), oropharyngeal colonization with gram-negative bacilli (10), obesity (*9*), antibiotic therapy (*6*), reflux esophagitis (*124*), and previous pneumonia (*124*).

The risk factors associated with the development of VAP have been determined in studies using multivariate analysis techniques, Cox regression techniques, and case–control designs, or have been suggested on the basis of reviews. Determination of risk factors for VAP has several clinical implications. They offer prognostic information about the probability of developing VAP, they help to reveal the pathogenesis of VAP, and they may provide possible targets for preventive strategies. By risk stratification, one can determine which patients may benefit most

from pneumonia prophylaxis (*125*). Risk factor analyses for ICU-acquired pneumonia (i.e., pneumonia diagnosed in ICU patients with or without MV) have clearly identified MV to be the most important risk factor (*85,89,91–93*). In general, the risk factors that have been identified can be divided into three groups: (a) risk factors that are well known (intubation, duration of MV, etc.) but very difficult to modify and that offer no or only limited possibilities for prevention, (b) risk factors that seem to play a role in the pathogenesis of VAP and have stimulated the development of a number of preventive strategies, and (c) risk factors that have been identified only incidentally or need further investigations to assess their significance and the possibility for prevention. Several risk factor analyses identified previous antibiotic use to be significantly associated with the development of VAP (*94,95,99,100,107,112*). In contrast, antibiotics conferred protection for VAP in a risk factor analysis (*79*), and the absence of prior antibiotic treatment was a risk factor for VAP caused by *Haemophilus influenzae* (*113*). Lately, attention has been drawn to the association between the mode of MV, ventilator-induced lung injury, and inflammation or infection (*126,127*).

Mortality

Published crude mortality rates for healthcare-associated pneumonia range widely from 20% to 71% for hospital-wide, ICU, and ventilated patient groups with a median of 41.5% (*8,21,80–85,96,99,121,128–131*); within the wide reported range, it is not possible to distinguish between these groups. Several factors have been associated with a greater risk of mortality, most prominently *Pseudomonas aeruginosa* as a pathogen, severity of underlying illness, inappropriate antibiotic therapy, and age (*80,82,85,96,99,102,132–134*).

With regard to mortality and VAP, the existing controversy is whether patients die from or die with VAP. In a number of studies, VAP was not independently associated with mortality (*68,84,96,108,*135,*136,137*). A recent systematic review of all observational studies on VAP and mortality demonstrated extensive heterogeneity in outcome, precluding the possibility to quantify the association between VAP and mortality. Only in two subgroups, patients with trauma or ARDS, heterogeneity allowed any conclusions, and in both subgroups VAP was not associated with increased mortality (*138*).

Morbidity and Cost

Healthcare-associated pneumonia is associated with substantial morbidity. Reported rates of secondary bacteremia have ranged from 4% to 38% (*68,80,82,84,85,96,108,131*), and empyema developed in 5% to 8% of patients with healthcare-associated pneumonia (*68,139,140*).

The excess costs associated with healthcare-associated pneumonia are remarkable. According to estimates published by the CDC, an average of 5.9 days of increased length of stay and $5,683 in extra hospital charges result from each episode of healthcare-associated pneumonia (*141*). More recently, Warren et al. found the attributable costs of VAP, after adjustment for underlying severity of illness, to be approximately $11,897 (*3*). Published estimates of excess duration of hospitalization attributed to healthcare-associated pneumonia have ranged from 4 to 22 days (*3,82,128,133,134,137,142–146*), and total hospital costs and hospital length of stay are linearly related (147). A cost-effectiveness analysis of patients receiving oropharyngeal decontamination as a preventive strategy for healthcare-associated pneumonia showed an estimated cost saving of $13,430 for every episode of VAP prevented (*148*).

PATHOGENS

A variety of pathogens appear to be important as causes of healthcare-associated pneumonia. The National Healthcare Safety Network (NHSN) system provides the largest database describing microorganisms isolated from both ventilated and nonventilated patients with healthcare-associated pneumonia. According to NHSN system data from 2006 to 2007, the most frequently isolated pathogen is *Staphylococcus aureus* (24%), followed by *P. aeruginosa* (16%), *Enterobacter* spp. (8%), *Acinetobacter baumanni* (8%), and *Escherichia coli* (5%) (*149*). Problematic resistant pathogens account for a minority of infections (24%). *P. aeruginosa* and *Acinetobacter* spp. are more commonly reported in VAP than in non-VAP. Compared with data from 1997, the proportion of Enterobacteriaceae has decreased, and the proportions of *A. baumannii* and *S. aureus* have increased (*149*).

Besides the difference in duration of MV at time of diagnosis, early-onset and late-onset VAP also have a different etiologic spectrum. Early-onset VAP is mainly caused by *Streptococcus pneumoniae, S. aureus,* and *H. influenzae,* pathogens that presumably already colonize the respiratory tract at the time of intubation. Late-onset VAP is caused by healthcare-associated pathogens such as Enterobacteriaceae, *S. aureus,* and *P. aeruginosa*. Because these healthcare-associated pathogens are known to cause serious infections under certain circumstances, they are usually grouped and labeled as potentially pathogenic microorganisms (PPMO). In many studies, colonization and infection with PPMO is analyzed instead of the separate species. Although PPMO are regarded as a single group, it should be kept in mind that each species has its own characteristics with regard to preferred site of colonization, routes and vectors of transmission, and clinical spectrum.

Studies using quantitative cultures of BAL and/or PSB demonstrate that approximately 60% of all cases of VAP are associated with gram-negative bacteria, mainly *P. aeruginosa* (20%), and 35% with gram-positive bacteria (*80,131,150,151*). *S. aureus* is the most frequent gram-positive pathogen causing VAP (20%). In comatose multiple trauma patients, incidences of *S. aureus* VAP as high as 56% have been reported (*104,152–154*). VAP is often polymicrobial with incidences ranging from 20% to 60% of all episodes of VAP (*12,150,155*). The proportional distribution of the species causing VAP within the etiologic spectrum, as well as their antibiotic susceptibility, may vary considerably between hospital settings, patient populations, and countries.

The importance of anaerobic bacteria in the pathogenesis of VAP has not been studied extensively. Isolation of anaerobic bacteria requires specific transport conditions and culture media, which usually are not systematically achieved during bacteriologic investigation of respiratory tract samples. The incidence of VAP in which anaerobic bacteria are involved, therefore, is probably underestimated. In a prospective study of 130 episodes

of VAP, aerobic and anaerobic bacteria were isolated from PSB (≥10^3 CFU/mL) in 26 (20%) patients, and anaerobic bacteria only were isolated in four (3%) patients (*151*). In another prospective study, no anaerobic microorganisms were isolated in a group of 143 patients, of whom 63 were diagnosed with VAP, despite painstaking microbiological efforts (*156*). Moreover, only one nonpathogenic anaerobic microorganism was isolated in 25 patients with suspected aspiration pneumonia receiving MV of which 12 met the criteria of pneumonia (*156*).

Though less common, other pathogens may also be problematic. Additional work is needed to clarify the roles of influenza and other respiratory viruses, *Mycoplasma pneumoniae,* and *Chlamydia pneumoniae;* however, several reports suggest that these pathogens may account for a modest proportion of cases (*157–164*). More recently, reports on herpes simplex virus, human metapneumovirus, cytomegalovirus, and Epstein Barr virus infections in immunocompetent mechanically ventilated ICU patients have been presented, either as a primary cause of pneumonia or as part of a polymicrobial episode. The clinical relevance of these viral microorganisms, however, remains to be determined (*165,166*). *Legionella* can be an important cause of healthcare-associated pneumonia, particularly when there is colonization of the hospital hot water system (*167–171*). *Aspergillus* and cytomegalovirus are important pathogens in bone marrow transplant recipients (*172*) and other immunocompromised patients. The risk of *Aspergillus* infection may be increased by adjacent construction activity or by a faulty ventilation system (*172–174*). Healthcare-associated infections due to respiratory viruses, *Legionella, Aspergillus,* cytomegalovirus, and *Mycobacterium tuberculosis* are discussed at greater length in other chapters (*36,38,41,42*).

PATHOGENESIS

Colonization of the upper respiratory tract precedes the development of healthcare-associated pneumonia (*114*,135,*175*). For upper respiratory tract colonization and pneumonia to develop, pathogenic microorganisms must reach the distal lung and then multiply, overcoming host defenses at each step. Host defenses include filtration and humidification of air in the upper airways, epiglottic and cough reflexes, ciliary transport by respiratory epithelium, phagocytes and opsonins in the distal lung, and systemic cell-mediated and humoral immunity (*176,177*).

The predominant mode of inoculation is aspiration; however, inhalation (particularly *Aspergillus* and other fungal molds), seeding via the bloodstream, and reactivation of latent infection (*M. tuberculosis,* cytomegalovirus in immunocompromised patients) account for some pneumonias that develop in hospitalized patients. Translocation from the gastrointestinal tract has also been hypothesized as a mode of inoculation (*178*), but this has not been confirmed.

Colonization

The relationship between colonization of the upper respiratory tract and the development of VAP was established by Johanson and coworkers (10) in 1972. Healthcare-associated respiratory infections developed in 23% of ICU patients with upper respiratory tract colonization but in only 3% of noncolonized patients (10). Moreover, upper respiratory tract colonization increased with severity of illness. Repeated oropharyngeal cultures obtained from 33 normal subjects revealed gram-negative bacteria in 6% of subjects, while these pathogens were cultured from 35% of moderately ill hospitalized patients and 73% of moribund patients (179). Since then, many variables have been determined that enhance colonization and infection of the respiratory tract in ICU patients (*180*). Although increased exposure to pathogens may play a role, this cannot exclusively explain increased colonization rates. Nursing and medical staff have similar colonization rates as normal subjects not working in a hospital setting (179). A reduced capacity to clear pathogens and/or increased adherence of microorganisms are more likely mechanisms to account for the higher colonization rates in critically ill patients. The latter mechanisms can be the result of decreased host immunologic function, destruction of epithelial surfaces (*181,182*), impaired mucociliary clearance, proinflammatory enzymes, and fibronectin-reducing proteases (*183*). Furthermore, during ICU stay, approximately 60% of patients receive systemic antibiotics. Antibiotic therapy can rapidly change the commensal oropharyngeal flora, resulting in an increase in oropharyngeal and upper respiratory tract colonization with aerobic gram-negative or gram-positive bacilli and yeasts, possibly due to loss of the normal bacterial flora (*180,184*) and to selection of pathogens that are resistant to the antibiotics used (*185–189*).

Routes of Colonization Microorganisms reach the lungs after aspiration of colonized oropharyngeal fluid. Microaspiration occurs frequently, both in healthy people and in critically ill patients (*190,191*). Pathogens colonizing the respiratory tract and causing VAP are derived from either endogenous or exogenous sources. The stomach and intestine are the most important endogenous sources. In addition, pathogens colonizing the upper respiratory tract (oropharynx, sinus cavities, the nares, and dental plaque) may be aspirated. Contaminated environment (sinks, faucets, sheets, etc.), contaminated equipment (MV devices, ventilator circuits, radiographic equipment, etc.), contaminated enteral feeding, and other colonized patients in ICU are potential exogenous sources.

Several routes of colonization by which pathogens are transported from their endogenous or exogenous sources to the upper respiratory tract of the patient are possible. In the gastropulmonary route of colonization (*192,193*), endogenous bacteria reach the upper respiratory tract via the stomach and subsequently colonize the oropharynx and trachea, after which the bacteria are aspirated in the lower respiratory tract. This route of colonization has been propagated as important in the pathogenesis of VAP for many years. The rectopulmonary route of colonization has attracted less attention. In this route, intestinal microorganisms spread from the rectal area via the patient's skin or the hands of healthcare personnel to the upper respiratory tract. Finally, transfer of pathogens from exogenous sources most probably occurs via

hands of nursing and medical staff, which enables direct inoculation of microorganisms into the tracheobronchial tree during manipulation of ventilator circuits or tubes (*194–196*). This is called the exogenous route of colonization or cross-colonization when another patient is the exogenous source.

Essential Conditions to Study the Pathogenesis of VAP Since colonization is not always followed by infection, infection rates with a certain pathogen form only the tip of the iceberg of the complete epidemiology (*175,195*). When studying the epidemiology of microorganisms in ICU, surveillance of colonization is indispensable. In clinical practice, surveillance is advised only for high-risk patients in specific clinical settings (*197*). However, when determining the epidemiology of ICU pathogens in detail, surveillance should include all patients within the ICU, as well as equipment and environmental surfaces for certain pathogens. Surveillance cultures from patients should be taken on admission and subsequently with a frequency high enough to study sequences of colonization from initial body sites to other body sites. Moreover, patients may be colonized or infected with multiple genotypes of the same species, both at one particular body site and at different body sites (*194*). Therefore, analysis of a single isolate may not accurately represent the bacterial flora. Analysis of several isolates and determination of similarity of isolates is crucial (*198*).

Comparison of bacterial phenotypes, such as antibiotic susceptibility patterns, serotypes, phage types, and outer membrane protein types, is relatively easy to perform, but lacks specificity (*198,199*). Genomic DNA fingerprinting techniques, such as pulsed-field gel electrophoresis, random amplification of polymorphic DNA, arbitrarily primed polymerase chain reaction, and multiple loci variable-number tandem repeats analysis (MLVA), have a higher specificity and discriminatory power while maintaining epidemiologic linkage. These techniques, therefore, are considered the methods of choice to determine identity of bacterial isolates in the epidemiology of healthcare-associated outbreaks (*200–202*). However, the techniques are often cumbersome and expensive, and therefore not always feasible in routine practice.

In summary, the optimal study design to study routes of colonization that may lead to VAP includes (a) determination of the incidence of VAP, preferably diagnosed by bronchoscopic techniques; (b) performance of surveillance cultures of all patients present in ICU, and possibly environment and equipment; (c) culturing several body sites on admission and with a sufficient frequency thereafter; (d) analyzing several isolates of each species, cultured from each site; and (e) determination of similarity of isolates of a certain pathogen by genotyping techniques.

Endogenous Routes

Gastric Colonization and the Gastropulmonary Route In critically ill patients, gastric acidity may be decreased (i.e., pH value higher) due to decreased acid production, because of the application of enteral feeding or stress-ulcer prophylaxis (antacids, H_2-antagonists, H^+K^+–adenosine triphosphatase [ATPase] inhibitors). If the gastric environment favors bacterial growth, bacteria may multiply; hence, colonization with gram-negative bacteria occurs frequently at this site (*12,192,193*). Because of the simultaneous occurrence of gastric colonization and the development of VAP, a causal relationship has been assumed. In the so-called gastropulmonary route of colonization, bacteria presumably reach the upper respiratory tract by retrograde movement from the colonized stomach, and bacteria are aspirated into the lower respiratory tract. Based on studies reporting correlations between development of VAP and concurrent or preceding gastric colonization with the same species, a central role in the pathogenesis of VAP was assigned to gastric colonization (*11,192,203*). The importance of gastric colonization was investigated in several studies (*11,12,204–211*), and percentages of patients in whom the stomach served as a source of colonization or infection of the respiratory tract ranged from 4% to 24% for colonization and from 0% to 15% for the development of VAP (*4*). Thus, the role of the stomach and gastropulmonary route of colonization remains a subject of debate (*15*). Nevertheless, based on the alleged importance of gastric colonization, modulation of colonization at this site is still being used as a measure to prevent VAP.

Oropharyngeal Colonization The results of studies performed by Johanson and coworkers (10,179) in the early 1970s pointed toward an association between colonization of the upper respiratory tract and the development of VAP. However, at that time, VAP could not be diagnosed with bronchoscopy and the diagnosis relied on relatively nonspecific clinical, radiographic, and microbiologic criteria. Moreover, only antibiotic susceptibility patterns and serotyping were employed to determine the similarity of isolates, because molecular genotyping techniques were not yet available. Remarkably, in the following years, research on the pathogenesis of VAP almost exclusively focused on the role of gastric colonization and the gastropulmonary route of colonization. Approximately 20 years later, new studies on sequences of colonization in patients who developed VAP provided additional evidence in support of Johanson et al.'s earlier findings (*192,207*). In a number of other studies, serial cultures of multiple body sites were obtained to determine sequences of colonization leading to VAP, all supporting a more important role of oropharyngeal than gastric colonization in the pathogenesis of VAP (*12,204–206,208,212*).

In conclusion, the evidence at hand strongly suggests an important role for the oropharynx in the pathogenesis of VAP that offers a potential target for preventive strategies.

Intestinal Colonization and the Rectopulmonary Route The intestines are a large endogenous source of gram-negative bacteria, which may spread to the upper respiratory tract via the patients' skin or hands of healthcare personnel. This so-called rectopulmonary route of colonization, in reality, is an exogenous route for endogenous microorganisms. Still, due to decreased intestinal peristalsis and gastric emptying in critically ill patients, bacteria can colonize the proximal small intestine and subsequently migrate to the stomach via duodenogastric reflux (*211,213*). The rectopulmonary route of colonization has attracted little attention, especially when compared with other routes

of colonization. To our knowledge, only four studies have been performed with special attention to the rectopulmonary route (*194,214–216*), and the available data suggest that rectal colonization with *Enterobacter* spp. and *P. aeruginosa* frequently occurs in critically ill patients, but secondary colonization of the upper respiratory tract seems infrequent. The relevance of rectal colonization and the rectopulmonary route of colonization in the pathogenesis of VAP remains largely undetermined.

Exogenous Routes Data on the role of exogenous sources in colonization and infection of ICU patients are derived mainly from case reports and descriptions of outbreaks. Sinks (*217–219*), distilled water systems (*220*), faucets (*221*), tube-feeding formulas (*222,223*), and ventilator circuits (*224*) have been reported as exogenous sources of PPMO, causing outbreaks of healthcare-associated infections. Especially *P. aeruginosa* possesses the ability to proliferate in aqueous sources throughout the hospital. In addition, patients themselves are major reservoirs of healthcare-associated pathogens (*225*). It is unlikely that airborne transmission contributes to the spread of staphylococci and gram-negative bacilli (*225*). Therefore, transfer of these pathogens most probably occurs via hands of nursing and medical staff or equipment (stethoscopes, blood pressure cuffs, etc.) (*194–196*). Direct inoculation of pathogens into the tracheobronchial tree from contaminated hands is possible during manipulation of ventilator circuits or tubes. If the tracheobronchial epithelium is able to bind pathogens, colonization and subsequent pneumonia may occur. This hypothesis is supported by studies reporting lower incidences of healthcare-associated infections after increasing hand-washing frequency or use of gloves or antiseptic hand-washing products (*226–228*). The importance of cross-colonization in nonepidemic situations has rarely been studied (*195,219,229–233*).

In summary, multiple data have shown that cross-colonization, mainly from patient to patient via hands of healthcare workers or equipment may be an important route of colonization. However, endogenous colonization, usually driven by selective pressure, may be equally or even more important, even in settings with high levels of endemic prevalence.

PREVENTION

Guidelines for the prevention of hospital-acquired or healthcare-associated pneumonia have been formulated by the American Thoracic Society (ATS)/Infectious Disease Society of America (234) and the CDC, with the consensus recommendations of the Hospital Infection Control Practices Advisory Committee (HICPAC) (235). Both guidelines, updated in 2004 and 2003, respectively, incorporate general recommendations regarding infection control practices that decrease the incidence of many infections, sometimes including VAP, such as pneumococcal and influenza vaccination of at-risk populations, hand-washing protocols, isolation of patients with multiply resistant respiratory tract pathogens, staff education, maintaining adequate staffing levels, and surveillance for bacterial pneumonia in high-risk ICU patients (234,235). Furthermore, an extensive list of recommendations regarding interruption of transmission of microorganisms from human or inanimate sources to patients is described. These recommendations include sterilization, disinfection, maintenance instructions for ventilator systems and circuits, hand washing, and barrier precautions (235). Moreover, a number of recommendations have been added in these updated guidelines that may reduce duration of MV and ICU stay and, thereby, reduce the incidence of VAP although these recommendations have no direct effect on the development of VAP. These measures include using a ventilator weaning and sedation protocol (*236*), a restricted red blood cell transfusion trigger policy (*237*), early goal-directed therapy in case of sepsis (*238*), and intensive insulin therapy (*239*). Finally, there are a number of preventive strategies considered effective in preventing VAP and recommended by the ATS guidelines with an evidence level I or II (234) or advised by the CDC/HICPAC guideline with a categorization of recommendation Category I or II (235), which are described in the following section.

Selective Decontamination of the Digestive Tract

In 1971, the concept of colonization resistance was proposed by van der Waaij et al. (*240*), who suggested a beneficial effect of the anaerobic flora in resisting colonization by aerobic gram-negative bacilli in the digestive tract. Many infections are caused by these enteric bacilli. SDD was developed to selectively eliminate the aerobic gram-negative bacilli and yeasts from the digestive tract, leaving the anaerobic flora unaffected. The first clinical studies with this technique were performed in granulocytopenic patients and showed favorable results (*241*). In the early 1980s, Stoutenbeek and coworkers (242) adapted the technique for ICU patients. The full concept of SDD aims to eradicate microorganisms from the intestine, the stomach, and the oropharynx by nonabsorbable antibiotics, which are combined with systemic antibiotic prophylaxis during the first days of ICU admission. In the SDD regimen, the combination of colistin and an aminoglycoside is generally used both of which are effective against gram-negative bacilli and *S. aureus*. Moreover, both agents are nonabsorbable and do not affect the anaerobic intestinal flora. Amphotericin B was added to prevent overgrowth with yeasts and systemic prophylaxis to prevent early infections. Since the introduction of this preventive strategy, dozens of studies in a variety of ICU populations (*77,185–187*,242,*243–273*,274,*275*) and many meta-analyses have been performed.

