enjoyed popularity among athletes who seek to enhance their performance. Another alkylated androgen, 7 α -methyl-19-nortestosterone, is poorly converted to dihydrotestosterone.

Selective Androgen-Receptor Modulators. Stimulated by the development of selective estrogen receptor modulators, which have estrogenic effects in some tissues but not others (Chapter 40), investigators are attempting to develop selective androgen receptor modulators. Another stimulus is the desirable effects of testosterone in some tissues, such as muscle and bone, and the undesirable effects in other tissues, such as the prostate. Nonsteroidal molecules have been developed that bind to the androgen receptor and have greater effect on muscle and bone than on the prostate. Some of these compounds have begun trials in humans (Narayanan et al., 2008).

Therapeutic Uses of Androgens

Male Hypogonadism. The best established indication for administration of androgens is testosterone deficiency in men (i.e., treatment of male hypogonadism). Any of the testosterone preparations or testosterone esters just described can be used to treat testosterone deficiency. Monitoring treatment for beneficial and deleterious effects differs somewhat in adolescents and the elderly from that in other men.

Monitoring for Efficacy. The goal of administering testosterone to a hypogonadal man is to mimic as closely as possible the normal serum concentration. Therefore, measuring the serum testosterone concentration during treatment is the most important aspect of monitoring testosterone treatment for efficacy. When the serum testosterone concentration is measured depends on the testosterone preparation used (Figure 41-7). Occasional random fluctuations can occur, however, so measurements should be repeated for any dose. When the enanthate or cypionate esters of testosterone are administered once every 2 weeks, the serum testosterone concentration measured midway between doses should be normal; if not, the dosage schedule should be adjusted accordingly. If testosterone deficiency results from testicular disease, as indicated by an elevated serum LH concentration, adequacy of testosterone treatment also can be judged indirectly by the normalization of LH within 2 months of treatment initiation (Findlay et al., 1989; Snyder and Lawrence, 1980).

Normalization of the serum testosterone concentration induces normal virilization in prepubertal boys and restores virilization in men who became hypogonadal as adults. Within a few months, and often sooner, libido, energy, and hematocrit return to normal. Within 6 months, muscle mass increases and fat mass decreases. Bone density, however, continues to increase for 2 years (Snyder et al., 2000).

Monitoring for Deleterious Effects. When testosterone itself is administered, as in one of the transdermal preparations or as an ester that is hydrolyzed to testosterone, it has no “side effects” (i.e., no effects that endogenously secreted testosterone does not have), as long as the dose is not excessive. Modified testosterone compounds, such as the 17 α -alkylated androgens, do have undesirable effects even when dosages are targeted at physiological replacement. Some of these

undesirable effects occur shortly after testosterone administration is initiated, whereas others usually do not occur until administration has been continued for many years. Raising the serum testosterone concentration from prepubertal or mid-pubertal levels to that of an adult male at any age can result in undesirable effects similar to those that occur during puberty, including acne, gynecomastia, and more aggressive sexual behavior. Physiological amounts of testosterone do not appear to affect serum lipids or apolipoproteins. Replacement of physiological levels of testosterone occasionally may have undesirable effects in the presence of concomitant illnesses. For example, stimulation of erythropoiesis would increase the hematocrit from subnormal to normal in a healthy man but would raise the hematocrit above normal in a man with a predisposition to erythrocytosis, such as in chronic pulmonary disease. Similarly, the mild degree of sodium and water retention with testosterone replacement would have no clinical effect in a healthy man but would exacerbate preexisting congestive heart failure. If the testosterone dose is excessive, erythrocytosis and, uncommonly, salt and water retention and peripheral edema occur even in men who have no predisposition to these conditions. When a man's serum testosterone concentration has been in the normal adult male range for many years, whether from endogenous secretion or exogenous administration, and he is >40 years of age, he is subject to certain testosterone-dependent diseases, including benign prostatic hyperplasia and prostate cancer.

The principal adverse effects of the 17α -alkylated androgens are hepatic, including cholestasis and, uncommonly, peliosis hepatis, blood-filled hepatic cysts. Hepatocellular cancer has been reported rarely. Case reports of cancer regression after androgen cessation suggest a possible causal role, but an etiologic link is unproven. The 17α -alkylated androgens, especially in large amounts, may lower serum high-density lipoprotein cholesterol.

Monitoring at the Anticipated Time of Puberty. Administration of testosterone to testosterone-deficient boys at the anticipated time of puberty should be guided by the considerations just described but also by the fact that testosterone accelerates epiphyseal maturation, leading initially to a growth spurt but then to epiphyseal closure and permanent cessation of linear growth. Consequently, the height and growth-hormone status of the boy must be considered. Boys who are short because of growth-hormone deficiency should be treated with growth hormone before their hypogonadism is treated with testosterone.

Male Senescence. Preliminary evidence suggests that increasing the serum testosterone concentration of men whose serum levels are subnormal for no reason other than their age will increase their bone mineral density and lean mass and decrease their fat mass (Amory et al., 2004; Kenny et al., 2001; Snyder et al., 1999a, 1999b). It is entirely uncertain at this time, however, if such treatment will worsen benign prostatic hyperplasia or increase the incidence of clinically detectable prostate cancer.

Female Hypogonadism. Little data exist regarding whether increasing the serum testosterone concentrations of women whose serum testosterone concentrations are below normal will improve their libido,

energy, muscle mass and strength, or bone mineral density. In a study of women with low serum testosterone concentrations due to panhypopituitarism, increasing the testosterone concentration to normal was associated with small increases in bone mineral density, fat-free mass, and sexual function compared to placebo (Miller et al., 2006).

Enhancement of Athletic Performance. Some athletes take drugs, including androgens, to attempt to improve their performance. Because androgens for this purpose usually are taken surreptitiously, information about their possible effects is not as complete as that for androgens taken for treatment of male hypogonadism. Citing potentially serious health risks, the FDA has recommended against the use of body-building products that are marketed as containing steroids or steroid-like substances (FDA, 2009).

Kinds of Androgens Used. Virtually all androgens produced for human or veterinary purposes have been taken by athletes. When use by athletes began more than two decades ago, 17α -alkylated androgens and other compounds that were thought to have greater anabolic effects than androgen effects relative to testosterone (so-called anabolic steroids) were used most commonly. Because these compounds can be detected readily by organizations that govern athletic competitions, preparations that increase the serum concentration of testosterone itself, such as the testosterone esters or hCG, have increased in popularity. Testosterone precursors, such as androstenedione and dehydroepiandrosterone (DHEA), also have increased in popularity recently because they are treated as nutritional supplements and thus are not regulated by national governments or athletic organizations.

A new development in use of androgens by athletes is represented by tetrahydrogestrinone (THG), a potent androgen that appears to have been designed and synthesized in order to avoid detection by antidoping laboratories on the basis of its novel structure (Figure 41-6) and rapid catabolism.

Efficacy. There have been few controlled studies of the effects of pharmacological doses of androgens on muscle strength. In one controlled study, 43 normal young men were randomized to one of four groups: strength training \pm 600 mg of testosterone enanthate once a week (more than six times the replacement dose); or no exercise \pm testosterone. The men who received testosterone experienced an increase in muscle strength compared to those who received placebo, and the men who exercised simultaneously experienced even greater increases (Bhasin et al., 1996). In another study, normal young men were treated with a GnRH analog to reduce endogenous testosterone secretion severely and in a random blinded fashion, weekly doses of testosterone enanthate from 25 mg to 600 mg. There was a dose-dependent effect of testosterone on muscle strength (Bhasin et al., 2001).

In a double-blind study of androstenedione, men who took 100 mg three times a day for 8 weeks did not experience an increase in muscle strength compared to men who took placebo. Failure of this treatment to increase muscle strength is not surprising because it also did not increase the mean serum testosterone concentration (King et al., 1999).

Side Effects. All androgens suppress gonadotropin secretion when taken in high doses and thereby suppress endogenous testicular function. This decreases endogenous testosterone and sperm production, resulting in diminished fertility. If administration continues for many years, testicular size may diminish. Testosterone and sperm production usually return to normal within a few months of discontinuation but may take longer. High doses of androgens also cause erythrocytosis (Drinka et al., 1995).

When administered in high doses, androgens that can be converted to estrogens, such as testosterone itself, cause gynecomastia. Androgens whose A ring has been modified so that it cannot be aromatized, such as dihydrotestosterone, do not cause gynecomastia even in high doses.

The 17 α -alkylated androgens are the only androgens that cause hepatotoxicity. These androgens also appear to be much more likely than others, when administered in high doses, to affect serum lipid concentrations, specifically to decrease high-density lipoprotein (HDL) cholesterol and increase low-density lipoprotein (LDL) cholesterol. Other side effects have been suggested by many anecdotes but have not been confirmed, including psychological disorders and sudden death due to cardiac disease, possibly related to changes in lipids or to coagulation activation.

Certain side effects occur specifically in women and children. Both experience virilization, including facial and body hirsutism, temporal hair recession in a male pattern, and acne. Boys experience phallic enlargement, and women experience clitoral enlargement. Boys and girls whose epiphyses have not yet closed experience premature closure and stunting of linear growth.

Detection. An androgen other than testosterone can be detected by gas chromatography and mass spectroscopy if the athlete is still taking it when he is tested. Exogenous testosterone itself can be detected by one of two methods. One is the T/E ratio, the ratio of testosterone glucuronide to its endogenous epimer, epitestosterone glucuronide, in urine. Administration of exogenous testosterone suppresses secretion of both testosterone and epitestosterone and replaces them with only testosterone, so the T/E ratio is higher than normal. This technique is limited, however, by heterozygosity in the UDP-glucuronosyl transferase that converts testosterone to testosterone glucuronide. An athlete who has a deletion of one or both copies of the gene coding for this enzyme and who takes exogenous testosterone will have a much lower T/E ratio than one who have both copies (Schulze, 2008).

A second technique for detecting administration of exogenous testosterone employs gas chromatography-combustion-isotope ratio mass spectrometry to detect the presence of ^{13}C and ^{12}C compounds. Urinary steroids with a low $^{13}\text{C}/^{12}\text{C}$ ratio are likely to have originated from pharmaceutical sources as opposed to endogenous physiological sources (Aguilera et al., 2001).

Male Contraception. Androgens inhibit LH secretion by the pituitary and thereby decrease endogenous testosterone production. Based on these observations, scientists have tried for more than a decade to use androgens, either alone or in combination with other drugs, as a male contraceptive. Because the concentration of testosterone within the testes, ~100 times that in the peripheral circulation, is necessary for spermatogenesis, suppression of endogenous testosterone production greatly diminishes spermatogenesis. Initial use of testosterone alone, however, required supraphysiologic doses, and addition of GnRH antagonists required daily injections. A more

promising approach is the combination of a progestin with a physiological dose of testosterone to suppress LH secretion and spermatogenesis but provide a normal serum testosterone concentration (Bebb et al., 1996). One trial employed injections of testosterone undecanoate with a depot progestin every 2 months (Gu et al., 2004). Another androgen being tested as part of a male contraceptive regimen is 7 α -methyl-19-nortestosterone, a synthetic androgen that cannot be metabolized to dihydrotestosterone (Cummings et al., 1998).

Catabolic and Wasting States. Testosterone, because of its anabolic effects, has been used in attempts to ameliorate catabolic and muscle-wasting states, but this has not been generally effective. One exception is in the treatment of muscle wasting associated with acquired immunodeficiency syndrome (AIDS), which often is accompanied by hypogonadism. Treatment of men with AIDS-related muscle wasting and subnormal serum testosterone concentrations increases their muscle mass and strength (Bhasin et al., 2000).

Angioedema. Chronic androgen treatment of patients with angioedema effectively prevents attacks. The disease is caused by hereditary impairment of C1-esterase inhibitor or acquired development of antibodies against it (Cicardi et al., 1998). The 17 α -alkylated androgens, such as stanozolol and danazol, stimulate the hepatic synthesis of the esterase inhibitor. In women, virilization is a potential side effect. In children, virilization and premature epiphyseal closure prevent chronic use of androgens for prophylaxis, although they are used occasionally to treat acute episodes. As an alternative to prophylactic androgens, concentrated C1-esterase inhibitor derived from human plasma (CINRYZE) may be used for protection in patients with hereditary angioedema.

Blood Dyscrasias. Androgens once were employed to attempt to stimulate erythropoiesis in patients with anemias of various etiologies, but the availability of erythropoietin has supplanted that use. Androgens, such as danazol, still are used occasionally as adjunctive treatment for hemolytic anemia and idiopathic thrombocytopenic purpura that are refractory to first-line agents.

ANTI-ANDROGENS

Because some effects of androgens are undesirable, at least under certain circumstances, agents have been developed specifically to inhibit androgen synthesis or effects. Other drugs, originally developed for different purposes, have been accidentally found to be antiandrogens and now are used intentionally for this indication. See Chapter 63 for a more detailed discussion of androgen deprivation therapy for prostate cancer.

Inhibitors of Testosterone Secretion. Analogs of GnRH effectively inhibit testosterone secretion by inhibiting LH secretion. GnRH “superactive” analogs, given repeatedly, downregulate the GnRH receptor and are available for treatment of prostate cancer. An extended-release form of the GnRH antagonist, abarelix (PLENAXIS; no longer available in the U.S.) is used for treating prostate cancer (Trachtenberg et al., 2002). Because it

does not transiently increase sex steroid production, this preparation may be especially useful in prostate cancer patients in whom any stimulus to tumor growth might have serious adverse consequences, such as patients with metastases impinging on the spinal cord, in whom further tumor growth could cause paralysis.

Some antifungal drugs of the imidazole family, such as ketoconazole (Chapter 57), inhibit CYPs and thereby block the synthesis of steroid hormones, including testosterone and cortisol. Because they may induce adrenal insufficiency and are associated with hepatotoxicity, these drugs generally are not used to inhibit androgen synthesis but sometimes are employed in cases of glucocorticoid excess (Chapter 42).

Inhibitors of Androgen Action

These drugs inhibit the binding of androgens to the androgen receptor or inhibit 5α -reductase.

Androgen Receptor Antagonists.

Flutamide, Bicalutamide, and Nilutamide. These relatively potent androgen receptor antagonists have limited efficacy when used alone because the increased LH secretion stimulates higher serum testosterone concentrations. They are used primarily in conjunction with a GnRH analog in the treatment of metastatic prostate cancer (Chapter 63). In this situation, they block the action of adrenal androgens, which are not inhibited by GnRH analogs. Flutamide also has been used to treat hirsutism in women, and it appears to be as effective as other treatments for this purpose (Venturoli et al., 1999); however, its association with hepatotoxicity warrants caution against its use for this cosmetic purpose.

Flutamide

Bicalutamide

Nilutamide

Spirolactone. *Spirolactone* (ALDACTONE; Chapter 25) is an inhibitor of aldosterone that also is a weak inhibitor of the androgen receptor and a weak inhibitor of testosterone synthesis. When the agent is used to treat fluid retention or hypertension in men, gynecomastia is a common side effect (Caminos-Torres et al., 1977). In part because of this adverse effect, the selective mineralocorticoid receptor antagonist eplerenone (INSARA) was developed. Spirolactone can be used in women to treat hirsutism; it is moderately effective (Cumming et al., 1982) but may cause irregular menses.

Cyproterone Acetate. Cyproterone acetate is a progestin and a weak antiandrogen by virtue of binding to the androgen receptor. It is moderately effective in reducing hirsutism alone or in combination with an oral contraceptive (Venturoli et al., 1999) but is not approved for use in the U.S.

5α -Reductase Inhibitors. Finasteride (PROSCAR) is an antagonist of 5α -reductase, especially the type II; dutasteride (AVODART) is an antagonist of both type I and type II. Both agents block the conversion of testosterone to dihydrotestosterone, especially in the male external genitalia. These drugs were developed to treat benign prostatic hyperplasia, and they are approved in the U.S. and many other countries for this purpose. When they are administered to men with moderately severe symptoms due to obstruction of urinary tract outflow, serum and prostatic concentrations of dihydrotestosterone decrease, prostatic volume decreases, and urine flow rate increases (McConnell et al., 1998). Impotence is a well-documented, albeit infrequent, side effect of this use, although the mechanism is not understood. Gynecomastia is an even less common side effect (Thompson, 2003).

Finasteride also is approved for use in the treatment of male pattern baldness under the trade name PROPECIA, even though that effect is presumably mediated via the type I enzyme. It appears to be as effective as flutamide and the combination of estrogen and cyproterone in the treatment of hirsutism (Venturoli et al., 1999).

Finasteride

CLINICAL SUMMARY

Testosterone is the principal circulating androgen in men. The varied effects of testosterone are due to its ability to act by at least three mechanisms: by binding to the androgen receptor; by conversion in certain tissues

to dihydrotestosterone, which also binds to the androgen receptor; and by conversion to estradiol, which binds to the estrogen receptor. Consequences of testosterone deficiency depend on whether the deficiency occurs in utero, before puberty, or in adulthood.

Testosterone delivery systems are designed to avoid the rapid hepatic catabolism that occurs when native testosterone is ingested orally. Available delivery systems include injectable esters of testosterone, implants, and several transdermal preparations. The major therapeutic indication for testosterone treatment is male hypogonadism. Treatment should be monitored for efficacy by measurement of the serum testosterone concentration and for deleterious effects by evaluating for obstruction to urine flow due to benign prostatic hyperplasia, for prostate cancer, and for erythrocytosis.

ACTH, Adrenal Steroids, and Pharmacology of the Adrenal Cortex

Bernard P. Schimmer
and John W. Funder

Adrenocorticotrophic hormone (ACTH, corticotropin) and the steroid hormone products of the adrenal cortex are considered together because the major physiological and pharmacological effects of ACTH result from its action to increase the circulating levels of adrenocortical steroids. Synthetic derivatives of ACTH are used principally in the diagnostic assessment of adrenocortical function. Because all known therapeutic effects of ACTH can be achieved with corticosteroids, synthetic steroid hormones generally are used therapeutically instead of ACTH.

Corticosteroids and their biologically active synthetic derivatives differ in their metabolic (glucocorticoid) and electrolyte-regulating (mineralocorticoid) activities. These agents are employed at physiological doses for replacement therapy when endogenous production is impaired. In addition, glucocorticoids potently suppress inflammation, and their use in a variety of inflammatory and autoimmune diseases makes them among the most frequently prescribed classes of drugs. Because glucocorticoids exert effects on almost every organ system, the clinical use of and withdrawal from corticosteroids are complicated by a number of serious side effects, some of which are life threatening. Therefore, the decision to institute therapy with systemic corticosteroids always requires careful consideration of the relative risks and benefits in each patient.

Agents that inhibit steps in the steroidogenic pathway and thus alter the biosynthesis of adrenocortical steroids are discussed in this chapter, as are synthetic

steroids that inhibit glucocorticoid action. Agents that inhibit the action of aldosterone are presented in Chapter 25; agents used to inhibit growth of steroid-dependent tumors are discussed in Chapters 60-62.

History. Addison described fatal outcomes in patients with adrenal destruction in a presentation to the South London Medical Society in 1849. These studies were soon extended when Brown-Séquard demonstrated that bilateral adrenalectomy was fatal in laboratory animals. It later was shown that the adrenal cortex, rather than the medulla, was essential for survival in these ablation experiments and that the adrenal cortex regulated both carbohydrate metabolism and fluid and electrolyte balance. The isolation and identification of the adrenal steroids by Reichstein and Kendall and the effects of these compounds on carbohydrate metabolism (hence the term *glucocorticoids*) culminated with the synthesis of *cortisone*, the first pharmacologically effective glucocorticoid to become readily available. Subsequently, Tait and colleagues isolated and characterized a distinct corticosteroid, *aldosterone*, which potently affected fluid and electrolyte balance and therefore was termed a *mineralocorticoid*. The isolation of distinct corticosteroids that regulated carbohydrate metabolism or fluid and electrolyte balance led to the concept that the adrenal cortex comprises two largely independent units: an outer zone that produces mineralocorticoids and an inner region that synthesizes glucocorticoids and androgen precursors.

Studies of adrenocortical steroids also played a key part in delineating the role of the anterior pituitary in endocrine function. As early as 1912, Cushing described patients with hypercorticism, and later he recognized that pituitary basophilism caused the adrenal overactivity, thus establishing the link between the anterior pituitary and adrenal function. These studies led to the purification of ACTH and the determination of its chemical structure. ACTH was further shown to be essential for maintaining the structural integrity and steroidogenic capacity of the inner cortical zones. Harris established

the role of the hypothalamus in pituitary control and postulated that a soluble factor produced by the hypothalamus activated ACTH release. These investigations culminated with the determination of the structure of corticotropin-releasing hormone (CRH), a hypothalamic peptide that, together with arginine vasopressin, regulates secretion of ACTH from the pituitary.

Shortly after synthetic cortisone became available, Hench and colleagues demonstrated its dramatic effect in the treatment of rheumatoid arthritis. These studies set the stage for the clinical use of corticosteroids in a wide variety of diseases, as discussed in this chapter.

ADRENOCORTICOTROPIC HORMONE (ACTH; CORTICOTROPIN)

As summarized in Figure 42–1, ACTH is synthesized as part of a larger precursor protein, pro-opiomelanocortin (POMC), and is liberated from the precursor through proteolytic cleavage at dibasic residues by the serine endoprotease, prohormone convertase 1 (also known as prohormone convertase 3). The importance of this enzyme in POMC processing is best illustrated in a rare group of patients with prohormone convertase 1 mutations who present with impaired POMC processing, secondary hypocortisolism, childhood obesity, hypogonadotropic hypogonadism, diabetes, and neonatal onset enteropathy (Farooqi et al., 2007). A number of other biologically important peptides, including

endorphins, lipotropins, and the melanocyte-stimulating hormones (MSH), also are produced by proteolytic processing of the same POMC precursor (Chapter 18).

Human ACTH is a peptide of 39 amino acids (Figure 42–1). Whereas removal of a single amino acid at the amino terminus considerably impairs biological activity, a number of amino acids can be removed from the carboxyl-terminal end without a marked effect. The structure–activity relationships of ACTH have been studied extensively, and it is believed that a stretch of four basic amino acids at positions 15–18 is an important determinant of high-affinity binding to the ACTH receptor, whereas amino acids 6–10 are important for receptor activation.

The actions of ACTH and the other melanocortins liberated from POMC are mediated by their specific interactions with five melanocortin receptor (MC1–5R) subtypes comprising a distinct subfamily of G protein-coupled receptors. The well-known effects of MSH on pigmentation result from interactions with the MC1R on melanocytes. MC1Rs also are found on cells of the immune system and are thought to mediate the anti-inflammatory effects of α -MSH in experimental models of inflammation. ACTH, which is identical to α -MSH in its first 13 amino acids (Ser-Tyr-Ser-Met-Glu-His-Phe-Arg-Trp-Gly-Lys-Pro-Val), exerts its effects on the adrenal cortex through the MC2R. The affinity of ACTH for the MC1R is much lower than for the MC2R; however, under pathological conditions in which ACTH levels are persistently elevated, such as primary adrenal insufficiency, ACTH also can signal through the MC1R and cause hyperpigmentation. Recent studies have defined key roles for β -MSH (Lee et al., 2006) and possibly other melanocortins acting via the MC4R (Farooqi et al., 2003) and MC3R (Mencarelli et al., 2008) in the hypothalamic regulation of appetite and body weight, and they therefore are the subject of considerable investigation as possible targets for drugs that affect appetite. The role of MC5R is less well defined, but studies in rodents suggest that MSH triggers aggressive, pheromone-related behavior via the MC5R (Morgan and Cone, 2006).

Actions on the Adrenal Cortex. Acting via MC2R, ACTH stimulates the adrenal cortex to secrete glucocorticoids, mineralocorticoids, and the androgen precursor dehydroepiandrosterone (DHEA) that can be converted peripherally into more potent androgens. The adrenal cortex histologically and functionally can be separated into three zones that produce different steroid products under different regulatory influences. The outer zona glomerulosa secretes the mineralocorticoid aldosterone, the middle zona fasciculata secretes the glucocorticoid cortisol, and the inner zona reticularis secretes DHEA (Figure 42–2) and its sulfated derivative DHEAS, which circulates at concentrations 1000 times greater than DHEA. DHEAS can be converted to DHEA in the periphery by DHEA sulfatase.

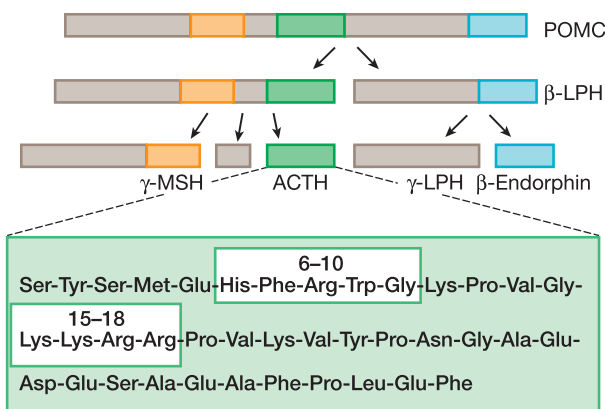

Figure 42–1. Processing of pro-opiomelanocortin to adrenocorticotrophic hormone and the sequence of adrenocorticotrophic hormone. The pathway by which pro-opiomelanocortin (POMC) is converted to adrenocorticotrophic hormone (ACTH) and other peptides in the anterior pituitary is depicted. The amino acid sequence of human ACTH is shown. The light blue boxes behind the ACTH structure indicate regions identified as important for steroidogenic activity (residues 6–10) and binding to the ACTH receptor (15–18). α -Melanocyte-stimulating hormone also derives from the POMC precursor and contains the first 13 residues of ACTH. LPH, lipotropin; MSH, melanocyte-stimulating hormone.

Figure 42–2. The adrenal cortex contains three anatomically and functionally distinct compartments. The major functional compartments of the adrenal cortex are shown, along with the steroidogenic enzymes that determine the unique profiles of corticosteroid products. Also shown are the predominant physiological regulators of steroid production: angiotensin II (Ang II) and K⁺ for the zona glomerulosa and ACTH for the zona fasciculata. The physiological regulator(s) of dehydroepiandrosterone (DHEA) production by the zona reticularis are not known, although ACTH acutely increases DHEA biosynthesis.

Cells of the outer zone have receptors for angiotensin II and express aldosterone synthase (CYP11B2), an enzyme that catalyzes the terminal reactions in mineralocorticoid biosynthesis. Although ACTH acutely stimulates mineralocorticoid production by the zona glomerulosa, this zone is regulated predominantly by angiotensin II and extracellular K⁺ (Chapter 25) and does not undergo atrophy in the absence of ongoing stimulation by the pituitary gland. In the setting of persistently elevated ACTH, mineralocorticoid levels initially increase and then return to normal (a phenomenon termed *ACTH escape*).

In contrast, cells of the zona fasciculata have fewer receptors for angiotensin II and express two enzymes, steroid 17 α -hydroxylase (CYP17) and 11 β -hydroxylase (CYP11B1), that catalyze the production of glucocorticoids. In the zona reticularis, CYP17 carries out an additional C17-20 lyase reaction that converts C21 corticosteroids to C19 androgen precursors.

In the absence of the anterior pituitary, the inner zones of the cortex atrophy, and the production of glucocorticoids and adrenal androgens is markedly impaired.

Persistently elevated levels of ACTH, due either to repeated administration of large doses of ACTH or to excessive endogenous production, induce hypertrophy and hyperplasia of the inner zones of the adrenal cortex, with overproduction of cortisol and adrenal androgens. Adrenal hyperplasia is most marked in congenital disorders of steroidogenesis, in which ACTH levels are continuously elevated as a secondary response to impaired cortisol biosynthesis. There is some debate regarding the relative roles of ACTH versus other POMC-derived peptides in stimulating adrenal growth, but the essential role of the anterior pituitary in maintaining the integrity of the zona fasciculata is indisputable.

Mechanism of Action. ACTH stimulates the synthesis and release of adrenocortical hormones. Because specific mechanisms for steroid hormone secretion have not been defined and steroids do not accumulate appreciably in the gland, it is believed that the actions of ACTH to increase steroid hormone production are mediated predominantly at the level of *de novo* biosynthesis.

ACTH, binding to MC2R (a GPCR), activates the G_s-adenylyl cyclase-cyclic AMP-PKA pathway. Cyclic AMP is an obligatory second messenger for most, if not all, effects of ACTH on steroidogenesis. Mutations in MC2R account for ~25% of the cases of familial glucocorticoid deficiency, a rare syndrome of familial resistance to ACTH (Clark et al., 2005).

Temporally, the response of adrenocortical cells to ACTH has two phases. The acute phase, which occurs within seconds to minutes, largely reflects increased supply of cholesterol substrate to the steroidogenic enzymes. The chronic phase, which occurs over hours to days, results largely from increased transcription of the steroidogenic enzymes. A summary of the pathways of adrenal steroid biosynthesis and the structures of the major steroid intermediates and products of the human adrenal cortex are shown in Figure 42–3. The rate-limiting step in steroid hormone production is the conversion of cholesterol to pregnenolone, a reaction catalyzed by CYP11A1, the cholesterol side-chain cleavage enzyme. Most of the enzymes required for steroid hormone biosynthesis, including CYP11A1, are members of the cytochrome P450 superfamily of mixed-function oxidases that play important roles in the metabolism of xenobiotics such as drugs and environmental pollutants, as well as in the biosynthesis of such endogenous compounds as steroid hormones, vitamin D, bile acids, fatty acids, prostaglandins, and biogenic amines (Chapter 6). The rate-limiting components in this reaction regulate the mobilization of substrate cholesterol and its delivery to CYP11A1 in the inner mitochondrial matrix.

To ensure an adequate supply of substrate for steroidogenesis, the adrenal cortex uses multiple sources of cholesterol (Kraemer, 2007), including:

- circulating cholesterol and cholesterol esters taken up via the low-density lipoprotein and high-density lipoprotein receptor pathways
- endogenous cholesterol liberated from cholesterol ester stores via activation of cholesterol esterase
- endogenous cholesterol from *de novo* biosynthesis.

The mechanisms by which ACTH stimulates the translocation of cholesterol to the inner mitochondrial matrix are not fully defined. A 37,000-Da phosphoprotein—designated the steroidogenic acute regulatory protein—clearly plays essential roles in cholesterol delivery. Mutations in the gene encoding this phosphoprotein are found in patients with congenital lipoid adrenal hyperplasia, a rare congenital disorder in which adrenal cells become engorged with cholesterol deposits secondary to an inability to synthesize any steroid hormones (Stocco, 2002). An important component of the trophic effect of ACTH is the enhanced transcription of genes that encode the individual steroidogenic enzymes, with associated

Figure 42–3. Pathways of corticosteroid biosynthesis. The steroidogenic pathways used in the biosynthesis of the corticosteroids are shown, along with the structures of the intermediates and products. The pathways unique to the zona glomerulosa are shown in orange box, whereas those that occur in the inner zona fasciculata and zona reticularis are shown in gray box. The zona reticularis does not express 3 β -HSD and thus preferentially synthesizes DHEA. CYP11A1, cholesterol side-chain cleavage enzyme; 3 β -HSD, 3 β -hydroxysteroid dehydrogenase; CYP17, steroid 17 α -hydroxylase; CYP21, steroid 21-hydroxylase; CYP11B1, steroid 11 β -hydroxylase; CYP11B2, aldosterone synthase.

increases in the steroidogenic capacity of the gland. Myriad transcriptional regulators participate in the induction of steroid hydroxylases by ACTH. Among these is the nuclear receptor NR5A1 (steroidogenic factor 1), a transcription factor required for the development of the adrenal cortex and for the expression of most of the steroidogenic enzymes (Parker et al., 2002).

Extra-Adrenal Effects of ACTH. In large doses, ACTH causes a number of metabolic changes in adrenalectomized animals, including ketosis, lipolysis, hypoglycemia (immediately after treatment), and resistance to insulin (later after treatment). Given the large doses of ACTH required, the physiological significance of these extra-adrenal effects is questionable. ACTH also reportedly improves learning in experimental animals, an effect postulated to be mediated via distinct receptors in the CNS.

Regulation of ACTH Secretion.