The full regimen of SDD (including oropharyngeal and intestinal decontamination and systemic prophylaxis) was studied in at least 17 trials (242,*244–256,269–271*) with VAP or respiratory tract infections as the end point. Only four of these had a double-blind placebo-controlled design (*247,251,269,270*). Twelve reported beneficial effects on incidence of VAP (*244,246,248,251,254,269,271*) or all respiratory tract infections (242,*245,249,256,270*), including only two of the four double-blind studies. The overall RRR of VAP in these 17 trials was 0.68 (95% CI: 0.61–0.73).

Several meta-analyses of SDD studies have been published, with more or less comparable results. They conclude that SDD decreases the incidence of VAP caused by aerobic gram-negative bacteria with RRRs ranging from

0.40 to 0.78, the reported outcomes regarding prevention of VAP, however, are related to the methodological quality of the individual studies (*276*).

As an alternative to SDD, investigators have evaluated the effects of selective oropharyngeal decontamination (SOD) alone (*77,266,267*). In a prospective randomized placebo-controlled double-blind study, 87 patients received topical antimicrobial prophylaxis in the oropharynx and 139 patients received placebo. The aim of the study was to prevent VAP by modulation of oropharyngeal colonization, without influencing gastric and intestinal colonization and without systemic prophylaxis. Oropharyngeal colonization present on admission was eradicated in 75% of the patients (4% among control patients), and only 10% of study patients acquired oropharyngeal colonization, as compared to 61% of control patients. There were no significant differences in gastric and intestinal colonization. This regimen resulted in an RRR for VAP of 0.62 (95% CI: 0.26–0.98) (274).

There is only one study in which SDD and SOD (using the same topical antibiotics in the oropharyngeal paste) were compared. This was a multicenter cluster-randomized crossover study in 13 ICUs in the Netherlands (277). During study periods of 6 months, all eligible patients (those receiving MV > 48 hours) received SDD, and the next 6 months all patients received either SOD or standard care (no SDD and no SOD), and the final regimen was used for all patients in the third study period. The order of the two interventions and standard care was randomized per center. Overall, 89% of all eligible patients were included and the total study population consisted of 5,939 patients. The day-28 mortality rate associated with standard care was 27.5%, and this rate was reduced by an estimated 3.5% (relative reduction of 13%) and 2.9% (relative reduction of 11%) during SDD and SOD, respectively. These reductions correspond to number needed to treat to prevent one casualty at day 28 of 29 and 34 for SDD and SOD, respectively. In this study, no attempts were made to measure the effects of SDD and SOD on the incidence of VAP. Overall intravenous antibiotic use (including the 4 days of cefotaxim during SDD) was 11.9% and 10.1% lower during SDD and SOD, respectively.

However, SDD has some potential drawbacks such as antibiotic resistance of gram-negative bacteria and the occurrence or selection of resistant gram-positive microorganisms. Although a number of studies reported no increased incidences of resistant bacteria (*244,248,250,254, 255,259–261,266,267*), overgrowth and even infections with gram-positive bacteria, resistant to the antibiotics used for SDD, have been reported in several trials (*185–189,249, 251,252,257,262,265,269,278–280*), as were increased colonization and infection rates due to gram-negative resistant bacteria (*245,249,251,252*). Moreover, the lack of cost-benefit analyses and of beneficial effects on mortality rates has further limited the widespread use of SDD (*281*).

In the before-mentioned multicenter cluster-randomized crossover study in 13 ICUs in the Netherlands, point- prevalence surveys were performed every third Tuesday of each month (277). On that day, rectal swabs and throat swabs were obtained from all patients present in the ICU, regardless whether they were receiving SDD or SOD. In all, 2,963 patients were included in these point-prevalence surveys, and the prevalence of carriage with antibiotic-resistant pathogens was <5% in all study periods, and was—for rectal carriage—lowest during SDD for all microorganism–drug combinations evaluated. In the respiratory tract, antibiotic resistance levels were similar for SDD and SOD, and lower than during standard care. Yet, when analyzed longitudinally, some unexpected findings emerged. For instance, rectal carriage with ceftazidime-resistant gram-negative bacteria was lowest during SDD, but was higher in study periods after SDD, than before SDD (282). Furthermore, respiratory tract carriage with ceftazidime-resistant gram-negative bacteria was lowest during SDD/SOD, but resistance prevalence gradually increased during these interventions. These findings demonstrated the ecological effects of SDD and SOD on the bacterial ecology in ICUs, with lowest levels of resistance during interventions. Yet, the data also suggest a rebound effect of intestinal carriage of ceftazidime resistance in the ICU after discontinuing SDD and a gradual increase of resistance in the respiratory tract during interventions.

In summary, SDD has been shown to decrease VAP; this effect seems mainly due to the SOD component in SDD. SOD has been shown to effectively decrease the incidence of VAP significantly. The largest SDD study up until now has shown reduced mortality of both SOD and SDD making it the standard of care in ICUs. Whether SDD or SOD has advantages in terms of development of antimicrobial resistance remains to be established.

Another way to achieve oropharyngeal decontamination, not using antibiotics, is the use of chlorhexidine. For instance, an oral rinse of 0.12% chlorhexidine reduced the incidence of respiratory tract infections among 353 cardiosurgical patients from 9% in control patients to 3% in patients receiving oropharyngeal decontamination with chlorhexidine (*283*), mainly due to a reduction of infections with gram-negative pathogens. This was repeated more recently in a study by Segers et al. randomizing 991 cardiosurgical patients. They found an ARR of 6.5%, which means that 16 patients need to be treated with oropharyngeal chlorhexidine gluconate to prevent one healthcare-associated pneumonia. Bacteremia, deep wound infections, and sternal infections were also significantly reduced (*284*). In a mixed ICU population, 2% chlorhexidine (CHX) alone or 2% chlorhexidine in combination with 2% colistin (CHX/COL) showed a reduced daily risk of VAP with hazard ratio of 0.35 for CHX and 0.45 for CHX/COL as compared to placebo. Moreover, CHX/COL provided significant reduction in oropharyngeal colonization with both gram-negative and gram-positive microorganisms, whereas CHX alone mainly affected gram-positive microorganisms (*285*). However, it is not known to what extent prolonged application of chlorhexidine will affect oral, esophageal, and gastric mucosa in critically ill ICU patients; the above-mentioned studies did not report serious complications. Moreover, the risk of chlorhexidine resistance after long-term application has scarcely been studied, although some studies report decreased susceptibility to chlorhexidine in some bacteria, however, with only slight increases in minimum inhibitory concentration (*284–289*).

Subglottic Secretions Drainage During MV, subglottic secretions and oropharyngeal fluids may accumulate above the inflated endotracheal cuff. This fluid will contain large amounts of microorganisms. Microaspiration of

these secretions along the tracheal cuff results in colonization and possibly infection of the lower respiratory tract. Drainage of subglottic secretions with specifically designed devices may therefore prevent VAP. This preventive measure has now been evaluated in five single-center studies all showing statistically significant or tendencies toward significant reductions in incidences of VAP (*14,*290,*291–293*). A meta-analysis of these studies concluded that subglottic secretions drainage was effective in reducing the rate of early-onset VAP (*294*). Recently, the first multicenter randomized controlled trial was published in which all study patients ($n = 333$) were intubated with a tracheal tube allowing drainage of subglottic secretions but were randomly assigned to undergo intermittent subglottic secretions drainage ($n = 169$) or not ($n = 164$). Moreover, diagnosis of VAP was performed by quantitative cultures of PSB or BAL. Microbiologically confirmed VAP occurred in 15% of study patients and 26% in the control group (RRR 42% and NNT approximately 10). Using a day-5 threshold, the beneficial effect of subglottic secretions drainage in reducing VAP was observed in both early- and late-onset VAP (*295*). Moreover, from a theoretical decision-model analysis, it was concluded that the use of endotracheal tubes allowing subglottic suctioning may result in cost savings in mechanically ventilated ICU patients (*296*). Pneumatikos et al. (*297*) determined the effects of subglottic secretion drainage in combination with decontamination of the subglottic area with nonabsorbable antibiotics (polymyxin, tobramycin, and amphotericin B). This combined intervention reduced the incidence of VAP with an RRR of 0.68.

In summary, subglottic secretion drainage appears to reduce VAP and the use of endotracheal tubes permitting subglottic secretion drainage should be considered by ICU physicians and physicians involved in pre-ICU care.

Body Position Enteral feeding increases gastric volume, especially in critically ill patients who often have reduced gastric motility and delayed gastric emptying due to the underlying disease or as a result of medication (*298*). In these patients, the risk of aspiration of gastric contents is enhanced. Torres and coworkers (*191*) analyzed gastroesophageal reflux in ventilated patients on enteral feeding, using radioactive-labeled gastric nutrition. They found that patients in the supine position had higher counts of radioactivity in endobronchial secretions compared with patients treated in a semirecumbent position. Moreover, the length of time in the supine position appeared to be a risk factor for aspiration of gastric contents. In a follow-up study in 15 patients by the same group, it was concluded that gastroesophageal reflux occurs irrespective of body position, and that the semirecumbent position does not protect completely from gastroesophageal reflux (*299*). These data confirmed the results reported by Ibáñez et al. (*190*) in a similar study. The semirecumbent patient position has been evaluated in a randomized design twice (*300*,301). In a small randomized trial, a semirecumbent position was associated with a significant reduction in the incidence of VAP as compared to the supine position (5% and 23%, respectively; $p = .018$). However, the combination of a supine position while receiving enteral feeding might have been responsible for this large difference (*300*). The study by van Nieuwenhoven et al. randomized 221 patients to standard care (supine position with backrest elevation of 10 degrees) or semirecumbent position (target backrest elevation of 45 degrees) and, importantly, backrest elevation was measured continuously. The most prominent conclusion was that a backrest elevation of 45 degrees for semirecumbent positioning was not feasible in daily practice. The target semirecumbent position of 45 degrees was not achieved for 85% of the study time, and these patients more frequently changed position than supine-positioned patients. The achieved difference in treatment position (average elevations of 10 degrees vs. 28 degrees) in this study did not prevent the development of VAP. The main conclusion regarding the preventive effect of body position on the incidence of VAP is that even in the presence of a dedicated team to control and maintain patient positioning, the semirecumbent treatment position with an aimed backrest elevation of 45 degrees is not feasible for mechanically ventilated patients (301).

In addition to the patient's position, gastroesophageal reflux may be influenced by the presence and even size of the nasogastric tube (*190,299,302*). However, the effects on incidences of VAP were not evaluated in any of these studies (301).

Other Preventive Strategies Intubation and MV clearly are the most important risk factors for VAP. Unnecessary intubation, therefore, should be avoided at all times. Noninvasive positive-pressure ventilation (NIPPV) using a face mask could be used as an alternative ventilation mode in ICU patients. The beneficial effects of NIPPV on the development of VAP and patient survival have been determined in randomized trials for patients with acute exacerbations with chronic obstructive pulmonary disease (COPD) (*303*), acute respiratory failure (*304*), and in immunosuppressed patients with pulmonary infiltrates, fever, and respiratory failure (*305*). In addition, the risk for VAP increases with duration of ventilation. As a result, strategies to reduce the duration of ventilation may decrease the risk for development of VAP. Examples of such strategies are protocols to improve methods of sedation administration (*306,307*), accelerate weaning (*308*), or combining these protocols (*236*). Furthermore, staffing levels may influence the length of stay of patients in ICU, with an inverse relationship between adequacy of staffing levels and duration of stay and subsequent development of VAP (*309,310*). Understaffing can also lead to lapses in infection control practices, facilitating transmission of antibiotic-resistant bacteria (*311*).

Bacterial contamination of the ventilator tubing circuit may predispose to the development of VAP (*224*). Frequent changing of these circuits (including inline suction catheters, heat and moisture exchangers, and heated humidifiers) may be beneficial to decrease the bacterial burden. On the other hand, frequent manipulation of ventilator tubing circuits may lead to introduction of healthcare-associated pathogens. Five studies have addressed the effects of lengthening intervals between circuit changes on colonization of the patient and circuits, and the incidence of VAP (*130,312–315*). They all concluded that decreasing the frequency of ventilator circuit changes did not increase incidences of VAP or patient and circuit colonization. Therefore, substantial reductions in the costs of MV can be

obtained without apparent adverse effect. Studies using a closed-suction catheter system for endotracheal suctioning found similar incidences of pneumonia compared with the open-suction system with single-use sterile suction catheters (*316–319*). During MV, heating and humidifying inspired gases are necessary. Heated humidifiers are used most frequently, but these cause accumulation of water in the circuit that may become colonized with bacteria (*224*). Heat and moisture exchangers are a possible alternative in which the formation of condensate in ventilation circuits is avoided due to the combination of humidification with antimicrobial filtering properties. However, heat and moisture exchangers failed to reduce the incidence of pneumonia in five studies comparing both methods (*320–324*). Kirton and coworkers (*325*) are the only investigators to report a significant reduction in late-onset VAP, but not early-onset VAP, with the use of heat and moisture exchangers. More recently, the effect of heat and moisture exchanger filters with a different composition of the condensation surface, either $CaCl_2$ or $AlCl_2$ based, was compared. No difference was observed in the incidence of tracheal colonization and VAP (*326*).

Administering probiotics has been advocated as a means to prevent various infections, including VAP. Probiotics may exert immunomodulatory properties and maintain the host's microbial balance in oropharynx and upper digestive tract, which potentially reduces the incidence of VAP. Several studies have been performed and five of those were critically reviewed in a meta-analysis of randomized controlled trials by Siempos et al. concluding that administration of probiotics was beneficial in terms of incidence of VAP, length of ICU stay, and respiratory tract colonization with *P. aeruginosa*. No effect on mortality was seen (327). More recently, Morrow et al. compared oropharyngeal and gastric administration of *Lactobacillus rhamnosus* with placebo in a blinded, randomized, controlled trial, using quantitative BAL cultures for diagnosis of VAP. In all, 138 highly selected critically ill ICU patients were randomized. The patients receiving probiotics were less likely to develop VAP (19.1% vs. 40%, $p = .007$) and had fewer days of antibiotics prescribed for VAP (5.6 days vs. 8.6 days, $p = .05$) when compared to patients treated with placebo. No adverse affects related to probiotic administration were identified (*328*). Given the increasing antimicrobial resistance, the use of probiotics as a preventive strategy for VAP deserves consideration.

The endotracheal tube contributes to the pathogenesis of VAP, which involves colonization of the endotracheal tube from which the oropharyngeal cavity becomes colonized, eventually leading to the development of VAP. Colonization of the endotracheal tube is facilitated by biofilm formation. To prevent bacterial colonization and biofilm formation, a silver-coated endotracheal tube was designed since silver, *in vitro*, has broad-spectrum antimicrobial activity, reduces bacterial adhesion to the tube, and blocks biofilm formation. Rello et al. (*329*) were the first to report that the silver-coated endotracheal tube was feasible and well tolerated and showed delayed colonization, reduced colonization, and lower maximal bacterial burden in tracheal aspirates. Kollef studied the silver-coated endotracheal tube in a large, prospective, randomized, single-blind, controlled trial with VAP as primary outcome. The incidence of VAP was reduced (7.5% in control group and 4.8% in the study group [$p = .03$]), and the occurrence of VAP was significantly delayed (330). Moreover, it was suggested that the use of silver-coated endotracheal tubes was associated with reduced mortality in patients with VAP, a finding that needs confirmation in future trials (*331*).

The Institute for Healthcare Improvement has come forward to assist healthcare institutions with programs to implement evidence-based practice guidelines. The standard component of these programs are "bundles" of care defined as a small, straightforward set of practices that when performed collectively and reliably, have been proven to improve patient outcomes. Specific to VAP, the "ventilator bundle" was put forward, consisting of four evidence-based practices to improve the outcomes of MV: (a) peptic ulcer disease prophylaxis, (b) deep venous thrombosis prophylaxis, (c) elevation of the head of the bed, and (d) daily sedation vacation and assessment of readiness to wean. Several studies, mainly before-after studies, have been performed on the influence of implementing the ventilator bundle on incidences of VAP. In general, the studies showed a decrease in the number of episodes of VAP after implementation of the bundle. However, as concluded in a systematic literature review, the lack of methodologic rigor of the studies precludes any conclusive statements about the bundle's effect on prevention of VAP. Moreover, whether the four practices, included in the ventilator bundle, are the best (evidence-based) practices regarding prevention of VAP is matter of debate (*332*). Recently, a European care bundle for prevention of VAP was presented with five practices including not implementing ventilatory circuit changes unless specifically indicated, the use of strict hand hygiene using alcohol, the use of appropriately educated and trained staff, the incorporation of sedation vacation and weaning protocols into patient care, and oral care with chlorhexidine. The validation of this bundle in a prospective study is ongoing (*333*).

CONCLUSION

It remains difficult to define firm conclusions after a critical assessment of the various studies on the prevention of VAP. Due to small numbers of patients studied, heterogeneous ICU populations, and differences in diagnostic criteria and quality of the studies, a comparison of the studies is hampered. Moreover, some strategies have scarcely been studied. Ideally, preventive strategies are studied in well-designed multicenter trials, including large numbers of comparable patients.

The use of SDD has been studied most frequently and seems to have the best potential to reduce the incidence of VAP. However, SDD was considered of unproven value by the ATS (category 3), and a strategy for which insufficient evidence is available by the CDC (Category UI). Large recent studies showed that SDD and SOD improve patient survival and reduce overall antibiotic use. However, such strategies may be contraindicated in ICU settings with high-levels of multiresistant microorganisms. In settings, where resistance levels are low, the long-term effects of antibiotic prophylaxis should be carefully monitored.

The various preventive strategies associated with enteral feeding and (prevention of) gastric aspiration are thought to be efficacious by ATS (category 2); very few studies on their efficacy have been performed, and the results are controversial. The CDC considers these recommendations to be an unresolved issue (category UI), although a semirecumbent body position during MV was strongly recommended (category IB), even though definitive scientific evidence for this recommendation is lacking. There is now one randomized trial favoring the semirecumbent position, while another showed that the semirecumbent position with backrest position at 45 degrees is not feasible in daily care.

Subglottic secretions drainage is regarded "promising in efficacy and being used by some hospitals on a regular basis" in accordance with an ATS category 2 recommendation, which is in line with the scientific evidence. Subglottic secretion drainage appears to reduce VAP and the use of endotracheal tubes permitting subglottic secretion drainage should be considered. However, the CDC considers this strategy to be a practice for which insufficient evidence or consensus regarding efficacy exists (category UI) in their last guideline.

Although preventive strategies aimed at ventilator circuits are categorized as promising in efficacy (category 2) by the ATS, the accessory guidelines in fact indicate that the proposed measures (i.e., heat and moisture exchangers; frequent, infrequent, or no change of circuits and closed-suction systems) do not seem to add to the risk of developing VAP. This is congruent with the categorization of the CDC (category UI) recommendation.

Finally, noninvasive ventilation, weaning and sedation protocols aimed to reduce endotracheal intubation and duration of ventilation have proven efficacious in preventing VAP. Evidence in support of the use of probiotics and silver-coated endotracheal tubes is compiling and should be considered. The use of the "ventilator bundle" appears attractive in many ways although the choice of practices incorporated in this bundle needs critical evaluation.

CHAPTER 23

Healthcare-Associated Sinusitis

Marc J.M. Bonten

Healthcare-associated sinusitis (HAS) is a common, unrecognized cause of fever and even sepsis in mechanically ventilated patients. Underestimation of its incidence is at least partly due to the difficulty in diagnosing HAS. The reported cumulative incidence ranges from 1% to 83% in studies specifically designed to investigate HAS. Combined with pneumonia, catheter-related sepsis, and urinary tract infection, HAS has been considered as one of the four "horsemen" of clinically important healthcare-associated infections in critically ill patients *(1)*. HAS is most often caused by enteric gram-negative bacteria or *Staphylococcus aureus*. The infection is a result of disturbances of local anatomy, colonization of the upper respiratory tract with potentially pathogenic microorganisms, and the severity of underlying illness in critically ill patients. The most important risk factors are prolonged nasotracheal intubation, mechanical ventilation, and the presence of a nasogastric tube. Basic infection control procedures and avoidance of nasotracheal intubation seem to be most important for prevention of HAS.

DEFINITION

Because of the wide variation of definitions used for HAS, interpretation of the whole body of literature dedicated to this topic is difficult, mainly because of the problems encountered in diagnosing HAS. It is usually diagnosed using a combination of clinical suspicion of infection, with fever and leukocytosis, together with radiologic evidence of HAS. The latter may be based on radiographic, ultrasonographic, or computed tomography (CT) examinations. Finally, the diagnosis is confirmed by microbiologic cultures. The value of each of these diagnostic modalities is discussed later. In what probably is the most detailed prospective study of HAS, Rouby et al. (2) distinguished between radiologic maxillary sinusitis and infectious maxillary sinusitis (Fig. 23-1). Radiologic maxillary sinusitis was defined as total opacification of one or both maxillary sinuses or as the presence of an air-fluid level within one or both maxillary sinuses on CT image. Based on microbiologic cultures and Gram staining, the diagnosis of infectious maxillary sinusitis was established or refuted.

CLINICAL RELEVANCE OF HEALTHCARE-ASSOCIATED SINUSITIS

HAS was first described in 1974. Arens et al. *(3)* described four patients who had undergone nasotracheal intubation for coronary artery bypass surgery and who developed HAS. All patients had been intubated <36 hours, and evidence of HAS appeared in 6 to 10 days postoperatively. In later studies, HAS was usually described in patients who were still intubated. The true incidence of HAS and its relevance as a source of fever are unknown. Large studies determining prevalences and incidences of healthcare-associated infections, such as the National Nosocomial Infection Surveillance system from the Centers for Disease Control and Prevention or the European Prevalence of Infection in Intensive Care Study, did not include HAS as an infectious entity *(4,5)*. However, the cumulative incidence of HAS was remarkably high in several studies carefully analyzing causes of fever in mechanically ventilated patients, with the reported cumulative incidence ranging from 1% to 83% (Table 23-1). Meduri et al. (16) subjected 50 patients with a clinical suspicion of ventilator-associated pneumonia to a systematic diagnostic protocol, which included CT scanning of the sinuses and aspiration of the maxillary sinuses for microbiologic analysis when air-fluid levels or opacifications were encountered. A definitive source of fever was identified in 45 patients and HAS was diagnosed in 12 of them. HAS was in all cases accompanied by another infection, which in most cases (72%) was caused by pathogens other than those isolated from maxillary aspirates. In a large prospective study in medical intensive care unit (ICU) patients with endotracheal intubation, the cumulative incidence of HAS was 7.7%, with incidence rates of 12 cases per 1,000 patient-days and 19.8 cases per 1,000 nasoenteric tube days (11). Furthermore, cumulative incidences from 9% to 26% have been reported in neurosurgical ICU patients (13,14,*18*).

These studies suggest that HAS may occur often in selected patient groups. However, it is unknown to what extent HAS affects morbidity and patient outcome. Interestingly, HAS may occur concomitantly with other infections. For instance, Borman et al. *(21)* described 19 patients with

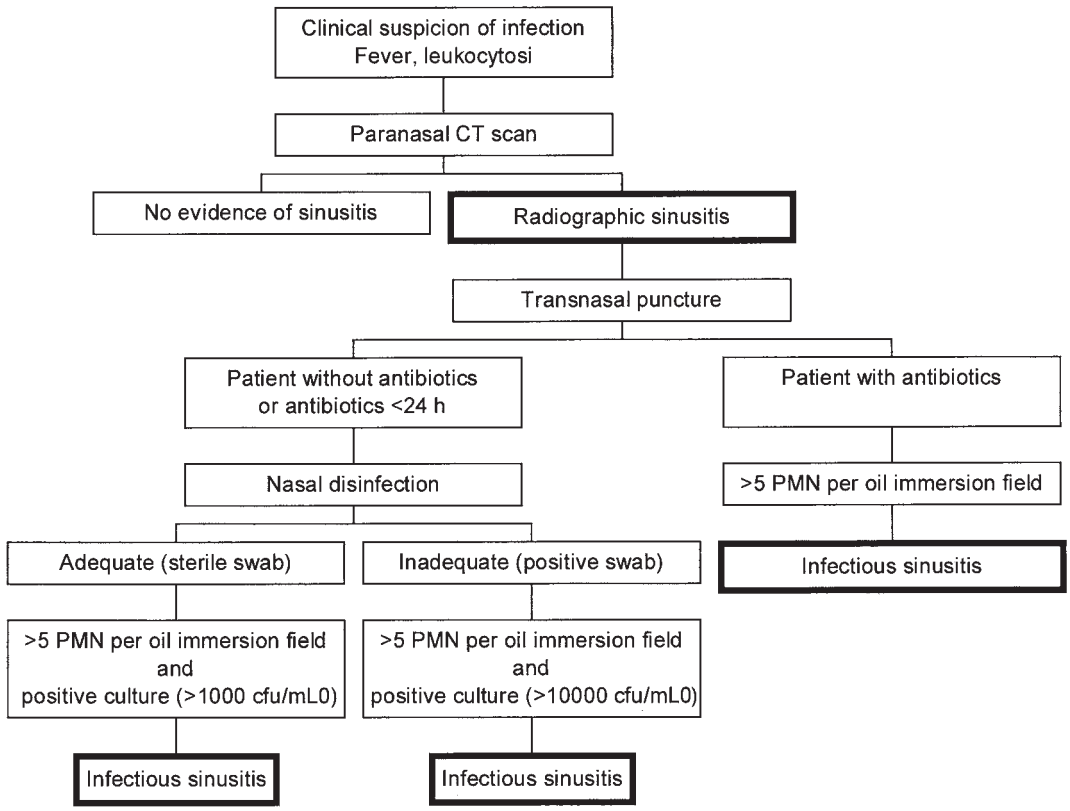

FIGURE 23-1 Possible diagnostic track for patients with a clinical suspicion of HAS. (Modified from Rouby JJ, Laurent P, Gosnach M, et al. Risk factors and clinical relevance of Healthcare-associated maxillary sinusitis in the critically ill. *Am J Respir Crit Care Med* 1994;150:776–783, with permission).

radiographic evidence of HAS, and 10 of these patients had positive cultures of antral aspirates. Evaluation of causes of fever in these patients revealed that fever was definitely caused by HAS in only one patient, possibly in two, and definitely not caused by HAS in the remaining 16 patients.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Clinical Presentation

In previously healthy and ambulatory patients, acute sinusitis usually results in localized pain, nasal congestion, and purulent nasal drainage. Sinus disease is an inherent part of the common cold syndrome, and 87% of ambulatory patients with colds have sinus cavity disease *(22)*. In these patients, sinusitis is rarely associated with systemic symptoms or fever *(23)*. Pain cannot be expressed by most intubated patients, and findings of physical examination, such as tenderness and purulent nasal discharge, are often absent. As a result, physical examination usually does not contribute to establishing the diagnosis of HAS *(12)*. Nonspecific symptoms such as fever or leukocytosis often are the first signs of HAS. Because fever and leukocytosis, in this patient population, may have many other causes, both infectious and noninfectious, HAS may not be considered as the cause of infection by clinicians. Careful radiographic and microbiologic analyses are, therefore, mandatory.

Radiologic Examination

Sinus radiography usually includes three views *(24)*: the straight anterior–posterior view (Caldwell view) for examining the frontal and ethmoid sinuses; the Water's view to visualize the maxillary sinuses (also a straight anterior–posterior view with the patient's head tilted upward); and the lateral view to visualize the sphenoid sinus. Because of the complex labyrinthine structure of air cells separated by bony septa, the ethmoid sinus is difficult to evaluate. In addition, the sphenoid sinus is localized centrally and surrounded by bony structures and, therefore, is also difficult to evaluate. In critically ill patients, the diagnostic yields of conventional radiography are further diminished by the use of portable equipment, difficulties in placing patients in the upright position, and interference of nasogastric and nasotracheal tubes with x-ray images. Conventional multiview plain sinus radiographs, therefore, are regarded as inaccurate for diagnosing HAS (6).

Computed axial tomography displays bony details and can distinguish soft tissue swelling or fluid within the sinuses. In healthy subjects, sinuses are aerated. Signs suggestive for infection include maxillary mucosal thickening, total opacification, or the presence of an air-fluid level in one or both maxillary sinuses (2). CT scanning definitely has multiple advantages over conventional radiography for diagnosing HAS. However, mucosal thickening or fluid accumulation within sinus cavities are not proof of infection, and CT scan is unable to distinguish between blood and other fluids, which may be problematic in patients

TABLE 23-1

Cumulative Incidence of Healthcare-Associated Sinusitis According to Patient Population and Diagnostic Techniques Used

Study (Ref)	*No. of Patients*	*No. of Cases*	*Cumulative Incidence*	*Population Studied*	*Diagnostic Criteria*
Kaups et al. (6)	100	1	1%	Surgical ICU 54% multiple trauma 90% mechanically ventilated	Unexplained fever Bedside ultrasonography Positive antral puncture
Caplan and Hoyt *(7)*	2,368	32	1.3%	Trauma unit All patients admitted	Opacification or air-fluid level on bedside radiography with purulent nasal discharge or purulent aspirate from the involved sinus
Mevio et al. *(8)*	1,126	27	2%	ICU	Unexplained fever Imaging evidence of fluid in maxillary sinus Antral puncture
Bert and Lambert-Zechousky *(9)*	4,509	103	2.3% (0.1–8.8%)	Six ICUs All patients admitted	Clinical suspicion of HAS Positive transnasal culture
Aebert et al. *(10)*	171	4	2.3%	Trauma ICU Nasotracheal intubation	Unexplained fever or purulent nasal discharge Opacification or air-fluid level on bedside radiography Purulent aspirate from the involved sinus
George et al. (1)	366	28	7.7%	Medical ICU Expected mechanical ventilation >3 d	Opacification or air-fluid level on bedside radiography or CT evidence of HAS ≥1 micro-organism in culture of aspiration fluid
Bell et al. *(12)*	139	11	7.8%	Trauma ICU Intubated and ventilated	Unexplained fever Opacification or air-fluid level on bedside radiography or CT evidence of HAS Purulent aspirate from the involved sinus
Korinek et al. (13)	123	11	9%	Neurosurgical ICU Intubated and ventilated	Unexplained fever Opacification or air-fluid level on CT Purulent aspirate from the involved sinus
Westergren et al. (14)	15	2	13%	Neurosurgical ICU >7 d on mechanical ventilation	Unexplained fever Bedside ultrasonography Positive antral puncture after sinoscopy
Holzapfel et al. (15)	300	54	18%	Mixed ICU Expected duration of intubation >7 d	CT evidence for maxillary sinusitis Quantitative cultures from transnasal puncture
Meduri et al. (16)	50	12	24%	Medical ICU Intubated and ventilated >48 h	CT evidence for maxillary sinusitis Cultures from transnasal puncture
Bach et al. (17)	68	17	25%	Postoperative patients Mechanically ventilated >4 d	Opacification or air-fluid level on bedside radiography with purulent nasal discharge or purulent aspirate from the involved sinus
Deutschman et al. *(18)*	43	11	26%	Neurosurgical ICU Nasotracheal intubation and ventilated >72 h No surgery or trauma of paranasal sinuses	Clinical suspicion of HAS or unexplained fever Radiography or CT evidence of HAS Positive culture from transnasal puncture
Rouby et al. (2)	162	51	31%	Surgical ICU Intubated and ventilated on admission	CT evidence for maxillary sinusitis Quantitative cultures from transnasal puncture
Holzapfel et al. (19)	199	80	40%	Mixed ICU Expected duration of intubation >7 d	Opacification or air-fluid level on CT, purulent nasotracheal sinus aspiration with $\geq 10^3$ CFU/mL in quantitative culture
Guerin et al. *(20)*	30	25	83%	ICU Nasotracheal intubation >6 d	Evidence for sinusitis on routine CT scan Cultures from transnasal puncture

ICU, intensive care unit; HAS, healthcare-associated sinusitis; CT, computed tomography.

with facial trauma. Even total opacification of one or both maxillary sinuses or an air-fluid level within one or both maxillary sinuses had specificities for infectious maxillary sinusitis ranging from 38% to 69% (2,15,*21*). Furthermore, CT scan is costly and requires transport of patients, which may, in itself, be a risk factor for healthcare-associated infections *(25)*.

Bedside sinus ultrasonography may be a reliable, noninvasive, and cheap alternative to CT scanning. This method, when compared with culture of antral aspirates as a gold standard, has been demonstrated to be accurate in ambulatory adults and children (26). However, clinical experience in mechanically ventilated patients is limited (6,14,27,28). In one study, 100 patients were examined with bedside sinus ultrasonography on admission and every 48 hours thereafter. CT scanning of the head was performed at the discretion of attending physicians and was performed in 61 patients. Fifteen patients had fluid within the maxillary sinus detected by ultrasonography, and in nine other patients sinus fluid was detected by a head CT scan but not by bedside sinus ultrasonography. None of these nine patients, however, had clinical sepsis without another clearly documented source. The authors concluded that the head CT scan is more sensitive but may detect abnormalities that have little clinical significance (6). In another study, left and right paranasal sinuses were examined by ultrasonography in the supine and semirecumbent position in 15 neurosurgical ICU patients in whom HAS was suspected on clinical grounds. Findings of ultrasonography were compared with observations made by sinoscopy. Sensitivities of ultrasonography for the presence of fluid and edema were higher in the semirecumbent position (91% and 81%, respectively). However, specificity was only 25% for the presence of fluid. Moreover, edema and/or secretions were demonstrated in 29 of 30 sinus cavities examined, but microorganisms were cultured from only two antra (14). In a third study, A-mode ultrasonography of maxillary and frontal sinuses was performed in 50 comatose patients that needed cerebral CT for another reason than suspicion of sinusitis (28). With CT images as gold standard, ultrasonography had a specificity of 72% to 98% and sensitivity of 63% to 86% for maxillary sinuses, and of 96% to 99% and 14% to 57%, respectively, for frontal sinuses. With areas under the receiver-operating characteristic curves of 0.89 and 0.76, for maxillary and frontal sinuses, respectively, the authors concluded that ultrasonography was an accurate tool to detect secretions in maxillary sinuses (28). In addition, excellent agreement levels (with kappa statistic >0.9) between B-mode ultrasonographic examination of both maxillary sinuses and CT imaging have been reported (27). In a subsequent study, it was demonstrated that ultrasound evidence of sinusitis was highly predictive for receiving fluids (for microbiological cultures) after transnasal puncture (29). These data suggest that ultrasonography may be a useful screening test, but whether it can be used as the sole diagnostic method remains to be established.

Microbiologic Analysis

The problem of microbiologic analyses in many ICU-acquired infections is distinguishing between colonization and infection. Colonization of the upper respiratory tract (e.g., nares, oropharynx, and trachea) is universal in mechanically ventilated patients. Nasal swab cultures will grow upper respiratory tract flora and are believed to be of little value to determine pathogens causing sinusitis (30). Mucociliary clearance and drainage may keep the sinuses clean. Therefore, antral aspirate cultures are regarded as the gold standard. The frontal, ethmoid, and sphenoid sinuses can only be drained surgically and are not amenable to aspiration at the bedside. However, the maxillary sinuses can be drained, and these cavities are most often involved. CT imaging demonstrated that the maxillary sinuses are involved in almost all ICU patients who develop HAS, and radiographic evidence of maxillary sinusitis was associated with radiologic abnormalities of ethmoid and sphenoid sinuses in >80% of ventilated patients. However, according to Rouby et al.'s (2) study, 50% of the patients with normal maxillary sinuses on CT had radiologic signs of ethmoid and/or sphenoid sinusitis, as did 92% of patients with mucosal thickening in maxillary sinuses. The contribution of infection of the ethmoid and sphenoid sinuses has never been studied.

Aspiration cultures from maxillary sinuses are representative for microorganisms causing pansinusitis, and irrigation at this site is often therapeutic. Insertion is performed with a specialized trocar, which has an inner needle obturator with an outer sleeve. Once inserted, the needle can be removed and irrigation can be performed via the hollow sleeve *(24)*. Because of colonization of the nares, even transnasal cultures can be falsely positive because of introduction of pathogens into the sinus cavity. Adequate disinfection, therefore, has been recommended (2). Disinfection of the nares with a povidone-iodine solution proved to be totally adequate (sterile cultures) in 51%, partially effective (decrease in nasal bacterial burden) in 38%, and completely ineffective (increase in nasal bacterial burden) in 11% (2). In Rouby et al.'s study, patients underwent transnasal puncture of the affected maxillary sinus after nasal disinfection. The diagnosis was changed to infectious maxillary sinusitis when there were more than five polymorphonuclear leukocytes per oil immersion field and a positive culture from sinus aspirate. In patients who did not receive antibiotics, the diagnosis of infectious maxillary sinusitis was established by quantitative cultures depending on the effectiveness of nasal disinfection (cutoff points were $>10^3$ colony forming units [CFU]/mL with adequate nasal disinfection [sterile nasal swab] and $>10^4$ CFU/mL with inadequate nasal disinfection [positive nasal swab]) (2). Two studies reported poor correlations between endoscopically guided middle meatal cultures and cultures from antral lavage aspirates or taps in patients with clinical suspicion of HAS (31,32).

A diagnostic scheme incorporating clinical, radiographic, and microbiologic evaluation is depicted in Fig. 23-1. It should be mentioned that few studies prospectively determined the incidence of HAS and that the clinical relevance of this infection largely remains unknown. The schemes, therefore, should be viewed merely as a possible approach to the diagnosis of sinusitis. Whether such an extensive diagnostic approach influences patient care or will be cost-effective remains to be established.

Recent guidelines for evaluating fever in critically ill patients, developed by the Task Force of the Society of Critical Care Medicine and the Infectious Diseases Society of America, recommend that a CT scan be performed when clinical evaluation suggests that HAS could be the source of

fever. If CT findings are consistent with sinusitis, puncture and aspiration of the sinuses should be performed under sterile conditions, and the aspirate should be Gram stained and cultured for aerobic and anaerobic bacteria and yeasts *(33)*. This clinical guideline has been evaluated by Holzapfel et al. (19). They randomized 399 patients to receive either standard evaluation of fever occurring during the course of ICU stay or a specific diagnostic strategy directed at the possibility of HAS. The strategy included sinus CT scans on days 4 and 8 after tracheal intubation and thereafter every 7 days if fever was present. When CT scan showed an air-fluid level and/or opacification of the maxillary sinus, transnasal puncture was performed for culture, drains were placed, and antibiotics were adjusted according to culture results. Radiographic evidence of HAS was observed in 55% of the patients randomized to this diagnostic strategy and 80 patients (40%) fulfilled microbiologic criteria of HAS. In the control group, no patient was treated for HAS. Interestingly, the incidence of healthcare-associated pneumonia and mortality at 2 months after randomization were lower in study patients. Although striking, the absence of a mechanism explaining this favorable outcome and the fact that all patients were nasotracheally intubated, which is not the standard of care in most ICUs, warrants a cautious interpretation of these results *(34)*.

CAUSE

The cause of HAS closely resembles the spectrum of pathogens causing other healthcare-associated respiratory tract infections and differs from the etiologic spectrum of acute community-acquired sinusitis in ambulatory patients. Acute sinusitis is usually caused by streptococci or *Haemophilus influenzae (35,36)*, whereas gram-negative enteric bacteria (e.g., *Escherichia coli*, *Proteus mirabilis*, *Klebsiella* species, *Enterobacter* species), *Acinetobacter* species, *Pseudomonas aeruginosa*, and *S. aureus*, are most often isolated from patients with HAS. *Candida* species also have been identified as the cause of HAS, especially in long-term intubated patients receiving broad-spectrum antibiotics *(37,38)*. One case of HAS resulting from *Legionella pneumophila* has been reported in a patient with acquired immunodeficiency syndrome (AIDS) *(39)*. An analysis of microorganisms isolated from patients with HAS as described in 33 studies yielded 723 pathogens and revealed that 60% of the pathogens were gram-negative bacteria, 31% were gram-positive bacteria, and 9% were yeasts *(38)*. A considerable proportion (20–50%) of patients with HAS have polymicrobial infection, usually containing a mixture of the aforementioned pathogens. When analyzed quantitatively, 60% of the microorganisms isolated from sinus aspirates from patients with infectious maxillary sinusitis grew in concentrations $\geq 10^3$ CFU/mL. Concentrations $<10^3$ CFU/mL were found exclusively in patients on antibiotic therapy, and concentrations $>10^4$ CFU/mL were only found in patients not treated with antibiotics (2).

PATHOGENESIS AND RISK FACTORS

To humidify and clear inspired air, the nose and paranasal sinuses secrete approximately 1 L of mucus daily *(24,40)*. Via ciliated columnar epithelial lining, the mucus flows in a specific pattern through the natural ostium of each individual sinus posteriorly toward the nasopharynx. Patency of the sinus ostia is essential for this flow to occur. Obstruction of this flow, leading to mucus stasis, may result in infection. In healthy people, obstruction may occur because of an anatomic deformity or mucosal inflammation. HAS is a result of local factors such as disturbances of anatomy and colonization of the upper respiratory tract with potentially pathogenic microorganisms and systemic factors such as the severity of underlying illness in critically ill patients.

Local Factors

In ICU patients, several local factors predispose to HAS. Intubation in itself impairs reflex mechanisms, such as coughing, sneezing, and nose blowing that help to cleanse the nasal passage. Avoiding intubation, for example, by using noninvasive positive-pressure ventilation, will probably reduce the incidence of HAS *(41)*. Nasotracheal intubation is considered as the most important risk factor for HAS, and the risk of HAS increases with the duration of intubation (2,*42*). Nasotracheal intubation may be preferred over orotracheal intubation, because it provides greater stability of the tube, less difficulty with removal of oral secretions, decreased vocal cord injury because of less tube motion, and less patient discomfort *(24,43–46)*. However, nasotracheal intubation will ultimately cause irritation of the nasal mucosa, resulting in edema and possibly sinus obstruction. A large tube may directly obstruct drainage from sinus cavities. Moreover, as compared with orotracheal intubation, nasotracheal intubation took more time and was more often accompanied by nasal bleeding in cardiac surgery patients randomized to either of the intubation routes. After the procedure, bacteremia with microorganisms usually colonizing nose, mouth, and throat was demonstrated in 9% of the patients with nasotracheal and 2% of the patients with orotracheal intubation *(47)*.