Hypothalamic-Pituitary-Adrenal Axis. The rate of glucocorticoid secretion is determined by fluctuations in the release of ACTH by the pituitary corticotropes. These corticotropes are regulated by corticotropin-releasing hormone (CRH) and arginine vasopressin (AVP), peptide hormones released by specialized neurons of the endocrine hypothalamus, which, in turn, are regulated by several neurotransmitters from the CNS. These three organs collectively are referred to as the hypothalamic-pituitary-adrenal (HPA) axis, an integrated system that maintains appropriate levels of glucocorticoids (Figure 42–4). The three characteristic modes of regulation of the HPA axis are diurnal rhythm in basal steroidogenesis, negative feedback regulation by adrenal corticosteroids, and marked increases in steroidogenesis in response to stress. The diurnal rhythm is entrained by higher neuronal centers in response to sleep-wake cycles, such that levels of ACTH peak in the early morning hours, causing the circulating glucocorticoid levels to peak at ~8 A.M. As discussed later, negative feedback regulation occurs at multiple levels of the HPA axis and is the major mechanism that maintains circulating glucocorticoid levels in the appropriate range. Stress can override the normal negative feedback control mechanisms, leading to marked increases in plasma concentrations of glucocorticoids.

Following release into the hypophyseal plexus, CRH is transported via this portal system to the anterior pituitary, where it binds to specific membrane receptors on corticotropes. Upon CRH binding, the CRH receptor activates the G_s -adenylyl cyclase–cyclic AMP pathway within corticotropes, ultimately stimulating both ACTH biosynthesis and secretion. CRH and CRH-related peptides called urocortins also are produced at other sites, including the amygdala

Figure 42–4. Overview of the hypothalamic-pituitary-adrenal (HPA) axis and the immune-inflammatory network. Also shown are inputs from higher neuronal centers that regulate CRH secretion. + indicates a positive regulator, – indicates a negative regulator, + and – indicates a mixed effect, as for NE (norepinephrine). In addition, arginine vasopressin stimulates release of ACTH from corticotropes.

and hindbrain, gut, skin, adrenal gland, adipose tissue, placenta, and additional sites in the periphery. The classical CRH receptor, now designated CRF_1 receptor, belongs to the class II family of G protein-coupled receptors that includes receptors for calcitonin, parathyroid hormone, growth hormone-releasing hormone, secretin, glucagon, and glucagon-like peptide. A second CRH receptor, designated CRF_2 receptor, shares 70% homology at the amino acid level and is distinguished from the CRF_1 receptor in its binding specificities for CRH and the urocortins. In mice, the CRF_2 receptor opposes those effects mediated by the CRF_1 receptor thereby, providing a highly complex neural network that modulates the adaptive response to stress (Bale and Vale, 2004). The finding that the HPA axis often is altered in patients suffering from major depressive disorders illustrates the complex relationships between stress and mood and has stimulated considerable interest in the possible use of CRH antagonists in disorders such as anxiety and depression (Holsboer and Ising, 2008).

Arginine Vasopressin. Arginine vasopressin (AVP) also acts as a secretagogue for corticotropes, significantly potentiating the effects of CRH. Animal studies suggest that the potentiation of CRH action by AVP probably contributes to the full magnitude of the stress response *in vivo*. Like CRH, AVP is produced in the parvocellular neurons of the paraventricular nucleus and secreted into the pituitary plexus from the median eminence. After binding to V_{1b} receptors, AVP activates the

1214 G_q -PLC-IP₃-Ca²⁺ pathway to enhance the release of ACTH. In contrast to CRH, AVP apparently does not increase ACTH synthesis (Surget and Belzung, 2008).

Negative Feedback of Glucocorticoids. Glucocorticoids inhibit ACTH secretion via direct and indirect actions on CRH neurons to decrease CRH mRNA levels and CRH release and via direct effects on corticotropes. The indirect inhibitory effects on CRH neurons appear to be mediated by specific corticosteroid receptors in the hippocampus. At lower cortisol levels, the mineralocorticoid receptor (MR), which has a higher affinity for glucocorticoids than classical glucocorticoid receptors (GR), is the major receptor species occupied. As glucocorticoid concentrations rise and saturate the MR, the GR becomes increasingly occupied. Both the MR and GR apparently control the basal activity of the HPA axis, whereas feedback inhibition by glucocorticoids predominantly involves the GR.

In the pituitary, glucocorticoids act through the GR to inhibit the release of ACTH from corticotropes and the expression of POMC. These effects are both rapid (occurring within seconds to minutes) and delayed (requiring hours and involving changes in gene transcription mediated through the GR).

The Stress Response. Stress overcomes negative feedback regulation of the HPA axis, leading to a marked rise in corticosteroid production. Examples of stress signals include injury, hemorrhage, severe infection, major surgery, hypoglycemia, cold, pain, and fear. Although the precise mechanisms that underlie this stress response and the essential actions played by corticosteroids are not fully defined, it is clear that their increased secretion is vital to maintain homeostasis in these stressful settings. As discussed later, complex interactions between the HPA axis and the immune system may be a fundamental physiological component of this stress response (Elenkov and Chrousos, 2006).

Assays for ACTH. Initially, ACTH levels were assessed by bioassays that measured induced steroid production or the depletion of adrenal ascorbic acid. Immunochemiluminescent assays that use two separate antibodies directed at distinct epitopes on the ACTH molecule now are widely available. These assays increase considerably the ability to differentiate patients with primary hypoadrenalism due to intrinsic adrenal disease, who have high ACTH levels due to the loss of normal glucocorticoid feedback inhibition, from those with secondary forms of hypoadrenalism, due to low ACTH levels resulting from hypothalamic or pituitary disorders. The immunochemiluminescent ACTH assays also are useful in differentiating between ACTH-dependent and ACTH-independent forms of hypercorticism: High ACTH levels are seen when the hypercorticism results from pituitary adenomas (e.g., Cushing's disease) or nonpituitary tumors that secrete ACTH (e.g., the syndrome of ectopic ACTH), whereas

low ACTH levels are seen in patients with excessive glucocorticoid production due to primary adrenal disorders. Despite their considerable utility, one problem with the immunoassays for ACTH is that their specificity for intact ACTH can lead to falsely low values in patients with ectopic ACTH secretion; these tumors can secrete aberrantly processed forms of ACTH that have biological activity but do not react in the antibody assays.

Therapeutic Uses and Diagnostic Applications of ACTH. There are anecdotal reports that selected conditions respond better to ACTH than to corticosteroids (e.g., multiple sclerosis), and some clinicians continue to advocate therapy with ACTH. Despite this, ACTH currently has only limited utility as a therapeutic agent. Therapy with ACTH is less predictable and less convenient than therapy with corticosteroids. In addition, ACTH stimulates mineralocorticoid and adrenal androgen secretion and may therefore cause acute retention of salt and water, as well as virilization. Although ACTH and the corticosteroids are not pharmacologically equivalent, all proven therapeutic effects of ACTH can be achieved with appropriate doses of corticosteroids with a lower risk of side effects.

Testing the Integrity of the HPA Axis. The major clinical use of ACTH is in testing the integrity of the HPA axis. Other tests used to assess the HPA axis include the insulin tolerance test (Chapter 38) and the metyrapone test (discussed later in this chapter). Cosyntropin (CORTROSYN, SYNACTHEN) is a synthetic peptide that corresponds to residues 1-24 of human ACTH. At the considerably supraphysiological dose of 250 µg, cosyntropin maximally stimulates adrenocortical steroidogenesis. In the standard cosyntropin stimulation test, 250 µg of cosyntropin is administered either intramuscularly or intravenously, with cortisol measured just before administration (baseline) and 30-60 minutes after cosyntropin administration. An increase in the circulating cortisol to a level greater than 18-20 µg/dL indicates a normal response. Some accept an increase of 9 µg/dL over the baseline value as a positive response. In patients with pituitary or hypothalamic disease of recent onset or shortly after surgery for pituitary tumors, the standard cosyntropin stimulation test may be misleading because the duration of ACTH deficiency may have been insufficient to cause significant adrenal atrophy with frank loss of steroidogenic capacity. For these patients, some experts advocate a "low-dose" cosyntropin stimulation test, in which 1 µg of cosyntropin is administered intravenously, and cortisol is measured just before and 30 minutes after cosyntropin administration; the cutoff for a normal response is the same as that for the standard test. Care must be taken to avoid adsorption of the cosyntropin to plastic tubing and to measure the plasma cortisol precisely at 30 minutes after the cosyntropin injection. Although some studies indicate that the low-dose test is more sensitive than the standard 250-µg test, others report that this test also may fail to detect secondary adrenal insufficiency.

As already noted, primary adrenocortical insufficiency and secondary adrenocortical insufficiency are reliably distinguished by available sensitive assays for ACTH. More protracted ACTH stimulation tests rarely are used to differentiate between these disorders.

CRH Stimulation Test. Ovine CRH (corticotorelin [ACTHREL]) and human CRH are available for diagnostic testing of the HPA axis, with the former used in the U.S. and the latter preferred in Europe. In patients with documented ACTH-dependent hypercorticism, CRH testing may help differentiate between a pituitary source (i.e.,

Cushing's disease) and an ectopic source of ACTH. After two baseline blood samples are obtained 15 minutes apart, CRH (1 µg/kg) is administered intravenously over a 30- to 60-second interval, and peripheral blood samples are obtained at 15, 30, and 60 minutes for ACTH measurement. It is important that the blood samples be handled as recommended for the ACTH assay. At the recommended dose, CRH generally is well tolerated, although flushing may occur, particularly if the dose is administered as a bolus. Patients with Cushing's disease respond to CRH with either a normal or an exaggerated increase in ACTH, whereas ACTH levels generally do not increase in patients with ectopic sources of ACTH. This test is not perfect: ACTH levels are induced by CRH in occasional patients with ectopic ACTH, and ~5-10% of patients with Cushing's disease fail to respond.

To improve the diagnostic accuracy of the CRH stimulation test, many authorities advocate sampling of blood from the inferior petrosal sinuses and the peripheral circulation after peripheral administration of CRH. In this test, an inferior petrosal/peripheral ratio of >2.5 supports a pituitary source of ACTH. When performed by a skilled neuroradiologist, this procedure increases diagnostic accuracy with a tolerable risk of complications from the catheterization procedure (Arnaldi et al., 2003).

Absorption and Fate. ACTH is readily absorbed from parenteral sites. The hormone rapidly disappears from the circulation after intravenous administration; in humans, the $t_{1/2}$ in plasma is ~15 minutes, primarily due to rapid enzymatic hydrolysis.

Toxicity of ACTH. Aside from rare hypersensitivity reactions, the toxicity of ACTH is primarily attributable to the increased secretion of corticosteroids. Cosyntropin generally is less antigenic than native ACTH; thus, cosyntropin is the preferred agent for clinical use.

ADRENOCORTICAL STEROIDS

The adrenal cortex synthesizes two classes of steroids: the *corticosteroids* (glucocorticoids and mineralocorticoids), which have 21 carbon atoms, and the *androgens*, which have 19 carbons (Figure 41–3). The actions of corticosteroids historically were described as glucocorticoid (reflecting their carbohydrate metabolism–regulating activity) and mineralocorticoid (reflecting their electrolyte balance–regulating activity). In humans, *cortisol* (*hydrocortisone*) is the main glucocorticoid and aldosterone is the main mineralocorticoid. Table 42–1 shows typical rates of secretion of cortisol and aldosterone, as well as their normal circulating concentrations.

Although the adrenal cortex is an important source of androgen precursors in women, patients with adrenal insufficiency can be restored to normal life expectancy by replacement therapy with glucocorticoids and mineralocorticoids. Adrenal androgens are not essential for survival. The levels of dehydroepiandrosterone (DHEA) and its sulfated derivative DHEA-S peak in the third decade of life and decline progressively thereafter. Moreover, patients with a number of chronic diseases have very low DHEA levels, leading some to propose that DHEA treatment might at least partly alleviate the loss

Table 42–1

Normal Daily Production Rates and Circulating Levels of the Predominant Corticosteroids

	CORTISOL	ALDOSTERONE
Rate of secretion under optimal conditions	10 mg/day	0.125 mg/day
Concentration in peripheral plasma:		
8 A.M.	16 µg/100 mL	0.01 µg/100 mL
4 A.M.	4 µg/100 mL	0.01 µg/100 mL

of libido, the decline in cognitive function, the decreased sense of well-being, and other adverse physiological consequences of aging. Whereas some studies have shown that addition of DHEA to the standard replacement regimen in women with adrenal insufficiency improved subjective well-being and sexuality, others have failed to show any benefit of DHEA replacement in either men or women (Chang et al., 2008). Nevertheless, DHEA is widely used as an over-the-counter nutritional supplement for its alleged health benefits, despite the absence of definitive data.

Physiological Functions and Pharmacological Effects

Physiological Actions. Corticosteroids have numerous and widespread effects, which include alterations in carbohydrate, protein, and lipid metabolism; maintenance of fluid and electrolyte balance; and preservation of normal function of the cardiovascular system, the immune system, the kidney, skeletal muscle, the endocrine system, and the nervous system. In addition, corticosteroids endow the organism with the capacity to resist such stressful circumstances as noxious stimuli and environmental changes. In the absence of the adrenal cortex, survival is made possible only by maintaining an optimal environment, including adequate and regular feeding, ingestion of relatively large amounts of sodium chloride, and maintenance of an appropriate environmental temperature; stresses such as infection, trauma, and extremes in temperature in this setting can be life threatening.

Traditionally, the effects of administered corticosteroids have been viewed as physiological (reflecting actions of corticosteroids at doses corresponding to normal daily production levels) or pharmacological (representing effects seen only at doses exceeding the normal daily production of corticosteroids). More recent concepts suggest that the anti-inflammatory and immunosuppressive actions

of corticosteroids—one of the major “pharmacological” uses of this class of drugs—also provide a protective mechanism in the physiological setting. Many of the immune mediators associated with the inflammatory response decrease vascular tone and could lead to cardiovascular collapse if unopposed by the adrenal corticosteroids. This hypothesis is supported by the fact that the daily production rate of cortisol can rise at least 10-fold in the setting of severe stress. In addition, the pharmacological actions of corticosteroids in different tissues and the physiological effects are mediated by the same receptor. Thus the various glucocorticoid derivatives used as pharmacological agents generally have side effects on physiological processes that parallel their therapeutic effectiveness.

The actions of corticosteroids are related to those of other hormones. For example, in the absence of lipolytic hormones, cortisol has virtually no effect on the rate of lipolysis by adipocytes. Likewise, in the absence of glucocorticoids, epinephrine and norepinephrine have only minor effects on lipolysis. Administration of a small dose of glucocorticoid, however, markedly potentiates the lipolytic action of these catecholamines. Those effects of corticosteroids that involve concerted actions with other hormonal regulators are termed *permissive* and most likely reflect steroid-induced changes in protein synthesis that, in turn, modify tissue responsiveness to other hormones.

Corticosteroids are grouped according to their relative potencies in Na⁺ retention, effects on carbohydrate metabolism (i.e., hepatic deposition of glycogen and gluconeogenesis), and anti-inflammatory effects. In general, potencies of steroids as judged by their ability to sustain life in adrenalectomized animals closely parallel those determined for Na⁺ retention, whereas potencies based on effects on glucose metabolism closely parallel those for anti-inflammatory effects. The effects on Na⁺ retention and the carbohydrate/anti-inflammatory

actions are not closely related and reflect selective actions at distinct receptors.

Based on these differential potencies, the corticosteroids traditionally are divided into mineralocorticoids and glucocorticoids. Estimates of potencies of representative steroids in these actions are listed in Table 42–2. Some steroids that are classified predominantly as glucocorticoids (e.g., cortisol) also possess modest but significant mineralocorticoid activity and thus may affect fluid and electrolyte handling in the clinical setting. At doses used for replacement therapy in patients with primary adrenal insufficiency, the mineralocorticoid effects of these “glucocorticoids” are insufficient to replace that of aldosterone, and concurrent therapy with a more potent mineralocorticoid generally is needed. In contrast, aldosterone is exceedingly potent with respect to Na⁺ retention but has only modest potency for effects on carbohydrate metabolism. At normal rates of secretion by the adrenal cortex or in doses that maximally affect electrolyte balance, aldosterone has no significant glucocorticoid activity and thus acts as a pure mineralocorticoid.

General Mechanisms for Corticosteroid Effects.

Corticosteroids bind to specific receptor proteins in target tissues to regulate the expression of corticosteroid-responsive genes, thereby changing the levels and array of proteins synthesized by the various target tissues (Figure 42–5). As a consequence of the time required to modulate gene expression and protein synthesis, most effects of corticosteroids are not immediate but become

Table 42–2

Relative Potencies and Equivalent Doses of Representative Corticosteroids

COMPOUND	ANTI-INFLAMMATORY POTENCY	Na ⁺ -RETAINING POTENCY	DURATION OF ACTION ^a	EQUIVALENT DOSE (mg) ^b
Cortisol	1	1	S	20
Cortisone	0.8	0.8	S	25
Fludrocortisone	10	125	I	^c
Prednisone	4	0.8	I	5
Prednisolone	4	0.8	I	5
6 α -Methylprednisolone	5	0.5	I	4
Triamcinolone	5	0	I	4
Betamethasone	25	0	L	0.75
Dexamethasone	25	0	L	0.75

^aS, short (i.e., 8–12 hour biological $t_{1/2}$); I, intermediate (i.e., 12–36 hour biological $t_{1/2}$); L, long (i.e., 36–72 hour biological $t_{1/2}$).

^bThese dose relationships apply only to oral or intravenous administration, as glucocorticoid potencies may differ greatly following intramuscular or intraarticular administration.

^cThis agent is not used for glucocorticoid effects.

Figure 42–5. Intracellular mechanism of action of the glucocorticoid receptor. The figure shows the molecular pathway by which cortisol (labeled S) enters cells and interacts with the glucocorticoid receptor (GR) to change GR conformation (indicated by the change in shape of the GR), induce GR nuclear translocation, and activate transcription of target genes. The example shown is one in which glucocorticoids activate expression of target genes; the expression of certain genes, including proopiomelanocortin (POMC) expression by corticotropes, is inhibited by glucocorticoid treatment. CBG, corticosteroid-binding globulin; GR, glucocorticoid receptor; S, steroid hormone; HSP90, the 90-kd heat-shock protein; HSP70, the 70-kd heat-shock protein; IP, the 56-kd immunophilin; GRE, glucocorticoid-response elements in the DNA that are bound by GR, thus providing specificity to induction of gene transcription by glucocorticoids. Within the gene are introns (gray) and exons (red); transcription and mRNA processing leads to splicing and removal of introns and assembly of exons into mRNA.

apparent after several hours. This fact is of clinical significance because a delay generally is seen before beneficial effects of corticosteroid therapy become manifest. Although corticosteroids predominantly act by increasing gene transcription, there are well-documented examples in which glucocorticoids decrease gene transcription, as discussed later. In addition, corticosteroids may exert some of their immediate effects by nongenomic mechanisms (Stahn and Buttgerit, 2008).

Glucocorticoid Receptors. The receptors for corticosteroids are members of the nuclear receptor family of transcription factors that transduce the effects of a diverse array of small hydrophobic ligands, including the steroid hormones, thyroid hormone, vitamin D, and retinoids. These receptors share two highly conserved domains: a region of ~70 amino acids forming two zinc-binding domains, called *zinc fingers*, that are essential for the interaction of the receptor with specific DNA sequences, and a region at the carboxyl terminus that interacts with ligand (the ligand-binding domain). The GR resides predominantly in the cytoplasm in an inactive form until it binds glucocorticoids (Figure 42–5). Steroid binding results in receptor activation and translocation to the nucleus. The inactive GR is complexed with other proteins, including heat-shock protein (HSP) 90, a member of the heat-shock family of stress-induced proteins; HSP70; and a 56,000-Da immunophilin, one of the group of intracellular proteins that bind the immunosuppressive agents cyclosporine and tacrolimus (see Chapter 35). HSP90, through interactions with the steroid-binding domain, may facilitate folding of the GR into an appropriate conformation that permits ligand binding.

The gene encoding the GR is located on human chromosome 5 and gives rise to several receptor isoforms as the result of alternative RNA splicing. Of these, GR α is the prototypical glucocorticoid-responsive isoform already discussed and is the best studied. A second major GR isoform, GR β , is a truncated dominant negative variant that lacks 35 amino acids at the C-terminus and is unable to bind glucocorticoids or activate gene expression. GR β expression is enhanced by tumor necrosis factor α and other pro-inflammatory cytokines and its relative abundance is thought to contribute to glucocorticoid resistance in some patients. Other splice variants have been identified that retain their ligand-binding activity but have amino acid insertions or deletions of the DNA-binding domain that reduce their transcriptional activity (Gross and Cidlowski, 2008). Finally, polymorphisms have been identified in the human GR that are associated with differences in GR function and have been linked to glucocorticoid insensitivity (Derijk et al., 2008).

Although complete loss of GR function apparently is lethal, mutations leading to partial loss of GR function occur in rare patients with generalized glucocorticoid resistance (Charmandari et al., 2008). These patients harbor mutations in the GR, most of which impair glucocorticoid binding and decrease transcriptional activation. As a consequence of these mutations, cortisol levels that normally mediate feedback inhibition fail to suppress the HPA axis completely. In this setting of partial loss of GR function, the HPA axis resets to a higher level to provide compensatory increases in ACTH and cortisol secretion. Because the GR defect is partial, adequate compensation for the end-organ insensitivity can result from the elevated cortisol level, but the excess ACTH secretion also stimulates the production of mineralocorticoids and adrenal androgens. Because the mineralocorticoid receptor (MR) and the androgen receptor are intact, these subjects present with manifestations of mineralocorticoid excess (hypertension and hypokalemic alkalosis) and/or of increased androgen levels (acne, hirsutism, male pattern baldness, menstrual irregularities, anovulation, and infertility). In children, the excess adrenal androgens can cause precocious sexual development.

Regulation of Gene Expression by Glucocorticoids. After ligand binding, the GR dissociates from its associated proteins and translocates

to the nucleus. There, it interacts with specific DNA sequences within the regulatory regions of affected genes. The short DNA sequences that are recognized by the activated GR are called *glucocorticoid responsive elements* (GREs) and provide specificity to the induction of gene transcription by glucocorticoids. The consensus GRE sequence is an imperfect palindrome (GGTACAnnTGTTCT, where n is any nucleotide) to which the GR binds as a receptor dimer. The mechanisms by which GR activates transcription are complex and not completely understood, but they involve the interaction of the GR with transcriptional coactivators and with proteins that make up the basal transcription apparatus. Genes that are negatively regulated by glucocorticoids also have been identified. One well-characterized example is the pro-opiomelanocortin gene. In this case, the GR appears to inhibit transcription by a direct interaction with a GRE in the *POMC* promoter, thereby contributing to the negative feedback regulation of the HPA axis. Other genes negatively regulated by glucocorticoids include genes for cyclooxygenase-2 (COX-2), inducible nitric oxide synthase (NOS2), and inflammatory cytokines.

In some cases, the inhibitory effects of glucocorticoids on gene expression have been linked to protein–protein interactions between the GR and other transcription factors rather than to negative effects of the GR at specific GREs. Indeed, protein–protein interactions have been observed between the GR and the transcription factors NF- κ B and AP-1, which regulate the expression of a number of components of the immune system (De Bosscher et al., 2003). Such interactions repress the expression of genes encoding a number of cytokines—regulatory molecules that play key roles in the immune and inflammatory networks—and enzymes, such as collagenase and stromelysin, that are proposed to play key roles in the joint destruction seen in inflammatory arthritis. Thus, these protein–protein interactions and their consequent negative effects on gene expression appear to contribute significantly to the anti-inflammatory and immunosuppressive effects of the glucocorticoids.

The recognition that the metabolic effects of glucocorticoids generally are mediated by transcriptional activation, whereas the anti-inflammatory effects largely are mediated by transrepression, suggests that selective GR ligands may maintain the anti-inflammatory actions while lessening the metabolic side effects (McMaster and Ray, 2008). Recent reports describing steroidal and nonsteroidal compounds that exhibit anti-inflammatory actions but have little effect on blood glucose suggest that such selective glucocorticoid agonists may emerge from ongoing research.

Regulation of Gene Expression by Mineralocorticoids. Like the GR, the MR also is a ligand-activated transcription factor and binds to a very similar, if not identical, hormone-responsive element. Although its actions have been studied in less detail than the GR, the basic principles of action appear to be similar; in particular, the MR also associates with HSP90 and activates the transcription of discrete sets of genes within target tissues. Studies have not yet identified differences in the DNA recognition motifs for the GR and the MR that would explain their differential capacities to activate discrete sets of target genes. The GR and MR differ in their ability to inhibit AP-1-mediated gene activation, suggesting that differential interactions with other transcription factors may underlie their distinct effects on cell function. The MR has a restricted expression: it is expressed in epithelial tissues involved in electrolyte transport (i.e., the kidney, colon, salivary glands,

and sweat glands) and in nonepithelial tissues (e.g., hippocampus, heart, vasculature and adipose tissue) where its functions are less well understood.

Aldosterone exerts its effects on Na⁺ and K⁺ homeostasis primarily via its actions on the principal cells of the distal renal tubules and collecting ducts, whereas the effects on H⁺ secretion largely are exerted in the intercalated cells. The binding of aldosterone to the MR in the kidney initiates a sequence of events that includes the rapid induction of serum- and glucocorticoid-regulated kinase, which in turn phosphorylates and activates amiloride-sensitive epithelial Na⁺ channels in the apical membrane. Thereafter, increased Na⁺ influx stimulates the Na⁺, K⁺-ATPase in the basolateral membrane. In addition to these rapid genomic actions, aldosterone also increases the synthesis of the individual components of these membrane proteins as part of a more delayed effect.

Receptor-Independent Mechanism for Corticosteroid Specificity. The availability of cloned genes encoding the GR and MR led to the surprising finding that aldosterone (a classic mineralocorticoid) and cortisol (generally viewed as predominantly glucocorticoid) bind the MR with equal affinity. This raised the question of how the apparent specificity of the MR for aldosterone was maintained in the face of much higher circulating levels of glucocorticoids. We now know that the type 2 isozyme of 11 β -hydroxysteroid dehydrogenase (11 β HSD2) plays a key role in corticosteroid specificity, particularly in the kidney, colon, and salivary glands (Hammer and Stewart, 2006). This enzyme metabolizes glucocorticoids such as cortisol to receptor-inactive 11-keto derivatives such as cortisone (Figure 42–6). Because its predominant form in physiological settings is the hemiacetal derivative (Figure 42–7), which is resistant to 11 β HSD action, aldosterone escapes this inactivation and maintains mineralocorticoid activity. In the absence of 11 β HSD2, as occurs in an inherited disease called the *syndrome of apparent mineralocorticoid excess*, the MR is activated by cortisol, leading to severe hypokalemia and mineralocorticoid-related hypertension. A state of mineralocorticoid excess also can be induced by inhibiting 11 β HSD

Figure 42–6. Receptor-independent mechanism by which 11 β -hydroxysteroid dehydrogenase confers specificity of corticosteroid action. Type 2 11 β -hydroxysteroid dehydrogenase (11 β -HSD2) converts cortisol, which binds to both the mineralocorticoid receptor (MR) and the glucocorticoid receptor (GR), to cortisone, which binds to neither MR nor GR, thereby protecting the MR from the high circulating concentrations of cortisol. This inactivation allows specific responses to aldosterone in sites such as the distal nephron. The type 1 isozyme of 11 β -HSD (11 β -HSD1) catalyzes the reverse reaction, which converts inactive cortisone to active cortisol in such tissues as liver and fat. Only ring C of the corticosteroid is depicted; see Figure 42–7 for complete structure.

Figure 42-7. Structure and nomenclature of corticosteroid products and selected synthetic derivatives. The structure of hydrocortisone is represented in two dimensions. Note that the steroid ring system is not completely planar and the orientation of the groups attached to the steroid rings is an important determinant of the biological activity. The methyl groups at C18 and C19 and the hydroxyl group at C11 project upward (*forward* in the two-dimensional representation and shown by a solid line connecting the atoms) and are designated β . The hydroxyl at C17 projects below the plane (*behind* in the two-dimensional representation, and represented by the dashed line connecting the atoms) and is designated α .

with *glycyrrhizic acid*, a component of licorice implicated in licorice-induced hypertension.

Carbohydrate and Protein Metabolism. Corticosteroids profoundly affect carbohydrate and protein metabolism, which can be viewed as protecting glucose-dependent tissues (e.g., the brain and heart) from starvation. They stimulate the liver to form glucose from amino acids and glycerol and to store glucose as liver glycogen. In the periphery, glucocorticoids diminish glucose utilization, increase protein breakdown and the synthesis of glutamine, and activate lipolysis, thereby providing amino acids and glycerol for gluconeogenesis. The net result is to increase blood glucose levels. Because of their effects on glucose metabolism, glucocorticoids can worsen glycemic control in patients with overt diabetes and can precipitate the onset of hyperglycemia in susceptible patients.

The mechanisms whereby glucocorticoids inhibit glucose utilization in peripheral tissues are not fully understood. Glucocorticoids decrease glucose uptake in adipose tissue, skin, fibroblasts, thymocytes, and polymorphonuclear leukocytes; these effects are postulated to result from translocation of the glucose transporters from the plasma membrane to an intracellular location. These peripheral effects are associated with a number of catabolic actions, including atrophy of

lymphoid tissue, decreased muscle mass, negative nitrogen balance, and thinning of the skin.

Similarly, the mechanisms by which the glucocorticoids promote gluconeogenesis are not fully defined. Amino acids mobilized from a number of tissues in response to glucocorticoids reach the liver and provide substrate for the production of glucose and glycogen. In the liver, glucocorticoids induce the transcription of a number of enzymes involved in gluconeogenesis and amino acid metabolism, including phosphoenolpyruvate carboxykinase (PEPCK), glucose-6-phosphatase, and the bifunctional enzyme fructose-2,6-bisphosphatase. Analyses of the molecular basis for regulation of PEPCK gene expression have identified complex regulatory influences involving an interplay among glucocorticoids, insulin, glucagon, and catecholamines. The effects of these hormones and amines on PEPCK gene expression mirror the complex regulation of gluconeogenesis in the intact organism.

Lipid Metabolism. Two effects of corticosteroids on lipid metabolism are firmly established. The first is the dramatic redistribution of body fat that occurs in settings of endogenous or pharmacologically induced hypercorticism, such as Cushing's syndrome. In this setting, there is increased fat in the back of the neck ("buffalo hump"), face ("moon facies"), and supraclavicular area, coupled with a loss of fat in the extremities. The other is the permissive facilitation of the lipolytic

1220 effect of other agents, such as growth hormone and β adrenergic receptor agonists, resulting in an increase in free fatty acids after glucocorticoid administration.

One hypothesis for the redistribution of body fat is that peripheral and truncal adipocytes differ in their relative sensitivities to insulin and to glucocorticoid-facilitated lipolytic effects. Truncal adipocytes respond predominantly to elevated levels of insulin resulting from glucocorticoid-induced hyperglycemia, whereas peripheral adipocytes are less sensitive to insulin and respond mostly to the glucocorticoid-facilitated effects of other lipolytic hormones. This differential sensitivity may reflect differences in the expression of 11β HSD1 that converts inactive cortisone into active cortisol in target tissues (Figure 42–6). Consistent with this idea, overexpression of 11β HSD1 in adipocytes causes obesity in a transgenic mouse model. The potential role of this enzyme in adipocyte function has prompted speculation that 11β HSD1 inhibitors may have a role in the treatment of obesity.

Electrolyte and Water Balance. Aldosterone is by far the most potent endogenous corticosteroid with respect to fluid and electrolyte balance. Thus, electrolyte balance is relatively normal in patients with adrenal insufficiency due to pituitary disease, despite the loss of glucocorticoid production by the inner cortical zones. Mineralocorticoids act on the distal tubules and collecting ducts of the kidney to enhance reabsorption of Na^+ from the tubular fluid; they also increase the urinary excretion of K^+ and H^+ . Conceptually, it is useful to think of aldosterone as stimulating a renal exchange between Na^+ and K^+ or H^+ , although this does not involve a simple 1:1 exchange of cations in the renal tubule.

These actions on electrolyte transport, in the kidney and in other tissues (e.g., colon, salivary glands, and sweat glands), appear to account for the physiological and pharmacological activities that are characteristic of mineralocorticoids. Thus, the primary features of hyperaldosteronism are positive Na^+ balance with consequent expansion of extracellular fluid volume, normal or slight increases in plasma Na^+ concentration, normal or low plasma K^+ , and alkalosis. Mineralocorticoid deficiency, in contrast, leads to Na^+ wasting and contraction of the extracellular fluid volume, hyponatremia, hyperkalemia, and acidosis. Indeed, mineralocorticoid-deficient patients are especially predisposed to Na^+ loss and volume depletion through excessive sweating in hot environments. Chronically, hyperaldosteronism causes hypertension, whereas aldosterone deficiency can lead to hypotension and vascular collapse.

Further insights into the roles of aldosterone target genes in fluid and electrolyte balance have emerged from analyses of patients with rare genetic disorders of mineralocorticoid action, such as *pseudohypoaldosteronism* and *pseudoaldosteronism*. Despite elevated

levels of mineralocorticoids, patients with classical pseudohypoaldosteronism (i.e., type 1 disease) present with clinical manifestations suggestive of deficient mineralocorticoid action (i.e., volume depletion, hypotension, hyperkalemia, and metabolic acidosis). Molecular analyses have defined discrete subpopulations of patients with this disorder. One form of the disease is caused by autosomal dominant mutations in the MR that impair its activity. A second, autosomal recessive form results from loss-of-function mutations in genes encoding subunits of the amiloride-sensitive epithelial Na^+ channel. A nonclassical pseudohypoaldosteronism (type 2, also known as Gordon's syndrome) presents with hyperkalemia, mild metabolic acidosis, and familial hypertension. In some of these patients, the disease is caused by autosomal dominant mutations in the protein kinase genes *WNK1* and *WNK4* that inhibit the sodium chloride cotransporter. Pseudoaldosteronism, also termed Liddle's syndrome, is an autosomal dominant disease that results from mutations in subunits of the amiloride-sensitive Na^+ channel that interfere with its downregulation. The constitutive activity of this channel leads to hypertension, hypokalemia, and metabolic alkalosis, despite low levels of plasma renin and aldosterone.

Glucocorticoids also exert effects on fluid and electrolyte balance, largely due to permissive effects on tubular function and actions that maintain glomerular filtration rate. Glucocorticoids play a permissive role in the renal excretion of free water. In part, the inability of patients with glucocorticoid deficiency to excrete free water results from the increased secretion of AVP, which stimulates water reabsorption in the kidney.

In addition to their effects on monovalent cations and water, glucocorticoids also exert multiple effects on Ca^{2+} metabolism. Steroids lower Ca^{2+} uptake from the gut and increase Ca^{2+} excretion by the kidney. These effects collectively lead to decreased total body Ca^{2+} stores.

Cardiovascular System. The most striking effects of corticosteroids on the cardiovascular system result from mineralocorticoid-induced changes in renal Na^+ , as is evident in primary aldosteronism. Studies have shown direct effects of MR activation on the heart and vessel wall; aldosterone induces hypertension and interstitial cardiac fibrosis in animal models. The increased cardiac fibrosis is proposed to result from direct mineralocorticoid actions in the heart rather than from the effect of hypertension because treatment with spironolactone, a MR antagonist, blocks the development of fibrosis without altering blood pressure. Indeed, in age-, sex-, and blood pressure-matched hypertensive patients, those with primary aldosteronism have a higher prevalence of atrial fibrillation, stroke, and myocardial infarction, indicating direct effects of increased aldosterone on the cardiovascular system. Similar cardiac effects of MR activation in human beings may explain the beneficial effects of spironolactone in patients with congestive heart failure (Chapter 28).

The second major action of corticosteroids on the cardiovascular system is to enhance vascular reactivity

to other vasoactive substances. Hypoadrenalism is associated with reduced responsiveness to vasoconstrictors such as norepinephrine and angiotensin II, perhaps due to decreased expression of adrenergic receptors in the vascular wall. Conversely, hypertension is seen in patients with excessive glucocorticoid secretion, occurring in most patients with Cushing's syndrome and in a subset of patients treated with synthetic glucocorticoids (even those lacking any significant mineralocorticoid action).

The underlying mechanisms in glucocorticoid-induced hypertension also are unknown; the hypertension related to the endogenous secretion of cortisol, as seen in patients with Cushing's syndrome, likely results from multiple effects mediated by the GR and MR. Unlike hypertension caused by high aldosterone levels, the hypertension secondary to excess glucocorticoids is generally resistant to Na^+ restriction (Magiakou et al., 2006).

Skeletal Muscle. Permissive concentrations of corticosteroids are required for the normal function of skeletal muscle, and diminished work capacity is a prominent sign of adrenocortical insufficiency. In patients with Addison's disease, weakness and fatigue are frequent symptoms. Excessive amounts of either glucocorticoids or mineralocorticoids also impair muscle function. In primary aldosteronism, muscle weakness results primarily from hypokalemia rather than from direct effects of mineralocorticoids on skeletal muscle. In contrast, glucocorticoid excess over prolonged periods, either secondary to glucocorticoid therapy or endogenous hypercorticism, causes skeletal muscle wasting. This effect, termed *steroid myopathy*, accounts in part for weakness and fatigue in patients with glucocorticoid excess and is discussed in more detail later.

Central Nervous System. Corticosteroids exert a number of indirect effects on the CNS, through maintenance of blood pressure, plasma glucose concentrations, and electrolyte concentrations. Increasingly, direct effects of corticosteroids on the CNS have been recognized, including effects on mood, behavior, and brain excitability.

Patients with adrenal insufficiency exhibit a diverse array of neurological manifestations, including apathy, depression, and irritability; some patients are frankly psychotic. Appropriate replacement therapy corrects these abnormalities. Conversely, glucocorticoid administration can induce multiple CNS reactions. Most patients respond with mood elevation, which may impart a sense of well-being despite the persistence of underlying disease. Some patients exhibit more pronounced behavioral changes, such as mania, insomnia, restlessness, and increased motor activity. A smaller but significant

percentage of patients treated with glucocorticoids become anxious, depressed, or overtly psychotic. A high incidence of neuroses and psychoses is seen in patients with Cushing's syndrome. These abnormalities usually disappear after cessation of glucocorticoid therapy or treatment of the Cushing's syndrome.

The mechanisms whereby corticosteroids affect neuronal activity are unknown, but it has been proposed that steroids produced locally in the brain (termed *neurosteroids*) may regulate neuronal excitability. In rodent models, very high doses of glucocorticoids decrease survival and function of hippocampal neurons; in association with these changes, memory also is diminished. In one study in human subjects, basal cortisol levels correlated directly with hippocampal atrophy and memory deficits. To the extent that these results are confirmed, they may have important prognostic implications for age-related memory decline, and for therapeutic approaches directed at diminishing the negative effects of glucocorticoids on hippocampal neurons with aging.

Formed Elements of Blood. Glucocorticoids exert minor effects on hemoglobin and erythrocyte content of blood, as evidenced by the frequent occurrence of polycythemia in Cushing's syndrome and of normochromic, normocytic anemia in adrenal insufficiency. More profound effects are seen in the setting of autoimmune hemolytic anemia, in which the immunosuppressive effects of glucocorticoids can diminish the self-destruction of erythrocytes.

Corticosteroids also affect circulating white blood cells. Addison's disease is associated with an increased mass of lymphoid tissue and lymphocytosis. In contrast, Cushing's syndrome is characterized by lymphocytopenia and decreased mass of lymphoid tissue. The administration of glucocorticoids leads to a decreased number of circulating lymphocytes, eosinophils, monocytes, and basophils. A single dose of hydrocortisone leads to a decline of these circulating cells within 4-6 hours; this effect persists for 24 hours and results from the redistribution of cells away from the periphery rather than from increased destruction. In contrast, glucocorticoids increase circulating polymorphonuclear leukocytes as a result of increased release from the marrow, diminished rate of removal from the circulation, and decreased adherence to vascular walls. Finally, certain lymphoid malignancies are destroyed by glucocorticoid treatment, an effect that may relate to the ability of glucocorticoids to activate programmed cell death.

Anti-inflammatory and Immunosuppressive Actions. In addition to their effects on lymphocyte number, corticosteroids profoundly alter the immune responses of lymphocytes. These effects are an important facet of the anti-inflammatory and immunosuppressive actions of the glucocorticoids. Glucocorticoids can prevent or suppress inflammation in response to multiple inciting events, including radiant, mechanical, chemical, infectious, and immunological stimuli. Although the use of glucocorticoids as anti-inflammatory agents does not address the underlying cause of the disease, the

suppression of inflammation is of enormous clinical utility and has made these drugs among the most frequently prescribed agents. Similarly, glucocorticoids are of immense value in treating diseases that result from undesirable immune reactions. These diseases range from conditions that predominantly result from humoral immunity, such as urticaria (Chapter 65), to those that are mediated by cellular immune mechanisms, such as transplantation rejection (Chapter 35). The immunosuppressive and anti-inflammatory actions of glucocorticoids are inextricably linked, perhaps because they both involve inhibition of leukocyte functions.

Multiple mechanisms are involved in the suppression of inflammation by glucocorticoids. Glucocorticoids inhibit the production by multiple cells of factors that are critical in generating the inflammatory response. As a result, there is decreased release of vasoactive and chemoattractive factors, diminished secretion of lipolytic and proteolytic enzymes, decreased extravasation of leukocytes to areas of injury, and ultimately, decreased fibrosis. Glucocorticoids can also reduce expression of pro-inflammatory cytokines, as well as COX-2 and NOS2. Some of the cell types and mediators that are inhibited by glucocorticoids are summarized in Table 42–3. The net effect of these actions on various cell types is to diminish markedly the inflammatory response.

The influence of stressful conditions on immune defense mechanisms is well documented, as is the contribution of the HPA axis to the stress response (Elenkov and Chrousos, 2006). This has

led to a growing appreciation of the importance of glucocorticoids as physiological modulators of the immune system, where glucocorticoids appear to protect the organism against life-threatening consequences of a full-blown inflammatory response (Chrousos, 1995).

Stresses such as injury, infection, and disease result in the increased production of cytokines, a network of signaling molecules that integrate actions of macrophages/monocytes, T lymphocytes, and B lymphocytes in mounting immune responses. Among these cytokines, interleukin (IL)-1, IL-6, and tumor necrosis factor α (TNF- α) stimulate the HPA axis, with IL-1 having the broadest range of actions. IL-1 stimulates the release of CRH by hypothalamic neurons, interacts directly with the pituitary to increase the release of ACTH, and may directly stimulate the adrenal gland to produce glucocorticoids. As detailed earlier, the increased production of glucocorticoids, in turn, profoundly inhibits the immune system at multiple sites. Factors that are inhibited include components of the cytokine network, including interferon γ (IFN- γ), granulocyte-macrophage colony-stimulating factor (GM-CSF), interleukins (IL-1, IL-2, IL-3, IL-6, IL-8, and IL-12), and TNF- α . Thus, the HPA axis and the immune system are capable of bidirectional interactions in response to stress, and these interactions appear to be important for homeostasis (Chrousos, 1995).

Absorption, Transport, Metabolism, and Excretion

Absorption. Hydrocortisone and numerous congeners, including the synthetic analogs, are orally effective. Certain water-soluble esters of hydrocortisone and its

Table 42–3

Effects of Glucocorticoids on Components of Inflammatory/Immune Responses

CELL TYPE	FACTOR	COMMENTS
Macrophages and monocytes	Arachidonic acid and its metabolites (prostaglandins and leukotrienes) Cytokines, including: interleukin (IL)-1, IL-6, and tumor necrosis factor- α (TNF- α) Acute phase reactants	Mediated by glucocorticoid inhibition of COX-2 and PLA ₂ . Production and release are blocked. The cytokines exert multiple effects on inflammation (e.g., activation of T cells, stimulation of fibroblast proliferation). These include the third component of complement.
Endothelial cells	ELAM-1 and ICAM-1 Acute phase reactants Cytokines (e.g., IL-1) Arachidonic acid derivatives	ELAM-1 and ICAM-1: critical for leukocyte localization. Same as above, for macrophages and monocytes.
Basophils	Histamine, LTC ₄	IgE-dependent release inhibited by glucocorticoids.
Fibroblasts	Arachidonic acid metabolites	Same as above for macrophages and monocytes. Glucocorticoids also suppress growth factor-induced DNA synthesis and fibroblast proliferation.
Lymphocytes	Cytokines (IL-1, IL-2, IL-3, IL-6, TNF- α , GM-CSF, interferon- γ)	Same as above for macrophages and monocytes.

ELAM-1, endothelial-leukocyte adhesion molecule-1; ICAM-1, intercellular adhesion molecule-1.

synthetic congeners are administered intravenously to achieve high concentrations of drug rapidly in body fluids. More prolonged effects are obtained by intramuscular injection of suspensions of hydrocortisone, its esters, and congeners. Minor changes in chemical structure may markedly alter the rate of absorption, time of onset of effect, and duration of action.

Glucocorticoids also are absorbed systemically from sites of local administration, such as synovial spaces, the conjunctival sac, skin, and respiratory tract. When administration is prolonged, when the site of application is covered with an occlusive dressing, or when large areas of skin are involved, absorption may be sufficient to cause systemic effects, including suppression of the HPA axis.

Transport, Metabolism, and Excretion. After absorption, $\geq 90\%$ of cortisol in plasma is reversibly bound to protein under normal circumstances. Only the fraction of corticosteroid that is unbound is active and can enter cells. Two plasma proteins account for almost all of the steroid-binding capacity: corticosteroid-binding globulin (CBG; also called transcortin), and albumin. CBG is an α -globulin secreted by the liver that has high affinity for steroids (estimated dissociation constant of $\sim 1.3 \times 10^{-9}$ M) but relatively low total binding capacity, whereas albumin, also produced by the liver, has a relatively large binding capacity but low affinity (estimated dissociation constant of 1×10^{-3} M). Because of its higher dissociation constant, albumin-bound corticosteroid makes a greater contribution to the active corticosteroid fraction in tissues that have a slow capillary transit time (e.g., liver and spleen) than in tissues with rapid capillary transit times (e.g., kidney). At normal or low concentrations of corticosteroids, most of the hormone is protein bound. At higher steroid concentrations, the capacity of protein binding is exceeded, and a greater fraction of the steroid exists in the free state. Corticosteroids compete with each other for binding sites on CBG. CBG has relatively high affinity for cortisol and some of its synthetic congeners and low affinity for aldosterone and glucuronide-conjugated steroid metabolites; thus, greater percentages of these latter steroids are found in the free form.

A special state of physiological hypercorticism occurs during pregnancy. The elevated circulating estrogen levels induce CBG production, and CBG and total plasma cortisol increase severalfold. The physiological significance of these changes remains to be established.

All of the biologically active adrenocortical steroids and their synthetic congeners have a double bond in the 4,5 position and a

ketone group at C3 (Figure 42–7). As a general rule, the metabolism of steroid hormones involves sequential additions of oxygen or hydrogen atoms, followed by conjugation to form water-soluble derivatives. Reduction of the 4,5 double bond occurs at both hepatic and extrahepatic sites, yielding inactive compounds. Subsequent reduction of the 3-ketone substituent to the 3-hydroxyl derivative, forming tetrahydrocortisol, occurs only in the liver. Most of these A ring-reduced steroids are conjugated through the 3-hydroxyl group with sulfate or glucuronide by enzymatic reactions that take place in the liver and, to a lesser extent, in the kidney. The resultant sulfate esters and glucuronides are water soluble and the predominant forms excreted in urine. Neither biliary nor fecal excretion is of quantitative importance in humans.

Synthetic steroids with an 11-keto group, such as cortisone and prednisone, must be enzymatically reduced to the corresponding 11 β -hydroxy derivative before they are biologically active. The type 1 isozyme of 11 β -hydroxysteroid dehydrogenase (11 β HSD1) catalyzes this reduction, predominantly in the liver, but also in specialized sites such as adipocytes, bone, eye, and skin. In settings in which this enzymatic activity is impaired, it is prudent to use steroids that do not require enzymatic activation (e.g., hydrocortisone or prednisolone rather than cortisone or prednisone). Such settings include severe hepatic failure and patients with the rare condition of cortisone reductase deficiency, who are unable to activate the 11-keto steroids because of a defect in the enzyme hexose-6-phosphate dehydrogenase, which regulates the activity of 11 β -hydroxysteroid dehydrogenase by supplying required reducing equivalents (Lavery et al., 2008).

Structure–Activity Relationships

Chemical modifications to the cortisol molecule have generated derivatives with greater separations of glucocorticoid and mineralocorticoid activity; for a number of synthetic glucocorticoids, the effects on electrolytes are minimal even at the highest doses used (Table 42–2). In addition, these modifications have led to derivatives with greater potencies and with longer durations of action. A vast array of steroid preparations is available for oral, parenteral, and topical use. Some of these agents are summarized in Table 42–4. None of these currently available derivatives effectively separates anti-inflammatory effects from effects on carbohydrate, protein, and fat metabolism, or from suppressive effects on the HPA axis.

The structures of hydrocortisone (cortisol) and some of its major derivatives are shown in Figure 42–7. Changes in chemical structure may alter the specificity and/or potency due to changes in affinity and intrinsic activity at corticosteroid receptors, and alterations in absorption, protein binding, rate of metabolic transformation, rate of excretion, or membrane permeability. The effects of various substitutions on glucocorticoid and mineralocorticoid activity and on duration of action are summarized in Table 42–2. The 4,5 double bond and the 3-keto group on ring A are essential for glucocorticoid and mineralocorticoid activity; an 11 β -hydroxyl group on ring C is required for glucocorticoid activity but not mineralocorticoid activity; a hydroxyl group at C21 on ring D is present on all natural corticosteroids and on most of the active synthetic analogs, and seems to be an absolute requirement for mineralocorticoid but not glucocorticoid activity. The 17 α -hydroxyl group on ring D is a substituent on cortisol and on all of the currently used synthetic glucocorticoids. Although steroids without the 17 α -hydroxyl group

(e.g., corticosterone) have appreciable glucocorticoid activity, the 17 α -hydroxyl group gives optimal potency.

Introduction of an additional double bond in the 1,2 position of ring A, as in prednisolone or prednisone, selectively increases glucocorticoid activity, and results in an enhanced glucocorticoid/mineralocorticoid potency ratio. This modification also results in compounds that are metabolized more slowly than hydrocortisone.

Fluorination at the 9 α position on ring B enhances both glucocorticoid and mineralocorticoid activity, possibly related to an electron-withdrawing effect on the nearby 11 β -hydroxyl group. Fludrocortisone (9 α -fluorocortisol) has enhanced activity at the GR (10 times relative to cortisol) but even greater activity at the MR (125 times relative to cortisol). It is used in mineralocorticoid replacement therapy and has no appreciable glucocorticoid effect at usual daily doses of 0.05-0.2 mg. When combined with the 1,2 double bond in ring A plus other substitutions at C16 on ring D (Figure 42-7), the 9 α -fluoro derivatives formed (e.g., triamcinolone, dexamethasone, and betamethasone) have marked glucocorticoid activity—the substitutions at C16 virtually eliminate mineralocorticoid activity.

Other Substitutions. 6 α Substitution on ring B has somewhat unpredictable effects. 6 α -Methylcortisol has increased glucocorticoid and mineralocorticoid activity, whereas 6 α -methylprednisolone has somewhat greater glucocorticoid activity and somewhat less mineralocorticoid activity than prednisolone. A number of modifications convert the glucocorticoids to more lipophilic molecules with enhanced topical/systemic potency ratios. Examples include the introduction of an acetonide between hydroxyl groups at C16 and C17, esterification of the hydroxyl group with valerate at C17, esterification of hydroxyl groups with propionate at C17 and C21, and substitution of the hydroxyl group at C21 with chlorine. Other approaches to achieve local glucocorticoid activity while minimizing systemic effects involve the formation of analogs that are rapidly inactivated after absorption (e.g., C21 carboxylate or carbothioate glucocorticoid esters, which are rapidly metabolized to inactive 21-carboxylic acids) or the formation of inactive analogs that are selectively activated at their site of action (e.g., glucocorticoid C21 isobutyryl or propionyl esters that are hydrolyzed to active C21 alcohols by airway-specific esterases).

Toxicity of Adrenocortical Steroids

Two categories of toxic effects result from the therapeutic use of corticosteroids: those resulting from withdrawal of steroid therapy and those resulting from continued use at supraphysiological doses. The side effects from both categories are potentially life threatening and require a careful assessment of the risks and benefits in each patient.

Withdrawal of Therapy. The most frequent problem in steroid withdrawal is flare-up of the underlying disease for which steroids were prescribed. Several other complications are associated with steroid withdrawal. The most severe complication of steroid cessation, acute adrenal insufficiency, results from overly rapid withdrawal of corticosteroids after prolonged therapy has

suppressed the HPA axis. The therapeutic approach to acute adrenal insufficiency is detailed later. There is significant variation among patients with respect to the degree and duration of adrenal suppression after glucocorticoid therapy, making it difficult to establish the relative risk in any given patient. Many patients recover from glucocorticoid-induced HPA suppression within several weeks to months; however, in some individuals the time to recovery can be a year or longer.

In an effort to diminish the risk of iatrogenic acute adrenal insufficiency, protocols for discontinuing corticosteroid therapy in patients receiving long-term treatment with corticosteroids have been proposed, generally without rigorous documentation of their efficacy. Patients who have received supraphysiological doses of glucocorticoids for a period of 2-4 weeks within the preceding year should be considered to have some degree of HPA impairment in settings of acute stress and should be treated accordingly.

In addition to this most severe form of withdrawal, a characteristic glucocorticoid withdrawal syndrome consists of fever, myalgia, arthralgia, and malaise, which may be difficult to differentiate from some of the underlying diseases for which steroid therapy was instituted (Hochberg et al., 2003). Finally, *pseudotumor cerebri*, a clinical syndrome that includes increased intracranial pressure with papilledema, is a rare condition that sometimes is associated with reduction or withdrawal of corticosteroid therapy.

Continued Use of Supraphysiological Glucocorticoid Doses. Besides the consequences that result from the suppression of the HPA axis, a number of other complications result from prolonged therapy with corticosteroids. These include fluid and electrolyte abnormalities, hypertension, hyperglycemia, increased susceptibility to infection, osteoporosis, myopathy, behavioral disturbances, cataracts, growth arrest, and the characteristic habitus of steroid overdose, including fat redistribution, striae, and ecchymoses.

Fluid and Electrolyte Handling. Alterations in fluid and electrolyte handling can cause hypokalemic alkalosis and hypertension, particularly in patients with primary hyperaldosteronism secondary to an adrenal adenoma or in patients treated with potent mineralocorticoids. Similarly, hypertension is a relatively common manifestation of glucocorticoid excess, even in patients treated with glucocorticoids lacking appreciable mineralocorticoid activity.

Metabolic Changes. The effects of glucocorticoids on intermediary metabolism have already been described. Hyperglycemia with glycosuria usually can be managed with diet and/or insulin, and its occurrence should not be a major factor in the decision to continue corticosteroid therapy or to initiate therapy in diabetic patients.

Immune Responses. Because of their multiple effects to inhibit the immune system and the inflammatory response, glucocorticoid use is associated with an increased susceptibility to infection and a risk for reactivation of latent tuberculosis. In the presence of known infections of some consequence, glucocorticoids should be administered only if absolutely necessary and concomitantly with appropriate and effective antimicrobial or antifungal therapy.

Table 42-4

Available Preparations of Adrenocortical Steroids and Their Synthetic Analogs

NONPROPRIETARY NAME	TRADE NAME	TYPE OF PREPARATION
Alclometasone dipropionate	ACLOVATE	Topical
Amcinonide		Topical
Betamethasone acetate and sodium phosphate	CELESTONE SOLUSPAN	Injectable
Beclomethasone dipropionate	BECONASE AQ, QVAR40, QVAR80	Inhaled
	DIPROLENE, DIPROLINE AF	Topical
Betamethasone sodium phosphate	CELESTONE	Oral
Betamethasone valerate	BETA-VAL, DERMABET, LUXIQ	Topical
Budesonide	ENTOCORT EC	Oral
	PULMICORT	Inhaled
	RHINOCORT	Nasal
Ciclesonide	ALVESCO, OMNARIS	Inhaled
Clobetasol propionate	CLOBEX, CORMAX EMBELINE, OLUX, TEMOVATE	Topical
Clocortolone pivalate	CLODERM	Topical
Desonide	DESONATE, DESOWEN, VERDESO	Topical
Desoximetasone	TOPICORT	Topical
Dexamethasone		Oral
Dexamethasone sodium phosphate	MAXIDEX	Ophthalmic
Diflorasone diacetate	PSORCON	Topical
Fludrocortisone acetate*		Oral
Flunisolide	AEROBID, AEROSPAN HFA	Inhaled
	NASAREL	Nasal
Fluocinolone acetonide	DERMA-SMOOTH/FS, FS, SYNALAR	Topical
	RETISERT	Intravitreal implant
Fluocinonide	LIDEX, LIDEX-E, VANOS	Topical
Fluorometholone	FML, FML FORTE	Ophthalmic
Fluorometholone acetate	FLAREX	Ophthalmic
Flurandrenolide	CORDRAN CORDRAN SP	Topical
Halcinonide	HALOG	Topical
Hydrocortisone	ALA-CORT, HYTONE, NUTRACORT, STIE-CORT, SYNACORT, TEXACORT	Topical
	CORTEF	Oral
Hydroxycortisone acetate	MICORT-HC	Topical
	CORTIFOAM	Rectal
Hydroxycortisone butyrate	LOCOID	Topical

(Continued)

Table 42-4

Available Preparations of Adrenocortical Steroids and Their Synthetic Analogs (Continued)

NONPROPRIETARY NAME	TRADE NAME	TYPE OF PREPARATION
Hydrocortisone cypionate	CORTEF	Oral
Hydrocortisone sodium succinate	A-HYDROCORT, SOLU-CORTEF	Injectable
Hydrocortisone valerate	WESTCORT	Topical
Methylprednisolone acetate	MEDROL	Oral
	DEPO-MEDROL	Injectable
Methylprednisolone sodium succinate	A-METHAPRED, SOLU-MEDROL	Injectable
Mometasone furoate	ASMANEX	Inhaled
	NASONEX	Nasal
	ELOCON	Topical
Prednisolone		Oral
Prednisolone acetate	FLO-PRED	Oral
	OMNIPRED, PRED FORT, PRED MILD	Ophthalmic
Prednisolone sodium phosphate	ORAPRED, ORAPRED ODT, PEDIAPRED	Oral
Prednisone		Oral
Triamcinolone acetonide	AZMACORT	Inhaled
	NASACORT AQ	Nasal
	KENOLOG	Topical
	KENOLOG-10, KENALOG-40, TRIESENCE, TRIVARIS	Injectable
Triamcinolone hexacetonide	ARISTOSPAN	Injectable
	AZMACORT	Inhaled

*Fludrocortisone acetate is intended for use as a mineralocorticoid.

Note: *Topical* preparations include agents for application to skin or mucous membranes in creams, solutions, ointments, gels, pastes (for oral lesions), and aerosols; *ophthalmic* preparations include solutions, suspensions, and ointments; *inhalation* preparations include agents for nasal or oral inhalation.

Possible Risk of Peptic Ulcers. There is considerable debate about the association between peptic ulcers and glucocorticoid therapy. The possible onset of hemorrhage and perforation in these ulcers and their insidious onset make peptic ulcers a serious therapeutic problem (Chapter 45); estimating the degree of risk from corticosteroids has received much study. Most patients who develop gastrointestinal bleeding while receiving corticosteroids also receive nonsteroidal anti-inflammatory agents, which are known to promote ulceration, such that the pathogenic role of corticosteroids remains open to debate. Nonetheless, it is prudent to be especially vigilant for peptic ulcer formation in patients receiving therapy with corticosteroids, especially if administered concomitantly with nonsteroidal anti-inflammatory drugs.

Myopathy. Myopathy, characterized by weakness of proximal limb muscles, can occur in patients taking large doses of corticosteroids and also is part of the clinical picture in patients with endogenous

Cushing's syndrome. It can be of sufficient severity to impair ambulation and is an indication for withdrawal of therapy. Attention also has focused on steroid myopathy of the respiratory muscles in patients with asthma or chronic obstructive pulmonary disease (Chapter 36); this complication can diminish respiratory function. Recovery from the steroid myopathies may be slow and incomplete.

Behavioral Changes. Behavioral disturbances are common after administration of corticosteroids and in patients who have Cushing's syndrome secondary to endogenous hypercorticism; these disturbances may take many forms, including nervousness, insomnia, changes in mood or psyche, and overt psychosis. Suicidal tendencies are not uncommon. A history of previous psychiatric illness does not preclude the use of steroids in patients for whom they are otherwise indicated. Conversely, the absence of a history of previous psychiatric illness does not guarantee that a given patient will not develop psychiatric disorders while on steroids.

Cataracts. Cataracts are a well-established complication of glucocorticoid therapy and related to dosage and duration of therapy. Children appear to be particularly at risk. Cessation of therapy may not lead to complete resolution of opacities, and the cataracts may progress despite reduction or cessation of therapy. Patients on long-term glucocorticoid therapy at doses of prednisone of ≥ 10 -15 mg/day should receive periodic slit-lamp examinations to detect glucocorticoid-induced posterior subcapsular cataracts.

Osteoporosis. Osteoporosis, a frequent serious complication of glucocorticoid therapy, occurs in patients of all ages and is related to dosage and duration of therapy (Woolf, 2007). A reasonable estimate is that 30-50% of all patients who receive chronic glucocorticoid therapy ultimately will develop osteoporotic fractures. Glucocorticoids preferentially affect trabecular bone and the cortical rim of the vertebral bodies; the ribs and vertebrae are the most frequent sites of fracture. Glucocorticoids decrease bone density by multiple mechanisms, including inhibition of gonadal steroid hormones, diminished gastrointestinal absorption of Ca^{2+} , and inhibition of bone formation due to suppressive effects on osteoblasts and stimulation of resorption by osteoclasts via changes in the production of osteoprotegerin and RANK ligand. In addition, glucocorticoid inhibition of intestinal Ca^{2+} uptake may lead to secondary increases in parathyroid hormone, thereby increasing bone resorption.

The considerable morbidity of glucocorticoid-related osteoporosis has led to efforts to identify patients at risk for fractures and to prevent or reverse bone loss in patients requiring chronic glucocorticoid therapy. The initiation of glucocorticoid therapy—that is, ≥ 5 mg/day prednisone (or its equivalent) for ≥ 3 months—is considered an indication for bone densitometry to detect abnormalities in trabecular bone. Because bone loss associated with glucocorticoids predominantly occurs within the first 6 months of therapy, densitometric evaluation, preferably with techniques such as dual-energy x-ray absorptiometry of the lumbar spine and hip, along with prophylactic measures should be initiated with therapy or shortly thereafter. Most authorities advocate maintaining a Ca^{2+} intake of 1500 mg/day by diet plus Ca^{2+} supplementation and vitamin D intake of 800 IU/day, assuming that these measures do not increase urinary calcium excretion above the normal range. Although gonadal hormone replacement therapy has been widely used in specific groups of patients receiving chronic glucocorticoid therapy, this is the subject of considerable debate based on recently published results from randomized placebo-controlled trials (Chapter 40). Recombinant parathyroid hormone 1-34 (teriparatide, FORTEO) also has received considerable attention as a potential therapy of glucocorticoid-induced osteoporosis.

The most important advance to date in the prevention of glucocorticoid-related osteoporosis is the successful use of bisphosphonates, which have been shown to decrease the decline in bone density and the incidence of fractures in patients receiving glucocorticoid therapy. Additional discussion of these issues is found in Chapters 40 and 44.

Osteonecrosis. Osteonecrosis (also known as avascular or aseptic necrosis) is a relatively common complication of glucocorticoid therapy. The femoral head is affected most frequently, but this process also may affect the humeral head and distal femur. Joint pain and stiffness usually are the earliest symptoms, and this diagnosis should be considered in patients receiving glucocorticoids who abruptly

develop hip, shoulder, or knee pain. Although the risk increases with the duration and dose of glucocorticoid therapy, osteonecrosis also can occur when high doses of glucocorticoids are given for short periods of time. Osteonecrosis generally progresses, and most affected patients ultimately require joint replacement.