When compared with nonintubated healthy subjects, radiologic evidence of HAS, such as thickening of maxillary mucosa, fluid levels in, and opacification of sinuses on CT images are clearly related to any kind of intubation, whether it be naso- or orotracheal intubation (14). Sixteen patients with nasotracheal intubation were prospectively studied with CT scanning of the paranasal sinuses on the second or third day and again on the eighth day after intubation. At day 2, three patients had signs of maxillary sinusitis and three of sphenoid sinusitis, and at day 8 all patients had radiographic sinusitis of at least one sinus cavity *(48)*. In another study, paranasal sinusitis, diagnosed by CT scan and aspiration, developed in 13 of 31 (42%) patients with nasotracheal intubation and in 3 of 65 (5%) patients with orotracheal intubation. However, these patients were not randomized to the routes of intubation *(43)*. Associations between nasotracheal intubation and HAS have been further established in a series of studies comparing the effects of both routes of intubation (Table 23-2). Strict comparison of the different studies is hampered because of differences in study populations and diagnostic criteria and modalities used. Rouby et al. (2) randomized 40 patients with no evidence of maxillary sinusitis on baseline CT scan to nasotracheal or orotracheal intubation. In addition, gastric tubes were placed accordingly. After 7 days, radiologic maxillary sinusitis was demonstrated in all but one patient

HAS, healthcare-associated sinusitis; OT, orotracheal intubation; NT, nasotracheal intubation; ARR, absolute risk reduction (incidence NT – incidence OT); RRR, relative risk reduction (1 – [incidence OT/incidence NT]).

with nasotracheal intubation and in only four patients with orotracheal intubation. However, the results of cultures of maxillary sinus aspirates for these patients were not reported. All patients with radiologic maxillary sinusitis also had radiologic evidence of ethmoid and/or sphenoid sinusitis.

Holzapfel et al. (15) randomized 300 ICU patients to nasotracheal (n = 149) and orotracheal (n = 151) intubation. CT scans were performed every 7 days or earlier when HAS was clinically suspected. Radiographic sinusitis was observed in 45 (30%) and 33 (22%) of patients with nasotracheal and orotracheal intubation, respectively (p = .08). The radiographic suspicion of HAS was microbiologically confirmed in 29 (19%) and 25 (17%) of the patients with nasotracheal and orotracheal intubation, respectively (15).

Bach et al. (17) randomized 68 postoperative patients, without infection at baseline, to nasotracheal or orotracheal intubation. Sinus radiographs were performed at regular intervals and transnasal needle punctures were performed when HAS was suspected. Radiologic findings suggestive for HAS were found in 47% of patients with orotracheal and in 69% of patients with nasotracheal intubation. Infectious sinusitis was confirmed by microbiologic cultures in 6% and 42% of the patients, respectively (p < .01).

Michelson et al. *(50)* randomized 20 mechanically ventilated patients to nasotracheal intubation and 24 to orotracheal intubation. With the patient in the semirecumbent position, maxillary sinuses were sonographically examined daily for signs compatible with sinusitis. Diagnostic aspirates were performed in patients with abnormal findings on sonography. Nineteen (95%) patients with nasotracheal and 15 (63%) patients with orotracheal intubation had sonographic evidence of sinusitis after approximately 2 days in both groups. Diagnostic aspiration was performed in 22 patients (13 nasally and 9 orally intubated) and pathogenic microorganisms were cultured in 7 of 13 and 2 of 9 cultures, respectively.

Salord et al. *(45)* randomized 111 adult patients to orotracheal (n = 53) or nasotracheal (n = 58) intubation. All patients were ventilated for at least 2 days, and HAS was diagnosed by complete opacification or an air-fluid level in the maxillary sinus on bedside radiography (reversed Waters' view). HAS occurred in 2% of the patients in the orotracheal group and in 43% of the patients with nasotracheal intubation.

When the results of these studies are summarized, orotracheal intubation is, when compared with nasotracheal intubation, associated with a reduced incidence of radiologic HAS, but the beneficial effects on the development of infectious HAS are much smaller. Orotracheal intubation results in an absolute risk reduction for the occurrence of radiographic HAS of 0.23 (95% confidence interval 0.15–0.31) and a relative risk reduction of 0.49 (95% confidence interval 0.33–0.65). For the occurrence of infectious HAS, orotracheal intubation has an absolute risk reduction of 0.08 (95% confidence interval 0.01–0.15) and a relative risk reduction of 0.44 (95% confidence interval 0.07–0.81) (Table 23-2).

Nasogastric tubes are probably less harmful than nasotracheal tubes, because they are smaller and, therefore, cause less irritation (*49*). Secretions were more often found in sinuses adjacent to a nasal cavity with a nasotracheal tube than in sinuses adjacent to a nasogastric tube (8). In addition, facial and head trauma can lead to accumulation of blood and debris in the sinuses and can disrupt mucosal structures. This provides a favorable medium for proliferation of microorganisms. Furthermore, patient immobility in the supine position may further predispose to sinusitis. The role of gravity and positional changes facilitate mucus drainage in physiologic circumstances. Finally, the supine position may decrease venous blood flow from the head and neck to the heart, leading to nasal congestion and narrowing of the maxillary sinus ostia *(51)*. This effect can be exacerbated by mechanical ventilatory support with positive inspiratory and end-expiratory pressure by virtue of increasing central venous pressure. However, patient positioning and modes of mechanical ventilation on development of HAS have never been studied. Recently, it was demonstrated that HAS was associated with inhibition of epithelial expression of nitric oxide synthases (NOS2), which generates NO that has a major role

in the nonspecific host defense (52). The decrease in NO activity may impair nonspecific host defenses. Appropriate treatment of sinusitis (with drainage, lavage, and removal of the nasogastric tube) was associated with increased maxillary and nasal NO concentrations (53).

Systemic Factors

Because of the severity of their underlying illnesses, mechanically ventilated patients are prone to develop any healthcare-associated infection, and there is no reason to assume that this does not hold true for HAS. Corticosteroids may further suppress immune function in these patients. As mentioned earlier, colonization of the upper respiratory tract (e.g., nares, oropharynx, and trachea) is universal in mechanically ventilated patients, and nasal colonization with enteric gram-negative bacteria was an independent risk factor for HAS in a recent study (11). In addition, the use of sedatives and a Glasgow Coma Score ≤7 at admission were independent risk factors in that study.

ASSOCIATION WITH HEALTHCARE-ASSOCIATED PNEUMONIA

Because of the resemblance of the etiologic spectrum of pathogens causing HAS and healthcare-associated pneumonia, a causal relationship between both infections has been suggested (15,17,54). Incidences of pneumonia were found to be higher among patients with HAS as compared with unaffected patients—14/26 (54%) versus 4/85 (5%) *(45)*—and HAS increased the risk for pneumonia by a factor of 3.8 in multivariable analysis in another study (15). In this study, pneumonia was diagnosed in 16 of 54 patients with HAS, and the same microorganism was isolated from the lungs and sinus in 9 of 16 episodes (15). In a third study, incidences of pneumonia demonstrated within 7 days after evidence of maxillary sinusitis on CT scan were 67% and 43% for patients with and without pathogens isolated from sinus aspirates. However, identical pathogens were isolated from the distal airways in only 38% of the patients with previous infectious maxillary sinusitis (2). Among 271 ICU patients with bacteriologically documented HAS (cultures obtained by maxillary sinus puncture), the percentage of concurrent episodes of pneumonia (cultures obtained via bronchoscopic techniques) caused by similar pathogens ranged widely. More than 25% of episodes of sinusitis caused by *S. aureus*, *P. aeruginosa*, *Acinetobacter baumannii*, *E. coli*, and *Hemophilus* species were followed by episodes of pneumonia caused by the same pathogens. In contrast, HAS caused by coagulase-negative staphylococci, streptococci, enterococci, *Klebsiella* species, *Proteus* species, *Enterobacter* species, and yeasts were succeeded by pneumonia caused by these pathogens in <10% of the cases *(55)*. A similar pattern of concurrent recovery of pathogens from sinus cavities and lungs was reported by Rouby et al. (2). It has been hypothesized that differences between microorganisms in their capacity to adhere to mucus surrounding endotracheal tubes might influence increased colonization of the tracheobronchial tree from the sinus reservoir *(56)*. Whether HAS really leads to pneumonia or whether sinusitis just reflects extensive airway colonization and infection has not been elucidated. A recent study of patients with nasotracheal intubation suggested that early treatment of episodes of HAS was associated with a reduction in incidence of healthcare-associated pneumonia and improved patient survival (19).

COMPLICATIONS

Failure to diagnose HAS as the cause of sepsis may lead to bacteremia and even hemodynamic instability. Because of the anatomic location of the sinuses, infectious complications are prone to extend to orbital or intracranial spaces (Table 23-3). The frontal and ethmoid sinuses are separated from the orbit by a thin bony plate. Infection, therefore, may extend directly via vascular channels or neurologic foramina, resulting in periorbital cellulitis, muscle edema, and even ophthalmoplegia. When pus collects between the periorbital structures and the bony wall of the orbit, a subperiosteal abscess develops. Orbital extension of infection causes fat necrosis and may lead to orbital abscess formation.

The venous system draining the nose, paranasal sinuses, and the orbital system has no valves, facilitating spread of orbital infection to the cavernous sinus. This should be suspected in case of spread of orbital cellulitis to the opposite eye, severe retinal venous engorgement, and rapid clinical deterioration. In addition to direct spread of pus, thrombosis may develop.

Secondary intracranial complications may also occur along preformed pathways resulting from retrograde thrombophlebitis or by direct hematogenous spread. Meningitis is the most common intracranial complication, most often caused by sphenoid infection. Meningitis occurs less often after ethmoidal, frontal, or maxillary sinusitis *(24)*. Kaufman et al. *(57)* described 17 cases of subdural empyema

Thoracic empyema

(Modified from Seiden AM. Sinusitis in the critical care patient. *New Horizons* 1993;5:261–270.)

induced by community-acquired sinusitis. This complication occurred most often in young men, possibly because during maturation the posterior wall of the sinus may be an incomplete barrier to intracranial spread of microorganisms. The empyemas, therefore, were usually located directly behind the sinuses.

Veins from the frontal sinus communicate directly with the dura. Spread of infection may result in epidural abscess when pus collects superficial to the dura, and a subdural empyema may result from collection of pus between the dura and pia arachnoid. Because there is little resistance to the spread of infection, cerebral abscesses may develop at multiple locations. CT scanning will establish most of the diagnoses, and surgical exploration should be considered if abscess is demonstrated.

PREVENTION

Measures to prevent the development of HAS can be subdivided into general measures, device-related measures, and patient-specific measures.

General measures include the principles of conventional infection control policies *(58)*. Colonized and infected patients and environmental contamination or common sources of microorganisms should be identified as reservoirs of pathogens. When identified, environmental contamination should be cleared by cleaning and disinfection, and common sources should be eliminated. In addition, transmission from patient to patient should be prevented by improving compliance with standard infection control practices in the ICU, such as hand washing. Barrier precautions (gloves, gowns) should be used to prevent cross-transmission of multiply resistant bacteria or when taking care of a patient with open wounds.

The most important device-specific measure to prevent HAS is to avoid intubation *(41)* and especially nasotracheal intubation. In addition, the duration of orotracheal and nasogastric intubation should be minimized. Whether the mode of mechanical ventilation influences the development of HAS is unknown; therefore, no advice on how best to ventilate patients can be provided.

With regard to patient-specific preventive measures, the relevance of adequate treatment of the underlying illness is obvious. Corticosteroids should be administered only when indicated, and antibiotic prescription policy should be restrictive and rational. The relationship between antibiotic use and subsequent colonization and superinfection with antibiotic-resistant microorganisms and/or pathogens that are difficult to treat (such as yeasts) should be known to all intensivists.

Based on the pathogenesis of HAS, several preventive strategies may be hypothesized, although clinical experience is scarce or completely absent. These measures are discussed but are not (yet) recommended. Prevention of colonization of the upper respiratory tract is likely to reduce the incidence of HAS. Application of topical antibiotics in the oropharynx, usually in combination with nonabsorbable antibiotics administered via the nasogastric tube and systemic antibiotics during the first days of ventilation (selective decontamination of the digestive tract [SDD]), decreases the incidence of healthcare-associated respiratory tract infection *(59)*, and has been associated with improved patient outcome in some settings *(60,61)*. Few studies testing the SDD concept determined its effects on HAS. In one double-blind, placebo-controlled study, neurosurgical patients were randomized to receive topical antibiotics (tobramycin, polymyxin E, amphotericin B) in the oropharynx and in the stomach. Vancomycin was added to the oropharyngeal paste. HAS diagnosed by CT scan and microbiologic cultures occurred in 2 of 63 (3%) study patients and 9 of 60 (15%) control patients ($p < .02$) (13). However, objections against widespread use of SDD include the threat of selection of antibiotic resistance *(62)*. The same objections apply to the prophylactic use of systemic antibiotics in high-risk patients for HAS, such as trauma patients with facial fractures.

Recently, the preventive effects of locally applied nasal decongestant agents and corticosteroids were determined in 79 mechanically ventilated trauma patients (63). Patients were randomized to receive either two drops twice/day of xylometazoline nasal solution 0.1% and 100 μg budesonide or placebo, and radiological (CT scanning) maxillary sinusitis was detected in 54% of treated and 82% of the control patients ($p < .01$). Infectious sinusitis was detected in 8% of the treated and 20% of control patients ($p = .11$).

Based on the physiology of mucociliary clearance from the sinus cavities, a supine position of the patient may be associated with an increased risk for development of HAS. In this position, the physiologic process of mucociliary clearance may be diminished and ostia may be narrowed because of nasal congestion resulting from decreased venous blood flow to the heart. However, it is unknown to what extent a change in nursing care (e.g., placing patients in semirecumbent position as soon as possible) affects incidence of HAS.

CONCLUSION

An increasing number of studies suggest that the incidence of HAS among mechanically ventilated ICU patients is underreported. However, the true incidence and clinical relevance of this infection still are unknown. HAS is usually caused by those microorganisms known to colonize the upper and lower respiratory tract in ICU patients such as Enterobacteriaceae, *P. aeruginosa,* and *S. aureus*. Development of HAS is a result of disturbances of local anatomy, colonization of the upper respiratory tract with potentially pathogenic microorganisms, and severe underlying illness. Nasotracheal intubation has been convincingly demonstrated to be the most important risk factor and should, therefore, be avoided. Other preventive measures include prevention of cross-colonization by standard infection control measures and avoidance of unnecessary use of antibiotics and corticosteroids. Future studies should determine the incidence of HAS in large patient populations and elucidate its role as a risk for the subsequent development of pneumonia. Based on these findings, the need for specific regimens for prevention of HAS can be judged. In addition, cost-benefit analyses of the different diagnostic tracks are warranted. An excellent review of the clinical entity of HAS has been published by Westergren et al. *(64)*.

CHAPTER 24

Healthcare-Associated Gastrointestinal Tract Infections

Nicolas A. Melgarejo and Herbert L. DuPont

Although infectious diarrhea is well recognized in the outpatient setting, enteric infections acquired in the hospital are less well studied. A number of factors associated with being admitted to a healthcare facility contribute to the occurrence of diarrhea including antibiotic use, change of diet and administration of feedings, procedures involving the gastrointestinal tract (e.g., endoscopic and surgical procedures) and underlying diseases; one or a combination of these factors leads to the development of diarrhea, either infectious or noninfectious. Furthermore, microorganisms that cause foodborne illnesses in the community have the potential for causing disease in hospitalized patients.

Certain forms of noncommunicable foodborne gastroenteritis or diarrheal disease, such as those originating from the ingestion of bacterial toxins derived from *Clostridium perfringens, Clostridium botulinum, Staphylococcus aureus*, and *Bacillus cereus*, as well as those produced by the ingestion of food contaminated with group A streptococci and *Vibrio parahemolyticus* may occur in the hospital with their control depending on adequate food handling practices. Other etiological agents, such as *Clostridium difficile*, nontyphoid *Salmonella*, diarrhea-producing *Escherichia coli*, *Shigella*, *Yersinia enterocolitica*, *Staphylococcus aureus*, rotaviruses, and noroviruses (NoVs), can be transmitted between hospitalized individuals and will be the subject of more detailed review in this chapter.

Enteric infections acquired in the hospital may occur in the form of epidemic clusters from exogenous sources. Hospitalized individuals who are admitted with infectious gastroenteritis can potentially transmit a virulent microorganism to other patients and hospital workers. Hospital personnel can also facilitate the spread, either as short-term intestinal carriers of microorganisms or via their hands when attending to different patients.

It is of importance to know the epidemiology of healthcare-associated diarrhea, as well as the mechanisms involved in the acquisition and transmission of disease. Several diagnostic techniques are available, and the effective treatment and containment of outbreaks depend on an accurate clinical assessment and appropriate management.

DEFINITIONS

Healthcare-associated diarrhea is defined as the passage of three or more soft or liquid bowel movements per day beginning at least 72 hours after admission to the hospital *(1)*. For infectious healthcare-associated diarrhea, an enteric infection has been acquired after hospitalization. Iatrogenic healthcare-associated diarrhea is defined as noninfectious diarrhea associated with an in-hospital exposure (e.g., medications, antibiotics, feedings, or procedures).

EPIDEMIOLOGY

The incidence of healthcare-associated diarrhea is estimated to be between 6% and 30% of hospitalized patients, with the majority occurring on the geriatric wards and critical care units. Healthcare-associated diarrhea can also be seen in children, showing an incidence of 1.2% to 2.1% for patients admitted to pediatric teaching hospitals *(2)* and 1.5% for children admitted to general pediatric wards *(3)*. Although it is commonly underreported, the incidence of infectious gastroenteritis in adult patients approximates 29.4% of hospitalized patients, with *Clostridium difficile* being the most important definable cause of the disease and other bacterial pathogens being found in a small percentage of cases (4). Norovirus infections have also been reported in hospital populations, with an incidence up to 1.19 per 1,000 admissions. In children, viral pathogens play a larger role. The incidence of viral pathogens in pediatric populations has been reported to be 4.6 cases per 1,000 admissions (with a range of 0.40–11.9) for norovirus and 4.04 cases per 1,000 admissions for rotavirus infections (5).

Healthcare-associated diarrhea represents not only a cause of morbidity but also of mortality, particularly in high-risk patients. The most important definable enteric cause of death is *C. difficile*, with 30-day mortality rates as high as 38% *(6)*. Death rates are far less from other pathogens and noninfectious causes. In pediatric patients, mortality due to healthcare-associated rotavirus infection is very low (7). There is evidence that patients who develop healthcare-associated diarrhea have an increased length of stay when compared with control cases. Patients with infectious gastroenteritis have longer lengths of stay when compared with those in which healthcare-associated diarrhea is from noninfectious causes (iatrogenic diarrhea) (4). Patients with infectious gastroenteritis tend to have more severe underlying conditions and be older than those with diarrhea from noninfectious causes.

Healthcare-associated infectious gastroenteritis also is associated with a measurable economic impact. A study done in Germany (8) showed that each *C. difficile* diarrhea (CDD) case costs an excess of approximately US$ 10,353 per patient. Rotavirus healthcare-associated outbreaks may also increase the cost of care by up to $3,546 per episode. Hospital outbreaks of diarrhea are particularly costly. According to one study in the United Kingdom (9), gastroenteritis outbreaks represented a national cost of $2,301,864 (United States) during a 1-year period. These costs included the days of empty beds when units were closed to new inpatient admissions and days of productivity lost by staff who acquired disease.

PATHOGENESIS

Predisposing Host Factors

Individuals in the hospital setting are admitted because of disease, and therefore have unique predisposing factors for enteric infection. Their immune systems may be impaired because of age, seen in infants and the elderly, underlying disease, such as HIV/AIDS, hematological malignancies or organ transplantation, or because of iatrogenic interventions, including the administration of enteral feedings, antibiotics, steroids, or chemotherapy. In a study of patients with renal transplantation, drugs and infectious agents contributed to the development of diarrhea, of which 14.6% were healthcare associated *(10)*. Other underlying medical conditions that can increase susceptibility to acquire infectious diarrhea include renal disease, liver disorders, and diabetes.

Defective intestinal defenses also represent a form of local immune impairment. Gastric acid plays a role in the defense against ingested microorganisms. A lower microorganism inoculum can produce enteric infection with reduced gastric acidity. Achlorydia or hypochloridia may be iatrogenically produced by the use of antacids such as H2 blockers or proton pump inhibitors. Antacids have been shown to greatly facilitate the colonization of the intestine with enteric vaccine strains as well as to increase the frequency of gastrointestinal acquisition of healthcare-associated strains of aerobic gram-negative rods. Anticholinergic medications may have similar effects.