Regulation of Growth and Development. Growth retardation in children can result from administration of relatively small doses of glucocorticoids. Although the precise mechanism is unknown, there are reports that collagen synthesis and linear growth in these children can be restored by treatment with growth hormone; further studies are needed to define the role of concurrent treatment with growth hormone in this setting. Further studies also are needed to explore the possible effects of exposure to corticosteroids *in utero*. In experimental animals, antenatal exposure to glucocorticoids is clearly linked to cleft palate and altered neuronal development, ultimately resulting in complex behavioral abnormalities. Thus, although the actions of glucocorticoids to promote cellular differentiation play important physiological roles in human development in late gestation and in the neonatal period (e.g., production of pulmonary surfactant and induction of hepatic gluconeogenic enzymes), the possibility remains that antenatal steroids can lead to subtle abnormalities in fetal development.

Therapeutic Uses

With the exception of replacement therapy in deficiency states, the use of glucocorticoids largely is empirical. Based on extensive clinical experience, a number of therapeutic principles can be proposed. Given the number and severity of potential side effects, the decision to institute therapy with glucocorticoids always requires a careful consideration of the relative risks and benefits in each patient. For any disease and in any patient, the appropriate dose to achieve a given therapeutic effect must be determined by trial and error and must be reevaluated periodically as the activity of the underlying disease changes or as complications of therapy arise. *A single dose of glucocorticoid, even a large one, is virtually without harmful effects, and a short course of therapy (up to 1 week), in the absence of specific contraindications, is unlikely to be harmful. As the duration of glucocorticoid therapy is increased beyond 1 week, there are time- and dose-related increases in the incidence of disabling and potentially lethal effects.* Except in patients receiving replacement therapy, glucocorticoids are neither specific nor curative; rather, they are palliative by virtue of their anti-inflammatory and immunosuppressive actions. Finally, *abrupt cessation of glucocorticoids after prolonged therapy is associated with the risk of adrenal insufficiency, which may be fatal.*

These principles have several implications for clinical practice. When glucocorticoids are to be given over long periods, the dose must be determined by trial

and error and must be the lowest that will achieve the desired effect. When the therapeutic goal is relief of painful or distressing symptoms not associated with an immediately life-threatening disease, complete relief is not sought, and the steroid dose is reduced gradually until worsening symptoms indicate that the minimal acceptable dose has been found. Where possible, the substitution of other medications, such as nonsteroidal anti-inflammatory drugs, may facilitate tapering the glucocorticoid dose once the initial benefit of therapy has been achieved. When therapy is directed at a life-threatening disease (e.g., pemphigus or lupus cerebritis), the initial dose should be a large one aimed at achieving rapid control of the crisis. If some benefit is not observed quickly, then the dose should be doubled or tripled. After initial control in a potentially lethal disease, dose reduction should be carried out under conditions that permit frequent accurate observations of the patient. It is always essential to weigh carefully the relative dangers of therapy and of the disease being treated.

The lack of demonstrated deleterious effects of a single dose of glucocorticoids within the conventional therapeutic range justifies their administration to critically ill patients who may have adrenal insufficiency. If the underlying condition does result from deficiency of glucocorticoids, then a single intravenous injection of a soluble glucocorticoid may prevent immediate death and allow time for a definitive diagnosis to be made. If the underlying disease is not adrenal insufficiency, the single dose will not harm the patient.

In the absence of specific contraindications, short courses of high-dose systemic glucocorticoids also may be given for diseases that are not life threatening, but the general rule is that long courses of therapy at high doses should be reserved for life-threatening disease. In selected settings, as when a patient is threatened with permanent disability, this rule is justifiably violated.

In an attempt to dissociate therapeutic effects from undesirable side effects, various regimens of steroid administration have been used. To diminish HPA axis suppression, the intermediate-acting steroid preparations (e.g., prednisone or prednisolone) should be given in the morning as a single dose. Alternate-day therapy with the same glucocorticoids also has been employed because certain patients obtain adequate therapeutic responses on this regimen. Alternatively, pulse therapy with higher glucocorticoid doses (e.g., doses as high as 1 to 1.5 g/day of methylprednisolone for 3 days) frequently is used to initiate therapy in patients with fulminant, immunologically related disorders such as acute transplantation rejection, necrotizing glomerulonephritis, and lupus nephritis. The benefit of such pulse therapy in long-term maintenance regimens remains to be defined.

Replacement Therapy. Adrenal insufficiency can result from structural or functional lesions of the adrenal cortex (primary adrenal insufficiency or Addison's disease) or from structural or functional lesions of the anterior pituitary or hypothalamus (secondary adrenal

insufficiency). In developed countries, primary adrenal insufficiency most frequently is secondary to autoimmune adrenal disease, whereas tuberculous adrenalitis is the most frequent etiology in developing countries. Other causes include adrenalectomy, bilateral adrenal hemorrhage, neoplastic infiltration of the adrenal glands, acquired immunodeficiency syndrome, inherited disorders of the steroidogenic enzymes, and X-linked adrenoleukodystrophy (Carey, 1997). Secondary adrenal insufficiency resulting from pituitary or hypothalamic dysfunction generally presents in a more insidious manner than does the primary disorder, probably because mineralocorticoid biosynthesis is preserved.

Acute Adrenal Insufficiency. This life-threatening disease is characterized by GI symptoms (nausea, vomiting, and abdominal pain), dehydration, hyponatremia, hyperkalemia, weakness, lethargy, and hypotension. It usually is associated with disorders of the adrenal rather than the pituitary or hypothalamus, and it sometimes follows abrupt withdrawal of glucocorticoids used at high doses or for prolonged periods.

The immediate management of patients with acute adrenal insufficiency includes intravenous therapy with isotonic sodium chloride solution supplemented with 5% glucose and corticosteroids and appropriate therapy for precipitating causes such as infection, trauma, or hemorrhage. Because cardiac function often is reduced in the setting of adrenocortical insufficiency, the patient should be monitored for evidence of volume overload such as rising central venous pressure or pulmonary edema. After an initial intravenous bolus of 100 mg, hydrocortisone (cortisol) should be given by continuous infusion at a rate of 50-100 mg every 8 hours. At this dose, which approximates the maximum daily rate of cortisol secretion in response to stress, hydrocortisone alone has sufficient mineralocorticoid activity to meet all requirements. As the patient stabilizes, the hydrocortisone dose may be decreased to 25 mg every 6-8 hours. Thereafter, patients are treated in the same fashion as those with chronic adrenal insufficiency.

For the treatment of suspected but unconfirmed acute adrenal insufficiency, 4 mg of dexamethasone sodium phosphate can be substituted for hydrocortisone because dexamethasone does not cross-react in the cortisol assay and will not interfere with the measurement of cortisol (either basally or in response to the cosyntropin stimulation test). A failure to respond to cosyntropin in this setting is diagnostic of adrenal insufficiency. Often, a sample for the measurement of plasma ACTH also is obtained because it will provide information about the underlying etiology if the diagnosis of adrenocortical insufficiency is established.

Chronic Adrenal Insufficiency. Patients with chronic adrenal insufficiency present with many of the same manifestations seen in adrenal crisis but with lesser severity. These patients require daily treatment with corticosteroids (Coursin and Wood, 2002).

Traditional replacement regimens have used hydrocortisone in doses of 20-30 mg/day. Cortisone acetate, which is inactive until converted to cortisol by 11β HSD1, also has been used in doses ranging from 25-37.5 mg/day. In an effort to mimic the normal diurnal rhythm of cortisol secretion, these glucocorticoids generally have been given in divided doses, with two-thirds of the dose given in the morning and one-third given in the afternoon. Based on revised estimates of daily cortisol production and clinical studies showing that subtle degrees of glucocorticoid excess can decrease bone density in patients on conventional replacement regimens, many authorities advocate a lower hydrocortisone dose of 15-20 mg/day divided into either two doses (e.g., 10-15 mg on awakening and 5 mg in late afternoon) or three doses (e.g., 10 mg on awakening, 5 mg at lunch, and 5 mg in late afternoon). Others prefer to use intermediate- (e.g., prednisone) or long-acting (e.g., dexamethasone) glucocorticoids because no regimen employing shorter-acting steroids can reproduce the peak serum glucocorticoid levels that normally occur before awakening in the morning. The superiority of any one of these regimens has not been rigorously demonstrated. Although some patients with primary adrenal insufficiency can be maintained on hydrocortisone and liberal salt intake, most of these patients also require mineralocorticoid replacement; fludrocortisone acetate generally is used in doses of 0.05-0.2 mg/day. For patients with secondary adrenal insufficiency, the administration of a glucocorticoid alone is generally adequate because the zona glomerulosa, which makes mineralocorticoids, is intact. When initiating treatment in patients with panhypopituitarism, it is important to administer glucocorticoids before initiating treatment with thyroid hormone because the administration of thyroid hormone may precipitate acute adrenal insufficiency by increasing the metabolism of cortisol.

The adequacy of corticosteroid replacement therapy is judged by clinical criteria and biochemical measurements. The subjective well-being of the patient is an important clinical parameter in primary and secondary disease. In primary adrenal insufficiency the disappearance of hyperpigmentation and the resolution of electrolyte abnormalities are valuable indicators of adequate replacement. Overtreatment may cause manifestations of Cushing's syndrome in adults and decreased linear growth in children. Plasma ACTH levels may be used to monitor therapy in patients with primary adrenal insufficiency; the early-morning ACTH level should not be suppressed but should be <100 pg/mL (22 pmol/L). Although advocated by some endocrinologists, assessments of daily profiles of cortisol based on multiple blood samples or measurements of urinary free cortisol have been used more frequently as research tools than as a routine part of clinical practice.

Standard doses of glucocorticoids often must be adjusted upward in patients who also are taking drugs that increase their metabolic clearance (e.g., phenytoin, barbiturates, or rifampin). Dosage adjustments also are needed to compensate for the stress of intercurrent illness, and proper patient education is essential for the execution of these adjustments. All patients with adrenal insufficiency should wear a medical alert bracelet or tag that lists their diagnosis and carries information about their steroid regimen. During minor illness, the glucocorticoid dose should be doubled. Patients should be instructed to contact their physician if nausea and vomiting preclude the retention of oral medications. The patient and family members should also be trained to administer parenteral dexamethasone (4 mg subcutaneously or intramuscularly) in the event that severe nausea or

vomiting precludes the oral administration of medications; they then should seek medical attention immediately. Based largely on empirical data, glucocorticoid doses also are adjusted when patients with adrenal insufficiency undergo either elective or emergency surgery (Axelrod, 2003). In this setting, the doses are designed to approximate or exceed the maximal cortisol secretory rate of 200 mg/day; a standard regimen is hydrocortisone, 100 mg parenterally every 8 hours. Following surgery, the dose is halved each day until it is reduced to routine maintenance levels. Although some data suggest that increases in dose to this degree are not essential for survival even in major surgery, this approach remains the standard clinical practice.

Congenital Adrenal Hyperplasia. This term denotes a group of genetic disorders in which the activity of one of the several enzymes required for the biosynthesis of glucocorticoids is deficient. The impaired production of cortisol and the consequent lack of negative feedback inhibition lead to increased release of ACTH. As a result, other hormonally active steroids that are proximal to the enzymatic block in the steroidogenic pathway are produced in excess. Congenital adrenal hyperplasia (CAH) includes a spectrum of disorders for which precise clinical presentation, laboratory findings, and treatment depend on which of the steroidogenic enzymes is deficient.

In ~90% of patients, CAH results from mutations in CYP21, the enzyme that carries out the 21-hydroxylation reaction (Figure 42-3). Clinically, patients are divided into those with classic CAH, who have severe defects in enzymatic activity and first present during childhood, and those with nonclassic CAH, who present after puberty with signs and symptoms of mild androgen excess such as hirsutism, amenorrhea, infertility, and acne. Female patients with classic CAH, if not treated *in utero* with glucocorticoids, frequently are born with virilized external genitalia (female pseudohermaphroditism), which results from elevated production of adrenal androgen precursors at critical stages of sexual differentiation *in utero*. Males appear normal at birth and later may have precocious development of secondary sexual characteristics (isosexual precocious puberty). In both sexes, linear growth is accelerated in childhood, but the adult height is reduced by premature closure of the epiphyses.

A subset of patients with classical CAH are unable to conserve Na^+ normally and thus are called "salt wasters." These patients can present with cardiovascular collapse secondary to volume depletion. In an effort to prevent such life-threatening events, especially in males who appear normal at birth, many centers routinely screen all newborn babies for elevated levels of 17-hydroxyprogesterone, the immediate steroid precursor to the enzymatic block.

All patients with classical CAH require replacement therapy with hydrocortisone or a suitable congener, and those with salt wasting also require mineralocorticoid replacement. The goals of therapy are to restore levels of physiological steroid hormones to the normal range and to suppress ACTH and thereby abrogate the effects of overproduction of adrenal androgens. The typical oral dose of hydrocortisone is ~0.6 mg/kg daily in two or three divided doses. The

mineralocorticoid used is fludrocortisone acetate (0.05-0.2 mg/day). Many experts also administer table salt to infants (one-fifth of a teaspoon dissolved in formula daily) until the child is eating solid food. Therapy is guided by gain in weight and height, by plasma levels of 17-hydroxyprogesterone, and by blood pressure. Elevated plasma renin activity suggests that the patient is receiving an inadequate dose of mineralocorticoid. Sudden spurts in linear growth often indicate inadequate pituitary suppression and excessive androgen secretion, whereas growth failure suggests overtreatment with glucocorticoid.

The ability to detect classical CAH (21-hydroxylase deficiency) prenatally has made possible the treatment of affected females with glucocorticoids *in utero*, potentially eliminating the need for genital surgery to correct the virilization of the external genitalia. To suppress fetal adrenal androgen production effectively and consequent virilization, glucocorticoid therapy (e.g., dexamethasone, 20 µg/kg taken daily orally by mothers at risk) must be initiated before 10 weeks of gestation, before a definitive diagnosis of CAH can be made. The genotype and sex of the fetus then are determined, and steroid therapy is stopped if the sex is male or there is at least one wild-type allele for 21-hydroxylase. If genotyping reveals an affected female, steroid therapy is continued until delivery. A large-scale study currently is in progress to determine if exposure to glucocorticoids *in utero* has developmental consequences. To date, no adverse effects on developmental milestones and cognitive development have been noted; however, increased shyness and internalization behavior have been observed in small pilot study and will need to be reevaluated in the larger trial. Potential maternal side effects include hypertension, weight gain, edema, and mood changes.

Therapeutic Uses in Nonendocrine Diseases. Outlined next are important uses of glucocorticoids in diseases that do not directly involve the HPA axis. The disorders discussed are not inclusive; rather, they illustrate the principles governing glucocorticoid use in selected diseases for which glucocorticoids are more frequently employed. The dosage of glucocorticoids varies considerably depending on the nature and severity of the underlying disorder. For convenience, approximate doses of a representative glucocorticoid (generally prednisone) are provided. This choice is not an endorsement of one particular glucocorticoid preparation over other congeners but is made for illustrative purposes only.

Rheumatic Disorders. Glucocorticoids are used widely in the treatment of a variety of rheumatic disorders and are a mainstay in the treatment of the more serious inflammatory rheumatic diseases, such as systemic lupus erythematosus, and a variety of vasculitic disorders, such as polyarteritis nodosa, Wegener's granulomatosis, Churg-Strauss syndrome, and giant cell arteritis. For these more serious disorders, the starting dose of glucocorticoids should be sufficient to suppress the disease rapidly and minimize resultant tissue damage. Initially, prednisone (1 mg/kg per day in divided doses) often is used, generally followed by consolidation to a single daily dose, with subsequent tapering to a minimal effective dose as determined by the clinical picture.

Although they are an important component of treatment of rheumatic diseases, glucocorticoids are often used in conjunction

with other immunosuppressive agents such as cyclophosphamide and methotrexate, which offer better long-term control than steroids alone. The exception is giant cell arteritis, for which glucocorticoids remain superior to other agents. Caution should be exercised in the use of glucocorticoids in some forms of vasculitis (e.g., polyarteritis nodosa), for which underlying infections with hepatitis viruses may play a pathogenetic role. Although glucocorticoids are indicated in these cases, there is at least a theoretical concern that glucocorticoids may complicate the course of the viral infection by suppressing the immune system. To facilitate drug tapering and/or conversion to alternate-day treatment regimens, the intermediate-acting glucocorticoids such as prednisone and methylprednisolone are generally preferred over longer-acting steroids such as dexamethasone.

In rheumatoid arthritis, because of the serious and debilitating side effects associated with chronic use, glucocorticoids are used as stabilizing agents for progressive disease that fails to respond to first-line treatments such as physiotherapy and nonsteroidal anti-inflammatory agents. In this case, glucocorticoids provide relief until other, slower-acting antirheumatic drugs, such as methotrexate or agents targeted at tumor necrosis factor, take effect. A typical starting dose is 5-10 mg of prednisone per day. In the setting of an acute exacerbation, higher doses of glucocorticoids may be employed (typically 20-40 mg/day of prednisone or equivalent), with rapid taper thereafter. Complete relief of symptoms is not sought, and the symptomatic effect of small reductions in dose (decreases of perhaps 1 mg/day of prednisone every 2-3 weeks) should be tested frequently while concurrent therapy with other measures is continued, to maintain the lowest possible prednisone dose. Alternatively, patients with major symptomatology confined to one or a few joints may be treated with intra-articular steroid injections. Depending on joint size, typical doses are 5-20 mg of triamcinolone acetate or its equivalent.

In noninflammatory degenerative joint diseases (e.g., osteoarthritis) or in a variety of regional pain syndromes (e.g., tendinitis or bursitis), glucocorticoids may be administered by local injection for the treatment of episodic disease flare-up. It is important to use a glucocorticoid that does not require bioactivation (e.g., prednisolone rather than prednisone) and to minimize the frequency of local steroid administration whenever possible. In the case of repeated intra-articular injection of steroids, there is a significant incidence of painless joint destruction, resembling Charcot's arthropathy. It is recommended that intra-articular injections be performed with intervals of at least 3 months to minimize complications.

Renal Diseases. Patients with nephrotic syndrome secondary to minimal change disease generally respond well to steroid therapy, and glucocorticoids clearly are the first-line treatment in both adults and children. Initial daily doses of prednisone are 1-2 mg/kg for 6 weeks, followed by a gradual tapering of the dose over 6-8 weeks, although some nephrologists advocate alternate-day therapy. Objective evidence of response, such as diminished proteinuria, is seen within 2-3 weeks in 85% of patients, and >95% of patients have remission within 3 months. Cessation of steroid therapy frequently is complicated by disease relapse, as manifested by recurrent proteinuria. Patients who relapse repeatedly are termed *steroid-resistant* and often are treated with other immunosuppressive drugs such as azathioprine or cyclophosphamide. Patients with renal disease secondary to systemic lupus erythematosus also are generally given a therapeutic trial of glucocorticoids.

Studies with other forms of renal disease, such as membranous and membranoproliferative glomerulonephritis and focal sclerosis, have provided conflicting data on the role of glucocorticoids. In clinical practice, patients with these disorders often are given a therapeutic trial of glucocorticoids with careful monitoring of laboratory indices of response. In the case of membranous glomerulonephritis, many nephrologists recommend a trial of alternate-day glucocorticoids for 8-10 weeks (e.g., prednisone, 120 mg every other day), followed by a 1- to 2-month period of tapering.

Allergic Disease. The onset of action of glucocorticoids in allergic diseases is delayed, and patients with severe allergic reactions such as anaphylaxis require immediate therapy with epinephrine. The manifestations of allergic diseases of limited duration—such as hay fever, serum sickness, urticaria, contact dermatitis, drug reactions, bee stings, and angioneurotic edema—can be suppressed by adequate doses of glucocorticoids given as supplements to the primary therapy. In severe disease, intravenous glucocorticoids (methylprednisolone, 125 mg intravenously every 6 hours, or equivalent) are appropriate. In less severe disease, antihistamines are the drugs of first choice. In allergic rhinitis, intranasal steroids are now viewed as the drug of choice by many experts.

Bronchial Asthma and Other Pulmonary Conditions. Corticosteroids frequently are used in bronchial asthma (Chapter 36). Although they sometimes are employed in chronic obstructive pulmonary disease (COPD), particularly when there is some evidence of reversible obstructive disease, data supporting the efficacy of corticosteroids are much less convincing than for bronchial asthma. The increased use of corticosteroids in asthma reflects an increased appreciation of the role of inflammation in the immunopathogenesis of this disorder. In severe asthma attacks requiring hospitalization, treatment with high-dose parenteral glucocorticoids is essential. Symptomatic relief sometimes is very rapid; however, the onset of a maintained response may take up to 6-12 hours. Intravenous administration of 60-120 mg methylprednisolone (or equivalent) every 6 hours is used initially, followed by daily oral doses of prednisone (30-60 mg) as the acute attack resolves. The dose then is tapered gradually, with withdrawal planned for 10 days to 2 weeks after initiation of steroid therapy. In general, patients subsequently can be managed on their prior medical regimen.

Less severe acute exacerbations of asthma (as well as acute flares of COPD) often are treated with brief courses of oral glucocorticoids. In adult patients, 30-60 mg prednisone is administered daily for 5 days; an additional week of therapy at lower doses also may be required. Upon resolution of the acute exacerbation, the glucocorticoids generally can be rapidly tapered without significant deleterious effects. Any suppression of adrenal function usually dissipates within 1-2 weeks. In the treatment of severe chronic bronchial asthma (or, less frequently, COPD) that is not controlled by other measures, the long-term administration of glucocorticoids may be necessary. As with other long-term uses of these agents, the lowest effective dose is used, and care must be exercised when withdrawal is attempted. Given the risks of long-term treatment with glucocorticoids, it is especially important to document objective evidence of a response (e.g., an improvement in pulmonary function tests). In addition, these risks dictate that long-term glucocorticoid therapy be reserved for those patients who have failed to respond to adequate regimens of other medications (Chapter 36).

In many patients, inhaled steroids (see Table 42-4) can either reduce the need for oral corticosteroids or replace them entirely. Many physicians prefer inhaled glucocorticoids over previously recommended oral theophylline in the treatment of children with moderately severe asthma, in part because of the behavioral toxicity associated with chronic theophylline administration. The oral bioavailability of inhaled corticosteroids varies considerably; however, when used as recommended, inhaled glucocorticoids are effective in reducing bronchial hyperreactivity and are less likely to suppress adrenal function than are the oral glucocorticoids. Dysphonia or oropharyngeal candidiasis may develop, but the incidence of such side effects can be reduced substantially by maneuvers that reduce drug deposition in the oral cavity, such as spacers and mouth rinsing or by using corticosteroids with low oral bioavailability. For example, ciclesonide (ALVESCO, OMNARIS) and beclomethasone dipropionate (BECONASE AQ, QVAR), are inactive compounds that are activated on site by lung esterases; therefore they are less likely to adversely affect the oral cavity (Derendorf et al., 2006). The status of glucocorticoids in asthma therapy is discussed in Chapter 36.

Antenatal glucocorticoids are used frequently in the setting of premature labor, decreasing the incidence of respiratory distress syndrome, intraventricular hemorrhage, and death in infants delivered prematurely. Betamethasone (12 mg intramuscularly every 24 hours for two doses) or dexamethasone (6 mg intramuscularly every 12 hours for four doses) is administered to women with definitive signs of premature labor between 26 and 34 weeks of gestation (Roberts and Dalziel, 2006). Due to evidence of decreased birthweight and adrenal suppression in infants whose mothers were given repeated courses of glucocorticoids, only a single course of glucocorticoids should be administered.

Infectious Diseases. Although the use of immunosuppressive glucocorticoids in infectious diseases may seem paradoxical, there are a limited number of settings in which they are indicated in the therapy of specific infectious pathogens. One dramatic example of such beneficial effects is seen in AIDS patients with *Pneumocystis carinii* pneumonia and moderate to severe hypoxia; addition of glucocorticoids to the antibiotic regimen increases oxygenation and lowers the incidence of respiratory failure and mortality. Similarly, glucocorticoids clearly decrease the incidence of long-term neurological impairment associated with *Haemophilus influenzae* type b meningitis in infants and children ≥ 2 months of age.

A long-standing controversy in medicine is the use of glucocorticoids in septic shock (Sprung et al., 2008). Supraphysiologic doses of glucocorticoids had been used routinely as adjunctive therapy in subjects with septic shock associated with gram-negative bacteremia until it was recognized that glucocorticoid therapy in supraphysiologic doses actually increased mortality. Subsequent studies then examined the benefit of somewhat lower doses of glucocorticoids (e.g., 100 mg hydrocortisone every 8 hours) administered to patients early in the course of their disease. In one multicenter randomized placebo-controlled trial, beneficial effects of hydrocortisone plus fludrocortisone were seen only in subjects with adrenal insufficiency as determined by the rapid cosyntropin stimulation test. Although a second large study using hydrocortisone alone failed to demonstrate a beneficial effect regardless of adrenal status, current guidelines suggest that hydrocortisone be used in adult patients with septic shock whose blood pressure fails to respond adequately to fluids and vasopressors (Dellinger et al., 2008).

1232 **Ocular Diseases.** Ocular pharmacology, including some consideration of the use of glucocorticoids, is discussed in Chapter 64. Glucocorticoids frequently are used to suppress inflammation in the eye and can preserve sight when used properly. They are administered topically for diseases of the outer eye and anterior segment and attain therapeutic concentrations in the aqueous humor after instillation into the conjunctival sac. For diseases of the posterior segment, intraocular injection or systemic administration is required. Generally, ocular use of glucocorticoids should be supervised by an ophthalmologist.

A typical prescription is 0.1% dexamethasone sodium phosphate solution (ophthalmic), 2 drops in the conjunctival sac every 4 hours while awake, and 0.05% dexamethasone sodium phosphate ointment (ophthalmic) at bedtime. For inflammation of the posterior segment, typical doses are 30 mg of prednisone or equivalent per day, administered orally in divided doses.

Topical glucocorticoid therapy frequently increases intraocular pressure in normal eyes and exacerbates intraocular hypertension in patients with antecedent glaucoma. The glaucoma is not always reversible on cessation of glucocorticoid therapy. Intraocular pressure should be monitored when glucocorticoids are applied to the eye for >2 weeks.

Topical administration of glucocorticoids to patients with bacterial, viral, or fungal conjunctivitis can mask evidence of progression of the infection until sight is irreversibly lost. Glucocorticoids are contraindicated in herpes simplex keratitis because progression of the disease may lead to irreversible clouding of the cornea. Topical steroids should not be used in treating mechanical lacerations and abrasions of the eye because they delay healing and promote the development and spread of infection.

Skin Diseases. Glucocorticoids are remarkably efficacious in the treatment of a wide variety of inflammatory dermatoses. As a result, a large number of different preparations and concentrations of topical glucocorticoids of varying potencies are available. A typical regimen for an eczematous eruption is 1% hydrocortisone ointment applied locally twice daily. Effectiveness is enhanced by application of the topical steroid under an occlusive film, such as plastic wrap; unfortunately, the risk of systemic absorption also is increased by occlusive dressings, and this can be a significant problem when the more potent glucocorticoids are applied to inflamed skin. Glucocorticoids are administered systemically for severe episodes of acute dermatological disorders and for exacerbations of chronic disorders. The dose in these settings is usually 40 mg/day of prednisone. Systemic steroid administration can be lifesaving in pemphigus, which may require daily doses of up to 120 mg of prednisone. Further discussion of the treatment of skin diseases is presented in Chapter 65.

Gastrointestinal Diseases. Glucocorticoid therapy is indicated in selected patients with inflammatory bowel disease (chronic ulcerative colitis and Crohn's disease; Chapter 47). Patients who fail to respond to more conservative management (i.e., rest, diet, and sulfasalazine) may benefit from glucocorticoids; steroids are most useful for acute exacerbations. In mild ulcerative colitis, hydrocortisone (100 mg) can be administered as a retention enema with beneficial effects. In more severe acute exacerbations, oral prednisone (10-30 mg/day) frequently is employed. For severely ill patients—with fever, anorexia, anemia, and impaired nutritional status—larger doses should be used (40-60 mg prednisone per day). Major complications of ulcerative

colitis or Crohn's disease may occur despite glucocorticoid therapy, and glucocorticoids may mask signs and symptoms of complications such as intestinal perforation and peritonitis.

Budesonide, a highly potent synthetic glucocorticoid that is inactivated by first-pass hepatic metabolism, reportedly exhibits diminished systemic side effects commonly associated with glucocorticoids. Oral administration of budesonide in delayed-release capsules (ENTOCORT, 9 mg/day) facilitates drug delivery to the ileum and ascending colon; the drug also has been used as a retention enema in the treatment of ulcerative colitis.

Hepatic Diseases. The use of corticosteroids in hepatic disease has been highly controversial. Glucocorticoids clearly are of benefit in autoimmune hepatitis, where as many as 80% of patients show histological remission when treated with prednisone (40-60 mg daily initially, with tapering to a maintenance dose of 7.5-10 mg daily after serum transaminase levels fall). The role of corticosteroids in alcoholic liver disease is not fully defined; the most recent meta-analysis of previously published reports failed to establish a beneficial role of corticosteroids, even in patients with severe disease (Rambaldi et al., 2008). Further studies are needed to confirm or refute the role of steroids in this setting. In the setting of severe hepatic disease, prednisolone should be used instead of prednisone, which requires hepatic conversion to be active.

Malignancies. Glucocorticoids are used in the chemotherapy of acute lymphocytic leukemia and lymphomas because of their antilymphocytic effects. Most commonly, glucocorticoids are one component of combination chemotherapy administered under scheduled protocols. Glucocorticoids once were frequently employed in the setting of hypercalcemia of malignancy, but more effective agents, such as the bisphosphonates, now are the preferred therapy.

Cerebral Edema. Corticosteroids are of value in the reduction or prevention of cerebral edema associated with parasites and neoplasms, especially those that are metastatic. Although corticosteroids are frequently used for the treatment of cerebral edema caused by trauma or cerebrovascular accidents, controlled clinical trials do not support their use in these settings.

Miscellaneous Diseases and Conditions. *Sarcoidosis.* Corticosteroids are indicated therapy for patients with debilitating symptoms or life-threatening forms of sarcoidosis. Patients with severe pulmonary involvement are treated with 10-20 mg per day of prednisone, or an equivalent dose of alternative steroids, to induce remission. Higher doses may be required for other forms of this disease. Maintenance doses, which often are required for long periods of time, may be as low as 5 mg/day of prednisone. These patients, like all patients who require chronic glucocorticoid therapy at doses exceeding the normal daily production rate, are at increased risk of secondary tuberculosis; therefore, patients with a positive tuberculin reaction or other evidence of tuberculosis should receive prophylactic antituberculosis therapy.

Thrombocytopenia. In thrombocytopenia, prednisone (0.5 mg/kg) is used to decrease the bleeding tendency. In more severe cases, and for initiation of treatment of idiopathic thrombocytopenia, daily doses of prednisone (1-1.5 mg/kg) are employed. Patients with refractory idiopathic thrombocytopenia may respond to pulsed high-dose glucocorticoid therapy.

Autoimmune Destruction of Erythrocytes. Patients with autoimmune destruction of erythrocytes (i.e., hemolytic anemia with a positive

Coombs test) are treated with prednisone (1 mg/kg per day). In the setting of severe hemolysis, higher doses may be used, with tapering as the anemia improves. Small maintenance doses may be required for several months in patients who respond.

Organ Transplantation. In organ transplantation, high doses of prednisone (50–100 mg) are given at the time of transplant surgery, in conjunction with other immunosuppressive agents, and most patients are kept on a maintenance regimen that includes lower doses of glucocorticoids (Chapter 35). For some solid organ transplants (e.g., pancreas), protocols that either withdraw corticosteroids early after transplantation or that avoid them completely are becoming more common (Meier-Kriesche et al., 2006).

Spinal Cord Injury. A meta-analysis of several randomized, controlled trials (Bracken, 2002) demonstrated significant decreases in neurological defects in patients with acute spinal cord injury treated within 8 hours of injury with large doses of methylprednisolone sodium succinate (30 mg/kg initially followed by an infusion of 5.4 mg/kg per hour for 23 hours). One trial showed further improvement with an additional 24 hours of treatment. The ability of corticosteroids at these high doses to decrease neurological injury may reflect inhibition of free radical-mediated cellular injury, as occurs following ischemia and reperfusion. Potential side effects include increased susceptibility to infection and other wound complications.