Endoscopic evaluation of patients has become routine with more than eight million or more such interventions being performed annually in the United States. Although infectious gastroenteritis after endoscopic procedures is uncommon, they have been reported. The infectious agents having been acquired by this route include *Salmonella* sp., *C. difficile*, and *Campylobacter* spp. It is difficult to sterilize the instruments employed, since they have complex structures and fragile parts that do not tolerate aggressive sterilization procedures. Preventing transmission of pathogenic microorganisms is of utmost importance, and can be achieved through adequate training of the personnel in charge of this task, stressing meticulous cleaning, the use and adequate contact time with the appropriate disinfectant, and drying thoroughly all parts before storage. Specific guidelines for handling endoscopes have been published *(11,12)*. (see also Chapter 62)

Antibiotic use is perhaps one of the greatest factors in the development of healthcare-associated diarrhea. With the availability of broad spectrum antibiotics with suppressive effects on gut flora, antibiotic-associated diarrhea (AAD) has become an important medical problem in the hospital. Antibiotics such as macrolides and clavulanic acid can alter the motility of the gastrointestinal tract influencing the development of bacterial overgrowth. Microflora of the gut is also altered by antimicrobials, with reductions of anaerobe populations, which can cause an osmotic diarrhea by decreased breakdown of carbohydrates. Alterations of gut flora also predispose to infection by strains of *C. difficile*, which can be found in the hospital environment. While the first CDD cases followed use of clindamycin, essentially all antibiotics have been associated with development of CDD. It occurs in approximately 2% to 5% of hospital inpatients treated with a variety of antibiotics. The cephalosporins and fluoroquinolones may have the highest rate of CDD development. The rates of diarrhea associated with parenterally administered antibiotics, especially those with enterohepatic circulation, are similar to rates associated with other orally administered agents. Furthermore, AAD may occasionally be caused by other enteric pathogens, including *Salmonella*, *C. perfringens* type A, *S. aureus*, *Klebsiella oxytoca*, and possibly *Candida albicans*.

Admission to the hospital also causes individuals to become colonized with hospital microorganisms. Evidence suggests that hospitalized adults have rates of colonization with *C. difficile* up to 20% to 30% when compared with the outpatient population. Although *S. aureus* can also be a part of the gut microflora, it has been reported that 7% of patients with AAD have enteric infection with enterotoxin-producing strains. Interestingly, affected patients often can be shown to be carriers of *C. difficile* (13).

Environmental Factors

As mentioned before, the hospital setting represents a unique environment. Several studies have demonstrated that increasing lengths of stay in the hospital are a risk factor for acquiring infections unique to this environment. There have also been studies that demonstrate high rates of environmental contamination by *C. difficile* in hospitals, as well as high rates of colonic colonization associated with hospitalization. *C. difficile* colonization rates of adult outpatients is seen in 2% to –3%, which increases to 20% to 30% with hospitalization and even higher with longer stays. Hospital food may rarely be a source of healthcare-associated diarrhea, especially outbreaks due to inadequate handling of food. However, the sanitary standards in most hospitals in industrialized countries are high and such outbreaks are unusual. Hospital outbreaks caused by *Bacillus cereus (14)*, *Salmonella* spp. *(15)*, and *C. perfringens (16)* have been reported. Crowding and staffing factors play a key role in the transmission of infectious gastroenteritis between patients. A ratio of staff to patients that is insufficient encourages deficiencies in effective hand washing and isolation techniques, especially in critical care areas. Even with careful hand washing, there is still some risk of transmission by direct and successive patient contact. Although most of the time crowding is associated with

low staff to patient ratios, it may also be an independent factor. There is an increase in the incidence of CDD in patients who have physical proximity to other *C. difficile*–infected patients (17).

DIAGNOSIS

Healthcare-associated diarrhea ranges in severity from mild illness to a fulminant picture of pseudomembranous entoerocolitis with sepsis and death. Patients can present with abdominal cramps or pain, loss of appetite, hematochezia, and fever. Children with acute diarrhea can also present with significant volume loss. The yield of stool cultures for healthcare-associated diarrhea is low. Enteropathogenic bacteria other than *C. difficile* are grown from 2.6% to 6.4% of stool cultures when patients are admitted with diarrhea and in only 0.6% of stool cultures obtained 3 days or more after admission. Therefore, performing stool cultures in patients after 72 hours of admission is unlikely to yield an enteric pathogen and should not be routinely performed. In special situations, the microbiologic yield for stool cultures may be higher, particularly in HIV-positive individuals, neutropenic patients receiving chemotherapy, and in individuals 65 years or older with an existing comorbid condition (18) and during a defined outbreak in the hospital. While a majority of patients with healthcare-associated diarrhea will not have an etiologic agent detected in stool samples, CDD is responsible for the majority of adult diarrhea cases with definable etiology. The specific diagnostic studies required in making an etiologic diagnosis are presented later when specific etiologic agents are considered.

CDD AND COLITIS

Clinical and Microbiological Features

CDD follows enteric infection by *C. difficile*, a spore forming, gram-positive, strictly anaerobic bacteria that produces one or two toxins, toxin A, an enterotoxin and toxin B, a cytotoxin. Both toxins are toxic to human enterocytes. The clinical presentation is broad, and the severity ranges from mild diarrhea to pseudomembranous colitis, sepsis, and death. Between 10% and 20% of all cases of AAD are secondary to *C. difficile* infection. The likelihood of *C. difficile* causing disease is higher in persons with more severe disease, particularly when illness is associated with pseudomembranous colitis. Risk factors for CDD include antibiotic exposure resulting in depletion of colonic bacterial flora, hospitalization with its exposure to spores of the microorganism, and host debility (advanced age or other infirmity). The antibiotics showing the highest risk for CDD include the cephalosporins, penicillins, and fluoroquinolones. Traditionally, clindamycin has been an important offender. CDD can also occur in patients who have been exposed to short prophylactic courses of antibiotics *(19)*. Elderly patients >65 years of age have as much as a 20-fold higher risk than younger patients. Other risk factors include underlying disease severity, nonsurgical gastrointestinal procedures, and possibly the use of proton pump inhibitor drugs that cause hypochlorhydria. Patients with a suppressed immune system or poor response to *C. difficile* toxin are also at increased risk of CDD and disease recurrence.

When a hospitalized patient develops important diarrhea, especially when the illness occurs in an elderly and infirm patient or when fever, dysentery, or leukocytosis are found, a stool should be collected and tested for *C. difficile* toxins. The most sensitive tests include the cell cytotoxicity test for toxin B, culture of the microorganism followed by testing of isolates for toxigenicity or commercial PCR test. These tests cannot be performed quickly, and they are technically demanding *(20)*. Enzyme immunoassays (EIAs) for detection of toxins A and B are less sensitive (around 70% positivity in known infection), since up to 100 to 1,000 pg of toxin is needed for detection, and can have a false-negative rate up to 40% of cases when compared to cell cytotoxicity assay or culture *(21)*. While culture has very high sensitivity *(22)*, its specificity is low, since the rate of carriage of toxigenic and nontoxigenic strains of *C. difficile* is high in hospitalized patients. Sensitivity of the EIAs can be increased by repeating the test with other collected stool samples. Glutamate dehydrogenase (GDH) testing does not assay for the toxins but is very sensitive for CDD and can be used to identify true *C. difficile*-negative cases of diarrhea, while the positive tests need to be confirmed with a toxin-based assay such as an EIA or cytotoxicity assay *(23)*. Other diagnostic modalities include radiographic imaging (CT) and endoscopy, but they are expensive and nonspecific. Finding pseudomembranous colitis at endoscopy is diagnostic, although there are other less common causes of this condition (24).

Epidemiological Considerations and Control

Spores of *C. difficile* can be found in the environment of hospitals and long-term care facilities. Thus, it is not surprising that patients in these facilities have higher rates of *C. difficile* colonization; rates are 10% to 25% among hospitalized patients and 4% to 20% among residents of long-term care facilities, compared with a rate of 2% to 3% for noninstitutionalized adults. In the pediatric population, over half of all healthy neonates are asymptomatic carriers of *C. difficile*, but disease in this population is rare. Although direct patient-to-patient spread of *C. difficile* is uncommon, the microorganism is easily spread from infected and colonized patients to the environment. Most transmission to previously uninfected patients is thought to occur through hand carriage by healthcare workers. Hand washing with antiseptic soaps may not kill *C. difficile* spores. Outbreaks of CDD have also been reported among geriatric populations in general hospitals or long-term care facilities *(25)*.

Several measures for infection control have been outlined (26). They include (a) performing *C. difficile* toxin assays on all patients with healthcare-associated diarrhea and those admitted from an outside hospital with diarrhea in attempting to diagnose most infected patients in the hospital; (b) practicing strict contact precautions for everyone entering a patient's room, including healthcare workers and visitors; (c) placing patients with CDD in single rooms with a designated toilet or commode, with designated staff to minimize the risk of cross-infection

to other patients; (d) wearing of disposable gloves and gowns by persons with contact with infected patients and employing meticulous hand washing methods by persons in contact with patients with CDD, ideally using soap and water. While alcohol-based soaps, gels, and wipes do not kill *C. difficile* spores, their general use has not increased the occurrence of healthcare-associated CDD; (e) cleaning of hospital rooms at least once a day and more often if environmental fecal soiling has occurred. The rooms of patients with CDD should be carefully disinfected after patient discharge, using a sporocidal agent, ideally a 1:10 dilution of sodium hypochlorite; (f) use of dedicated medical equipment and devices for patients with CDD, with all equipment being carefully cleaned and disinfected with disposal of single patient use items once the patient is discharged; and (g) use of antibiotic stewardship programs that decrease general use of particularly high-risk drugs for development of CDD and decrease the use of predisposing drugs in *C. difficile*–infected patients whenever feasible (see also Chapter 37).

STAPHYLOCOCCAL ENTEROCOLITIS

Clinical and Microbiological Features

Prior to the discovery of *C. difficile* as the cause of pseudomembranous enterocolitis (PMC), *S. aureus* was considered as the important cause of antibiotic-associated PMC. The infecting microorganisms did not appear to be transmissible from person to person, but healthcare-associated spread occasionally was identified. Methicillin-resistant *S. aureus* (MRSA) strains may cause outbreaks of enteric disease *(27)*, occasionally complicated by septicemia *(28)*. In certain hosts in whom there is impaired resistance due to surgery, antimicrobial therapy, alcoholism, or diabetes mellitus, staphylococci may grow to large numbers in the intestinal tract and be responsible for morphologic damage to the intestinal mucosa resulting in diarrhea and fever of varying severity. Like CDD, intestinal involvement in staphylococcal enteritis varies widely from minimal and self-limiting enteritis to fulminating PMC *(29)*. Patients with enteritis have diarrhea of a variable nature, often mild and watery, and may have low-grade fever, but they are not extremely toxic. PMC usually presents with fulminating and dehydrating dysentery with toxemia, fever, and leukocytosis. The entire colon may be involved with *S. aureus* disease of the gut, and there may be involvement of the small intestine. Mortality in such patients is high, ranging from 10% to 50%. The diagnosis is established by documenting abundant polymorphonuclear leukocytes together with sheets of gram-positive cocci in stool specimens by Gram stain, which on subsequent culture grows large numbers of *S. aureus*. Proctologic examination shows a white membrane that reflects areas of mucosal necrosis in those with pseudomembranous colitis.

Control

Prompt cessation of previously administered antibiotics and administration of oral vancomycin to patients with more serious staphylococcal enterocolitis may prevent the disease from progressing to pseudomembranous changes. Large numbers of *S. aureus* are often disseminated from patients with these diseases, and Contact Precautions should be strictly enforced.

DIARRHEAGENIC STRAINS OF *ESCHERICHIA COLI*

Clinical and Microbiologic Features

Enteropathogenic *E. coli* (EPEC) are rare causes of infectious healthcare-associated diarrhea. EPEC has previously been considered a common cause of nursery outbreaks, which sometimes were explosive, with a high attack rate and fulminant course *(30)*. Reports of such outbreaks have not been common in the United States in recent years. This may relate in part to failure to recognize the etiologic agent due to the decreasing availability of serotyping procedures in hospital diagnostic laboratories. During any hospital outbreak of diarrhea, particularly when it has occurred in the newborn nursery, EPEC should be considered in the differential diagnosis. The clinical expression of disease varies considerably, from minimal watery diarrhea to fulminating disease with septicemia. Incubation periods of EPEC disease are commonly 24 to 48 hours.

Enterotoxigenic *E. coli* (ETEC) is even a less common cause of hospital nursery outbreaks than EPEC strains *(31)*. ETEC is very rarely transmitted from person to person due to the high microorganism inoculum required to produce illness in humans.

Control of Outbreak Disease in Newborn Nurseries

Infection control measures in the nursery *(32)* unit include isolating patients with asymptomatic as well as symptomatic *E. coli* enteric infections in separate facilities. Contact Precautions should be routine. In nurseries in which Contact Precautions for individual cases is not possible, cohort systems should be used to minimize the risk of cross-infection. Infants who are ill or colonized with the epidemic microorganism can sometimes be grouped together in a cohort that is physically separated from noninfected infants. Personnel caring for infected infants should not care for noninfected ones. Only milk packaged in sterile containers should be used, common equipment shared among babies should be removed, and infants should be confined to their own bassinets or isolettes. To prevent additional spread of infection, infants born outside the hospital should not enter the nursery during an epidemic of diarrhea. Unnecessary contact with babies by hospital personnel or other infants should be avoided. Also, infected patients should be discharged home as soon as their condition permits in-home management. Uninfected infants should be discharged from the hospital as soon as possible.

SALMONELLA INFECTIONS

Microbiologic, Clinical, and Epidemiological Features

There are more than 2,000 serotypes of *Salmonella enterica*. The four most common serotypes isolated in 2006, seen in 45% of cases of salmonellosis include *S. typhimurium*,

S. enteritidis, *S. newport*, and *S. heidelberg (33)*. In general, the isolation of *Salmonella* from a stool culture is sufficient to make a diagnosis of salmonellosis, since these bacteria are highly pathogenic and their long-term carriage is unusual. The isolation of *Salmonella* in a symptom-free patient should be reported as a healthcare-associated infection only if previous cultures during hospitalization were negative.

Transmission of *Salmonella* can occur through the hands of healthcare workers or from person-to-person spread between aged, debilitated, or newborn patients. The communicability of this microorganism to hospital personnel is low since a relatively large inoculum is required to produce disease in healthy people, and precautions used routinely in hospitals when handling *Salmonella*-infected patients are usually effective. However, outbreaks of intestinal salmonellosis can occur among institutionalized patients. Between 1963 and 1972, 112 (28%) of the total number of reported *Salmonella* outbreaks occurred in institutions (hospitals, nursing homes, and custodial institutions) *(34)*. The economic burden of hospital outbreaks caused by *Salmonella* spp. can be significant. One outbreak can cost up to $52,463, with individual charges to the patient calculated at $1,588.78 ± $1,460.37 when compared to uninfected controls *(35)*.

Patients who are at special risk for *Salmonella* infection include the elderly, HIV-infected individuals, cancer patients, and the chronically debilitated. Patients with malignancy have a high risk of *Salmonella* bloodstream invasion. Newborns and infants <3 months of age have a special predisposition to *Salmonella* infection, particularly to systemic *Salmonella* infection. In a nursery outbreak, up to 50% of exposed infants can become infected with *Salmonella*, with a high rate of symptomatic infection once the infection is introduced into the nursery. Cultures may remain positive for up to a year in infants.

A common source is usually the initial focus of outbreaks of *Salmonella* in the hospital. Potential sources are products from the central kitchen such as previously contaminated raw or undercooked meats, other animal products like dairy or eggs, and/or food that has been contaminated after cooking because of microorganisms on equipment or surfaces in the kitchen. Rarely *Salmonella*-contaminated medications can be the vehicle of transmission in the hospital, especially enzymes and hormones of animal origin. Less frequent sources of healthcare-associated salmonellosis include yeast, dried coconut, carmine dye, and inadequately disinfected equipment. In homes for the elderly common source outbreaks of salmonellosis can occur from ingestion of contaminated foods, with secondary cases of infection occurring by way of the contaminated hands of healthcare workers.

Control

Safe food handling practices are especially important in the prevention of healthcare-associated outbreaks. The prompt identification and removal of common sources is essential, as well as the implementation of outbreak management measures as outlined earlier in this chapter. Prophylactic antibiotics are not recommended.

SHIGELLOSIS

Microbiologic, Clinical, and Epidemiological Features

Isolation of *Shigella* in asymptomatic individuals should be reported as healthcare-associated infection if other cultures obtained during hospitalization are previously negative. The incidence of healthcare-associated *Shigella* infections in industrialized regions is rare. The main risk factor for the occurrence of outbreaks is living under crowded conditions where poor personal hygiene prevails. This is especially important in facilities for chronic care of the mentally retarded. According to data from the National Healthcare-associated Infection Surveillance system, shigellosis was reported in only 1 of 3,363 patients with healthcare-associated enteric infections during the period between 1986 and 1989. *Shigella* has the potential of being transmitted efficiently between individuals, and a low inoculum can cause infection in exposed persons. Because of its striking clinical appearance, identification by the clinician is prompt and adequate measures are usually instituted. The usual sources of *Shigella* are short-term carriers of the microorganism who are either ill or convalescing from the disease. Long-term *Shigella* carriers are rare.

Control

Antibiotics are effective in eradicating susceptible strains of *Shigella* from the gastrointestinal tract. Thus, treatment of culture positive patients should be coupled with Contact Precautions to prevent spread of antibiotic resistant strains.

VIRAL GASTROENTERITIS

Rotaviruses have been shown to be important causes of healthcare-associated gastroenteritis in infants and young children. Viruses account for 91% to 94% of all causes of pediatric healthcare-associated diarrhea with rotaviruses being the single major etiologic agent (31–87% of cases in various outbreaks). Evidence has been provided to show that NoVs account for up to 17% to 46% of healthcare-associated diarrhea among the pediatric population (36).

ROTAVIRUS

Clinical Characteristics

Rotavirus strains are usually introduced to pediatric wards after hospitalization of children with community-acquired infection and/or following an exposure in the emergency department before hospitalization (37). Usually they become apparent between the second and sixth day of hospitalization. Typical symptoms are fever (60–100% of cases), together with vomiting and diarrhea with acute onset. Asymptomatic rotavirus infection is frequent in neonates and young infants (<3 months). Risk factors for acquiring viral gastroenteritis include duration of hospitalization, young age, prematurity, low birth weight, severe immunodeficiencies, and malnutrition. Other risk factors related to the hospital are low

staff to patient ratio, poor hygiene procedures, limited availability of disposable equipment, and the presence on the ward of individuals not involved in patient care, such as parents and relatives (38).

Rotavirus disease is highly infectious, and it can be spread from patients with disease to susceptible individuals by direct contact. The amount of viral particles required to cause disease is small, and rotavirus is excreted in very high concentrations in stools of infected children. Upper gastrointestinal secretions may be infectious. Airborne transmission (through respiratory droplets) has been suggested but remains controversial *(39,40)*.

Infected infants admitted to the hospital seem to be the primary source of healthcare-associated outbreaks. Transmission can be perpetuated through the hands of healthcare workers as well as person-to-person spread from patients with disease to susceptible patients. Adult hospital personnel in general are immune and are neither affected nor known to carry the virus. Since fluid rehydration is a standard practice in all hospitals, morbidity seems to be more related to diminished quality of children's lives, along with increased direct and indirect costs.

Control

Rotaviruses are highly immunogenic, and indeed a high level of immunity is seen in children and adults older than 5 years of age. Therefore, vaccination could theoretically achieve ultimate control of disease. Meanwhile, appropriate hand washing remains the most important and effective control measure *(41)*, especially with the routine use of alcohol-based hand sanitizers *(42)*. Unfortunately, in many settings compliance continues to be low. Other effective measures include physical barrier protection (gowns, masks, gloves) and physical isolation of children with diarrhea.

NOROVIRUSES

Microbiological and Clinical Characteristics

NoVs are single-stranded RNA viruses, enclosed in a nonenveloped protein coat belonging to the *Caliciviridae* family. Great diversity exists among NoV strains, and human strains have been classified according to their sequences in three genogroups (GI, GII, and GIV). NoV gastroenteritis develops after an incubation period of 10 to 51 hours and begins with vomiting, followed by abdominal cramps, fever (37–45% of cases), watery diarrhea, and other constitutional symptoms such as headache, chills, and myalgias. The illness normally lasts only 2 to 3 days, but it can last up to 4 days in healthcare-associated outbreaks and among children younger than 11 years of age. Shedding of the virus in stool usually lasts 8 weeks, although in certain patient populations fecal excretion can last longer than a year.

Healthcare-associated outbreaks of NoV have been reported (5,*43*). Transmission occurs in this setting via the fecal–oral route. Also, a low infectious dose is required for disease acquisition (18–1,000 viral particles) *(44)*. This enables the virus to spread more efficiently through droplets, fomites, person-to-person contact, and environmental contamination. The virus is shed in 30% of people before the onset of symptoms and continues for several weeks after symptoms improve, allowing secondary spread. The virus can also withstand a high variety of temperatures and persist on environmental surfaces, making decontamination difficult. Also, since there are a great variety of strains, mounting immunity against one particular strain does not protect against another strain.

Prevention and Control

Prevention and control of NoV epidemics once introduced is challenging. Contacts that become infected after exposure to contaminated food or water can spread the virus rapidly by person-to-person contact. Preventing the secondary spread of the virus through person-to-person contact and from contaminated environmental surfaces are critical to stopping the continuation of outbreaks such as those occurring in hospital wards and aboard cruise ships. Enforcing personal hygiene, using Contact Precautions, and decontaminating environmental surfaces may help. The effectiveness of alcohol-based hand sanitizers against NoVs is unsettled *(41,42,45,46)*. Washing with soap and water may be the most effective method to remove NoV from hands.

MANAGEMENT OF HEALTHCARE-ASSOCIATED INFECTIOUS GASTROENTERITIS

Infection Control

It is important to understand that the most important mode of cross-infection for enteric bacterial pathogens in the hospital is the fecal–oral route, by which indirect contact spread of microorganisms occurs from patient to patient on the hands of personnel. Hand washing remains the most effective measure to prevent infection, yet compliance continues to be low among healthcare workers and professionals. Although it will not remove the pathogen in its entirety, hand washing will reduce the amount present on the hands. Since some patients are highly susceptible to infection, other measures should be taken in order to avoid their contact with pathogens. Alcohol-based sanitizers may be sufficient to stop an outbreak due to certain pathogens. This approach is unlikely to influence the rate of *C. difficile* transmission in the hospital (Table 24-1).

Active surveillance is another key component in infectious diarrhea control. A program must be in place that is tailored to clinical patterns of infection in the hospital along with bacteriological monitoring. Such a program can detect outbreaks before they have reached important levels and can implement early appropriate control measures.

Prompt investigation of cases is the key to controlling outbreaks in the hospital setting. The occurrence of two or more cases of healthcare-associated diarrhea should prompt a review of the exposures common to these cases. Active epidemiological investigation measures include case–control studies, microbiological sampling of foods, medications, and equipment and culture surveys of asymptomatic patients and healthcare workers. Since hospital outbreaks can be caused by patients or hospital personnel who are short-term carriers of the pathogens, comparison

TABLE 24-1

Principles of Infection Control for Healthcare-Associated Diarrhea

Individual Measures	*Environmental Measures*	*General Epidemiologic Measures*	*Outbreak Management*
Hand washing Alcohol-based hand rub Meticulous hand washing with soap and water (*C. difficile*)	Prompt and thorough cleaning and disinfection of patient areas	Active surveillance	Prompt reporting and investigation of suspicious cases Case–control studies Judicious sample collection Use of molecular techniques
Use of protective clothing (gowns, aprons, etc.)	Thorough cleaning of contaminated toilets and/or bassinets	Periodic screening and early diagnosis	Isolation Individual rooms or patient cohorting Contact Precautions Dedicated nursing staff to infected or healthy patients only Avoidance of unnecessary contact
Individual isolettes and bassinets	Prompt notification to cleaning personnel of fecal soiling	Continuous education and communication (general awareness campaigns)	Reinforcement of hygienic measures
Individual medical equipment	Avoid crowding	Antibiotic stewardship	Implementation of specific policies Admission and discharge Patient placement Unit staffing
Use of disposable items whenever feasible	Safe and hygienic handling of food products		

of the exposure of cases and controls to specific personnel and review of the results of culture surveys may yield valuable information. Occasionally, environmental factors such as air, dust, mattresses, and equipment can serve as vehicles to spread pathogens, and their culture and epidemiological association can identify a common vehicle of dissemination. On certain occasions, epidemiological studies may identify the source in the central kitchen. Infected or ill food handlers should be removed from duty immediately in order to prevent disease transmission among patients.

Outbreak Management

Patients suspected of having an enteric disease with potential for spread should be segregated appropriately, with individual commodes, toilets, equipments, and rooms, with the lowest staff-to-patient ratio possible. If this is not possible, infected patients should be cohorted and cared for by the same personnel in order to avoid indirect transmission of disease. Adequate protective wear should also be worn by healthcare workers when working with patients, including gowns, gloves, and aprons that are discarded in the patient's room. In nurseries, only milk packaged in sterile containers should be used, and common equipment shared by babies should be removed. Infants should be confined to their own bassinettes, and infants born outside the area should not enter the nursery during an epidemic of diarrhea. Finally, the care of babies should be limited to essential personnel, and the number of people in the unit should be reduced as much as possible. This may include reductions in visitors to the unit.

CHAPTER 25

Healthcare-Associated Burn Wound Infections

C. Glen Mayhall

Burn patients are among the patients at highest risk for healthcare-associated infections. These patients have lost a portion of their integument that would ordinarily be a strong barrier to invasion by microorganisms. In addition, the necrotic tissue in the burn eschar combined with the presence of serum proteins provides a rich culture medium for microorganisms. Added to the loss of integument is the adverse effect of thermal injury on both local and systemic immunity *(1,2)*. Given these effects of burn trauma, it is easily understood why burn patients are at risk for healthcare-associated burn wound infections.

There are approximately 2 million fires in the United States annually leading to 1.2 million burn injuries. About 100,000 patients with moderate to severe burns require hospitalization, and about 5,000 of these burns are fatal *(3–7)*.

Data submitted from burn intensive care units (BICUs) to the National Nosocomial Infections Surveillance (NNIS) system at the Centers for Disease Control and Prevention indicate that the cumulative incidence for burn wound infections is 4.5% and the incidence rate is 6.8 cases per 1,000 patient days (R. Gaynes, personal communication, 1998). Infections are the most common cause of death in burn patients, and the most common sites of infection are the lungs and the burn wound *(8)*. The burn wound may also initiate and perpetuate a mediator-induced septic response accompanied by multiple-organ failure in the absence of an identifiable focus of infection and with negative blood culture results *(9)*. Thus, proliferation of microorganisms in the burn wound followed by invasion of subjacent viable tissue or the mediator-induced septic response may cause the clinical manifestations of sepsis.

Although the most important cause of death in burn patients is infection, the current overall mortality rate due to infections in the burn patient is unknown *(10)*. However, data from the NNIS system on patients with burn wound infection who died, and for whom the relationship of infection to death was reported, indicated that 18 (12.6%) of 143 deaths were caused by burn wound infection. Burn wound infection contributed importantly to death in 104 patients (72.7%), and the burn wound infection was unrelated to death in the remaining 21 patients (14.7%) (R. Gaynes, personal communication, 1998). It has also been observed that mortality in burn patients is significantly increased by bacteremia due to gram-negative bacilli *(11)*.

TYPES OF BURNS

Most burns are due to thermal injury. According to the National Burn Repository, for cases with a known etiology, 40% of cases are due to fire/flame injuries and 30% of cases are due to scald injuries. Nine percent of injuries are due to contact with a hot object. The remaining cases are due to electrical injury (4%) and chemical injury (3%) *(12)*.

PATHOGENESIS OF BURN WOUND INFECTIONS

Loss of the integument combined with the immune defects that accompany thermal injury place the burn patient at high risk for burn wound infection. Microorganisms are present on the skin at the time of burning and are readily acquired from the patient's gastrointestinal tract after the thermal injury has been sustained. Microorganisms are rapidly acquired from the environment of the burn care facility as well as from other burn patients cared for in the same unit.

In addition to the loss of the skin barrier, the rapid colonization of the burn wound from endogenous and exogenous sources, and the excellent culture medium provided by the burn wound, thermal injury has a substantial suppressive effect on the immune system. The nonspecific immune system is involved with long-term suppression of the neutrophil oxidative burst (13) and impairment of neutrophil chemotaxis (14). Abnormalities in cellular immunity are reflected by a decreased ratio of helper to suppressor lymphocytes and a decrease in natural killer cell activity *(2,15)*. Changes in monocyte function are reflected by an early release of high mobility group box protein 1 (HMGB1) after a burn injury and release of the cytokines IL-6, IL-8, and IL-10 (16). Higher levels of HMGB1 and IL-10 on admission were predictive of a fatal outcome. Another dysfunction of monocytes that occurs after burn injury is decreased production of human leukocyte antigen-DR (mHLA-DR) (17). Severe burn injury induces a marked decrease in the production of mHLA-DR by circulating monocytes. The marked reduction of mHLA-DR expression in severely burned patients leads to septic complications and a fatal outcome.

Thermal injury leads to local accumulation of cytokines in the areas of burn injury that "spill over" into the systemic circulation *(18)*. Thus, local accumulation of multiple cytokines in the area of injury that mediate the reparative process has a marked suppressive effect on host defenses when these cytokines enter the bloodstream and are distributed throughout the body.

With the loss of the integument, immunosuppression, and availability of nutrients for microbial proliferation, microorganisms contaminating the surface of the burn wound may multiply to high concentrations. Early colonization of the wound in the first 48 hours takes place with gram-positive microorganisms from within the depths of the sweat glands and hair follicles *(10,15,19)*. Between 3 and 21 days, the wound becomes colonized with gram-negative bacilli from the patient's own gastrointestinal tract or from other patients in the burn care facility *(10,15)*. If microorganisms reach a concentration of at least 10^5 colony-forming units (CFU) per gram of tissue, they may spread from the hair follicles along the dermal subcutaneous junction *(19)*. Perivascular colonization may result in thrombosis, vascular occlusion, and necrosis of the remaining viable elements. The resultant ischemia and bacterial autolysis may convert a partial-thickness injury to a full-thickness injury. In burn wounds with unexcised eschar, invasion of the subeschar viable subcutaneous tissue results in burn wound infection or burn wound sepsis and may be complicated by bacteremia.

CLINICAL MANIFESTATIONS OF BURN WOUND INFECTIONS

In burn wounds with unexcised eschar, clinical manifestations of burn wound infection appear when microorganisms reach high concentrations in the burn eschar and invade subjacent viable tissue. Clinical signs of infection may depend, to some extent, on the type of infecting microorganism. Hyperthermia and leukocytosis tend to be more marked in patients with gram-positive infection. Infections with gram-positive microorganisms are also more often associated with irrational behavior and mental confusion. The appearance of a wound infected by gram-positive microorganisms may be characterized by maceration with a ropy tenacious exudate and surrounding cellulitis *(19)*.

Patients with gram-negative burn wound infection are more likely to have hypothermia and leukopenia. Although they may have altered mental status with confusion, some patients with gram-negative burn wound infection may remain lucid until near death *(19,20)*. Patients with gram-negative infection may also have glucose intolerance with hyperglycemia, ileus and abdominal distention, respiratory distress syndrome, and oliguria *(20)*.

The wound infected by gram-negative microorganisms is characterized by (a) focal gangrene that coalesces and spreads throughout the wound; (b) conversion of a partial-thickness wound to a full-thickness wound; (c) hemorrhagic discoloration of subeschar tissue; (d) focal, multifocal, or generalized dark brown, black, or violaceous discoloration of the burn wound; and (e) changes in unburned skin at the wound margins characterized by edema and violaceous discoloration *(19,20)*. Bacteremia is a common complication of burn wound infection, but absence of bacteremia does not rule out burn wound infection. In fact, fatal burn wound infection may occur in the absence of bacteremia, particularly when the infection is caused by gram-negative microorganisms *(19)*.

DIAGNOSIS OF BURN WOUND INFECTION

Clinical Diagnosis

Examination of the burn wound and clinical signs and symptoms provide important clues to the diagnosis of burn wound infection. As noted above, changes in the wound characterized by dark brown, black, or violaceous discoloration; unexpectedly rapid separation of the eschar; hemorrhagic discoloration of subeschar tissue and edema; and violaceous discoloration of unburned skin at the wound margin suggest burn wound infection *(20)*. Clinical suspicion of infection is heightened when these local wound manifestations are accompanied by hypothermia (<36°C), hyperthermia (>38°C), hypotension (systolic blood pressure ≤90 mm Hg), oliguria (<20 mL/h), ileus with abdominal distention, glucose intolerance and hyperglycemia, or altered mental status *(20,21)*.

Microbiologic Diagnosis of Burn Wound Infection

In a study wherein about 80% of burn wound biopsies were obtained from patients with local signs of burn wound infection, Pruitt and Foley *(22)* observed that 75% of patients with more than 10^5 CFU/g of burn wound tissue died. When this density of microorganisms in the burn eschar was combined with a grade 6 histologic diagnosis ("invasive infection with microbial penetration into viable tissue beyond the depth of original necrosis"), the mortality rate was 100%. In another study comparing quantitative burn wound cultures and histopathologic examination of the same tissue, McManus et al. *(23)* observed that growth of at least 10^5 CFU/g of tissue identified burn wound infection diagnosed by histopathologic assessment of tissue 96.1% of the time. However, 64.3% of biopsies that showed negative results histopathologically also had at least 10^5 CFU/g of tissue. Thus, quantitative burn wound cultures have a high sensitivity (96.1%) but a low specificity (35.7%). Stated another way, burn wounds with $<10^5$ CFU/g of tissue are highly unlikely to be infected, whereas only about one-third of burn wounds with at least 10^5 CFU/g of tissue will be infected.

Although the threshold of at least 10^5 CFU/g of burn wound tissue has a high sensitivity and low specificity for burn wound infection, a threshold of over 10^8 CFU/g of tissue is highly suggestive of burn wound sepsis and impending death in the untreated patient *(24,25)*. Thus, even though the definitive diagnosis of burn wound infection may be made by histopathologic examination of a full-thickness biopsy of the burn wound (see below), it would appear that burn wound biopsies containing $<10^5$ CFU/g of tissue suggest that burn wound infection is unlikely and that biopsies with more than 10^8 CFU/g of tissue are highly suggestive of burn wound sepsis.

One problem with the interpretation of quantitative cultures of burn wound biopsies has been the uneven distribution of microorganisms, both qualitatively and quantitatively, throughout the burn wound. In a study wherein culture results were not correlated with clinical manifestations, appearance of the burn wound, or histopathologic examination of the tissue taken for culture, Woolfrey et al. *(26)* concluded, "Quantitative results derived from burn wound biopsy cultures are unreliable and may be significantly misleading when used for decision-making relative to patient care." These authors divided each biopsy specimen and cultured the two portions separately. Between the two segments, an average of 4.8 microorganism types was recovered. At the 10^5 CFU/g of tissue breakpoint, the paired quantitative results agreed within the same log increment for only 38% of biopsies. Although it is clear from the data of Woolfrey et al. that there may be large qualitative and quantitative differences in burn wound microbiology between immediately adjacent areas of the wound, it is unclear how their results relate to the appearance of the burn wound (and whether biopsies were taken from areas of the wound that appeared infected on clinical examination), histopathologic examination of the tissue taken for culture, and the clinical course of the patient.

Surface swab cultures, either qualitative or quantitative, have been used in the diagnosis of burn wound infections. Steer et al. *(27)* compared qualitative results and quantitative bacterial counts of 141 surface swabs and 141 wound biopsies taken from 74 burn patients. They observed a significant correlation between the total bacterial counts of surface swabs and the total bacterial counts of biopsies ($p < .001$), but the predictive value of the counts obtained by one method to predict the counts obtained by the other method was poor. The qualitative correlation was also poor, and only 54% of the biopsy/swab pairs yielded the same microorganism on culture. There were two exceptions to the latter observation. When *Staphylococcus aureus* was present in the burn wound biopsy, it was present on surface culture 95% of the time, and when *Pseudomonas aeruginosa* was recovered from the burn wound biopsy, it was cultured from the surface swabs 92% of the time. Thus, although *S. aureus* and *P. aeruginosa* in the burn wound may be detected by surface swabs, qualitative and quantitative surface cultures are generally not useful for predicting the qualitative and quantitative microbiology of the burn wound.

When the diagnosis of burn wound infection is made by histopathologic examination of a full-thickness burn wound biopsy (see below), quantitative culture of a portion of the biopsy may identify the causative microorganism(s) and provide antimicrobial susceptibility data for the selection of appropriate antimicrobial therapy. McManus et al. *(23)* observed a 100% concordance between microorganisms seen on histopathologic examination and those recovered on culture. Thus, burn wound biopsies should be both cultured and examined histopathologically. Although quantitative cultures may not be necessary for identification of the causative microorganism(s), quantitation might be useful in separating microorganisms on and in the nonviable tissue from those invading viable tissue. It would be unlikely that microorganisms recovered at a concentration below 10^5 CFU/g of tissue would be causing burn wound infection *(23)*.

Although some investigators have found a good correlation between the results of quantitative Gram-stained preparations and quantitative cultures of biopsy tissue *(28,29)*, others have not *(30)*. Even with a good correlation between quantitative Gram-stain and culture results, the results of microscopic examination of Gram-stained tissue should not be used for diagnosis of burn wound infection, because definitive diagnosis of burn wound infection requires histopathologic examination and culture.

Histopathologic Diagnosis of Burn Wound Infection

In burn wounds with unexcised eschar, the diagnosis of burn wound infection may be made by histopathologic examination of a full-thickness burn wound biopsy. The biopsy should be taken from the area of the wound with the most pronounced local changes (see above). A lenticular tissue sample should be obtained using a scalpel. The biopsy should measure from $0.5 \times 0.5 \times 0.5$ cm to $1 \times 1 \times 1$ cm and should weigh between 100 and 500 mg. The biopsy must include underlying or adjacent unburned tissue in addition to the eschar. The specimen should be divided; one half should be cultured quantitatively, and the other half should be placed in 10% neutral buffered formalin solution for processing for histopathologic examination. The tissue should be stained with hematoxylin and eosin stain, Brown Hopps Gram stain, and periodic acid-Schiff stain *(20,31)*.

Histopathologic examination may show microorganisms localized to the burn eschar surface or various degrees of penetration of the eschar. Burn wound infection or sepsis develops when microorganisms invade through the eschar and into viable tissue subjacent to the eschar. These histopathologic manifestations of burn wound infection were carefully described 47 years ago by Teplitz et al. *(32)* using rats as an experimental model. Their findings in the animal model appear to parallel those observed in humans with thermal injury.

Kim et al. *(33)* have described a frozen section technique for rapid evaluation of burn wound biopsies for burn wound infection. This technique reduces the time of processing from 4 hours (rapid technique) to 30 minutes. Application of the frozen section technique to burn wound biopsies had not been possible in the past because of the hardness of the eschar. However, advances in this technique, which made frozen sections of bone and cartilage possible, have permitted its application to burn wound biopsies as well. Frozen section diagnosis should always be confirmed by examination of permanent sections (rapid section technique).

DEFINITIONS OF BURN WOUND INFECTION

Although burn wound infection may be diagnosed by histopathologic examination of a full-thickness burn wound biopsy, and the causative agent may be established by culture of the biopsy or by histopathologic examination of the burn wound biopsy using special stains for microorganisms (e.g., periodic acid-Schiff stain for fungi), such studies may not be available in all burn care facilities. Further, when the

TABLE 25-1

Definitions for Burn Wound Infections

Burn infections must meet at least one of the following criteria:

1. Patient has a change in burn wound appearance or character, such as rapid eschar separation, or dark brown, black, or violaceous discoloration of the eschar, or edema at wound margin
   and
   histologic examination of burn biopsy shows invasion of organisms into adjacent viable tissue
2. Patient has a change in burn wound appearance or character, such as rapid eschar separation, or dark brown, black, or violaceous discoloration of the eschar, or edema at wound margin
   and
   at least **one** of the following:
   a. organisms cultured from blood in the absence of other identifiable infection.
   b. isolation of herpes simplex virus, histologic identification of inclusions by light or electron microscopy, or visualization of viral particles by electron microscopy in biopsies or lesion scrapings.
3. Patient with a burn has at least **two** of the following signs or symptoms with no other recognized cause: fever (>38 °C) or hypothermia (<36°C), hypotension, oliguria (<20 cc/h), hyperglycemia at previously tolerated level of dietary carbohydrate, or mental confusion
   and
   at least **one** of the following:
   a. histologic examination of burn biopsy shows invasion of organisms into adjacent viable tissue
   b. organisms cultured from blood
   c. isolation of herpes simplex virus, histologic identification of inclusions by light or electron microscopy, or visualization of viral particles by electron microscopy in biopsies or lesion scrapings.

Comments

- Purulence alone at the burn wound site is not adequate for the diagnosis of burn infections; such purulence may reflect incomplete wound care.
- Fever alone in a burn patient is *not* adequate for the diagnosis of a burn infection because fever may be the result of tissue trauma or the patient may have an infection at another site.
- Surgeons in Regional Burn Centers who take care of burn patients exclusively may require Criterion 1 for diagnosis of burn infection.
- Hospitals with Regional Burn Centers may further divide burn infections into the following: burn wound site, burn graft site, burn donor site, burn donor site-cadaver; NHSN, however, will code all of these as BURN.

(Reprinted from Horan TC, Andrus M, Dudeck MA. CDC/NHSN surveillance definition of healthcare-associated infection and criteria for specific types of infections in the acute care setting. *Am J Infect Control* 2008;36:309–332, with permission from Elsevier.)

burn wound has been excised, there may be no tissue to biopsy. Thus, case definitions are needed for surveillance and outbreak investigation that make use of other, more easily obtained data such as clinical observations, blood cultures, viral cultures, and microscopic examination of lesion scrapings for viral inclusions. Table 25-1 (34) shows case definitions for burn wound infections used by the National Healthcare Safety Network (NHSN).

One element missing from the NHSN definitions is that of the causative agent. Thus, if one were selecting a definition for burn wound infection in a suspected outbreak of burn wound infections caused by *S. aureus*, it would be appropriate to include culture of *S. aureus* from the burn wound in the case definition of infection. The source from which a culture must be taken to establish the cause of a burn wound infection is not described in the NHSN definitions. For bacterial infections, the culture should be taken from a full-thickness burn wound biopsy and not the surface of the burn wound. Another acceptable source is blood if no other possible site of infection can be identified. Although fungi may be cultured from a full-thickness burn wound biopsy, most fungal burn wound infections will probably be diagnosed by histopathologic examination of burn wound biopsies. Herpes simplex may be cultured from scrapings from the burn wound surface; viral inclusions may also be seen microscopically in burn wound scrapings.