Diagnostic Applications of Adrenocortical Steroids

In addition to its therapeutic uses, dexamethasone is used as a first-line agent to diagnose hypercortisolism and to differentiate among the different causes of Cushing's syndrome (Arnaldi et al., 2003).

To determine if patients with clinical manifestations suggestive of hypercortisolism have biochemical evidence of increased cortisol biosynthesis, an overnight dexamethasone suppression test has been devised. Patients are given 1 mg of dexamethasone orally at 11 P.M., and cortisol is measured at 8 A.M. the following morning. Suppression of plasma cortisol to $<1.8 \mu\text{g/dL}$ suggests strongly that the patient does not have Cushing's syndrome. Drugs such as barbiturates that enhance dexamethasone metabolism or drugs (estrogens) or conditions (pregnancy) that increase the concentrations of corticosteroid binding globulin can interfere with suppression and compromise the test. The formal dexamethasone suppression test is used in the differential diagnosis of biochemically documented Cushing's syndrome. Following determination of baseline cortisol levels for 48 hours, dexamethasone (0.5 mg every 6 hours) is administered orally for 48 hours. This dose markedly suppresses cortisol levels in normal subjects, including those who have nonspecific elevations of cortisol due to obesity or stress, but it does not suppress levels in patients with Cushing's syndrome. In the high-dose phase of the test, dexamethasone is administered orally at 2 mg every 6 hours for 48 hours. Patients with pituitary-dependent Cushing's syndrome (i.e., Cushing's disease) generally respond with decreased cortisol levels. In contrast, patients with ectopic production of ACTH or with adrenocortical tumors generally do not exhibit decreased cortisol levels. Despite these generalities, dexamethasone may suppress cortisol levels in some patients with ectopic ACTH production, particularly with tumors such as bronchial carcinoids, and many experts prefer to use inferior petrosal sinus sampling after CRH administration to make this distinction.

INHIBITORS OF THE BIOSYNTHESIS AND ACTION OF ADRENOCORTICAL STEROIDS

Hypercortisolism with its attendant morbidity and mortality is most frequently caused by corticotroph adenomas that overproduce ACTH (Cushing's disease) or by adrenocortical tumors or bilateral hyperplasias that overproduce cortisol (Cushing's syndrome). Less frequently, hypercortisolism may result from adrenocortical carcinomas or ectopic ACTH- or CRH-producing tumors. Although surgery is the treatment of choice, it is not always effective, and adjuvant therapy with inhibitors of steroidogenesis becomes necessary (Billir et al., 2008). In these settings, ketoconazole, metyrapone, etomidate, and mitotane are clinically useful. Ketoconazole, etomidate, and mitotane are discussed in more detail in other chapters. All of these agents pose the common risk of precipitating acute adrenal insufficiency; thus, they must be used in appropriate doses, and the status of the patient's HPA axis must be carefully monitored. Agents that act as glucocorticoid receptor antagonists (antiglucocorticoids) are discussed later in this chapter; mineralocorticoid antagonists are discussed in Chapter 25.

Ketoconazole. Ketoconazole (NIZORAL) is an antifungal agent, and this remains its most important clinical role (Chapter 57). In doses higher than those employed in antifungal therapy, it is an effective inhibitor of adrenal and gonadal steroidogenesis, primarily because of its inhibition of the activity of CYP17 (17 α -hydroxylase). At even higher doses, ketoconazole also inhibits CYP11A1, effectively blocking steroidogenesis in all primary steroidogenic tissues. Ketoconazole is the best tolerated and most effective inhibitor of steroid hormone biosynthesis in patients with hypercortisolism. In most cases, a dosage regimen of 600–800 mg/day (in two divided doses) is required, and some patients may require up to 1200 mg/day given in two to three doses. Side effects include hepatic dysfunction, which ranges from asymptomatic elevations of transaminase levels to severe hepatic injury. The potential of ketoconazole to interact with CYP isoforms can lead to drug interactions of serious consequence (Chapter 6). Further studies are needed to define the precise role of ketoconazole in the medical management of patients with excessive steroid hormonal production, and the FDA has not approved this indication for ketoconazole use.

Metyrapone. Metyrapone (METOPIRONE) is a relatively selective inhibitor of CYP11B1 (11 β -hydroxylase), which converts 11-deoxycortisol to cortisol in the terminal reaction of the glucocorticoid biosynthetic pathway. Because of this inhibition, the biosynthesis of cortisol is markedly impaired, and the levels of steroid precursors (e.g., 11-deoxycortisol) are markedly increased. Although the biosynthesis of aldosterone also is impaired, the elevated levels of 11-deoxycortisol sustain mineralocorticoid-dependent functions. In a diagnostic test of the entire HPA axis, metyrapone (30 mg/kg, maximum dose of 3 g) is administered orally with a snack at midnight, and plasma cortisol

and 11-deoxycortisol are measured at 8 A.M. the next morning. A plasma cortisol $<8 \mu\text{g/dL}$ validates adequate inhibition of CYP11B1; in this setting, an 11-deoxycortisol level $<7 \mu\text{g/dL}$ is highly suggestive of impaired hypothalamic-pituitary-adrenal function. An abnormal response does not identify the site of the defect; hypothalamic CRH release, ACTH production, or adrenal biosynthetic capacity could be impaired. Some authorities avoid overnight metyrapone testing in outpatients thought to have a reasonable probability of impaired HPA function because there is some risk of precipitating acute adrenal insufficiency. Others believe that the ability to assess the entire HPA axis with a relatively easy test justifies the use of metyrapone testing in outpatients.

Metyrapone also is used to diagnose patients with Cushing's syndrome who respond equivocally to the formal dexamethasone suppression test. Those with pituitary-dependent Cushing's syndrome exhibit a normal response, whereas those patients with ectopic secretion of ACTH exhibit no changes in ACTH or 11-deoxycortisol levels.

Therapeutically, metyrapone has been used to treat the hypercorticism resulting from either adrenal neoplasms or tumors producing ACTH ectopically. Maximal suppression of steroidogenesis requires doses of 4 g/day. More frequently, metyrapone is used as adjunctive therapy in patients who have received pituitary irradiation or in combination with other agents that inhibit steroidogenesis. In this setting, a dose of 500-750 mg three or four times daily is employed. The use of metyrapone in the treatment of Cushing's syndrome secondary to pituitary hypersecretion of ACTH is more controversial. Chronic administration of metyrapone can cause hirsutism, which results from increased synthesis of adrenal androgens upstream from the enzymatic block, and hypertension, which results from elevated levels of 11-deoxycortisol. Other side effects include nausea, headache, sedation, and rash.

Etomidate. Etomidate (AMIDATE), a substituted imidazole used primarily as an anesthetic agent and sedative, inhibits cortisol secretion at subhypnotic doses primarily by inhibiting CYP11B1 activity. It is administered intravenously and has been used off-label to treat hypercortisolism when rapid control is required in a patient who cannot take medication by the oral route. An international consensus panel recommends that etomidate be administered as a bolus of 0.03 mg/kg intravenously, followed by an infusion of 0.1 mg/kg per hour to a maximum of 0.3 mg/kg per hour (Billir et al., 2008).

Mitotane. Mitotane (o,p'-DDD; LYSODREN) is an adrenocorticolytic agent used to treat inoperable adrenocortical carcinoma. Its cytolytic action is due to its metabolic conversion to a reactive acyl chloride by adrenal mitochondrial CYPs and subsequent reactivity with cellular proteins. In a few centers, it has been used for long-term control of hypercortisolism. Doses range from 0.5-3 g administered three times daily. Its onset of action takes weeks to months, and GI disturbances and ataxia are its major toxicities.

Aminoglutethimide. Aminoglutethimide (α -ethyl-*p*-aminophenylglutarimide; CYTADREN) primarily inhibits CYP11A1, which catalyzes the initial and rate-limiting step in the biosynthesis of all physiological steroids and also inhibits CYP11B1 and CYP19 (aromatase). As a result, the production of all classes of steroid hormones is impaired. Although used at one time to treat hypercortisolism and advanced cancer of the breast and prostate, aminoglutethimide recently has been withdrawn from the market by the manufacturer and is no longer available.

Trilostane. Trilostane ($4\alpha,5\alpha,17\beta$)-4-5-epoxy-3,17-dihydroxyandrost-2-ene-2-carbonitrile, a competitive inhibitor of the type II β -

hydroxysteroid dehydrogenase (Figure 42-3), also interferes with the synthesis of both adrenal and gonadal hormones, but it is more effective in dogs than in humans. For this reason, trilostane is not used in humans but still has a place in veterinary medicine.

ANTI-GLUCOCORTICOIDS

The progesterone receptor antagonist *mifepristone* (MIFEPREX; RU-486; 11β -[*p*-(dimethylamino)phenyl]- 17β -hydroxy-17-(1-propynyl)estra-4,9-dien-3-one) has received considerable attention because of its use as an antiprogesterone that can terminate early pregnancy (Chapter 66). At higher doses, mifepristone also inhibits the GR, blocking feedback regulation of the HPA axis and secondarily increasing endogenous ACTH and cortisol levels. Because of its ability to inhibit glucocorticoid action, mifepristone also has been studied as a potential therapeutic agent in a small number of patients with hypercortisolism (Johanssen and Allolio, 2007). Currently, its use for this purpose is considered investigational and is restricted to patients with inoperable causes of cortisol excess that have not responded to other agents.

CLINICAL SUMMARY

Glucocorticoids are administered in multiple formulations (e.g., oral, parenteral, and topical) for disorders that share an inflammatory or immunological basis. Except in patients receiving replacement therapy for adrenal insufficiency, glucocorticoids are neither specific nor curative, but rather are palliative because of their anti-inflammatory and immunosuppressive actions. Given the number and severity of potential side effects, the decision to institute therapy with glucocorticoids always requires a careful consideration of the relative risks and benefits in each patient. After therapy is initiated, the minimal dose needed to achieve a given therapeutic effect must be determined by trial and error and must be reevaluated periodically as the activity of the underlying disease changes or as complications of therapy arise. A single dose of glucocorticoid, even a large one, is virtually without harmful effects, and a short course of therapy (up to 1 week) is unlikely to cause harm in the absence of specific contraindications. As the duration of glucocorticoid therapy increases beyond 1 week, adverse effects increase in a time- and dose-related manner. Abrupt cessation of glucocorticoids after prolonged therapy is associated with the risk of adrenal insufficiency due to suppression of the HPA axis, and it may be fatal.

Endocrine Pancreas and Pharmacotherapy of Diabetes Mellitus and Hypoglycemia

Alvin C. Powers
and David D'Alessio

Diabetes mellitus is a spectrum of common metabolic disorders, arising from a variety of pathogenic mechanisms, all resulting in hyperglycemia. The number of individuals with diabetes is rising rapidly throughout the world. Both genetic and environmental factors contribute to its pathogenesis, which involves insufficient insulin secretion, reduced responsiveness to endogenous or exogenous insulin, increased glucose production, and/or abnormalities in fat and protein metabolism. The resulting hyperglycemia may lead to both acute symptoms and metabolic abnormalities. However, the major sources of the morbidity of diabetes are the chronic complications that arise from prolonged hyperglycemia, including retinopathy, neuropathy, nephropathy, and cardiovascular disease. Fortunately, these chronic complications can be mitigated in many patients by sustained control of the blood glucose. There are now a wide variety of treatment options for hyperglycemia that target different processes involved in glucose regulation or dysregulation.

Following a brief review of glucose homeostasis and the pathogenesis of diabetes, this chapter discusses the general approaches and specific agents used in the therapy of diabetes. The last section describes agents used for hypoglycemia.

PHYSIOLOGY OF GLUCOSE HOMEOSTASIS

Regulation of Blood Glucose. In healthy humans, blood glucose is tightly maintained despite wide fluctuations in glucose consumption, utilization, and production. The maintenance of glucose homeostasis, generally termed *glucose tolerance*, is a highly developed systemic process involving the integration of several

major organs through multilayered communication (Figure 43–1). Although endocrine control of blood glucose, primarily through the actions of insulin, is of central importance, myriad levels of inter-organ communication, via other hormones, nerves, local factors and substrates, also play a vital role. The pancreatic β cell is central in this homeostatic process, adjusting the amount of insulin secreted very precisely to promote glucose uptake after meals and to regulate glucose output from the liver during fasting.

In the fasting state (Figure 43–1A), most of the fuel demands of the body are met by the oxidation of fatty acids. Importantly, the brain does not effectively utilize fatty acids to meet energy needs and in the fasting state requires glucose for normal function; glucose requirements are ~ 2 mg/kg per minute in adult humans, largely to supply the central nervous system (CNS) with an energy source. Fasting glucose requirements are primarily provided by the liver, with a minor contribution from the kidney. Liver glycogen stores provide some of this glucose; conversion of gluconeogenic precursors, primarily lactate, alanine and glycerol, into glucose accounts for the remainder. The dominant regulation of hepatic glycogenolysis and gluconeogenesis are the pancreatic islet hormones insulin and glucagon. Insulin inhibits hepatic glucose production at several levels, and the decline of circulating insulin concentrations in the postabsorptive state (fasting) is permissive for higher rates of glucose output. Glucagon maintains blood glucose concentrations at physiological levels in the absence of exogenous carbohydrate (overnight and in between meals) by stimulating gluconeogenesis and glycogenolysis by the liver.

Ingestion of a meal provides a substantial challenge to glucose homeostasis (Figure 43–1B). Adults

Figure 43-1. *Insulin, glucagon, and glucose homeostasis.* **A.** Fasting State—In healthy humans plasma glucose is maintained in a range from 4.4–5 mM, and fatty acids near 400 μM. In the absence of nutrient absorption from the GI tract, glucose is supplied primarily from the liver and fatty acids from adipose tissue. With fasting, plasma insulin levels are low, and plasma glucagon is elevated, contributing to increased hepatic glycogenolysis and gluconeogenesis; low insulin also releases adipocytes from inhibition, permitting increased lipolysis. Most tissues oxidize primarily fatty acids during fasting, sparing glucose for use by the CNS. **B.** Prandial State—During feeding, nutrient absorption causes an increase in plasma glucose, resulting in release of incretins from the gut and neural stimuli that promote insulin secretion. Under the control of insulin, the liver, skeletal muscle and adipose tissue actively take up glucose. Hepatic glucose production and lipolysis are inhibited, and total body glucose oxidation increases. The brain senses plasma glucose concentrations and provides regulatory inputs contributing to fuel homeostasis. The boldness of the arrows reflects relative intensity of action; a dashed line indicates little or no activity.

typically consume 30–90 g of carbohydrate in a single meal, considerably more than the extracellular glucose pool, which typically contains 15–20 g of glucose. Therefore, uptake and disposition of meal-derived glucose requires effective coordination of a range of processes, from digestion and absorption to intracellular glycolysis and glycogen synthesis, to prevent major shifts in plasma glucose concentrations. Regulation of nutrient disposition after meals is under the primary control of insulin. Insulin secretion is stimulated by food ingestion, nutrient absorption, and increases in blood glucose, and insulin promotes glucose, lipid, and protein anabolism. The centrality of insulin in glucose metabolism is emphasized by the fact that all the forms of human diabetes have as a root cause some abnormality of insulin secretion or action.

In healthy humans, β cell function is primarily controlled by plasma glucose concentrations. Elevations of blood glucose are necessary for insulin release above basal levels, and other stimuli are relatively ineffective when plasma glucose is in the fasting range (4.4–5.5 mM or 80–100 mg %). These other stimuli include nutrient substrates, insulinotropic hormones released from the gastrointestinal (GI) tract, and autonomic neural pathways. As a result, the pancreatic β cell is stimulated from the time of food presentation, through nutrient absorption, and until blood glucose returns to fasting levels. Neural stimuli cause some increase of insulin secretion prior to food consumption. In addition to these cephalic responses, neural stimulation of insulin secretion occurs throughout the meal and contributes significantly to glucose tolerance. Arrival of nutrient chyme to the intestine leads to the release of insulinotropic peptides from specialized endocrine cells in the intestinal mucosa. Glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide 1 (GLP-1), together termed *incretins*, are the essential gut hormones contributing to glucose tolerance. They are secreted in

proportion to the nutrient load ingested and relay this information to the islet as part of a feed-forward mechanism that allows an insulin response appropriate to meal size. Insulin secretion rates in healthy humans are highest in the early digestive phase of meals, preceding and limiting the peak in blood glucose. This pattern of premonitory insulin secretion is an essential feature of normal glucose tolerance. How to mimic this pattern is one of the key challenges for successful insulin therapy in diabetic patients.

Elevated circulating insulin concentrations lower glucose in blood by inhibiting hepatic glucose production and stimulating the uptake and metabolism of glucose by muscle and adipose tissue. These two important effects occur at different concentrations of insulin. Production of glucose is inhibited half-maximally by an insulin concentration of ~ 120 pmol/L, whereas glucose utilization is stimulated half-maximally at ~ 300 pmol/L. Some of the effects of insulin on the liver occur rapidly, within the first 20 minutes of meal ingestion, whereas stimulation of peripheral glucose uptake may require up to an hour to reach significant rates. This is probably due to the quick access of insulin to hepatocytes, via the hepatic-portal circulation and the liver sinusoids, and the slower passage of insulin to its receptors on muscle and adipose cells. Insulin has potent effects to reduce lipolysis from adipocytes, primarily through the inhibition of hormone-sensitive lipase, and increases lipid storage by promoting lipoprotein lipase synthesis and adipocyte glucose uptake. Finally, insulin stimulates amino acid uptake and protein synthesis and inhibits protein degradation in muscle and other tissues; it thus causes a decrease in the circulating concentrations of most amino acids.

The demand for glucose as an energy source for skeletal muscle increases dramatically during exercise. Glycogen stored in skeletal muscle is mobilized for some of these needs, but there are limited supplies that are used, mostly at the onset of activity. Most of the glucose support of exercise comes from hepatic gluconeogenesis. The dominant regulation of hepatic glucose production during exercise comes from epinephrine and norepinephrine. The catecholamines stimulate glycogenolysis and gluconeogenesis, inhibit insulin secretion, and enhance release of glucagon, all contributing to increased hepatic glucose output. In addition, catecholamines promote lipolysis, freeing fatty acids for oxidation in exercising muscle and glycerol for hepatic gluconeogenesis.

Pancreatic Islet Physiology and Insulin Secretion. The pancreatic islets comprise 1-2% of the pancreatic volume and are scattered throughout the exocrine pancreas. The pancreatic islet is a highly vascularized, highly innervated mini-organ containing five endocrine cell types: α cells that secrete glucagon, β cells that secrete glucose, δ cells that secrete somatostatin, cells that secrete pancreatic polypeptide, and ϵ cells that secrete ghrelin. The endocrine, exocrine, and ductal cells of the pancreas share a common embryologic heritage but in the adult are functionally distinct. Insulin and glucagon are important pharmacological agents in the treatment of diabetes, and an understanding of their synthesis, secretion, and action are important in the therapeutic efforts related to diabetes.

Figure 43–2. Synthesis and processing of insulin. The initial peptide, preproinsulin (110 amino acids) consists of a signal peptide (SP), B chain, C peptide, and A chain. The SP is cleaved and S-S bonds form as the proinsulin folds. Two prohormone convertases, PC1 and PC2, cleave proinsulin into insulin, C peptide, and two dipeptides. Insulin and C peptide are stored in granules and co-secreted in equimolar quantities.

Insulin is initially synthesized as a single polypeptide chain, preproinsulin (110 amino acid), which is processed first to proinsulin and then to insulin and C-peptide (Figure 43–2). This complex and highly regulated process involves the Golgi complex, the endoplasmic reticulum, and importantly the distinctive secretory granules of the β cell. Secretory granules are critical not only in bringing insulin to the cell surface for exocytosis, but also in the cleavage and processing of the prohormone to the final secretion products, insulin and C-peptide. The structure of insulin is discussed in the section describing its therapeutic use. Equimolar quantities of insulin and C-peptide (31 amino acids) are co-secreted. Insulin has a $t_{1/2}$ of 5-6 minutes due to extensive hepatic clearance. C-peptide, in contrast, with no known physiological function or receptor, has a $t_{1/2}$ of ~ 30 minutes. Because almost all of the C-peptide released into the portal vein reaches the peripheral circulation where it can be measured, this peptide is useful in assessment of β -cell secretion, and to distinguish endogenous and exogenous hyperinsulinemia (for example in the evaluation of insulin-induced hypoglycemia). Importantly, the β cell also synthesizes and secretes islet amyloid polypeptide (IAPP) or amylin, a 37-amino acid peptide. IAPP is not essential for life but influences GI motility and the speed of glucose absorption. Pramlintide is an agent used in the treatment of diabetes that mimics the action of IAPP. As reflected by its name, IAPP forms amyloid fibrils in the islets of individuals with type 2 diabetes; whether this is a cause or a consequence of the islet dysfunction of type 2 diabetes is not yet clear.

Insulin secretion is a tightly regulated process designed to provide stable concentrations of glucose in blood during both fasting and feeding. This regulation is achieved by the coordinated

interplay of various nutrients, GI hormones, pancreatic hormones, and autonomic neurotransmitters. Glucose, amino acids (arginine, etc.), fatty acids, and ketone bodies promote the secretion of insulin. Glucose is the primary insulin secretagogue, and insulin secretion is tightly coupled to the extracellular glucose concentration. Insulin secretion is much greater when the same amount of glucose is delivered orally compared to intravenously (incretin effect). Islets are richly innervated by both adrenergic and cholinergic nerves. Stimulation of α_2 adrenergic receptors inhibits insulin secretion, whereas β_2 adrenergic receptor agonists and vagal nerve stimulation enhance release. In general, any condition that activates the sympathetic branch of the autonomic nervous system (such as hypoxia, hypoglycemia, exercise, hypothermia, surgery, or severe burns) suppresses the secretion of insulin by stimulation of α_2 adrenergic receptors. Predictably, α_2 adrenergic receptor antagonists increase basal concentrations of insulin in plasma, and β_2 adrenergic receptor antagonists decrease them. Glucagon and somatostatin inhibit insulin secretion.

The pancreatic β cell is a highly specialized cell that has considerable structural and functional similarities to a sensory neuron: Both cell types quickly sense and respond to external stimuli. The molecular events controlling glucose-stimulated insulin secretion begin with the transport of glucose into the β cell via a facilitative glucose transporter (Figure 43–3). In rodents, this is the GLUT2, which has a distinctive, low affinity for glucose and is also the primary

glucose transporter in hepatocytes. Human β cells express primarily GLUT1 but little GLUT2. Upon entry into the β cell, glucose is quickly phosphorylated by glucokinase (GK; hexokinase IV); this phosphorylation is the rate-limiting step in glucose metabolism in the β cell. GK's distinctive affinity for glucose leads to a marked increase in glucose metabolism over the range of 5–10 mM glucose, where glucose-stimulated insulin secretion is most pronounced. The glucose-6-phosphate produced by GK activity enters the glycolytic pathway, producing changes in NADPH and the ratio of ADP/ATP. Elevated ATP inhibits an ATP-sensitive K^+ channel (K_{ATP} channel), leading to cell membrane depolarization. This K_{ATP} channel is a heteromeric protein that consists of an inward rectifying K^+ channel (Kir6.2) and a closely associated protein known as the sulfonylurea receptor (SUR), which was identified originally because of its interaction with this class of drugs. Mutations in the K_{ATP} channel are responsible for some types of neonatal diabetes or hypoglycemia. Membrane depolarization then leads to opening of a voltage-dependent Ca^{2+} channel and increased intracellular Ca^{2+} , resulting in exocytotic release of insulin from storage vesicles. These intracellular events are modulated by a number of processes, such as changes in cAMP production, amino acid metabolism, and the level of transcription factors. GPCRs for glucagon, GIP, and GLP-1 couple to G_s to stimulate adenylyl cyclase and insulin secretion; receptors for somatostatin and α_2 adrenergic agonists couple to G_i to reduce cellular cAMP production and secretion.

Figure 43–3. Regulation of insulin secretion from a pancreatic β cell. The pancreatic β cell in a resting state (fasting blood glucose) is hyperpolarized. Glucose, entering via GLUT transporters (primarily GLUT1 in humans, GLUT2 in rodents), is metabolized and elevates cellular ATP, which inhibits K^+ entry through the K_{ATP} channel; the decreased K^+ conductance results in depolarization, leading to Ca^{2+} -dependent exocytosis of stored insulin. The K_{ATP} channel, actually a hetero-octamer composed of SUR1 and Kir 6.2 subunits, is the site of action of several classes of drugs: ATP binds to and inhibits Kir 6.2; sulfonylureas and meglitinides bind to and inhibit SUR1; all 3 agents thereby promote insulin secretion. Diazoxide and ADP-Mg $^{2+}$ (low ATP) bind to and activate SUR1, thereby inhibiting insulin secretion. Incretins enhance insulin secretion.

The pancreatic α cell, which has considerable similarity to the β cell, secretes glucagon, primarily in response to hypoglycemia. Glucagon biosynthesis begins with preproglucagon, which is processed in a cell-specific fashion to several biologically active peptides such as glucagon, GLP-1, and glucagon-like peptide-2 (GLP-2) (Figure 43-9). The molecular mechanisms that control glucagon secretion are unclear but may involve paracrine regulation by the β cell and neural input. *In general, glucagon and insulin secretion are regulated in a reciprocal fashion; that is, the agents or processes that stimulate insulin secretion inhibit glucagon secretion. Notable exceptions are arginine and somatostatin: arginine stimulates and somatostatin inhibits the secretion of both hormones.*

Insulin Action. The insulin receptor is expressed on virtually all mammalian cell types, explaining the broad array of biological responses to insulin. The tissues that are considered critical for regulation of blood glucose are liver, skeletal muscle, and fat (Figure 43-1). However, recent evidence suggests that specific regions of the brain and the pancreatic islet are also important targets for insulin. Systemically, the actions of insulin are anabolic, and insulin signaling is critical for promoting the uptake, use, and storage of the major nutrients: glucose, lipids, and amino acids. Importantly, while insulin action stimulates glycogenesis, lipogenesis, and protein synthesis, it also inhibits the catabolism of these compounds. On a cellular level, insulin stimulates transport of substrates and ions into cells, promotes translocation of proteins between cellular compartments, regulates the action of specific enzymes, and controls gene transcription and mRNA translation. Some effects of insulin occur within seconds or minutes, such as activation of glucose and ion transport systems and phosphorylation or dephosphorylation of specific enzymes. Other effects, such as those promoting protein synthesis and regulating gene transcription, manifest over minutes to hours. The effects of insulin on cell proliferation and differentiation occur over days. Metabolic effects such as inhibition of lipolysis or hepatic glucose production occur rapidly, within minutes of increasing concentrations of plasma insulin; detectable increases in glucose clearance from the blood may take nearly an hour. The variability in the kinetics of insulin action probably relate to variable access to insulin receptors in different tissues, distinct intracellular signaling pathways, and the inherent kinetics of the various processes controlled by insulin.

The Insulin Receptor. Insulin action is transmitted through a receptor tyrosine kinase that bears functional similarity to the insulin-like growth factor 1

(IGF-1) receptor (Taniguchi et al., 2006). The insulin receptor is composed of linked (α/β subunit dimers that are products of a single gene; dimers linked by disulfide bonds form a transmembrane heterotetramer glycoprotein composed of two extracellular α -subunits and two membrane-spanning β -subunits (Figure 43-4). The number of receptors varies from as few as 40 per cell on the relatively insulin-insensitive erythrocytes, to 300,000 per cell on adipocytes and hepatocytes, cell types that are highly responsive to insulin.

The α -subunits inhibit the inherent tyrosine kinase activity of the β -subunits. Insulin binding to the α -subunits releases this inhibition and allows transphosphorylation of one β -subunit by the other, and autophosphorylation at specific sites from the juxtamembrane region to the intracellular tail of the receptor. There are two splice variants of the α -subunits, which lead to insulin receptors with differential expression and ligand binding. In addition, insulin receptor dimers can form complexes with IGF-1 receptor α/β dimers, creating another distinct receptor isoform. Activation of the insulin receptor initiates signaling by phosphorylating a set of intracellular proteins such as the insulin receptor substrates (IRS) and Src-homology-2-containing protein (Shc). These insulin receptor substrates interact with effectors that amplify and extend the signaling cascade. As an example, binding of Shc to IRS1 leads to activation of the GTPase Ras and initiation of the protein kinase cascade involving MAPK and ERK that are involved in insulin-mediated gene transcription and cell growth.

Insulin action, at least for glucose transport, is critically dependent on the activation of phosphatidylinositol-3-kinase (PI3K). PI3K is activated by interaction with IRS proteins and generates phosphatidylinositol 3,4,5-trisphosphate (PIP3), which regulates the localization and activity of several downstream kinases, including Akt, atypical isoforms of protein kinase C (PKC ζ and λ/τ), and mammalian target of rapamycin (mTOR) (Huang and Czech, 2007). The isoform Akt2 appears to control the downstream steps that are important for glucose uptake in skeletal muscle and adipose tissue, and to regulate glucose production in the liver. Substrates of Akt2 coordinate the translocation of the glucose transporter 4 (GLUT4) to the plasma membrane through processes involving actin remodeling and other membrane trafficking systems (Zaid et al., 2008). Despite the centrality of PI3K/Akt2 in mediating insulin signaling in key target tissues, it seems likely that there are additional effects mediated by the insulin receptor that do not directly involve these enzymes. Actions of small G-proteins, such as Rac and TC10, have been implicated in the actin remodeling necessary for GLUT4 translocation.

GLUT4 is expressed in insulin-responsive tissues such as skeletal muscle and adipose tissue that constitute important sites of glucose disposal after meal ingestion. GLUT4 is one of a family of 13 glucose transporters in humans that share 12 membrane-spanning domains. GLUT4 is noteworthy among these transporters as the most dependent on discrete stimuli by insulin or other effectors; in the basal state, most GLUT4 resides in the intracellular space; following activation of insulin receptors, GLUT4 is shifted rapidly and

Figure 43–4. Pathways of insulin signaling. The binding of insulin to its plasma membrane receptor activates a cascade of downstream signaling events. Insulin binding activates the intrinsic tyrosine kinase activity of the receptor dimer, resulting in the tyrosine phosphorylation (Y-P) of the receptor's β subunits and a small number of specific substrates (yellow shapes): the Insulin Receptor Substrate (IRS) proteins, Gab-1 and SHC; within the membrane, a caveolar pool of insulin receptor phosphorylates caveolin (Cav), APS, and Cbl. These tyrosine-phosphorylated proteins interact with signaling cascades via SH2 and SH3 domains to mediate the effects of insulin, with specific effects resulting from each pathway. In target tissues such as skeletal muscle and adipocytes, a key event is the translocation of the GLUT4 glucose transporter from intracellular vesicles to the plasma membrane; this translocation is stimulated by both the caveolar and non-caveolar pathways. In the non-caveolar pathway, the activation of PI3K is crucial, and PKB/Akt (anchored at the membrane by PIP3) and/or an atypical form of PKC is involved. In the caveolar pathway, caveolar protein flotillin localizes the signaling complex to the caveola; the signaling pathway involves series of SH2 domain interactions that add the adaptor protein CrkII, the guanine nucleotide exchange protein C3G, and small GTP-binding protein, TC10. The pathways are inactivated by specific phosphoprotein phosphatases (eg, PTB1B). In addition to the actions shown, insulin also stimulates the plasma membrane Na^+, K^+ -ATPase by a mechanism that is still being elucidated; the result is an increase in pump activity and a net accumulation of K^+ in the cell. Abbreviations: adaptor protein with PH and SH2 domains; CAP, Cbl associated protein; CrkII, chicken tumor virus regulator of kinase II; GLUT4, glucose transporter 4; Gab-1, Grb-2 associated binder; MAP kinase, mitogen-activated protein kinase; PDK, phosphoinositide-dependent kinase; PI3 kinase, phosphatidylinositol-3-kinase; PIP3, phosphatidylinositol trisphosphate; PKB, protein kinase B (also called Akt); aPKC, atypical isoform of protein kinase C; Y, tyrosine residue; Y-P, phosphorylated tyrosine residue.

in abundance to the plasma membrane, where it facilitates inward transport of glucose from the circulation. Insulin signaling also reduces GLUT4 endocytosis, increasing the residence time of the protein in the plasma membrane.

Following the facilitated diffusion into cells along a concentration gradient, glucose is phosphorylated to glucose-6-phosphate (G-6-P) by a family of hexokinases. Hexokinase II is found in association with GLUT4 in skeletal and cardiac muscle and in adipose tissue. Like GLUT4, hexokinase II is regulated transcriptionally by insulin. G-6-P is a branch-point substrate that can enter several pathways. G-6-P can be isomerized to G-1-P by phosphoglucomutase, and then the G-1-P can be stored as glycogen (insulin enhances the activity of glycogen synthase); G-6-P can enter the glycolytic pathway (leading to ATP production); G-6-P can also enter the pentose phosphate pathway.

PATHOPHYSIOLOGY AND DIAGNOSIS OF DIABETES MELLITUS

Glucose Homeostasis and the Diagnosis of Diabetes

Broad categories of glucose homeostasis as defined by the fasting blood glucose or the glucose level following an oral glucose challenge include:

- Normal glucose homeostasis: Fasting plasma glucose <5.6 mmol/L (100 mg/dL)
- Impaired fasting glucose (IFG): 5.6–6.9 mmol/L (100–125 mg/dL)

- Impaired glucose tolerance (IGT): Glucose level between 7.8 and 11.1 mmol/L (140-199 mg/dL) 120 minutes after ingestion of 75 g liquid glucose solution
- Diabetes mellitus (see Table 43–1)

The diagnosis of diabetes mellitus is currently based on the correlation of a diabetes-specific complication with a particular level of glycemia, that is, the level of glycemia at which a diabetes-specific complication like retinopathy begins to appear. The boundaries between normal glucose homeostasis, abnormal glucose homeostasis, and diabetes are described as abrupt transitions, but the data are best viewed as a spectrum.

Organizations such as the American Diabetes Association (ADA) and the World Health Organization (WHO) have adopted criteria for the diagnosis of diabetes, based on the fasting blood glucose, the glucose value following an oral glucose challenge, or the level of hemoglobin A_{1c} (HbA_{1c}; exposure of proteins to elevated [glucose] produces nonenzymatic glycation of proteins including Hb. Thus the level of HbA_{1c} represents a measure of the average glucose concentration to which the Hb has been exposed) (Table 43–1). Fasting plasma glucose is most widely used because of its convenience and low cost. The diagnostic criteria have recently (2009) been changed to also include a hemoglobin A_{1c} (A1C) value $\geq 6.5\%$. Impaired fasting glucose (IFG) and impaired glucose tolerance (IGT), previously termed prediabetes, or an A1C of 5.7-6.4% portend a markedly increased risk of progressing to

type 2 diabetes. An A1C of 5.7-6.4%, IFG, and IGT do not identify the same group of individuals, but all are associated with increased risk of cardiovascular disease.

The four broad categories of diabetes include type 1 diabetes, type 2 diabetes, other forms of diabetes, and gestational diabetes (Table 43–2). Although hyperglycemia is common to all forms of diabetes, the pathogenic mechanisms leading to diabetes are quite distinct. As our current understanding of the molecular pathogenesis of the hyperglycemia improves, these categories will likely be subdivided into a number of other types of diabetes.

Screening for Diabetes and Categories of Increased Risk of Diabetes. Many individuals with type 2 diabetes are asymptomatic at the time of diagnosis, and diabetes is often found on routine blood testing as an outpatient or upon admission to the hospital for nonglucose-related reasons. A long, asymptomatic phase in type 2 diabetes (up to a decade) is likely responsible for the observation that up to 50% of individuals with diabetes may have a diabetes-related complication at the time of diagnosis. For these reasons, the ADA recommends widespread screening for type 2 diabetes of these individuals with the following features:

- >45 years of age or
- Body mass index $>25 \text{ kg/m}^2$ with one of these additional risk factors: hypertension, low high-density lipoprotein, family history of type 2 diabetes, high-risk ethnic group (African American, Latino, Native American, Asian American, and Pacific Islander), abnormal glucose testing (IFG, IGT, A1C of 5.7-6.4%), cardiovascular disease, and women with polycystic ovary syndrome or who have previously delivered a large infant.

Earlier diagnosis and treatment of type 2 diabetes should delay diabetes-related complications and reduce the burden of the disease. Many also feel that earlier treatment may alter the natural history of the disease, but conclusive proof of this hypothesis is lacking. Likewise, informing individuals who are at increased risk for developing diabetes provides impetus to take steps to slow the progression to diabetes. A number of interventions including pharmacological agents and lifestyle modification are effective. Screening for type 1 diabetes is not currently recommended.

Pathogenesis of Type 1 Diabetes. Type 1 diabetes accounts for 5-10% of diabetes and results from autoimmune-mediated destruction of the β cells of the islet leading to total or near total insulin deficiency (von Herrath et al., 2007). Prior terminology included juvenile-onset diabetes mellitus or insulin-dependent diabetes mellitus. Although traditionally considered a disease of children and adolescents, type 1 diabetes resulting from autoimmune β cell destruction can occur at any age. In fact, in some reports, more than one-third of individuals developed type 1 diabetes after adolescence. Individuals with type 1 diabetes and their families have an increased prevalence of autoimmune diseases such

Table 43–1

Criteria for the Diagnosis of Diabetes

- Symptoms of diabetes plus random blood glucose concentration $\geq 11.1 \text{ mM}$ (200 mg/dL)^a or
- Fasting plasma glucose $\geq 7.0 \text{ mM}$ (126 mg/dL)^b or
- Two-hour plasma glucose $\geq 11.1 \text{ mM}$ (200 mg/dL) during an oral glucose tolerance test^c
- HbA_{1c} $\geq 6.5\%$

^aRandom is defined as without regard to time since the last meal.

^bFasting is defined as no caloric intake for at least 8 h.

^cThe test should be performed using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water; this test is not recommended for routine clinical use.

Note: In the absence of unequivocal hyperglycemia and acute metabolic decompensation, these criteria should be confirmed by repeat testing on a different day.

Adapted from Diabetes Care, 2010; 33:S62-S69.

Table 43–2**Different Forms of Diabetes Mellitus**

- I. Type 1 diabetes β -cell destruction, usually leading to absolute insulin deficiency)
 - A. Immune-mediated
 - B. Idiopathic
- II. Type 2 diabetes (may range from predominantly insulin resistance with relative insulin deficiency to a predominantly insulin secretory defect with insulin resistance)
- III. Other specific types of diabetes
 - A. Genetic defects of β cell function characterized by mutations in:
 1. Hepatocyte nuclear transcription factor (HNF) 4 α (MODY 1)
 2. Glucokinase (MODY 2)
 3. HNF-1 α (MODY 3)
 4. Insulin promoter factor-1 (IPF-1; MODY 4)
 5. HNF-1 β (MODY 5)
 6. NeuroD1 (MODY 6)
 7. Mitochondrial DNA
 8. Subunits of ATP-sensitive K⁺ channel
 9. Proinsulin or insulin sequence conversion
 - B. Genetic defects in insulin action
 1. Type A insulin resistance
 2. Leprechaunism
 3. Rabson-Mendenhall syndrome
 4. Lipodystrophy syndromes
 - C. Diseases of the exocrine pancreas—pancreatitis, pancreatectomy, neoplasia, cystic fibrosis, hemochromatosis, fibrocalculous pancreatopathy, mutations in carboxyl ester lipase
 - D. Endocrinopathies—acromegaly, Cushing’s syndrome, glucagonoma, pheochromocytoma, hyperthyroidism, somatostatinoma, aldosteronoma
 - E. Drug- or chemical-induced—Vacor (a rodenticide); see Table 43-3
 - F. Infections—congenital rubella, cytomegalovirus
 - G. Uncommon forms of immune-mediated diabetes—“stiff-person” syndrome, anti-insulin receptor antibodies
 - H. Other genetic syndromes sometimes associated with diabetes—Wolfram’s syndrome, Down’s syndrome, Klinefelter’s syndrome, Turner’s syndrome, Friedreich’s ataxia, Huntington’s chorea, Laurence-Moon-Biedl syndrome, myotonic dystrophy, porphyria, Prader-Willi syndrome
- IV. Gestational diabetes mellitus (GDM)

MODY- maturity onset of diabetes of the young. Copyright 2010 American Diabetes Association. From *Diabetes Care*, Vol. 33 (Suppl 1), 2010; S62. Reprinted with permission from the American Diabetes Association.

as autoimmune adrenal insufficiency (Addison’s disease), autoimmune thyroid disease (Graves’ and Hashimoto’s disease), pernicious anemia, vitiligo, and celiac sprue.

The concordance of type 1 diabetes in genetically identical twins is 40-60%, indicating a significant genetic component. The major genetic risk (40-50%) is conferred by HLA class II genes encoding HLA-DR and HLA-DQ (and possibly other genes with the HLA locus). Candidate gene association studies and recently genome-wide association studies have identified >20 additional loci that confer genetic susceptibility to type 1 diabetes (INS, PTPN22, CTLA4, and IL2RA, among others) (Concannon et al., 2009). However, there clearly is a critical interaction of genetics and an environmental or infectious agent. Most individuals with type 1

diabetes (~75%) do not have a family member with type 1 diabetes, and the genes conferring genetic susceptibility are found in a significant fraction of the nondiabetic population.

Genetically susceptible individuals are thought to have a normal β cell number or mass until β cell-directed autoimmunity develops and β cell loss begins. The first physiological abnormality that is detectable in affected subjects is loss of the first phase of glucose-stimulated insulin secretion. Prior to this, islet cell autoantibodies can be detected in the serum (known autoantigens include insulin, glutamate decarboxylase, protein tyrosine phosphatase IA-2 [ICA-512], and zinc transporter 8 [SLC30A8]). The initiating or triggering stimulus for the autoimmune process is not known, but most favor exposure to viruses (enterovirus, etc.) or other ubiquitous environmental agents. Histological examinations of human pancreata during the prediabetic period and at presentation are quite limited, but animal models of type 1 diabetes show a T cell infiltrate with a

predominance of CD8+ cells (insulinitis). The β cell destruction is cell mediated, and there is also evidence that infiltrating cells produce local inflammatory agents such as TNF- α , IFN- γ , and IL-1, all of which can lead to β cell death. The β cell destruction occurs over a period of months to years and when >80% of the β cells are destroyed, hyperglycemia ensues and the clinical diagnosis of type 1 diabetes is made. Sometimes the clinical presentation of type 1 diabetes is with a concurrent illness (viral syndrome) and this may result in diabetic ketoacidosis; at other times, the typical symptoms of diabetes lead to the diagnosis. Most patients report several weeks of polyuria and polydipsia, fatigue, and often abrupt and significant weight loss. Some adults with the phenotypic appearance of type 2 diabetes (obese, not insulin-requiring initially) have islet cell autoantibodies suggesting autoimmune-mediated β cell destruction and are diagnosed as expressing latent-autoimmune diabetes of adults (LADA).

Pathogenesis of Type 2 Diabetes. The pathogenesis of type 2 diabetes mellitus is complex, and the condition is best thought of as a heterogeneous syndrome of dysregulated glucose homeostasis associated with impaired insulin secretion and insulin action (Das and Elbein, 2006; Doria et al., 2008; Taylor, 2008). Overweight or obesity is a common correlate of type 2 diabetes that occurs in ~ 80% of affected individuals. Increased lipid accumulation in depots in the abdomen, skeletal muscle cells, and hepatocytes has been linked to some of the common impairments. For the vast majority of persons developing type 2 diabetes, there is no clear inciting incident, but rather the condition is thought to develop gradually over years with progression through identifiable prediabetic stages.

In fundamental terms, type 2 diabetes results when there is insufficient insulin action to maintain plasma

glucose levels in the normal range. Insulin action is the composite effect of plasma insulin concentrations (determined by islet β cell function) and insulin sensitivity of key target tissues (liver, skeletal muscle, and adipose tissue). These sites of regulation are all impaired to variable extents in patients with type 2 diabetes (Figure 43–5).

The etiology of type 2 diabetes has a strong genetic component (Das and Elbein, 2006; Grant et al., 2009). It is a heritable condition with a relative 4-fold increased risk of disease for persons having a diabetic parent or sibling, increasing to 6-fold if both parents have type 2 diabetes. Consistent with this, the concordance rates of diabetes in monozygotic twins are 2- to 3-fold those in dizygotic twins. Based on linkage analysis, candidate gene searches, and genome-wide association studies, type 2 diabetes appears to be a complex multigenic condition, with many loci of susceptibility contributing to the ultimate phenotype. Although more than 20 genetic loci with clear associations to type 2 diabetes have been identified through recent genome-wide association studies, the contribution of each is relatively small. The genetic locus with the largest relative risk is the transcription factor TCF7L2. Of note, most of the genes currently associated with type 2 diabetes have a relevant connection to β cell function, with fewer linked to the action of insulin in target cells.

Impaired β Cell Function. In persons with type 2 diabetes, the sensitivity of the β cell to glucose is impaired, and there is also a loss of responsiveness to other stimuli such as insulinotropic GI hormones and neural signaling. This results in delayed secretion of insufficient amounts of insulin, allowing the blood glucose to rise dramatically after meals, and failure to restrain liver glucose release during

Figure 43–5. Pathophysiology of type 2 diabetes mellitus. Graphs show data from diabetic (—) and non-diabetic (—) patients, comparing postprandial insulin and glucagon secretion and hepatic glucose production, and the sensitivities of muscle glucose use and adipocyte lipolysis to insulin.

fasting. Beyond the defect in functional properties of the β cell, the absolute mass of β cells is reduced in type 2 diabetes patients. It is estimated that persons with early type 2 diabetes have ~50% of the normal complement of β cells (Butler et al., 2003). This deficit is compounded by a gradual loss of β cell mass over time, potentially related to toxic effects of hyperglycemia. Progressive reduction of β cell mass and function explains the natural history of type 2 diabetes in most patients who require steadily increasing therapy to maintain glucose control.

Type 2 diabetic patients frequently have elevated levels of fasting insulin. This is not a reflection of accentuated β cell function but a result of their higher fasting glucose levels and insulin resistance. Another factor contributing to apparently high insulin levels early in the course of the disease is the presence of increased amounts of proinsulin. Proinsulin, the precursor to insulin, is inefficiently processed in the diabetic islet. Whereas healthy subjects have only 2-4% of total circulating insulin as proinsulin, type 2 diabetic patients can have 10-20% of the measurable plasma insulin in this form. Proinsulin has a considerably attenuated effect for lowering blood glucose compared to insulin.

Insulin Resistance. Insulin sensitivity is a quantifiable parameter that is measured as the amount of glucose cleared from the blood in response to a dose of insulin. The failure of normal amounts of insulin to elicit the expected response is referred to as *insulin resistance*. This is a relative term because there is inherent variability of insulin sensitivity among cells, tissues, and individuals. Insulin sensitivity is affected by many factors including age, body weight, physical activity levels, illness, and medications. Furthermore, insulin sensitivity varies within individuals over time and across groups or populations of subjects, even among healthy adults. Thus, insulin resistance is a relative designation but has considerable pathological significance because persons with type 2 diabetes or glucose intolerance have reduced responses to insulin and can easily be distinguished from groups with normal glucose tolerance.

The major insulin-responsive tissues are skeletal muscle, adipose tissue, and liver. Insulin resistance in muscle and fat is generally marked by a decrease in transport of glucose from the circulation. Hepatic insulin resistance generally refers to a blunted ability of insulin to suppress glucose production. Insulin resistance in adipocytes causes increased rates of lipolysis and release of fatty acids into the circulation, which can contribute to insulin resistance in liver and muscle, hepatic steatosis, and dyslipidemia. More generally the role of obesity in the etiology of type 2 diabetes is related to the insulin resistance in skeletal muscle and liver that comes with increased amounts of lipid storage, particularly in specific fat depots. The sensitivity of humans to the effects of insulin administration is inversely related to the amount of fat stored in the abdominal cavity; more visceral adiposity leads to more insulin resistance (Kahn, 2003). Similarly, intrahepatocyte or intramuscular fat, both commonly associated with obesity, are strongly linked to insulin resistance. Intracellular lipid or its byproducts may have direct effects to impede insulin signaling (Savage et al., 2007). Enlarged collections of adipose tissue, visceral or otherwise, is often infiltrated with macrophages and can become a site of chronic inflammation. Adipocytokines, secreted from adipocytes and immune cells, including TNF- α , IL-6, resistin, and retinol-binding protein 4, can also cause systemic insulin resistance. Insulin resistance is even more severe in obese persons with type 2

diabetes who have further reductions of insulin-stimulated glucose uptake into skeletal muscle and relatively low rates of nonoxidative glucose metabolism (glycogen synthesis), and impaired suppression of hepatic glucose production and adipocyte lipolysis, despite insulin concentrations that are often elevated.

Another important variable in determining insulin sensitivity is activity level. Sedentary persons are more insulin resistant than active ones, and physical training can improve insulin sensitivity. Physical activity can decrease the risk of developing diabetes and improve glycemic control in persons who have diabetes (Crandall et al., 2008). Insulin resistance is more common in the elderly; within populations, insulin sensitivity decreases linearly with age. Older individuals tend to be less physically active, which can contribute to insulin resistance. In addition, over the normal course of aging there is a decrease in muscle mass and an increase in fat mass, with an increased percentage of fat stored in the abdominal cavity.

At the cellular level, insulin resistance involves blunted steps in the cascade from the insulin receptor tyrosine kinase to translocation of GLUT4 transporters, but the molecular mechanisms are incompletely defined. There have been >75 different mutations in the insulin receptor discovered, most of which cause significant impairment of insulin action. These mutations affect insulin receptor number, movement to and from the plasma membrane, binding, and phosphorylation. Mutations involving the insulin binding domains of the extracellular α -chain cause the most severe syndromes, but specific variants in the intracellular portions of the receptor also cause severe insulin resistance. However, most insulin resistance associated with obesity and type 2 diabetes is not due to abnormalities of the insulin receptor. A central feature of the more common forms of insulin resistance is increased phosphorylation of serine, rather than tyrosine, in the insulin receptor and IRS proteins, inhibiting their activation and signaling. This process is mediated by protein serine/threonine kinases, which respond to an increased intracellular flux of fatty acids, specific lipid products, particularly diacylglycerol and ceramide, inflammatory mediators such as TNF α , and endoplasmic reticulum stress. In addition, chronic hyperinsulinemia, the typical correlate of insulin resistance, seems to increase IRS protein catabolism. It is known that insulin sensitivity is under genetic control, but it is unclear whether insulin-resistant individuals have mutations in specific components of the insulin signaling cascade or whether they have a complement of signaling effectors that operate at the lower range of normal. Regardless, it is apparent that insulin resistance clusters in families and is a major risk factor for the development of diabetes.

Dysregulated Hepatic Glucose Metabolism. In type 2 diabetes, hepatic glucose output is excessive in the fasting state and inadequately suppressed after meals. These are key components to the abnormal glycemic profile in diabetic patients, who have elevated glucose levels in the postabsorptive state and accentuated postprandial rises. Abnormal secretion of the islet hormones, both insufficient insulin and excessive glucagon, accounts for a significant portion of dysregulated hepatic glucose metabolism in type 2 diabetes. Increased concentrations of glucagon, especially in conjunction with hepatic insulin resistance, can lead to excessive hepatic gluconeogenesis and glycogenolysis and abnormally high fasting glucose concentrations.

The liver is also resistant to insulin action in type 2 diabetes. This contributes to the reduced potency of insulin to suppress hepatic

glucose production and promote hepatic glucose uptake and glycogen synthesis after meals. Despite ineffective insulin effects on hepatic glucose metabolism, the lipogenic effects of insulin in the liver are maintained and even accentuated by fasting hyperinsulinemia. This contributes to hepatic steatosis and further worsening of insulin resistance.

Pathogenesis of Other Forms of Diabetes. Mutations in key genes involved in glucose homeostasis cause monogenic diabetes, which is inherited in an autosomal dominant fashion. These fall in two broad categories: diabetes onset in the immediate neonatal period (<6 months of age) and diabetes in children or adults (Murphy et al., 2008; Vaxillaire and Froguel, 2008). Some forms of neonatal diabetes are caused by mutations in the sulfonylurea receptor or its accompanying inward rectifying K⁺ channel and mutations in the insulin gene. Monogenic diabetes beyond the first year of life may appear clinically similar to type 1 or type 2 diabetes. In other instances, young individuals (adolescence to young adulthood) may have monogenic forms of diabetes known as maturity onset diabetes of the young (MODY). Phenotypically, these individuals are not obese and are not insulin resistant, or they may initially have modest hyperglycemia. The most common causes are mutations in key islet-enriched transcription factors or glucokinase (see discussion about molecular mechanisms of insulin secretion; Table 43-2 and Figure 43-3). Most individual with MODY are treated similarly to those with type 2 diabetes. Importantly, sulfonylureas may be a particularly effective treatment of individuals with MODY-3 or neonatal diabetes caused by a mutation in the K_{ATP} channel complex.

Diabetes may also be the result of other pathological processes such as acromegaly and Cushing's disease (Table 43-2). A number of medications promote hyperglycemia or lead to diabetes by either impairing insulin secretion or insulin action (Table 43-3). Most notable are asparaginase, glucocorticoids, pentamidine, nicotinic acid, α -interferon, protease inhibitors, and in particular, atypical antipsychotics (Chapter 16).

Epidemiology of Diabetes. The number of individuals with diabetes is increasing worldwide. Although the annual rate of type 1 diabetes has increased modestly over the past decade, the increased frequency of type 2 diabetes has been dramatic. In the U.S., 7-10% of adults are affected, with up to three times that many at risk. There is clear ethnic variability in the prevalence of type 2 diabetes. Among adults living in the U.S., there is a spectrum of prevalence with Native Americans (15%), Hispanics (12%), and African Americans (12%) having greater rates than persons of European ancestry (8%). While the upward trends in the industrialized world have been similar in many countries, there are now alarming increases in rates of type 2 diabetes worldwide. Most notable are China, India, and other countries in the Far East where the disease was previously uncommon (Chan et al., 2009). The largest increase in the number of people with diabetes is predicted to take place in the regions or countries with developing economies. Parallel increases in obesity rates and changes in diet and activity appear to be the major factors in this marked increase in diabetes.

Diabetes-Related Complications. Diabetes can cause metabolic derangements or acute complications, such as the life-threatening metabolic disorders of diabetic ketoacidosis and hyperglycemic hyperosmolar state. These require hospitalization for insulin

Table 43-3

Some Drugs that may Promote Hyperglycemia or Hypoglycemia

HYPERGLYCEMIA	HYPOGLYCEMIA
Glucocorticoids	β Adrenergic antagonists
Antipsychotics (atypical, others)	Ethanol
Protease inhibitors	Salicylates
β Adrenergic agonists	Non-steroidal anti-inflammatory drugs
Diuretics (thiazide, loop)	Pentamidine
Hydantoins (phenytoin, others)	ACE inhibitors
Opioids (fentanyl, morphine, others)	Lithium chloride
Diazoxide	Theophylline
Nicotinic Acid	Bromocriptine
Pentamidine	Mebendazole
Epinephrine	
Interferons	
Amphotericin B	
Asparaginase	
Acamprosate	
Basiliximab	
Thyroid hormones

administration, rehydration with intravenous fluids, and careful monitoring of electrolytes and metabolic parameters. Chronic complications of diabetes have been described in all forms of the disease and are commonly divided into microvascular and macrovascular complications. Microvascular complications occur only in individuals with diabetes, whereas macrovascular complications occur more frequently in individuals with diabetes but are not diabetes specific. The common microvascular complications include retinopathy, nephropathy and neuropathy. Macrovascular complications refer to increased atherosclerosis-related events such as myocardial infarction and stroke. The pharmacological management of diabetes-related complications is discussed elsewhere (e.g., Chapters 25, 28, 31, 64).

In the U.S., diabetes is the leading cause of blindness in adults, the leading reason for renal failure requiring dialysis or renal transplantation, and the leading cause of nontraumatic lower extremity amputations. Fortunately, most of these diabetes-related complications can be prevented, delayed, or reduced by near normalization of the blood glucose on a consistent basis. How chronic hyperglycemia causes these complications is unclear. For microvascular complications, current hypothesis are that hyperglycemia leads to advanced glycosylation end products (AGEs), increased glucose metabolism via the sorbitol pathway, increased formation of diacylglycerol leading to PKC activation, and increased flux through the hexosamine pathway. Growth factors such as vascular endothelial growth factor α may be involved in diabetic retinopathy and TGF- β in diabetic nephropathy.

Goals of Therapy. The goals of therapy for diabetes are to alleviate the symptoms related to hyperglycemia (fatigue, polyuria, etc.) and to prevent or reduce the acute and chronic complications of diabetes. Accomplishment of these goals requires a multidisciplinary team (physicians, nurse educators, pharmacists) with expertise in pharmacology, nutrition, and patient education. Central to the treatment plan is the patient who must actively participate in the care of his or her diabetes.

Glycemic control is assessed using both short-term (blood glucose self-monitoring) and long-term metrics (A1C, fructosamine). Using capillary blood glucose measurements, the patient assesses capillary blood glucose on a regular basis (fasting, before meals, or postprandially) and reports these values to the diabetes management team. A1C reflects glycemic control over the prior 3 months; glycosylated albumin (fructosamine) is a measure of glycemic control over the preceding 2 weeks.

Approaches to diabetes care are sometimes termed intensive insulin therapy, intensive glycemic control, and tight control. This chapter uses the term *comprehensive diabetes care* to describe optimal therapy, which involves more than glucose management and includes aggressive treatment of abnormalities in blood pressure and lipids and detection and management of diabetes-related complications (Figure 43–6). Table 43–4 shows the ADA-recommended treatment goals for comprehensive diabetes care, for glucose, blood pressure, and lipids (Brunzell et al., 2008). Improved glycemic control reduces the complications when started relatively early in the course of both type 1 and type 2 diabetes, but very intensive glucose lowering (with A_{1c} near 6.0) has not shown benefit in individuals with type 2 diabetes and atherosclerotic disease (Duckworth et al., 2009; Holman et al., 2008; Skyler et al., 2009). A summary of available pharmacologic agents for the treatment of diabetes is at the end of this chapter (Table 43–9).

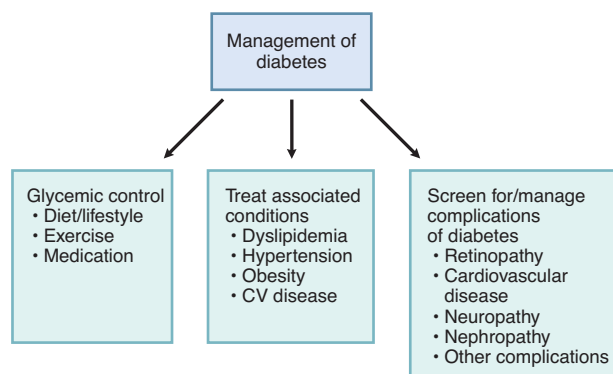

Figure 43–6. Components of comprehensive diabetes care.

Nonpharmacologic Aspects of Diabetes Therapy. The patient with diabetes should be educated about nutrition, exercise, and medications aimed at lowering the plasma glucose. The role of the certified diabetes educator, a healthcare professional (nurse, dietician, or pharmacist) with specialized patient education skills, is critical. In terms of diet, the ADA uses the term *medical nutrition therapy* to describe the diet that coordinates calorie intake and other aspects of diabetes therapy such as pharmacological agents and exercise. In type 1 diabetes, matching caloric intake and insulin dosing is very important. In type 2 diabetes, the diet is directed at weight loss and reducing blood pressure and atherosclerotic risk. Exercise provides multiple benefits for patients with diabetes, but dosing of the glucose-lowering therapy may require adjustment to avoid exercise-related hypoglycemia.

In addition to lifestyle modification, the other major nonpharmacological means to reduce the progression of abnormal glucose metabolism is bariatric surgery (Sjostrom et al., 2004). A number of procedures, including gastric banding, gastric bypass, and biliopancreatic diversion, improve glucose tolerance and prevent or reverse type 2 diabetes.

Insulin Therapy

Insulin is the mainstay for treatment of virtually all type 1 and many type 2 diabetes patients. Insulin may be administered intravenously, intramuscularly, or subcutaneously. Long-term treatment relies predominantly on subcutaneous injection. Subcutaneous administration of insulin differs from physiological secretion of insulin in two major ways:

- The absorption kinetics do not reproduce the rapid rise and decline of endogenous insulin in response to glucose following intravenous or oral administration.
- Injected insulin is delivered into the peripheral circulation instead of being released into the portal circulation. Thus the portal/peripheral insulin concentration is not physiological, and this may alter the influence of insulin on hepatic metabolic processes.

Nonetheless, insulin delivered into the peripheral circulation can lead to normal or near-normal glycemia.

History. The discovery of insulin is a dramatic story. The discovery is attributed to Frederick Banting, Charles Best, J.J.R. Macleod, and J.B. Collip at the University of Toronto, but others provided important observations and techniques that made it possible (Bliss, 2005). In 1869, a German medical student, Paul Langerhans, noted that the pancreas contains two distinct groups of cells—the acinar cells, which secrete digestive enzymes, and cells that are clustered in islands, or islets, which he suggested served a second function. Direct evidence for this function came in 1889, when Minkowski and von Mering showed that pancreatectomized dogs exhibit a syndrome similar to human diabetes mellitus. Thereafter, there were numerous attempts to extract the pancreatic substance responsible for regulating blood glucose. Between 1903 and 1909, the Romanian

Table 43-4

Goals of Therapy in Diabetes

INDEX	GOAL ^a
Glycemic control ^b	
A1C	<7.0% ^c
Preprandial capillary plasma glucose	3.9-7.2 mmol/L (70-130 mg/dL)
Peak Postprandial capillary plasma glucose	10.0 mmol/L (<180 mg/dL) ^d
Blood pressure	<130/80
Lipids ^e	
Low-density lipoprotein	<2.6 mmol/L (<100 mg/dL) ^f
High-density lipoprotein	>1.1 mmol/L (>40 mg/dL) ^g
Triglycerides	<1.7 mmol/L (<150 mg/dL)

^aAs recommended by the ADA goals should be individualized for each patient. Goals may be different for certain patient populations.

^bA1C is primary goal.

^cWhile the ADA recommends an A1C <7.0% in general, in the individual patient it recommends that an appropriate goal for the individual patient based on age, duration of diabetes, life expectancy, other medical conditions, cardiovascular disease).

^dOne to two hours after beginning of a meal.

^eIn decreasing order of priority

^fIn individuals with coronary artery disease, an LDL <1.8 mmol (70 mg/dL) is the goal.

^gFor women, some suggest a goal that is 0.25 mmol/L (10 mg/dL) higher.

Adapted from *Diabetes Care* 33:S11, 2010.

physiologist Nicolas Paulesco found that injections of pancreatic extracts reduced urinary sugar and ketones in diabetic dogs and published results clearly indicating isolation of a glucose-lowering compound. The significance of these findings was recognized only years later.

Unaware of much of this work, Frederick Banting, a young Canadian surgeon, convinced J.J.R. Macleod, a professor of physiology in Toronto, to allow him access to a laboratory to search for the antidiabetic principle of the pancreas. Banting began work on the assumption that the islets secreted a glucose-lowering hormone that was destroyed by proteolytic digestion prior to or during extraction. Together with Charles Best, a fourth-year medical student, he attempted to overcome the problem by ligating the pancreatic ducts so that the acinar tissue degenerated, leaving the islets undisturbed. Using an ethanol and acid extraction procedure, Banting and Best obtained a pancreatic isolate that decreased the concentration of blood glucose in diabetic dogs. Under the guidance of Macleod, Banting and Best received help from J.B. Collip, a chemist with expertise in extraction and purification of epinephrine. The first patient to receive the active extracts was Leonard Thompson, age 14. He presented at the Toronto General Hospital with a blood glucose level of 500 mg/dL (28 mM). Despite rigid control of his diet (450 kcal/day), he continued to excrete large quantities of glucose, and, without insulin, would likely have died within a few months. The administration of the pancreatic extracts reduced the plasma concentration and urinary excretion of glucose, and the patient demonstrated marked clinical improvement. Replacement therapy with the newly discovered hormone, insulin, had interrupted what was clearly an otherwise fatal metabolic disorder. Stable

extracts eventually were obtained, and patients in many parts of North America soon were being treated with insulin from porcine and bovine sources. The first of several Nobel Prizes associated with insulin was awarded to Banting and Macleod in 1923. A furor over credit followed immediately, and Banting announced that he would share his prize with Best; Macleod did the same with Collip (Bliss, 2005). Frederick Sanger established the amino acid sequence of insulin and received the Nobel Prize in 1958. Dorothy Hodgkin (Nobel prize for chemistry, 1964) and coworkers elucidated insulin's three-dimensional structure. Insulin was the hormone for which Yalow and Berson first developed the radioimmunoassay, which was recognized with the Nobel Prize in 1977.