The NHSN definitions are based on burn wounds containing unexcised eschar. Since burn wounds are treated in many centers now by early excision and coverage of the wound with autograft, cadaveric allograft, temporary biologic dressings, or dermal replacement (Integra) (35), definitions are needed for infections in surgically created wounds such as excised burns and donor sites. Further, definitions are needed for other types of infections related to the burn wound such as burn wound impetigo and burn wound cellulitis (36). For the purposes of surveillance, the NHSN lumps all wounds related to thermal injury and its treatment together as burn infections. However, when an outbreak occurs involving sites other than burn wound containing unexcised eschar, it will be necessary to use case definitions specific to the type of infection involved in the outbreak (Table 25-2).

TABLE 25-2

Proposed Definitions for Burn Wound Infections (Including Burn Wound Impetigo, Open Burn-Related Surgical Wound Infections, Cellulitis, and Infection of Unexcised Burn Wounds)

Infection	*Criterion (Must Meet the Following)*
Burn wound impetigo	Infection involves loss of epithelium from a previously reepithelialized surface such as grafted burns, partial-thickness burns allowed to close by secondary intention, or healed donor sites *and* Is not related to inadequate excision of the burn, mechanical disruption of the graft, or hematoma formation *and* Requires some change of or addition to antimicrobial therapy It may or may not be associated with systemic signs of infection such as hyperthermia (temperature >38.4°C) or leukocytosis (white blood cell count >10,000/m^3)
Open burn-related surgical wound infection	Infection occurs in surgically created wounds such as excised burns and donor sites that have not yet epithelialized *and* Has a purulent exudate that is culture positive *and* Requires change of treatment (which may include change of or addition to antimicrobial therapy, removal of wound covering, or increase in frequency of dressing changes) *and* Includes at least one of the following: 1. Loss of synthetic or biologic covering of the wound 2. Changes in wound appearance such as hyperemia 3. Erythema in the uninjured skin surrounding the wound 4. Systemic signs such as hyperthermia or leukocytosis
Burn wound cellulitis	Infection occurs in uninjured skin surrounding the burn wound or donor site *and* Is associated with erythema in the uninjured skin progressing beyond what is expected from the inflammation of the burn *and* Is not associated with other signs of infection in the wound itself *and* Requires change of or addition to antimicrobial therapy *and* Includes at least one of the following: 1. Localized pain or tenderness, swelling, or heat at the affected site 2. Systemic signs of infection such as hyperthermia, leukocytosis, or septicemia 3. Progression of erythema and swelling 4. Signs of lymphangitis and/or lymphadenitis
Invasive infection in unexcised burn wounds	Infection occurs in deep partial-thickness or full-thickness burn that has not been surgically excised *and* Is associated with change in burn wound appearance or character, such as rapid eschar separation, or dark brown, black, or violaceous discoloration of the eschar *and* Requires surgical excision of the burn and treatment with systemic antimicrobials *and* May be associated with, but not dependent on, any of the following: 1. Inflammation of the surrounding uninjured skin, such as edema, erythema, warmth, or tenderness 2. Histologic examination of the burn biopsy specimen that shows invasion of organism into adjacent viable tissue 3. Organism isolated from blood culture in absence of other identifiable infection 4. Systemic signs of infection such as hyperthermia or hypothermia, leukocytosis, tachypnea, hypotension, oliguria, hyperglycemia at previously tolerated level of dietary carbohydrate, or mental confusion

(Reprinted from Peck MD, Weber J, McManus A, et al. Surveillance of burn wound infections: a proposal for definitions. *J Burn Care Rehabil* 1998;19:386–389.)

ETIOLOGIES OF BURN WOUND INFECTIONS

Burn wound infections may be caused by bacteria, fungi, or viruses. Although not invariably the case *(37)*, bacteria probably cause the majority of infections in most burn care centers. Almost all burn wound infections caused by bacteria are due to aerobic microorganisms. Anaerobes cause up to 2% of all burn wound infections *(38,39)*.

Bacteria

S. aureus continues to be one of the most important bacterial causes of burn wound infections (40,*41*,42). More importantly, methicillin-resistant *S. aureus* (MRSA) continues to be an important pathogen for burn wound infections (43,*44*,*45*). More recently, there is evidence that community-acquired MRSA is beginning to enter some burn care facilities (46) but not others (47). In one center, 25 of 206 (12.1%) of patients colonized or infected with MRSA had USA300 (46). Differences between patients colonized or infected with USA300 community-acquired MRSA and healthcare-associated MRSA were that patients with community-acquired MRSA had frequent abscesses involving their burn wounds. Nasal colonization was present in only 31.6% of patients infected with community-acquired MRSA (46). Occasionally, strains of *S. aureus* that produce toxic shock syndrome toxin and exfoliative toxin cause burn wound infection (*48*,*49*,50,*51*). Although much less common, β-hemolytic group A streptococci may occasionally cause outbreaks of burn wound infection *(52)*. However, groups A, B, and G streptococci are the third most common cause of burn wound infections in the burn unit at the Karolinska Hospital in Stockholm *(53)* (see also Chapter 32).

P. aeruginosa continues to be a common cause of burn wound infections. *Pseudomonas* infections tend to occur more often in patients with burn wounds of >60% total body surface area (TBSA) and after 2 weeks of hospitalization *(54)*.

Acinetobacter baumannii has become the most frequently isolated pathogen in many BICU in civilian and military populations (*54–58*,59). *A. baumannii* is the most common microorganism isolated from war wounds including burn wounds *(57)*. *A. baumannii* becomes highly resistant to antimicrobial agents and forms biofilms that appear to increase its pathogenicity *(58)*. It is unclear at present whether or not *Acinetobacter* infections in burn patients are associated with an increase in mortality *(54,55,57)*.

Similar to healthcare-associated infections in other body sites, enterococci have become an important cause of burn wound infection. This is likely due to the widespread use of third-generation cephalosporins to which enterococci are resistant. In 1986, Jones et al. *(60)* reported on a series of cases of burn wound sepsis caused by enterococci. Enterococcal infection was diagnosed by recovery of at least 10^5 CFU/g of tissue on burn wound biopsy or by recovery of enterococci from blood cultures. They identified 38 enterococcal burn wound infections in 26 months. Twenty patients developed enterococcal bacteremia, and 10 of these patients died. Enterococci appear to be not only common but also virulent burn wound pathogens. In a more recent study, 97 isolates of vancomycin-resistant enterococci (VRE) and 652 isolates of vancomycin-susceptible enterococci (VSE) were recovered from burn patients *(61)*. No mention was made of infections caused by VSE, but none of the patients colonized by VRE developed VRE infections. As has been noted in other patient populations in the hospital, VRE have been reported to cause an outbreak of VRE colonization and infection in a BICU (62). Four cases of bacteremia due to VRE occurred during that outbreak.

While each of the genera among the Enterobacteriaceae still contribute pathogens as a cause of burn wound infections, only *Klebsiella pneumoniae* joins *S. aureus*, *A. baumannii*, and *P. aeruginosa* as one of the four most common causes of burn wound infections *(54)*. Those strains of *K. pneumoniae* that produce extended-spectrum beta-lactamase (ESBL) may result in higher mortality (63). Although the authors could not directly relate ESBL production to mortality, multivariate analysis did indicate that ESBL producing *K. pneumoniae* may be related to mortality in patients who are older and who are more badly burned.

Fungi

As bacterial burn wound infections have come under better control with use of topical antimicrobial agents, better isolation techniques, and, perhaps, early burn wound excision, the relative importance of fungal burn wound infections has increased. In a recently published autopsy series from the U.S. Army Institute of Surgical Research, the most common causes of fungal burn wound infection were *Aspergillus* species and *Candida* species *(64)*. Two publications from the same institution showed that fungal burn wound infection, not burn wound colonization, is significantly associated with mortality *(65,66)*.

Candida Species Invasive candidiasis occurs in 2% to 21% of burn patients (67). Mucosal disruption occurs in burn patients, which leads to fungal translocation. Mucosal atrophy in the gastrointestinal tract is related to the extent of the burn, and ileus complicates burns with >25% TBSA burned (67). *Candida albicans* is the most common species of *Candida* recovered from blood (65% of cases) with *Candida parapsilosis* causing 25% of cases and *Candida tropicalis* causing 10% of cases *(68)*. The most common source for *Candida* bloodstream infection is the burn wound and the risk increases with increasing size of the burn wound and with delay in burn wound excision *(69)*. The attributable mortality for candidemia in burn patients has been reported to range from 14% to 70% (67). However, whether or not *Candida* infections in burn patients are related to mortality remains controversial. In a recently published retrospective matched case–control study using prospectively collected data, no difference in mortality was observed between the patients with candidemia and the control group *(68)*.

Filamentous Fungi The great preponderance of burn wound infections caused by fungi is due to filamentous fungi. The filamentous fungi that most often cause burn wound infections are *Aspergillus* species, Zygomycetes (*Mucor* species, *Rhizopus* species), *Alternaria* species, and *Fusarium*

species. Less commonly isolated are *Cladosporium* species, *Penicillium* species, and *Trichosporon* species (43,*64,65*). Burn wounds may be colonized or infected by fungi, but only burn wound infection is significantly associated with mortality *(66)*. However, this relationship between burn wound infection and mortality is observed only in those patients with TBSA of 30% to 60% *(66)*. Importantly, 15.4% of patients with burn wound colonization progressed to burn wound infection and made up 40.7% of all patients with burn wound infection.

Viruses

Herpes Simplex Herpes simplex infections may occur in burn patients. Most of these infections appear to be reactivation infections and may be symptomatic or asymptomatic. Asymptomatic infections are detected by a fourfold or greater rise in antibody titer *(70)*. Symptomatic infections most commonly involve the burn wound and tend to occur in healing partial-thickness burn wounds that involve the face *(71–73)*. The infection, which apparently reactivates in the healing skin after burn injury, may disseminate to involve liver, adrenal glands, lungs, spleen, gastrointestinal tract, and urinary bladder *(71)*. No data are available on the incidence of herpes simplex infections of burn wounds. In one study, 25% of children with burns had serologic evidence of herpes simplex infection, and all were reactivation infections *(70)*. Only one of these children had a burn wound infection due to herpes simplex.

In one study of adult burn patients, 40% had serologic evidence of herpes virus infection, but apparently, there was no herpetic involvement of their burn wounds *(74)*. About 90% of these infections were reactivation infections, and about 10% appeared to be primary infections.

Cytomegalovirus In one published study of burn patients with a mean age of 29 years, the incidence of cytomegalovirus (CMV) infection was 33% *(74)*. These infections were due to reactivation of latent infections in 76% of the patients. There was no evidence that transfusion of blood products increased the incidence of primary or reactivation CMV infections. These infections were apparently asymptomatic, and none involved the burn wound. In a second study, 29% of the burn patients developed CMV infection, but again, none had any clinical manifestations of infection *(75)*.

In a series of pediatric burn patients, 33% of the patients developed CMV infections *(70)*. Unlike the adult patients, some pediatric patients developed fever and hepatitis. In a second study from the same institution, CMV infection was found to have caused initially unexplained fevers in four patients *(76)*. None of the patients in these two reports had involvement of the burn wound by CMV. In the former study, a few patients had adenovirus infections and reactivated Epstein–Barr virus and varicella-zoster virus (VZV) infections, but none of these infections involved the burn wound. In a more recent study cytomegalovirus was identified as a cause of pneumonia in a burn patient but the patient had no skin lesions suggestive of cutaneous involvement (*77*).

In pediatric burn hospitals, infections in patients due to VZV occur uncommonly but may cause serious disease such as VZV pneumonia *(78)*. Although there has been no significant involvement of the burn wound in these cases, pneumonia may be fatal. The lower morbidity, particularly involving the burn wound, may be due to the ready availability of acyclovir and varicella-zoster immune globulin. Due to the high degree of communicability of VZV, prompt detection and isolation of cases is very important in preventing spread among burn patients. That VZV can be effectively controlled in a pediatric burn hospital was shown by Sheridan et al. *(78)* (see also Chapter 43).

EPIDEMIOLOGY OF BURN WOUND INFECTIONS

The epidemiology of burn wound infection involves a reservoir or source for the causative microorganisms, a means of transmission of these microorganisms to the burn wound surface, and the presence or absence of certain factors (risk factors) that may promote colonization, multiplication, and invasion of wound surfaces by newly deposited microorganisms.

Reservoirs or Sources

Burn Wounds of Patients The collective burn wound surfaces of the patients in a burn treatment facility may make up an important reservoir of microorganisms that cause burn wound infections. The burn wound has been shown to be a reservoir for *P. aeruginosa, E. coli*, *K. pneumoniae*, *A. baumannii*, *Streptococcus pyogenes*, MRSA, and enterococci including VRE (40,*41,54*,62). Given the shift in the etiology of burn wound infections over the last 3 to 4 decades and the continuing trend toward early burn wound excision and closure, it is unclear how important the collective burn wounds of patients in burn care facilities are today as a reservoir for microorganisms that cause burn wound infections. With the improvement in control of bacterial pathogens as causes of burn wound infection, yeast and fungi have assumed a prominent role as causes of burn wound infections in the 21st century *(66,69)*.

Gastrointestinal Tract There is substantial evidence that microorganisms that colonize the burn patient's bowel may contaminate the burn wound and lead to burn wound infection *(78–80)*. In past years when *P. aeruginosa* was a common burn wound pathogen, the areas of the burn wound most often contaminated by feces (buttocks, perineum, lower abdomen, inside of the upper thighs) were the areas most often infected by *P. aeruginosa*. The previous species name for *P. aeruginosa* was *Pseudomonas pyocyanea*, and burns in the areas most often contaminated by feces were called pyocyaneus-prone burns *(81). P. aeruginosa* may reach the bowel by ingestion of these microorganisms as a result of cross-contamination from one burn patient's wound surface to the oropharynx of a patient in a nearby bed or by ingestion of food contaminated by *P. aeruginosa (78,79)*. It has also been suggested that gut flora may contaminate the burn wound by translocation from the gastrointestinal tract *(82)*.

Environment Microorganisms that cause burn wound infections have been recovered from a number of inanimate sites in the environments of burn care facilities *(83–91)*. Among the most important inanimate reservoirs or sources for microorganisms that cause burn wound infections is hydrotherapy equipment *(92)*.

Endogenous Flora Early burn wound infections caused by gram-positive cocci are due to microorganisms from the endogenous skin flora (42,*54*). Routine antibiotic prophylaxis to prevent these early infections, given in many burn treatment centers, has eliminated infections from this source. Within 8 to 72 hours, endogenous gram-negative bacteria from the patient's respiratory and gastrointestinal tracts colonize the burn wound *(54)*. After initial colonization with endogenous flora, the burn wound becomes colonized with *Pseudomonas*, *K. pneumoniae*, and *A. baumannii* from other patients and the environment *(54)*.

Modes of Transmission

Hands of Healthcare Workers As with other healthcare-associated infections, there is evidence that microorganisms are transmitted between patients on the hands of their caregivers *(7,8,83,84,87,88)*. Microorganisms may be transmitted directly between patients by the hands of medical personnel (patient to hands to patient) or they may be indirectly transmitted by contaminated hands (patient to hands to inanimate environmental surface to hands to patient).

Another source of hand contamination for healthcare workers in burn units is nonsterile examination gloves *(93)*. *Bacillus cereus* was disseminated among patients in a burn unit. When infection control measures failed to halt spread of the microorganism, cultures of unopened boxes of nitrile gloves revealed the source. The outbreak was cleared by use of latex and vinyl gloves.

Gastrointestinal Tracts of Patients As noted above, microorganisms that gain entrance to the gastrointestinal tract of a patient may be carried to the patient's burn wound surface by feces. The gastrointestinal tract may be inoculated with a burn wound pathogen by contact of the patient's oropharynx with the contaminated hands of a healthcare worker or by ingestion of contaminated food *(79)*. Contaminated food may carry the burn wound pathogen directly to the patient's gastrointestinal tract or may contaminate utensils used for food preparation, leading to secondary contamination of food *(79)*.

Hydrotherapy After hydrotherapy equipment becomes contaminated, subsequent patient contact with the equipment during hydrotherapy treatments may transfer the microorganisms to a burn patient's wounds *(83–86,88, 89,92)*.

Inanimate Environmental Surfaces Environmental surfaces frequently become contaminated with the microorganisms that cause burn wound infections. Other than hydrotherapy equipment and mattresses, it has been difficult to document transfer of microorganisms from environmental surfaces directly to the burn wound surfaces of patients.

Risk Factors for Burn Wound Colonization and Infection

After microorganisms are transmitted to the surface of the burn wound, there are several factors that determine whether the microorganisms will survive, colonize the surface, and invade the burn wound. These factors that promote colonization and burn wound invasion may be considered risk factors for burn wound infection.

Duration of Hospitalization Using Cox model survival analysis to analyze data from a retrospective study of bacterial wound colonization and duration of hospital stay, one group of investigators *(94)* observed a significant positive association between length of stay and colonization with Enterobacteriaceae or a combination of *S. aureus* and *P. aeruginosa*. Although the relationship observed by these workers was between duration of stay and wound colonization (not infection), it is likely that duration of stay is related to burn wound infection, since colonization is a necessary first step in the development of wound infection.

Burn Wound Size Intuitively, it would seem likely that the larger the burn wound, the more likely it would be contaminated and colonized with microorganisms. In a prospective study of 53 pediatric patients with burns in which the data were analyzed by multivariable analysis, Fleming et al. *(82)* showed a significant relationship between colonization of burn wounds with microorganisms from patients' fecal flora and the size of their burn wounds. Again, it is likely that risk factors for colonization also place the burn wound at greater risk for infection.

In a retrospective study in which data were analyzed by multiple regression analysis, Merrell et al. *(95)* found a significant relationship between burn wound size and subsequent occurrence of fatal sepsis. Fifty-four percent of the fatalities were due to burn shock. Graves et al. *(96)* also observed a significant relationship between burn wound size and infection in a retrospective study wherein data were analyzed by logistic regression analysis. Sites of infection in the latter two studies included burn wound *(95,96)*, lungs *(92,93)*, multiple organs *(93)*, and abdomen *(93)*. In a prospective cohort study in pediatric burn patients analyzed by multivariable techniques, Gastmeier et al. *(97)* observed a significant relationship between burn wound infections and percentage of TBSA affected. The authors also noted a significant relationship between duration of ventilation and pneumonia and duration of urinary catheter use and urinary tract infections.

Transfusions Graves et al. *(96)*, using multivariable analysis, also found a significant relationship between number of blood transfusions and infections. Although they recognized that the relationship may only be due to the possibility that more frequent transfusion identifies patients at a higher level of severity of injury and therefore at a higher risk of infection, the authors also noted that the relationship may be due to a specific depression of resistance to infection caused by the transfusions. In an investigation of an outbreak in a burn unit caused by *A. baumannii*, Simor et al. (59) identified receipt of blood products as a risk factor for acquisition of the outbreak strain. In the multivariable model, the odds ratio was 10.8 with a 95% confidence interval of 3.4 to 34.4, $p < .001$. Thus, blood transfusions may further suppress host defenses already impaired by the burn injury.

Hyperglycemia Poor plasma glucose control and the effect of hyperglycemia on the occurrence of infections and on mortality in pediatric burn patients were investigated

by Gore et al. *(98)* in a retrospective study with analysis of data limited to univariate statistics. Quantitative cultures of burn wound were done, and poor plasma glucose control was defined as >40% of glucose values ≥7.8 mmol/L and adequate control was indicated by ≤40% of glucose values of ≥7.8 mmol/L.

There was no association between adequate glucose control and wound infections defined as $>10^5$ CFU/g of burn wound tissue. There was no association between glucose control and bacteremia. However, patients with poor glucose control had a significantly higher rate of fungemia. When controlled for length of stay, patients with poor glucose control had significantly more bacteremia and fungemia, more skin-grafting procedures, and a lower percentage of graft takes for each procedure. Mortality was also significantly higher in patients with poor glucose control.

Although hyperglycemia did not appear to affect the incidence of burn wound infections, wound closure was apparently more difficult in patients with hyperglycemia, and patients with hyperglycemia had significantly more bacteremias and fungemias and a higher mortality rate.

Hypermetabolic Response Severe thermal injury defined as involvement of more than 40% of the TBSA leads to a hypermetabolic response that may last for 1 to 2 years (99). The primary mediators of this response are catecholamines and corticosteroids. For burns >40% TBSA, there is a 10- to 50-fold surge of plasma catecholamine and corticosteroid levels that last up to 9 months postburn. Immediately after the burn, cytokine levels peak and return to normal levels at 3 to 6 months postburn. The changes that occur in the immune response in catabolic patients lead to a further diminution in the burn patient's already suppressed immunity. Development of sepsis leads to further catabolism and energy expenditures. Early excision and grafting of burn wounds markedly reduce the hypermetabolic response.

Resistance of Microorganisms to Topical Antimicrobial Agents When microorganisms in a burn patient population become resistant to the topical antimicrobial agent used for suppression of growth of microorganisms in and on the burn wound, for any given patient the risk of uncontrolled growth of bacteria or fungi in the wound increases and invasion of viable tissue resulting in burn wound infection becomes more likely. Hendry and Stewart *(100)* observed that colonization of burn wounds by silver- and sulfonamide-resistant bacteria may occur within 2 weeks of admission.

Five outbreaks of burn wound infection or colonization due to gram-negative bacilli resistant (or relatively resistant) to topical antimicrobial agents have been reported *(83,87,101–103)*. The epidemic isolates from these outbreaks have been resistant to gentamicin *(83)*, silver sulfadiazine *(87)*, or silver nitrate *(101,103)*. No outbreaks due to mafenide acetate–resistant microorganisms have been reported.