Insulin Preparation and Chemistry. Human insulin, produced by recombinant DNA technology, is soluble in aqueous solution. Most preparations are supplied at neutral pH, which improves stability and permits short-term storage at room temperature. Beginning shortly after its discovery in 1921, patients were treated with insulin preparations prepared from porcine or bovine pancreatic extracts for >70 years. With the advent of human insulin, beef and pork insulin are no longer produced. A number of other insulin preparations that once were widely used such as lente, ultralente, and protamine zinc insulin are no longer available.

Doses and concentration of clinically used insulin preparations are expressed in international units. This tradition dates to a time when preparations of hormones were impure and the concentration of the hormone was standardized by bioassay. One unit of insulin is defined as the amount required to reduce the blood glucose concentration in a fasting rabbit to 45 mg/dL (2.5 mM).

Commercial preparations of insulin are supplied in solution or suspension at a concentration of 100 units/mL, which is ~3.6 mg insulin per milliliter (0.6 mM) and termed U-100. Insulin also is available in a more concentrated solution (500 units/mL or U-500) for patients who are resistant to the hormone. In the past, other concentrations of insulin such as U-40 were available. Other insulin formulations such as inhaled insulin and injected human proinsulin were tested but either were not clinically useful or were used for only a brief period of time. Work is ongoing to develop delivery approaches that do not involve injection.

Insulin Formulations. Preparations of insulin are classified according to their duration of action into short-acting and long-acting (Table 43–5). Within the short-acting acting category, some distinguish the very rapid-acting insulins (aspart, glulisine, lispro) from regular insulin. Likewise, some distinguish formulations with a longer duration of action (detemir, glargine) from NPH insulin. Two approaches are used to modify the absorption and pharmacokinetic profile of insulin. The first approach, which has been used for >70 years to alter the absorption profile of native insulin, is based on formulations that slow the absorption following subcutaneous injection. The other approach is to alter the amino acid sequence or protein structure of human insulin so that it retains its ability to bind the insulin

receptor, but its behavior in solution or following injection is either accelerated or prolonged in comparison to native or regular insulin (Figure 43–7).

The wide variability in the kinetics of insulin action between and even within individuals must be emphasized. The time to peak hypoglycemic effect and insulin levels can vary by 50%. This variability is caused, at least in part, by large variations in the rate of subcutaneous absorption.

Short-Acting Regular Insulin. Native or regular insulin molecules associate as hexamers in aqueous solution at a neutral pH and this aggregation slows absorption following subcutaneous injection. Regular insulin should be injected 30–45 minutes before a meal. Regular insulin also may be given intravenously or intramuscularly.

Short-Acting Insulin Analogs. The development of short-acting insulin analogs that retain a monomeric or dimeric configuration is a major advance in insulin therapy (Figures 43–7 and 43–8; Table 43–5). These analogs are absorbed more rapidly from subcutaneous sites than regular insulin. Consequently, there is a more rapid increase in plasma insulin concentration and an earlier response. Insulin analogs should be injected ≤15 minutes before a meal.

Insulin lispro (HUMALOG) is identical to human insulin except at positions B28 and B29, where the sequence of the two residues has been reversed to match the sequence in IGF-1 (which does not self-associate). Like regular insulin, lispro exists as a hexamer in commercially available formulations. Unlike regular insulin, lispro

Table 43–5

Properties of Insulin Preparations

PREPARATION	TIME OF ACTION		
	ONSET, h	PEAK, h	EFFECTIVE DURATION, h
Short-acting			
Aspart	<0.25	0.5-1.5	3-4
Glulisine	<0.25	0.5-1.5	3-4
Lispro	<0.25	0.5-1.5	3-4
Regular	0.5-1.0	2-3	4-6
Long-acting			
Detemir	1-4	— ^a	20-24
Glargine	1-4	— ^a	20-24
NPH	1-4	6-10	10-16
Insulin combinations			
75/25-75% protamine lispro, 25% lispro	<0.25	1.5 h	Up to 10-16
70/30-70% protamine aspart, 30% aspart	<0.25	1.5 h	Up to 10-16
50/50-50% protamine lispro, 50% lispro	<0.25	1.5 h	Up to 10-16
70/30-70% NPH, 30% regular	0.5-1	Dual ^b	10-16

^aGlargine and detemir have minimal peak activity.

^bDual: two peaks - one at 2-3 h; the second one several hours later.

Figure 43–7. Insulin analogs. Modifications of native insulin can alter its pharmacokinetic profile. Reversing amino acids 28 and 29 in the B chain (lispro) or substituting Asp for Pro^{28B} (aspart) gives analogs with reduced tendencies for molecular self-association that are faster acting. Altering Asp^{3B} to Lys and Lys^{29B} to Glu produces an insulin (glulisine) with a more rapid onset and a shorter duration of action. Substituting Gly for Asn^{21A} and lengthening the B chain by adding Arg³¹ and Arg³² produces a derivative (glargine) with reduced solubility at pH 7.4 that is, consequently, absorbed more slowly and acts over a longer period of time. Deleting Thr^{30B} and adding a myristoyl group to the ϵ -amino group of Lys^{29B} (detemir) enhances reversible binding to albumin, thereby slowing transport across vascular endothelium to tissues and providing prolonged action.

dissociates into monomers almost instantaneously following injection. This property results in the characteristic rapid absorption and shorter duration of action compared with regular insulin. Two therapeutic advantages have emerged with lispro as compared with regular insulin. First, the prevalence of hypoglycemia is reduced with

lispro; second, glucose control, as assessed by A1C, is modestly but significantly improved (0.3–0.5%).

Insulin aspart (NOVOLOG) is formed by the replacement of proline at B28 with aspartic acid. This reduces self-association to a degree similar to lispro. Like lispro, insulin aspart dissociates rapidly into monomers following injection. Comparison of a single subcutaneous dose of aspart and lispro in a group of type 1 diabetes patients revealed similar plasma insulin profiles. In clinical trials, insulin aspart and insulin lispro have had similar effects on glucose control and hypoglycemia frequency, with lower rates of nocturnal hypoglycemia as compared with regular insulin.

Insulin glulisine (APIDRA) is formed when glutamic acid replaces lysine at B29, and lysine replaces asparagine at B23; these substitutions result in a reduction in self-association and rapid dissociation into active monomers. The time–action profile of insulin glulisine is similar to that of insulin aspart and insulin lispro. Similar to insulin aspart, insulin glulisine has been approved in the U.S. for continuous subcutaneous insulin infusion (CSII) pump use.

Long-Acting Insulins. Neutral protamine hagedorn (NPH; insulin isophane) is a suspension of native insulin complexed with zinc and protamine in a phosphate buffer. This produces a cloudy or whitish solution in contrast to the clear appearance of other insulin solutions. Because of this formulation, the insulin dissolves more gradually when injected subcutaneously and thus its duration of action is prolonged. NPH insulin is usually given either once a day (at bedtime) or twice a day in combination with short-acting insulin. In patients with type 2 diabetes, long-acting insulin is often given at bedtime to help normalize fasting blood glucose. It should be noted that the use of long-acting basal insulin alone will not control postprandial glucose elevation in insulin-deficient type 1 or type 2 diabetes.

Insulin glargine (LANTUS) is a long-acting analog of human insulin that is produced following two alterations of human insulin. Two arginine residues are added to the C terminus of the B chain, and an asparagine molecule in position 21 on the A chain is replaced with glycine. Insulin glargine is a clear solution with a pH of 4.0,

Figure 43–8. Commonly used insulin regimens. Panel A shows administration of a long-acting insulin like glargine (detemir could also be used but often requires twice-daily administration) to provide basal insulin and a pre-meal short-acting insulin analog (Table 43–5). Panel B shows a less intensive insulin regimen with BID injection of NPH insulin providing basal insulin and regular insulin or an insulin analog providing meal-time insulin coverage. Only one type of shorting-acting insulin would be used. Panel C shows the insulin level attained following subcutaneous insulin (short-acting insulin analog) by an insulin pump programmed to deliver different basal rates. At each meal, an insulin bolus is delivered. B=breakfast; L=lunch; S=supper; HS=bedtime. Upward arrow shows insulin administration at mealtime. (Copyright 2008 American Diabetes Association. From Kaufman FR (ed), *Medical Management of Type 1 Diabetes*, Fifth Edition. Modified with permission from the American Diabetes Association.)

which stabilizes the insulin hexamer. When injected into the neutral pH of the subcutaneous space, aggregations occurs, resulting in prolonged, but predictable, absorption from the injection site. Owing to insulin glargine's acidic pH, it cannot be mixed with short-acting insulin preparations (i.e., regular insulin, aspart, or lispro) that are formulated at a neutral pH.

In clinical studies glargine has a sustained peakless absorption profile, and provides a better once-daily 24-hour insulin coverage than NPH insulin. Evidence from clinical trials also suggests that glargine has a lower risk of hypoglycemia, particularly overnight compared to NPH insulin. Glargine may be administered at any time during the day with equivalent efficacy and does not accumulate after several injections. Glargine has been shown in clinical studies to normalize fasting (postabsorptive) glucose levels following once-daily administration in patients with type 2 diabetes. Sometimes, splitting the dose of glargine may be needed in very insulin-sensitive type 1 diabetes patients to achieve fasting (basal) glucose levels in the target range and avoid hypoglycemia. Unlike traditional insulin preparations that are absorbed more rapidly from the abdomen than from the arm or leg, the site of administration does not influence the time–action profile of glargine. Similarly, exercise does not influence glargine's unique absorption kinetics, even when the insulin is injected into a working limb.

Glargine binds with a slightly greater affinity to IGF-1 receptors as compared with human insulin. However, this slightly increased binding is still approximately two log scales lower than that of IGF-1. Controversy currently exists whether glargine insulin is associated with an increased chance of malignancy or an acceleration of underlying malignancy, but most feel that the available evidence is circumstantial and not sufficiently convincing to change prescribing patterns (Pocock and Smeeth, 2009; Smith and Gale, 2009; Weinstein et al., 2009).

Insulin detemir (LEVEMIR) is an insulin analog modified by the addition of a saturated fatty acid to the ϵ amino group of LysB29, yielding a myristoylated insulin. When insulin detemir is injected subcutaneously, it binds to albumin via its fatty acid chain. Clinical studies in patients with type 1 diabetes have demonstrated that when insulin detemir is administered twice a day, it has a smoother time–action profile and produces a reduced prevalence of hypoglycemia than NPH insulin. The absorption profiles of glargine and detemir insulin are similar, but detemir often requires twice-daily administration.

Other Insulin Formulations. Stable, mixed combinations (Table 43–5) of NPH and regular insulin in proportions of 70:30 combinations are available. Combinations of lispro protamine/lispro (50/50 and 75/25) and aspart protamine/aspart (70/30) are also available in the U.S.

Insulin Delivery. Most insulin is injected subcutaneously. Pen devices containing prefilled regular, lispro, NPH, glargine, premixed lispro protamine-lispro, or premixed aspart protamine-aspart have proven to be popular with many diabetic patients. Jet injector systems that enable patients to receive subcutaneous insulin injections without a needle are available. Intravenous infusions of insulin are useful in patients with ketoacidosis or when requirements for insulin may change rapidly,

such as during the perioperative period, during labor and delivery, and in intensive care situations.

Continuous Subcutaneous Insulin Infusion. Short-acting insulins are the only form of the hormone used in subcutaneous infusion pumps. A number of pumps are available for continuous subcutaneous insulin infusion (CSII) therapy. CSII, or pump, therapy is not suitable for all patients because it demands considerable attention. However, for patients interested in intensive insulin therapy, a pump may be an attractive alternative to several daily injections. Insulin pumps provide a constant basal infusion of insulin and have the option of different infusion rates during the day and night to help avoid the dawn phenomenon (rise in blood glucose that occurs just prior to awakening from sleep) and bolus injections that are programmed according to the size and nature of a meal.

Glucose sensors that measure the interstitial glucose are now available and may be helpful in patients with labile blood glucose and frequent hypoglycemia (Juvenile Diabetes Research Foundation Continuous Glucose Monitoring Study Group, 2008). Although patients can use both a pump and a sensor, these devices are not yet integrated into a closed-loop system. Similar to the collected evidence with CSII, the benefits of continuous glucose monitoring have not been conclusively demonstrated, nor have clear selection criteria for appropriate patient groups been developed. However, the results from recent studies suggest that real-time glucose monitoring may lead to modest improvements in glycemic control and improved patient/family quality of life.

Pump therapy presents some unique problems. Because all the insulin used is short acting and there is a minimal amount of insulin in the subcutaneous pool at any given time, insulin deficiency and ketoacidosis may develop rapidly if therapy is interrupted accidentally. Although modern pumps have warning devices that detect changes in line pressure, mechanical problems such as pump failure, dislodgement of the needle, aggregation of insulin in the infusion line, or accidental kinking of the infusion catheter may occur. There also is a possibility of subcutaneous abscesses and cellulitis. Selection of the most appropriate patients is extremely important for success with pump therapy. Offsetting these potential problems, pump therapy is capable of producing a more physiological profile of insulin replacement during exercise (where insulin production is decreased) and therefore less hypoglycemia than do traditional subcutaneous insulin injections.

Factors That Affect Insulin Absorption. Factors that determine the rate of absorption of insulin after subcutaneous administration include the site of injection, the type of insulin, subcutaneous blood flow, smoking, regional muscular activity at the site of the injection, the volume and concentration of the injected insulin, and depth of injection (insulin has a more rapid onset of action if delivered intramuscularly rather than subcutaneously). Increased subcutaneous blood flow (brought about by massage, hot baths, or exercise) increases the rate of absorption.

Insulin usually is injected into the subcutaneous tissues of the abdomen, buttock, anterior thigh, or dorsal arm. Absorption is usually most rapid from the abdominal wall, followed by the arm, buttock, and thigh. If a patient is willing to inject into the abdomen, injections can be rotated throughout the entire area, thereby eliminating the injection site as a cause of variability in the rate of absorption. The

abdomen currently is the preferred site of injection in the morning because insulin is absorbed 20-30% faster from that site than from the arm. If the patient refuses to inject into the abdominal area, it is preferable to select a consistent injection site for each component of insulin treatment (e.g., before-breakfast dose into the thigh, evening dose into the arm). Rotation of insulin injection sites traditionally has been advocated to avoid lipohypertrophy or lipoatrophy, although these conditions are infrequent with current preparations of insulin. In a small group of patients, subcutaneous degradation of insulin has been observed, and this has necessitated the injection of large amounts of insulin for adequate metabolic control.

Insulin Dosing and Regimens. In most patients, insulin-replacement therapy includes long-acting insulin (basal) and a short-acting insulin to provide postprandial needs. In a mixed population of type 1 diabetes patients, the average dose of insulin is usually 0.6-0.7 units/kg body weight per day, with a range of 0.2-1 units/kg per day. Obese patients generally and pubertal adolescents require more (~1-2 units/kg per day) because of resistance of peripheral tissues to insulin. Patients who require less insulin than 0.5 units/kg per day may have some endogenous production of insulin or may be more sensitive to the hormone because of good physical conditioning. The basal dose suppresses lipolysis, proteolysis, and hepatic glucose production; it is usually 40-50% of the total daily dose with the remainder as prandial or pre-meal insulin. The insulin dose at meal time should reflect the anticipated carbohydrate intake (many patients with type 1 diabetes calculate a ratio of the insulin dose to the number of grams of carbohydrate). A supplemental scale of short-acting insulin is added to the prandial insulin dose to allow correction of the BG. With all insulin dosing, the provider should consider the insulin sensitivity of the patient and adjust the insulin dosing accordingly. *Insulin administered as a single daily dose of long-acting insulin, alone or in combination with short-acting insulin, is rarely sufficient to achieve euglycemia. More complex regimens that include multiple injections of long-acting or short-acting insulin are needed to reach this goal. In all patients, careful monitoring of therapeutic end points directs the insulin dose used. This approach is facilitated by self-glucose monitoring and measurements of A1C.*

A number of commonly used dosage regimens that include mixtures of insulin given in two or more daily injections are depicted in Figure 43-8. An effective regimen involving multiple daily injections consisting of basal administration of long-acting insulin (e.g., insulin glargine or detemir) either before breakfast or at bedtime and preprandial injections of a short-acting insulin (Weng et al., 2008). This method is called *basal/bolus* and is very similar to the pattern of insulin administration achieved with a subcutaneous infusion pump. Another regimen used is the *split-mixed regimen* involving the pre-breakfast and pre-supper injection of a mixture of short- and long-acting insulins. When the pre-supper NPH insulin is not sufficient to control hyperglycemia throughout the night, the evening dose may be divided into a pre-supper dose of regular insulin followed by NPH insulin at bedtime.

Individuals with diabetes may sometimes consume smaller amounts of food than originally planned. This, in the presence of a previously injected dose of insulin that was based on anticipation of a larger meal, could result in postprandial hypoglycemia. Thus, in patients who have gastroparesis or loss of appetite, injection of a

short-acting analog postprandially, based on the amount of food actually consumed, may provide smoother glycemic control.

Adverse Events. The most common adverse reaction during insulin therapy is hypoglycemia. Hypoglycemia is the major risk that must be weighed against benefits of efforts to normalize glucose control. Additional information about hypoglycemia and its treatment is provided later in this chapter. Insulin is an anabolic hormone, and insulin treatment of both type 1 and type 2 diabetes is associated with modest weight gain. Paradoxically, improved glycemic control may initially lead to the deterioration of retinopathy in rare patients, but this is followed by a long-term reduction in diabetes-related complications. There has been a dramatic decrease in the incidence of allergic reactions to insulin with the transition to recombinant human insulin; these may still occur as a result of reaction to the small amounts of aggregated or denatured insulin in preparations, to minor contaminants, or because of sensitivity to one of the components added to insulin in its formulation (protamine, Zn²⁺, etc.). Human insulin, as delivered to patients with diabetes, is immunogenic as reflected by the observation that many patients have circulating anti-insulin antibodies, but these do not alter insulin pharmacokinetics or action. Atrophy of subcutaneous fat at the site of insulin injection (lipoatrophy) was a rare side effect of older insulin preparations. Lipohypertrophy (enlargement of subcutaneous fat depots) has been ascribed to the lipogenic action of high local concentrations of insulin.

Insulin Treatment of Ketoacidosis and Other Special Situations.

Acutely ill diabetic patients may have metabolic disturbances that are sufficiently severe or labile to justify intravenous administration of insulin (Kitabchi et al., 2009). Such treatment is most appropriate in patients with ketoacidosis or severe hyperglycemia with a hyperosmolar state. Insulin infusion inhibits lipolysis and gluconeogenesis completely and produces near-maximal stimulation of glucose uptake. In most patients with diabetic ketoacidosis, blood glucose concentrations will fall by ~10% per hour; the acidosis is corrected more slowly. As treatment proceeds, it often is necessary to administer glucose along with the insulin to prevent hypoglycemia but to allow clearance of all ketones. Some physicians prefer to initiate therapy with a loading dose of insulin, but this tactic appears unnecessary because steady-state concentrations of the hormone are achieved within 30 minutes with a constant infusion. Patients with nonketotic hyperglycemic hyperosmolar state may be more sensitive to insulin than are those with ketoacidosis. Appropriate replacement of fluid and electrolytes is an integral part of the therapy in both situations because there is always a major deficit. *Regardless of the insulin regimen, the key to effective therapy is careful and frequent monitoring of the patient's clinical status, glucose, and electrolytes.* A frequent error in the management of such patients is the failure to administer long-acting insulin subcutaneously before the insulin infusion is discontinued.

Treatment of Diabetes in Children or Adolescents. Diabetes is one of the most common chronic diseases of childhood, and rates of type 1 diabetes in American youth are estimated at 1 in 300, with an increasing incidence over the past 20 years. One of the unfortunate corollaries of the growing rates of obesity over the past three decades is an increase in the numbers of children and adolescents with nonautoimmune, or type 2, diabetes. Current estimates are that 15-20% of

new cases of pediatric diabetes may in fact be type 2 diabetes; rates vary by ethnicity, with disproportionately high rates in Native Americans, African Americans, and Latinos. Because of a paucity of clinical trials performed in children, there is only limited information on which to base decisions for appropriate therapy. Thus the results in the Diabetes Control and Complications Trial with young and middle-aged adults have been extrapolated to the pediatric population such that current practice is for more intensive, physiologically based insulin replacement with a goal of tight glucose control (Diabetes Control Complications Trial Research Group, 1993). This is achieved with combinations of basal and prandial insulin replacement. The primary limiting factor of more aggressive insulin therapy is hypoglycemia, a problem with special concerns in young children. Diabetic patients <5 years old are at greater risk for hypoglycemia, have increased rates of severe hypoglycemia with seizures and coma, and may suffer permanent cognitive dysfunction as a result of repeated episodes of low blood glucose. Older children and adolescents do not seem to have demonstrable cognitive impairment related to hypoglycemia; good glycemic control is associated with better mental function (Kodl and Seaquist, 2008).

The treatment of type 1 diabetes in children and adolescents has changed with the availability of newer technologies. The standard for insulin treatment now includes multiple dose regimens with three to five injections per day or CSII. Split/mixed regimens using NPH and regular insulin have been increasingly supplanted by regimens using insulin analogs because they offer more flexibility in dosing and meal patterns. Similarly, CSII is used with increasing frequency in the pediatric diabetic population. Moreover, recent studies show that this approach is applicable to young children as well as older children and adolescents.

Because of the nearly uniform association of type 2 diabetes with obesity in the pediatric age group, lifestyle management is the recommended first step in therapy. Goals of reducing body weight while maintaining normal linear growth, and increasing physical activity, are broadly recommended and can be effective when patients are compliant. There have been few clinical trials of glucose lowering therapy in pediatric type 2 diabetes. The only medication currently approved by the FDA specifically for medical treatment of type 2 diabetes is *metformin*. Metformin is approved for children as young as 10 years of age and is available in a liquid formulation (100 mg/mL). Results from clinical trials have shown that both metformin and glimepiride effectively lower blood glucose in affected patients. Insulin is the typical second line of therapy after metformin; basal insulin can be added to oral agent therapy or multiple daily injections can be used when simpler regimens are not successful. Weight gain is a more significant problem than hypoglycemia with insulin treatment in pediatric type 2 diabetes. Other diabetes medications, such as thiazolidinediones, α -glucosidase inhibitors, DPP-4 inhibitors, and exenatide, have been tried empirically in type 2 diabetic adolescents, but there is no systematically collected data on efficacy or safety of these agents in the pediatric population.

Management of Diabetes in Hospitalized Patients. Hyperglycemia is common in hospitalized patients. Depending on how hyperglycemia is defined, prevalence estimates of elevated blood glucose among inpatients with and without a prior diagnosis of diabetes range between 20% and 100% for patients treated in intensive care units (ICUs) and 30% and 83% outside the ICU. Although most of these

individuals will have known diabetes, ~30% of hospitalized patients will have elevated blood glucose levels without a prior diagnosis of diabetes (Falciglia, 2007). Patients admitted to the hospital often have a number of challenges to glucose regulation in addition to those faced by diabetic outpatients (Donner and Flammer, 2008). Stress of illness has been associated with insulin resistance, possibly the result of counterregulatory hormone secretion, cytokines, and other inflammatory mediators. Food intake is often variable due to concurrent illness or preparation for diagnostic testing. Medications used in the hospital, such as glucocorticoids or dextrose-containing intravenous solutions, can exacerbate tendencies toward hyperglycemia. Finally fluid balance and tissue perfusion can affect the absorbance of subcutaneous insulin and the clearance of glucose. Therapy of hyperglycemia in hospitalized patients needs to be adjusted for these variables.

There is an emerging body of information indicating that hyperglycemia portends poor outcomes in hospitalized patients, most notably in the critically ill, and that this effect is independent of severity of illness (Finfer et al., 2009; van den Berghe et al., 2001). The mechanisms for this association have not been fully explained, and controversy persists about the optimal level of glycemia in hospitalized patients. The ADA currently suggests these blood glucose targets: 140-180 mg/dL (7.8-10.0 mM) in critically ill patients and random glucose of 180 mg/dL (10 mM) or pre-meal glucose of 140 mg/dL (7.8 mM) in noncritically ill patients. Great emphasis should be placed on steps taken to minimize hypoglycemia in both settings.

Insulin is the cornerstone of treatment of hyperglycemia in hospitalized patients (Moghissi et al., 2009). For critically ill patients and those with variable blood pressure, edema, and tissue perfusion, intravenous insulin is the treatment of choice. This method of insulin administration has been firmly established in the care of critically ill patients with elevated blood glucose and provides the most flexible and precise means of treatment. A number of algorithms have been adapted to allow rapid titration with adjustments to maintain blood glucose in a target range. For patients who are more stable, subcutaneous insulin regimens using combinations of basal and prandial insulin is the standard. There is considerable evidence that reactive treatment, using sliding scale regimens, is inferior and associated with wider fluctuations in blood glucose and greater rates of both hyper- and hypoglycemia. Oral agents have a limited place in treatment of hyperglycemic patients in the hospital because of slow onset of action, insufficient potency, need for intact GI function, and side effects. In general, oral glucose-lowering medications should be discontinued on hospital admission and can be restarted at discharge.

Intravenous administration of insulin also is well suited to the treatment of diabetic patients during the perioperative period and during childbirth. There is debate, however, about the optimal route of insulin administration during surgery. Although some clinicians advocate subcutaneous insulin administration, most recommend intravenous insulin infusion. Some physicians give patients half their normal daily dose of insulin as long-acting insulin subcutaneously on the morning of an operation and then administer 5% dextrose infusions during surgery to maintain glucose concentrations. This approach provides less minute-to-minute control than is possible with intravenous regimens and also may increase the likelihood of hypoglycemia. For patients with type 1 diabetes, failure to provide some basal insulin at all times can precipitate diabetic ketoacidosis.

INSULIN SECRETAGOGUES AND ORAL HYPOGLYCEMIC AGENTS

A variety of sulfonylureas, meglitinides, GLP-1 agonists, and inhibitors of dipeptidyl peptidase-4 (DPP-4) are used as secretagogues to stimulate insulin release (Table 43–6).

K_{ATP} Channel Modulators: Sulfonylureas

Chemistry. All members of this class of drugs are substituted arylsulfonylureas. They differ by substitutions at the para position on the benzene ring and at one nitrogen residue of the urea moiety. The sulfonylureas are divided into two groups or generations of agents. The first generation sulfonylureas (tolbutamide, tolazamide, and chlorpropamide) are rarely used now in the treatment of type 2 diabetes and are not discussed (information is available in prior editions of this book). The second, more potent generation of hypoglycemic sulfonylureas includes glyburide (glibenclamide; DIABETA, others), glipizide (GLUCOTROL, others), and glimepiride (AMARYL, others) (Table 43–7). Some are

available in an extended-release (glipizide) or a micronized (glyburide) formulation. 1255

Mechanism of Action. Sulfonylureas stimulate insulin release by binding to a specific site on the β cell K_{ATP} channel complex (the sulfonylurea receptor, SUR) and inhibiting its activity. K_{ATP} channel inhibition causes cell membrane depolarization and the cascade of events leading to insulin secretion (Figure 43–3). The acute administration of sulfonylureas to type 2 diabetes patients increases insulin release from the pancreas. Sulfonylureas may also reduce hepatic clearance of insulin, further increasing plasma insulin levels. In the initial months of sulfonylurea treatment, fasting plasma insulin levels and insulin responses to oral glucose challenges are increased. With chronic administration, circulating insulin levels decline to those that existed before treatment, but despite this reduction in insulin levels, reduced plasma glucose levels are maintained. The explanation for this is not clear, but it may relate to the fact that chronic hyperglycemia *per se* impairs insulin secretion (glucose toxicity), and with the initial

Table 43–6

Properties of Insulin Secretagogues

CLASS/GENERIC NAME	DAILY DOSAGE ^a , mg	DURATION OF ACTION, h
Sulfonylureas - first generation		
Chlorpropamide	100-500	>48
Tolazamide	100-1000	12-24
Tolbutamide	1000-3000	6-12
Sulfonylureas - second generation		
Glimepiride	1-8	24
Glipizide	5-40	12-18
Glipizide (extended release)	5-20	24
Glyburide	1.25-20	12-24
Glyburide (micronized)	0.75-12	12-24

Glimepiride (AMARYL)		

correction of plasma glucose circulating insulin has improved effects on its target tissues. The absence of acute stimulatory effects of sulfonylureas on insulin secretion during chronic treatment is attributed to downregulation of cell surface receptors for sulfonylureas on the pancreatic β cell. If chronic sulfonylurea therapy is discontinued, pancreatic β cell response to acute administration of the drug is restored.

Absorption, Distribution, and Elimination. Although the rates of absorption of the different sulfonylureas vary, all are effectively absorbed from the GI tract. However, food and hyperglycemia can reduce absorption. Sulfonylureas in plasma are largely (90-99%) bound to protein, especially albumin; plasma protein binding is greatest for glyburide. The volumes of distribution of most of the sulfonylureas are ~ 0.2 L/kg. Although their half-lives are short (3-5 hours), their hypoglycemic effects are evident for 12-24 hours, and they often can be administered once daily. The reason for the discrepancies between their half-lives and duration of action is not clear. The liver metabolizes all sulfonylureas, and the metabolites are excreted in the urine. Thus, sulfonylureas should be administered with caution to patients with either renal or hepatic insufficiency.

Adverse Effects and Drug Interactions. Not unexpectedly, sulfonylureas may cause hypoglycemic reactions, including coma. This is a particular concern in elderly patients with impaired hepatic or renal function who are taking longer-acting sulfonylureas (a major reason

first-generation agents are rarely used). Because of the long $t_{1/2}$ of some sulfonylureas, it may be necessary to monitor or treat elderly hypoglycemic patients for 24-48 hours with an intravenous glucose infusion in the in-patient setting. Weight gain of 1-3 kg is a common side effect of improving glycemic control with sulfonylurea treatment.

Less frequent side effects of sulfonylureas include nausea and vomiting, cholestatic jaundice, agranulocytosis, aplastic and hemolytic anemias, generalized hypersensitivity reactions, and dermatological reactions. Rarely, patients treated with these drugs develop an alcohol-induced flush similar to that caused by disulfiram or hyponatremia. A long-running debate has centered on whether treatment with sulfonylureas is associated with increased cardiovascular mortality (Bell, 2006). This likely reflects the expression of the sulfonylurea receptor on vascular smooth muscle cells and cardiac myocytes, where activation of the sulfonylurea prevents the beneficial effects of ischemic preconditioning. Glyburide, but not glimepiride, interacts with the sulfonylurea receptor in these non-islet sites and may be associated with increased cardiovascular risk. However, a recent randomized trial of glyburide, metformin, and rosiglitazone found a slightly lower cardiovascular mortality in individuals treated with glyburide (Kahn et al., 2006).

The hypoglycemic effect of sulfonylureas may be enhanced by various mechanisms (decreased hepatic metabolism or renal excretion, displacement from protein-binding sites). For example, some drugs (sulfonamides, clofibrate, and salicylates) displace the sulfonylureas from binding proteins, thereby transiently increasing the concentration of free drug. Ethanol may enhance the action of sulfonylureas and cause hypoglycemia. In addition, hypoglycemia

may be more frequent in patients taking a sulfonylurea and one of these agents: androgens, anticoagulants, azole antifungals, chloramphenicol, fenfluramine, fluconazole, gemfibrozil, histamine H₂ antagonists, magnesium salts, methyl dopa, monoamine oxidase inhibitors (MAOIs), probenecid, sulfapyrazone, sulfonamides, tricyclic antidepressants, and urinary acidifiers. Other drugs may decrease the glucose-lowering effect of sulfonylureas by increased hepatic metabolism, increased renal excretion, or inhibiting insulin secretion (β -blockers, Ca²⁺ channel blockers, cholestyramine, diazoxide, estrogens, hydantoin, isoniazid, nicotinic acid, phenothiazines, rifampin, sympathomimetics, thiazide diuretics, and urinary alkalinizers).