Resistance of Microorganisms to Systemically Administered Antimicrobial Agents Resistance to systemically administered antibiotics may also result in a selective advantage for the resistant microorganisms and place patients at greater risk for burn wound infection. Although it has been generally assumed that antimicrobial agents do not achieve therapeutic concentrations in the avascular burn eschar, Polk et al. *(104)* showed that gentamicin and tobramycin frequently reached therapeutic concentrations in both the superficial and the deep layers of the unexcised burn wound. Reporting on data from the same study, Mayhall et al. *(105)* observed that when the concentration of antibiotic in burn wound tissue exceeded the minimum bactericidal concentration of the microorganisms present in the tissue, the microorganisms usually were eliminated from the wound. In no case was a microorganism eliminated from tissue when its minimum inhibitory concentration (MIC) was higher than the concentration of antibiotics in tissue. Of particular importance was their observation that, during therapy, six patients developed superinfection of the burn wound with *Serratia marcescens* and that five of these isolates were highly resistant to the antibiotic being administered. In the five patients for whom tissue levels were available, the MICs of these strains exceeded concentrations of antibiotic present in the burn wound. Thus, when a microorganism present on the wounds of patients in a burn care unit becomes highly resistant to an antibiotic used frequently to treat burn wound infection, particularly when used empirically, use of this antibiotic may place patients at risk for burn wound infection.

Risk Factors for Burn Wound Colonization and Infection with Multidrug-Resistant Microorganisms

Methicillin-Resistant S. aureus Several studies have been published recently that report on risk factors for burn wound infections caused by MRSA. In a case–control study analyzed by univariate statistics, the risk factors included a long duration of stay, diabetes mellitus, and residence in a long-term care facility in the previous year (40). In two case control studies analyzed by multivariable analysis, risk factors included treatment with vancomycin, burns involving the head and the number of burn wound excisions *(44,45)*. One of the latter studies found older age (50.8 ± 21.9) to be protective when compared with younger age (35.9 ± 22.3) *(45)*. In a study of the community-acquired USA 300 strain of MRSA on a burn-trauma unit Wibbenmeyer et al. (46) reported on a case–control study analyzed by univariate analysis. Risk factors for acquisition of the USA 300 strain included age, comorbidities, hospitalization in the prior 6 months, and having had a surgical procedure in the prior 6 months.

Vancomycin-Resistant Enterococcus Although enterococci have been reported to cause serious burn wound infection *(60)*, burn wound infections due to VRE, to the author's knowledge, have not been reported. In one outbreak of burn wound colonization in a burn unit, four cases of bacteremia were identified and were caused by the same strain of VRE that colonized patients' burn wounds (62). In another study, patients who acquired VRE in a burn surgery step-down unit developed no burn wound infections due to VRE, but two patients acquired VRE urinary tract infections *(45)*. Reported risk factors for VRE colonization include presence of diarrhea, receipt of an antacid, extent of TBSA burn, and presence of a Foley catheter while in the burn unit (*45*,*61*,62). In one study, it appears that a greater depth of burn injury and administration of vancomycin

were protective against VRE acquisition *(61)*. Colonization of the burn wound with VRE does not appear to cause burn wound infection, but the colonized burn wound may be an important reservoir for development of VRE infections at other body sites, particularly at sites of indwelling devices.

PREVENTION AND CONTROL

There is good evidence that improvements in the prevention and control of infections in burn patients have led to improvements in patient survival *(3,106)*. The approach to control of infections in burn patients may be conveniently divided into the following categories: (a) use of barrier techniques to prevent cross-contamination of patients; (b) prevention of cross-contamination of patients during hydrotherapy treatments; (c) application of topical antimicrobial agents to the burn wound to diminish the colonization and growth of microorganisms on the surface of the burn wound; (d) appropriate use of systemically administered antimicrobial agents to reduce the pressure for selection of resistant microorganisms; (e) early excision and closure of the burn wound; (f) control of hyperglycemia; and (g) management of the hypermetabolic response.

Barrier Techniques

Barrier techniques and other related techniques for preventing cross-contamination between patients in burn care facilities have been shown to be effective in diminishing infection rates in burn patients *(107,108)*. The most important barrier techniques are those used to prevent contact transmission of microorganisms from patient to patient by the contaminated hands and clothing of personnel who provide direct patient care. Use of gloves and an apron made of impermeable material has been shown to decrease cross-contamination of burn patients *(108,109)*. Hands should be washed before donning gloves and after removing gloves. Gloves need not be sterile for routine noninvasive patient care, including dressing changes *(110)*. In order for personnel to practice frequent hand hygiene, there must be enough alcohol gel dispensers and hand-washing sinks appropriately located within the burn care unit to minimize the amount of time required for personnel to practice hand hygiene *(106,107)*. Given the evidence that gram-negative microorganisms may be difficult to remove from the hands of healthcare workers in intensive care units, alcohol gel dispensers and hand-washing agents containing antiseptics effective against gram-negative bacilli should be provided in a suitable dispenser at each sink *(111)*. Hand hygiene should be strictly enforced *(109)*.

Patients should have surveillance cultures performed on admission and at least weekly to identify patients who are colonized with multiply-resistant microorganisms. This will permit early identification of patients colonized with resistant microorganisms so that they may be promptly placed on Contact Precautions *(109,112)*.

Prevention of Cross-Contamination from Inanimate Surfaces and Food

Given the frequent contamination of inanimate surfaces in burn care facilities, attention must be paid to preventing cross-contamination via these surfaces. Each patient should be assigned his or her own stethoscope, blood pressure cuff, box of clean disposable gloves *(110)*, and container(s) of topical antimicrobial agent. Items of equipment that must be shared between patients should be thoroughly cleaned and disinfected between patients. Particular attention should be paid to mattress covers, since two outbreaks in burn units have been related to damaged mattress covers that led to contamination of the mattress foam *(90,91)*. Covers on mattresses should be inspected between patients, and mattresses with damaged covers should not be used for subsequent patients.

A recently discovered source of microorganisms for colonization of burn wound surfaces is that of computer keyboards. Neely et al. *(113)* noted an increase in the number of their patients being colonized with *A. baumannii* and recovered the microorganism from the plastic covers over keyboards on bedside computers. Control measures included having personnel put on gloves before using the computer and having the plastic covers over the keyboards cleaned on a daily basis.

Environmental surfaces in every patient's room and in any treatment rooms need to be thoroughly cleaned and disinfected every day. In the author's hospital, the patient's room surfaces are cleaned by environmental services staff, the equipment attached to patients is cleaned and disinfected by clinical equipment services staff and respiratory therapists clean and disinfect the ventilators. Extensive cleaning and disinfection of the burn patients environment is well supported by scientific studies conducted over the past 15 years (62,*114–116*,117). Although all but one of these studies were not conducted in burn units, they likely apply to burn units since burn patients have extensive burn surfaces heavily colonized with bacteria and burn unit environments are likely contaminated with bacteria from the patients.

Environmental surfaces should be cultured periodically to verify that decontamination is effective. This is particularly important when one or more of the patients is colonized or infected with a microorganism that is highly resistant to antimicrobial agents.

Since raw vegetables have been shown to be a source of *P. aeruginosa* microorganisms that cause burn wound infections *(79)*, burn patients should not be fed raw fruits and vegetables. Attention should also be paid to avoiding contamination of kitchen utensils with raw fruits and vegetables that may later contact uncontaminated foods before they are served to burn patients.

Prevention of Cross-Contamination from Convalescent Patients

McManus et al. *(107)* showed that convalescent burn patients may be a reservoir of microorganisms for cross-contamination and infection of burn patients in the acute phase of care. They caution that patients in nonintensive care areas of burn treatment facilities should be included in microbial surveillance and infection control programs. These patients are the least likely to become infected but may be ignored as a reservoir for patients in intensive care. Consideration might be given to assignment of nursing staff to either the intensive care unit or convalescent care area without crossover of nursing staff between these two patient care areas.

Hydrotherapy

Prevention of cross-contamination in the hydrotherapy treatment area also includes use of barrier techniques but is considered separately from barrier techniques because of the unique risks for cross-contamination encountered in this area. Hydrotherapy is provided in a common area using common equipment and involves exposure to water. Effective decontamination of complex equipment between patients in a limited period may be a major challenge to burn care personnel. Unlike the hands of personnel and inanimate surfaces, water in hydrotherapy tanks contacts the entire burn wound surface. To decrease the contamination of the burn wound surface that occurs with immersion hydrotherapy, many burn care facilities have replaced immersion hydrotherapy with showering patients on a flat surface *(89)*. In two studies, the lowest rates of burn wound colonization and infection occurred when all wound care was done at the patients' bedsides *(86,89)*.

Topical Antimicrobial Agents

Topical antimicrobial agents are applied to the burn wound surface to diminish colonization and multiplication of microorganisms on the surface of the wound. Multiplication of microorganisms on the burn wound surface may lead to invasion of the wound. For burn wounds with unexcised eschar, continued multiplication of microorganisms may lead to invasion of the subeschar space and then to invasion of the subeschar viable tissue and burn wound sepsis.

The most commonly used agents are silver sulfadiazine, mafenide acetate, and silver nitrate. Silver sulfadiazine is the most commonly used agent among these *(118)*. Cerium nitrate–silver sulfadiazine is used in some centers but is not commercially available in the United States *(119)*. Silver sulfadiazine has the fewest side effects of the three most commonly used agents; these side effects include rare crystalluria and methemoglobinemia and common but mild transient leukopenia *(118)*. Since there is an association between the use of the sulfonamide component and kernicterus, it should not be used during pregnancy or in infants *(119)*. Microbial resistance has been reported for all of the topical agents, but resistance to mafenide acetate has been uncommon. Other less commonly used topical agents include sodium hypochlorite (Dakin's solution), bacitracin, neomycin and other aminoglycosides, and mupirocin. Many of these topical antimicrobial agents are also used in pediatric burn patients *(120)*. Although topical antimicrobial agents are frequently effective against microorganisms that are resistant to antibiotics, a recent study indicates that multiply-resistant microorganisms are more resistant to topical antimicrobial agents than are microorganisms that are not multiply resistant to antibiotics *(121)*.

It should be kept in mind that resistance to the topical antimicrobial agent(s) in use in a burn care facility may develop and may be associated with an outbreak of infections caused by the resistant microorganism(s). When confronted with an outbreak, healthcare epidemiologists and IPs should keep in mind the possibility that the epidemic strain may be resistant to the topical antimicrobial agent in use at the time of the outbreak. Testing the outbreak strain for resistance to the topical antimicrobial agent in use prior to onset of the outbreak should be considered *(100,102,103)*.

Systemic Antimicrobial Agents

The extensive use of systemically administered antimicrobial agents in burn care facilities for the treatment of burn wound infections frequently leads to selection of resistant microorganisms.

Continued use of the same antibiotics provides a selective advantage for these microorganisms, and they are able to proliferate and displace the susceptible microorganisms in and on the burn wounds of the patients in the unit. Continued colonization of patients with large numbers of multiply resistant microorganisms with an epidemiologic advantage may lead to an outbreak. Polk et al. *(104)* showed that systemically administered antimicrobial agents penetrate the avascular burn wound, and Mayhall et al. *(105)* observed that susceptible microorganisms in the wound may be rapidly replaced by highly resistant gram-negative bacilli.

Thus, prevention of the emergence of such resistance depends on the appropriate use of antimicrobial agents. Use of antibiotics should be limited to clearly indicated situations, and their selection should be based, when possible, on the results of cultures and antimicrobial susceptibility tests. During outbreaks, control efforts should include examination of prescribing patterns, and appropriate changes and limitations in the use of antibiotics should be implemented. Detection and treatment of superinfection of burn wounds by multiply resistant microorganisms may require culture of burn wound biopsies.

There are currently no data in support of administration of antimicrobial agents for prophylaxis of burn wound infections *(122)*. There is evidence that perioperative antibiotics may prevent bacteremia during burn wound excision *(123)*. However, the authors observed that there were no cases of bacteremia in patients who had wound cleansing or wound excision in the first 10 days post burn and a TBSA burn <40%.

Hypermetabolic Response

Modulation of the hypermetabolic response is important for decreasing infections in burn patients because of its immunosuppressive effects superimposed on the immunosuppression due to the burn injury (124). Early burn wound excision and grafting has had a major effect on reducing the hypermetabolic response. Other important interventions include thermoregulation by increasing the ambient temperatures in the operating rooms and patient rooms, aggressive early enteral feeding, and an early exercise training program. Other effective therapies have been developed for controlling other manifestations of the hypermetabolic response. The latter are well described in a recent review of the topic (124).

Insulin Therapy

Recently published data indicate that intensive insulin therapy has a significant impact in reducing infections, other morbidities, and mortality (125,126). In a study with historical controls, Hemmila et al. studied the control group using standard glucose control methods. In the second year of the study, patients had intensive insulin therapy with a goal to maintain blood glucose levels between 100 and 140 mg/dL. After adjusting for patient risk, the group with intensive glucose therapy had significantly fewer cases of pneumonia, ventilator-associated

pneumonia, bacteremia, urinary tract infections, and burn wound infections (125). A minimum glucose of 70 mg/dL was not associated with an increased risk of mortality. A blood glucose >200 mg/dL was associated with increased risk of complications. In a prospective randomized trial of intensive insulin therapy in severely burned pediatric patients, Jeschke et al. (126) observed that patients in the intensive insulin therapy group had significantly fewer infections. Mortality was 4% in the intensive insulin therapy group and 11% in the control group.

Burn Wound Excision and Closure

Theoretically, early excision and closure of burn wounds should diminish the incidence of burn wound infection. If early excision and closure does reduce the rate of burn wound infections, it could be considered an important modality for prevention of burn wound infections. However, there is no scientific evidence that such treatment of burn wounds does reduce infection rates. Several studies have shown apparent reductions in burn wound infection rates related to early burn wound excision and closure *(127–130)*. However, these studies suffer from a number of flaws such as use of small study populations, absence of randomization, use of historical controls, and failure to define burn wound infection or nonuniformity of definitions. These are important deficits, because many aspects of burn care improved while early excision and wound closure were being introduced.

There have been three randomized prospective studies of early burn wound excision and closure versus nonoperative or exposure treatment published. In a study in which patients with burns of <20% TBSA were randomized to either early excision and grafting or nonoperative treatment, Engrav et al. *(131)* make no mention of burn wound infection in either group. Sørensen et al. *(132)* randomized burn patients with burns of all sizes to either acute excision or exposure treatment. They observed a significantly lower rate of burn wound infections only in patients with burn wounds of 1% to 15% of body surface area. Herndon et al. *(133)* randomized patients with >30% TBSA second-degree and >20% TBSA third-degree burns to early excision or conservative therapy. They noted no difference in the number of septic days between patients treated with early excision and those treated conservatively. They specifically noted that early excision did not prevent septic episodes in large burns.

McManus et al. *(37)* have made the point that if excision of the burn wound is to be cited as the reason for improvement in the survival of burn patients, this conclusion can be validated only by studies that include concurrent controls. They further note that the extent to which the reduction in the rate of burn wound infections can be attributed to burn wound excision is unclear.

In spite of the fact that early burn wound excision has not been scientifically proven to be an effective modality for the prevention of burn wound infections, it is a widely held belief among burn surgeons that early burn wound excision and closure significantly reduces burn wound infection and mortality from thermal injury *(134–138)*. In the absence of randomized clinical trials, two recent publications provide evidence that early excision does reduce the incidence of burn wound infection *(139,140)*.

In the first study, the authors prospectively studied 20 children with burns *(139)*. Patients admitted to the authors' hospital within 24 hours of burn injury had early burn wound excision. Patients transferred from other hospitals at 7 ± 2 days had burn wound excision at the time of admission. At the time of burn excision, specimens were taken from excised burn eschar and excised burn wound bed for quantitative cultures. The 12 patients in the early excision group had less than approximately 10^4 CFU/g of tissue in burn eschar and less than approximately 10^2 CFU/g of tissue in the excised wound bed. For the eight patients in the late excision group, burn eschar had more than approximately 10^5 CFU/g and in some cases had 10^6 CFU/g of tissue. Bacterial counts in the excised wound bed were less than approximately 10^4 CFU/g of tissue.

None of the patients in the early excision group had burn wound infections or graft loss. In the late excision group, three patients had infections and graft loss and two patients had sepsis after surgical excision of the burn wound. High bacterial counts and infection rates were associated with delayed excision ($p < .01$). Although this study was not a controlled trial and differences in potentially important variables between groups of patients could not be controlled for, this study lends further support to the widely held belief that early excision significantly reduces the incidence of burn wound infections.

In the second prospective study, the authors investigated the effects of early versus delayed wound excision on hypermetabolism, catabolism, and sepsis in children with burns *(140)*. The authors measured resting energy expenditure, skeletal muscle protein catabolism, and the concentration of microorganisms in burn wound tissue. Patients were divided into three groups: an early group (arrival within 72 hours of injury), a middle group (arrival 3–10 days after injury), and a late group (arrival at least 10 days after injury). The authors noted increased muscle catabolism in 1 to 3 weeks in the middle and late excision groups compared to the early excision group. Sepsis appeared to increase as excision and aggressive feeding were progressively delayed among the treatment cohorts ($p = .07$). The concentration of microorganisms in quantitative cultures taken 1 week after initiation of surgical and nutritional therapy was progressively increased with treatment delay ($p < .05$). Again, although not a controlled study, the data from this investigation show the benefit of early burn wound excision for reducing burn wound infections and muscle catabolism. In the absence of controlled clinical trials, these two studies provide further evidence that early burn wound excision significantly reduces the incidence of burn wound infections. However, it remains unclear how early burn wound excision and wound closure affect the epidemiology of burn wound infections in burn care facilities.

Currently, the rationale for early burn wound excision and wound closure is based on observed improvements in the altered physiology due to thermal injury (35). The positive effect of burn wound excision amelioration of the abnormal physiologic states such as the hypermetabolic response likely contributes to improvement in the immune response, which may reduce the incidence of burn wound infection.

Selective Decontamination of the Digestive Tract

Selective decontamination of the digestive tract (SDD) has been suggested as a preventive measure for burn wound infections. It is postulated that the elimination of potentially pathogenic microorganisms from the gastrointestinal tracts of burn patients by the oral administration of nonabsorbable antibiotics will diminish colonization and infection of burn wounds.

The first of only two randomized studies included only 27 patients and found no evidence that SDD decreased or delayed the colonization of the burn wound by enteric microorganisms *(141)*. On the contrary, *Pseudomonas* appeared earlier on the wound and in blood cultures of the treated group when compared with the control group. Enteric microorganisms appeared earlier in the blood cultures of the treatment group than in those of the control group. Thirty-three percent of the treated group had complications severe enough that prophylaxis had to be discontinued early. One study of 48 patients was uncontrolled *(142)*, and another study of 91 patients compared two regimens for SDD but contained no placebo control group *(143)*. In a prospective, nonrandomized study, Jarrett et al. *(144)* assigned 20 patients to receive SDD and compared them to 10 patients assigned to receive no SDD. No placebo was used for the control group. All of these patients were also treated in a laminar airflow burn unit using strict reverse isolation techniques. These authors observed a significant delay in burn wound colonization in the SDD group, but no significant differences were found in burn wound biopsies that yielded positive results ($>10^5$ CFU/g of tissue) or in the occurrence of bacteremia, burn wound sepsis, urinary tract infections, pneumonitis, or cellulitis. Mackie et al. *(145)* studied 64 patients in a nonrandomized study wherein 31 patients given SDD were compared with 33 historical control subjects. They noted a marked reduction in positive fecal culture results for Enterobacteriaceae and *Pseudomonas* and a significant decrease in burn wound colonization with gram-negative microorganisms in the SDD group. In addition, they noted significant reductions in respiratory infections and in septicemia. The mortality rate was also significantly lower in the SDD group. The authors did not report any differences in burn wound sepsis. No increase in antimicrobial resistance was observed after introduction of SDD.

The best study on SDD published to date is that of Barret et al. *(146)*, who carried out a prospective, randomized, double-blinded, placebo-controlled clinical trial. The treatment regimen was a suspension containing polymyxin E, tobramycin, and amphotericin B. The suspension was given by a nasogastric tube four times a day for the duration of the study. The placebo solution was Ringer's lactate. Oral nystatin was administered as "swish-and-swallow" to prevent oral and esophageal candidiasis. Routine cultures of sputum, urine, blood, wound, stool, and gastric aspirates were taken on admission and twice weekly during the study. Eleven patients were randomized to the treatment group and 12 to the placebo group. There were no significant differences in infections at various sites and no significant differences in results of cultures between the two groups. There was however a significant difference in the occurrence of diarrhea (82% in the SDD group vs. 17% in the placebo group, $p = .003$).

More recently, de La Cal et al. *(147)* published a randomized, placebo-controlled, double-blind trial on SDD in critically ill burned patients. These investigators observed significantly fewer cases of pneumonia and urinary tract infections in the group that received prophylaxis. There was no difference in the rate of burn wound infections between the groups.

From the available published data, it must be concluded that SDD is unproven as an effective modality for prevention of burn wound infection. Further, the side effects of such therapy may well outweigh any benefit. Finally, data are insufficient to determine whether such prophylaxis will lead to selection of resistant microorganisms in burn care facilities.