Dosage Forms Available. Treatment is initiated at lower end of the dose range and titrated upward based on the patient's glycemic response. Some have a longer duration of action and can be prescribed in a single daily dose (glimepiride), whereas others are formulated as extended-release or micronized formulations to extend their duration of action (Table 43–7). The dose for the extended-release glipizide or micronized glyburide is lower. Glyburide is not recommended when the creatinine clearance is < 50 mL/minute or in elderly individuals because reduced drug and metabolite clearance greatly increases the risk of hypoglycemia. Other sulfonylureas such as glipizide or glimepiride appear safer in elderly individuals with type 2 diabetes.

Therapeutic Uses. Sulfonylureas are used to treat hyperglycemia in type 2 diabetes. Between 50% and 80% of properly selected patients respond to this class of agents. All members of the class appear to be equally efficacious. A significant number of patients who respond initially later cease to respond to the sulfonylurea and develop unacceptable hyperglycemia (secondary failure). This may occur as a result of a change in drug metabolism or more likely from a progression of β -cell failure. A recent randomized trial found that the initial improvement in glycemic control was less durable with glyburide monotherapy (compared to metformin or rosiglitazone monotherapy), suggesting that the secondary failure rate is higher with this class of drugs (Kahn et al., 2006). Some individuals with neonatal diabetes or MODY-3 respond to these agents (this is an off-label use). Combinations of insulin and sulfonylureas and other oral agents are discussed later. Contraindications to the use of these drugs include type 1 diabetes, pregnancy, lactation, and, for the older preparations, significant hepatic or renal insufficiency.

K_{ATP} Channel Modulators:

Non-Sulfonylureas

Repaglinide. Repaglinide (PRANDIN) is an oral insulin secretagogue of the meglitinide class (Table 43–6). It

is a benzoic acid derivative structurally unrelated to the sulfonylureas, but like sulfonylureas, it stimulates insulin release by closing K_{ATP} channels in pancreatic β cells. The drug is absorbed rapidly from the GI tract, and peak blood levels are obtained within 1 hour. The $t_{1/2}$ is ~1 hour. These features allow for multiple preprandial use as compared with the classical once- or twice-daily dosing of sulfonylureas.

Repaglinide is metabolized primarily by the liver (CYP3A4) to inactive derivatives. Repaglinide should be used cautiously in patients with hepatic insufficiency. Because a small proportion (~10%) is metabolized by the kidney, dosing of the drug in patients with renal insufficiency also should be performed cautiously. As with sulfonylureas, the major side effect of repaglinide is hypoglycemia. Like sulfonylureas, repaglinide is associated with a decline in efficacy (secondary failure) after initially improving glycemic control. Certain drugs may potentiate the action of repaglinide by displacing it from plasma protein binding sites (β -blockers, chloramphenicol, coumarins, MAOIs, nonsteroidal anti-inflammatory drugs [NSAIDs], probenecid, salicylates, and sulfonamide) or altering its metabolism (gemfibrozil, itraconazole, trimethoprim, cyclosporine, simvastatin, clarithromycin).

Nateglinide. Nateglinide (STARLIX) is an orally effective insulin secretagogue derived from d-phenylalanine. Like sulfonylureas and repaglinide, nateglinide stimulates insulin secretion by blocking K_{ATP} channels in pancreatic β cells (Rosenstock et al., 2004). Nateglinide promotes a more rapid but less sustained secretion of insulin than other available oral antidiabetic agents. The drug's major therapeutic effect is reducing postprandial glycemic elevations in type 2 diabetes patients. Nateglinide is approved by the FDA for use in type 2 diabetes. It is most effective when administered in a dose of 120 mg, 1-10 minutes before a meal.

Nateglinide is metabolized primarily by hepatic CYPs [2C9, 70%; 3A4, 30%] and thus should be used cautiously in patients with hepatic insufficiency. About 16% of an administered dose is excreted by the kidney as unchanged drug. Dosage adjustment is unnecessary in renal failure. Some drugs reduce the glucose-lowering effect of nateglinide (corticosteroids, rifamycins, sympathomimetics, thiazide diuretics, thyroid products); others (alcohol, NSAIDs, salicylates, MAOIs, and nonselective β blockers) may increase the risk of hypoglycemia with nateglinide. Nateglinide therapy may produce fewer episodes of hypoglycemia than other currently available oral insulin secretagogues including repaglinide. As with sulfonylureas and repaglinide, secondary failure occurs.

A_{MPK} and PPAR γ activators

Metformin

Mechanism of Action. Metformin (GLUCOPHAGE, others) is the only member of the biguanide class of oral hypoglycemic drugs available for use today (Bailey and

Turner, 1996). Metformin increases the activity of the AMP-dependent protein kinase (AMPK) (Zhou et al., 2001). AMPK is activated by phosphorylation when cellular energy stores are reduced (i.e., lower concentrations of ATP and phosphocreatine). Activated AMPK stimulates fatty acid oxidation, glucose uptake, and nonoxidative metabolism, and it reduces lipogenesis and gluconeogenesis. The net result of these actions is increased glycogen storage in skeletal muscle, lower rates of hepatic glucose production, increased insulin sensitivity, and lower blood glucose levels.

Metformin causes a similar profile of effects and is dependent on AMPK activation (Shaw et al., 2005). Although the molecular mechanism by which metformin activates AMPK is not known, it is thought to be indirect, possibly by reducing intracellular energy stores. Consistent with this, metformin has been shown to inhibit cellular respiration by specific actions on mitochondrial complex I. Metformin has little effect on blood glucose in normoglycemic states and does not affect the release of insulin or other islet hormones and rarely causes hypoglycemia. However, even in persons with only mild hyperglycemia, metformin lowers blood glucose by reducing hepatic glucose production and increasing peripheral glucose uptake. This effect is at least partially mediated by reducing insulin resistance at key target tissues. The hepatic effect is probably the dominant mode of action and involves primarily suppression of gluconeogenesis. Table 43–8 compares metformin and thiazolidinediones (glitazones).

Table 43–8

Comparison of Metformin and Thiazolidinediones

PARAMETER	METFORMIN	THIAZOLIDINEDIONES
Molecular target	AMPK	PPAR γ
Pharmacologic action	Suppression of HGP	Enhanced insulin sensitivity
Reduction of HbA _{1c} ^a	1.0-1.25	0.5-1.4
Reduction of FFA	Minimal	Moderate
Stimulation of adiponectin	Minimal	Significant
Effect on body weight	Minimal	Increased
Peripheral edema	Minimal	Moderate
Fracture risk	None	Increased
Lactic Acidosis	Rare ^b	None

^aMagnitude of absolute reduction dependent on starting A1C value

^bIn renal insufficiency

HGP = hepatic glucose production

Absorption, Distribution, and Elimination. Metformin is absorbed primarily from the small intestine. The drug is stable, does not bind to plasma proteins, and is excreted unchanged in the urine. It has a $t_{1/2}$ in the circulation of ~2 hours. The transport of metformin into cells is mediated in part by organic cation transporters (see Chapter 5). Organic cation transporter 1 (OCT 1) is believed to carry the drug into cells such as hepatocytes and myocytes where it is pharmacologically active. Organic cation transporter 2 (OCT 2) is thought to transport metformin into renal tubules for excretion. There is recent evidence suggesting that genetic variation in OCT 1 among humans may affect the response to metformin.

Therapeutic Uses and Dosage. Metformin is currently the most commonly used oral agent to treat type 2 diabetes and is generally accepted as the first-line treatment for this condition. Metformin is effective as monotherapy and in combination with nearly every other therapy for type 2 diabetes, and its utility is supported by data from a large number of clinical trials. Fixed-dose combinations of metformin in conjunction with glipizide, glyburide, pioglitazone, repaglinide, rosiglitazone, and sitagliptin are available. Metformin is available as an immediate-release form, and treatment is best started with low doses and titrated over days to weeks to minimize side effects. The currently recommended dosing is 0.5-1.0 g twice daily, with a maximum dose of 2550 mg; there is no advantage of thrice-daily administration. A sustained-release preparation is available that is effective for once-daily dosing; the maximum dose for this compound is 2 g.

Metformin has superior or equivalent efficacy of glucose lowering compared to other oral agents used to treat diabetes, and reduces diabetes-related complications in patients with type 2 diabetes. Unlike many of the other oral agents, metformin does not typically cause weight gain and in some cases causes weight reduction. Metformin is not effective in the treatment of type 1 diabetes. Several observational studies suggest that diabetic patients treated with metformin may have lower rates of cardiovascular disease and mortality, compared to individuals treated with alternative therapies (Evans et al., 2006; Johnson et al., 2005). The results of the Diabetes Prevention Program indicate that in persons with impaired glucose tolerance, treatment with metformin delays the progression to diabetes. Metformin has been used as a treatment for infertility in women with the polycystic ovarian syndrome. Although not formally approved for this purpose, metformin has demonstrable effects to improve ovulation and menstrual cyclicality and reduce circulating androgens and hirsutism.

Adverse Effects and Drug Interactions. The most common side effects of metformin are gastrointestinal. Approximately 10-25% of patients starting this medication report nausea, indigestion, abdominal cramps or bloating, diarrhea, or some combination of these. Metformin has direct effects on GI function including glucose and bile salt absorption. Use of metformin is associated with 20-30% lower blood levels of vitamin B₁₂ (DeFronzo et al., 1995), probably

due to malabsorption, but neurological or hematological consequences of this have not been reported. Most GI adverse effects of metformin abate over time with continued use of the drug, and can be minimized by starting at low doses and gradually titrating to a target dose over several weeks, and by having patients take it with meals.

Like phenformin, metformin has been associated with lactic acidosis. The most concrete evidence of this is from cases of metformin overdose where very high circulating levels of the drug were associated with high plasma lactate and acidemia. However, the estimated incidence of lactic acidosis attributable to metformin use is 3-6 per 100,000 patient-years of treatment (Lalau and Race, 2001; Scarpello and Howlett, 2008), which is comparable to rates in type 2 diabetic patients not using metformin. Moreover, several recent analyses of this association have raised doubts as to whether the association of lactic acidosis with metformin is causal (Kamber et al., 2008). Many cases of lactic acidosis associated with the use of metformin have been reported in patients with concurrent conditions that can cause poor tissue perfusion such as sepsis, myocardial infarction, and congestive heart failure. Renal failure is another common comorbidity reported in patients having lactic acidosis associated with metformin use, and decreased glomerular filtration rates are thought to increase plasma metformin levels by reducing clearance of drug from the circulation. There are no consensus guidelines for renal contraindications for metformin use; because clearance of the drug is not altered significantly until the creatinine clearance drops below 50 mL/minute, metformin is probably safe in patients with this level of renal function (Herrington and Levy, 2008). It is important to assess renal function before starting metformin and to monitor function at least annually. Metformin should be discontinued preemptively in situations where renal function could decline precipitously, such as before radiographic procedures that use contrast dyes and during admission to hospital for severe illness. Metformin should not be used in severe pulmonary disease, decompensated heart failure, severe liver disease, or chronic alcohol abuse.

Cationic drugs that are eliminated by renal tubular secretion have the potential for interaction with metformin by competing for common renal tubular transport systems. Careful patient monitoring and dose adjustment of metformin is recommended in patients who are taking cationic medications such as cimetidine, furosemide, and nifedipine, excreted via the proximal renal tubular secretory system.

Thiazolidinediones

Chemistry and Mechanism of Action. Thiazolidinediones are ligands for the peroxisome proliferation activating receptor γ (PPAR γ) receptors, a group of nuclear hormone receptors that are involved in the regulation of genes related to glucose and lipid metabolism (Yki-Jarvinen, 2004). Two thiazolidinediones are currently available to treat patients with type 2 diabetes, rosiglitazone (AVANDIA) and pioglitazone (ACTOS). These compounds are generally similar but have several important differences. Although much is understood about the molecular mechanisms of action of the thiazolidinediones, they have complex effects on a wide variety of tissues, and much remains to be learned about their overall clinical impact

PPAR γ is expressed primarily in adipose tissue with lesser expression in cardiac, skeletal, and smooth muscle cells, islet β cells, macrophages, and vascular endothelial cells. The endogenous ligands for PPAR γ include small lipophilic molecules such as oxidized linoleic acid, arachidonic acid and the prostaglandin metabolite 15d-PGJ2; rosiglitazone and pioglitazone are synthetic ligands for PPAR γ . Ligand binding to PPAR γ causes heterodimer formation with the retinoid X receptor and interaction with PPAR response elements on specific genes, an interaction that is modulated by complex interactions with co-repressors and co-activators. The principal response to PPAR γ activation is adipocyte differentiation. Preclinical gain-of-function models show increased numbers of adipocytes and expansion of fat mass; loss-of-function models demonstrate lipodystrophy. Along with adipocyte differentiation, PPAR γ activity promotes uptake of circulating fatty acids into fat cells and shifts of lipid stores from extra-adipose to adipose tissue. One consequence of the concerted cellular responses to PPAR γ activation is increased tissue sensitivity to insulin, and this is the basis for the pharmacological application of thiazolidinediones to clinical medicine.

Pioglitazone and rosiglitazone are insulin sensitizers and increase insulin-mediated glucose uptake by 30-50% in patients with type 2 diabetes. Although adipose tissue seems to be the primary target for PPAR γ agonists, both clinical and preclinical models support a role for skeletal muscle, the major site for insulin-mediated glucose disposal, in the response to thiazolidinediones. It is still not clear whether thiazolidinedione-induced improvement of insulin resistance is due to direct effects on key target tissues (skeletal muscle and liver), indirect effects mediated by secreted products of adipocytes (e.g., adiponectin), or some combination of these. In addition to promoting glucose uptake into muscle and adipose tissue, the thiazolidinediones reduce hepatic glucose production and increase hepatic glucose uptake.

Beyond effects on insulin sensitivity and blood glucose, thiazolidinediones also affect lipid metabolism. Treatment with rosiglitazone or pioglitazone reduces plasma levels of fatty acids by increasing clearance and reducing lipolysis. These drugs also cause a shift of triglyceride stores from nonadipose to adipose tissues, and from visceral to subcutaneous fat depots. In clinical trials, pioglitazone reduces plasma triglycerides by 10-15%, and raises HDL-cholesterol levels. This has been attributed to a dual effect on PPAR α as well as PPAR γ ; rosiglitazone does not interact with PPAR α and

has minimal effects on plasma triglycerides and cholesterol. Because of these actions on plasma lipids, and beneficial effects on inflammatory markers, coagulation, and endothelial function, thiazolidinediones were predicted to reduce macrovascular complications of diabetes and insulin resistance. However, recently completed randomized clinical trials demonstrated a questionable benefit of pioglitazone (Dormandy et al., 2005), and no effect of rosiglitazone on major events related to atherosclerosis (Home et al., 2009). Because thiazolidinediones reduce hepatic triglyceride, they have been applied to the treatment of nonalcoholic fatty liver disease. Although results of these studies have been encouraging (Kashi et al., 2008), the thiazolidinediones are not yet approved for this use.

Absorption, Distribution, and Elimination. Both agents are absorbed within 2-3 hours, and bioavailability does not seem to be affected by food. The thiazolidinediones are metabolized by the liver and may be administered to patients with renal insufficiency, but should not be used if there is active hepatic disease or significant elevations of serum liver transaminases. The thiazolidinediones are metabolized by hepatic CYPs. CYPs 2C8 and 3A4 metabolize pioglitazone; rosiglitazone is metabolized by CYPs 2C9 and 2C8. Rifampin induces these enzymes and causes a significant decrease in plasma concentrations of rosiglitazone and pioglitazone; gemfibrozil impedes metabolism of the thiazolidinediones and can increase plasma levels by ~2-fold. It may be prudent to reduce the doses of the thiazolidinediones when they are used in conjunction with gemfibrozil. Rosiglitazone and pioglitazone do not seem to significantly affect the pharmacokinetics of other drugs.

Therapeutic Uses and Dosage. Rosiglitazone and pioglitazone are dosed once daily. The starting dose of rosiglitazone is 4 mg and should not exceed 8 mg daily. The starting dose of pioglitazone is 15-30 mg, up to a maximum of 45 mg daily. Thiazolidinediones have proven effects to enhance insulin action on liver, adipose tissue, and skeletal muscle. These composite effects on glucose metabolism confer improvements in glycemic control in persons with type 2 diabetes and cause average reductions in A1C of 0.5-1.4%. Thiazolidinediones require the presence of insulin for pharmacological activity and are not indicated to treat type 1 diabetes. Both pioglitazone and rosiglitazone are effective as monotherapy and as additive therapy to metformin, sulfonylureas, or insulin. The onset of action of thiazolidinediones is relatively slow; maximal effects on glucose homeostasis develop gradually over the course of 1-3 months.

There is evidence in drug-naïve diabetic subjects that the glucose-lowering effect of primary treatment with rosiglitazone is more durable than that of metformin or glyburide (Kahn et al., 2006). Treatment with rosiglitazone also reduced progression from prediabetes to type 2 diabetes (Gerstein et al., 2006).

Adverse Effects and Drug Interactions. The most common adverse effects of the thiazolidinediones are weight gain and edema. Edema attributable to thiazolidinedione treatment occurs in up to 10% of

patients in clinical trials and has been reported equally with pioglitazone and rosiglitazone. Beyond the effects of edema, treatment with thiazolidinediones causes an increase in body adiposity and an average weight gain of 2–4 kg over the first year of treatment. Importantly, in both preclinical models and in human studies the gain of body weight occurs peripherally, in subcutaneous adipose tissue, and visceral fat changes little or is reduced. The use of insulin with thiazolidinedione treatment roughly doubles the incidence of edema and amount of weight gain, compared with either drug alone.

Macular edema has been reported in patients using both rosiglitazone and pioglitazone (Ryan et al., 2006), usually in association with more general fluid retention. Beyond regular annual retinal exams, diabetic patients taking thiazolidinediones should be observed for visual changes.

Of greatest concern among the adverse effects of thiazolidinediones is the increased incidence of congestive heart failure. This has generally been attributed to the effect of the drugs to cause plasma volume expansion in type 2 diabetic patients who have significantly increased risk for heart failure. There does not appear to be an acute effect of pioglitazone or rosiglitazone to reduce myocardial contractility or ejection fraction. Yet exposure to these drugs over several years in clinical trials has been associated with an increased incidence of heart failure of up to 2-fold (Home et al., 2009). The use of thiazolidinediones in diabetic patients without a history of heart failure, or with compensated heart failure, can be initiated, but monitoring for signs and symptoms of congestive heart failure is important, especially when insulin is also used. Thiazolidinediones should not be used in patients with moderate to severe heart failure, and they should be discontinued in those who develop clinically apparent heart failure while being treated (Nesto et al., 2003).

Recent evidence suggests that rosiglitazone, but not pioglitazone, increases the risk of cardiovascular events (myocardial infarction, stroke). While the degree of the risk remains controversial, an expert panel reviewing this question for the FDA recommended caution in the use of rosiglitazone, but did not recommend its removal from the market (Rosen, 2010). Rather, as of September, 2010, the FDA requires that new prescriptions for rosiglitazone be issued under a risk evaluation and mitigation strategy and be limited to patients whose diabetes could not be adequately controlled by other medications (including pioglitazone). The European Medicines Agency has suspended marketing of rosiglitazone-containing formulations and recommended removal of rosiglitazone and rosiglitazone-containing formulations from the European market.

Evidence from clinical trials indicates that treatment with thiazolidinediones can increase the risk of bone fracture in women (Home et al., 2009; Kahn et al., 2006; Meier et al., 2008). This effect has been proposed to result from increased shunting of mesenchymal stem cells into the adipocyte lineage, and away from osteogenesis, as a result of increased PPAR γ activity. Treatment with thiazolidinediones has also been associated with a small but consistent reduction in the hematocrit. This has generally been attributed to hemodilution due to plasma volume expansion, but thiazolidinediones may conceivably shunt erythroid precursors into adipose tissue development.

The first thiazolidinedione released for treatment of diabetic patients, troglitazone, was removed from the market because of rare but severe, and sometimes fatal, hepatic failure. There have been few cases of severe hepatocellular damage attributable to the newer thiazolidinediones, and these have not caused death or required

transplantation. In general, pioglitazone and rosiglitazone have been associated with a lowering of transaminases, probably reflective of reductions in hepatic steatosis. It is recommended that thiazolidinediones be withheld from patients with clinically apparent liver disease and that liver function be monitored intermittently during treatment.

GLP-1-Based Agents

Incretins are GI hormones that are released after meals and stimulate insulin secretion. The two best known incretins are GLP-1 and GIP. Although these peptides share many similarities, they differ in that GIP is not effective for stimulating insulin release and lowering blood glucose in persons with type 2 diabetes, whereas GLP-1 is effective. Consequently, the GLP-1 signaling system has been a successful drug target.

Both GLP-1 and glucagon are products derived from proglucagon, a 180-amino acid precursor with five separately processed domains (Figure 43–9) (Drucker, 2006). An amino-terminal signal peptide is followed by glicentin-related pancreatic peptide, glucagon, GLP-1, and glucagon-like peptide 2 (GLP-2). Processing of the protein is sequential and occurs in a tissue-specific fashion. Pancreatic α -cells cleave proglucagon into glucagon and a large C-terminal peptide that includes both of the GLPs. Intestinal L-cells and specific hindbrain neurons process proglucagon into a large N-terminal peptide that includes glucagon or GLP-1 and GLP-2. GLP-2 impacts the proliferation of epithelial cells lining the GI tract. Teduglutide, a GLP-2 analog, is under development as a treatment for short bowel syndrome and has received orphan drug designation for the treatment of short bowel syndrome from the U.S. FDA and the European Medicines Agency.

Given intravenously to diabetic subjects in supraphysiologic amounts, GLP-1 stimulates insulin secretion, inhibits glucagon release, delays gastric emptying, reduces food intake, and normalizes fasting and postprandial insulin secretion. The insulinotropic effect of GLP-1 is glucose dependent in that insulin secretion at fasting glucose concentrations, even with high levels of circulating GLP-1, is minimal. The effects of GLP-1 to promote glucose homeostasis and the glucose dependence of these effects are beneficial aspects of this signaling system for treating type 2 diabetes. GLP-1 is rapidly inactivated by the enzyme dipeptidyl peptidase IV (DPP-4), with a plasma $t_{1/2}$ of 1–2 minutes; thus, the natural peptide, itself, is not a useful therapeutic agent.

Two broad strategies have been taken to applying GLP-1 to therapeutics, the development of injectable, DPP-4 resistant peptide agonists of the GLP-1 receptor, and the creation of small molecule inhibitors of DPP-4 (Figure 43–10; Table 43–6).

GLP-1 Receptor Agonists. There are currently two GLP-1 receptor agonists that have been approved for

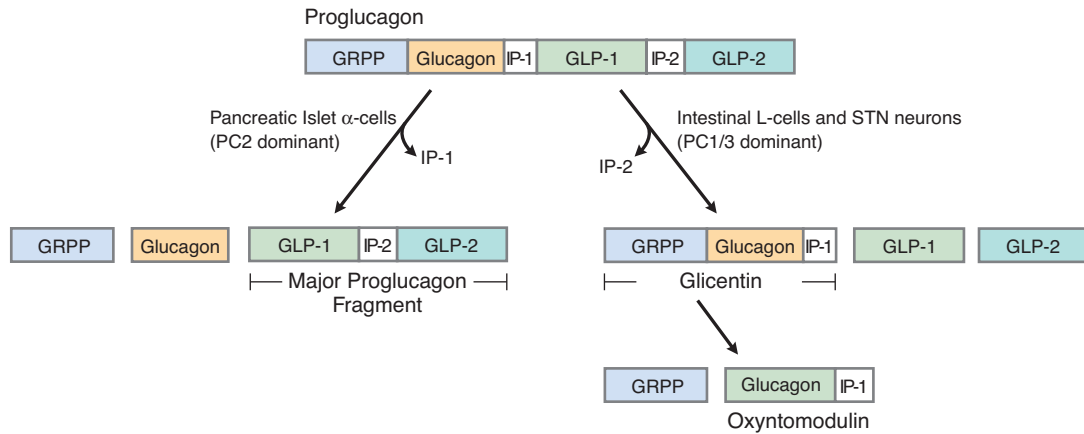

Figure 43–9. Processing of proglucagon to glucagon, GLP1, GLP-2, and GRPP. Proglucagon is synthesized in islet α cells, intestinal enteroendocrine cells (L cells) and a subset of neurons in the hindbrain. In α cells, prohormone processing is primarily by proconvertase 2, releasing glucagon, glicentin-related pancreatic polypeptide (GRPP), and a major proglucagon fragment, containing the two glucagon-like peptides (GLPs). In L cells and neurons, proglucagon cleavage is mostly through proconvertase 1/3, giving the larger C-terminal peptides, glicentin and oxyntomodulin, and the smaller GLP-1 and GLP-2. STN, solitary tract nucleus.

treatment diabetic patients in the U.S. and several others in advanced phases of development. Exendin-4 is a naturally occurring reptilian peptide of 39 amino acids with considerable homology to GLP-1. It is a potent

GLP-1 receptor agonist that shares many of the physiological and pharmacological effects of GLP-1. It is not metabolized by DPP-4 and so has a plasma $t_{1/2}$ of 2-3 hours following subcutaneous injection. Importantly,

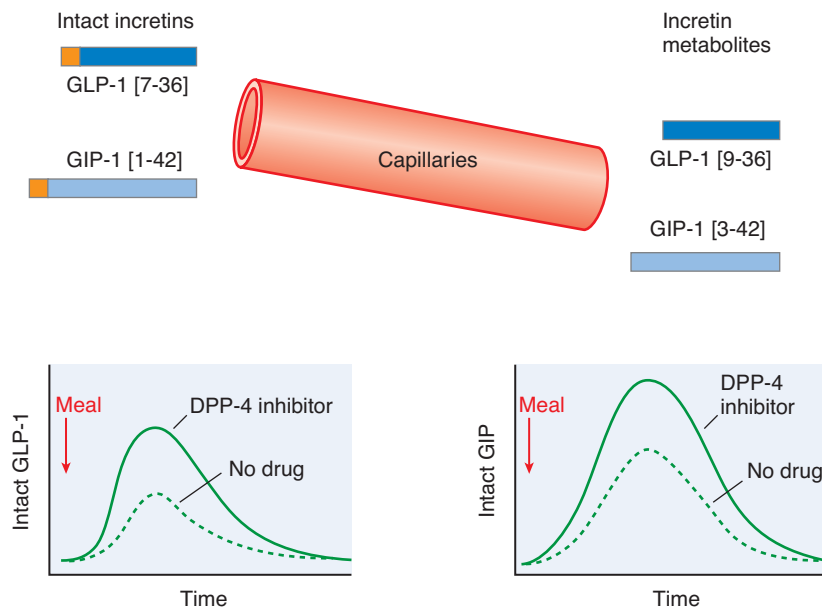

Figure 43–10. Pharmacological effects of DPP-4 inhibition. DPP-4, an ectoenzyme located on the luminal side of capillary endothelial cells metabolizes the incretins, glucagon-like peptide 1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP), by removing the two N-terminal amino acids. The target for DPP-4 cleavage is a proline or alanine residue in the second position of the primary peptide sequence. The truncated metabolites GLP-1[9-36] and GIP[3-42] are the major forms of the incretins in plasma and are inactive as insulin secretagogues. Treatment with a DPP-4 inhibitor increases the concentrations of intact GLP-1 and GIP.

exendin-4 causes glucose-dependent insulin secretion, delayed gastric emptying, lower glucagon levels, and reduced food intake.

Exenatide (BYETTA), synthetic exendin-4, is approved for use as monotherapy and as adjunctive therapy for type 2 diabetes patients not achieving glycemic targets with metformin, sulfonylurea, the combination of metformin and sulfonylurea, or thiazolidinedione. In clinical trials, exenatide, alone or in combination with metformin, sulfonylurea, or thiazolidinedione, was associated with improved glycemic control, as reflected in an ~1% decrease in HbA1C, and weight loss that averaged 2.5–4 kg (Amori et al., 2007).

Liraglutide is a second GLP-1 receptor agonist. Structurally, liraglutide is nearly identical to native GLP-1, with Lys³⁴ to Arg substitution and addition of a α -glutamic acid spacer coupled to a C16 fatty acyl group. The fatty acid side chain permits binding to albumin and other plasma proteins and accounts for an extended $t_{1/2}$ permitting once a day administration. The pharmacodynamic profile of liraglutide mimics GLP-1 and exenatide, and in clinical trials liraglutide caused both improvement in glycemic control and weight loss. In a single comparative trial, liraglutide reduced A1C ~30% more than exenatide (Buse et al., 2009). Liraglutide is indicated for adjunctive therapy in patients not achieving glycemic control with metformin, sulfonylurea, or the combination of metformin/sulfonylurea or metformin/thiazolidinedione.

There are a number of other GLP-1 receptor agonists in development. A sustained-release form of exenatide, exenatide LAR, is being tested as a once-weekly injection. This compound is composed of exenatide in microspheres with the biodegradable polymer D,L lactic-co-glycolic acid. In phase 3 studies, exenatide LAR shares the pharmacodynamic properties of exenatide but may be more potent (Kim et al., 2007). Other long-acting GLP-1 receptor agonists in advanced stages of development include albiglutide, a recombinant protein fusion of GLP-1 and albumin; tasoglutide, a modified GLP-1; lixisenatide, a modified exendin-4 based molecule; and CJC-1134, an exendin-4/albumin conjugate. These agonists all have extended half-lives relative to exenatide and liraglutide and may be suitable for once-weekly injection. The distinguishing feature among the drugs currently available or under investigation is their pharmacokinetics and the exposure time to the GLP-1 receptor.

Mechanism of Action. All GLP-1 receptor agonists share a common mechanism, activation of the GLP-1 receptor. GLP-1 receptors are expressed by β cells, cells in the peripheral and central nervous system, the heart and vasculature, kidney, lung, and GI mucosa. Binding of agonists to the GLP-1 receptor activates the cAMP-PKA pathway and several GEFs (guanine nucleotide

exchange factors) (Drucker, 2006). GLP-1 receptor activation also initiates signals through PKC and PI3K, and it alters the activity of several ion channels. In β cells, the end result of these actions is increased insulin biosynthesis and exocytosis in a glucose-dependent manner (Figure 43-3).

Absorption, Distribution, Metabolism, Excretion, and Dosing.

Exenatide is given as a subcutaneous injection twice daily, typically before meals. Exenatide is rapidly absorbed, reaches peak concentrations in ~2 hours, undergoes little metabolism in the circulation, and has a volume of distribution of nearly 30 L. Clearance of the drug occurs primarily by glomerular filtration, with tubular proteolysis and minimal reabsorption. Exenatide is marketed as a pen that delivers 5 or 10 μ g; dosing is typically started at the lower amount and increased as the response to therapy warrants.

Liraglutide is given as a subcutaneous injection once daily. Peak levels occur in 8–12 hours and the elimination $t_{1/2}$ is 12–14 hours. There is little renal or intestinal excretion of liraglutide, and clearance is primarily through the metabolic pathways of large plasma proteins. Liraglutide is supplied in a pen injector that delivers 0.6, 1.2, or 1.8 mg of drug; the low dose is for treatment initiation and generally advanced to the two higher doses based on clinical response.

Adverse Effects and Drug Interactions. The side effects of GLP-1 receptor agonists mimic the pharmacology of native GLP-1. Intravenous or subcutaneous administration of GLP-1 causes nausea and vomiting in a dose-dependent manner; the doses above which GLP-1 causes GI side effects are higher than those needed to regulate blood glucose. Despite this therapeutic window that minimizes adverse effects, nausea, vomiting, and other problems related to GI function are common with these drugs. Based on data from clinical trials, up to 40–50% of subjects given a GLP-1 receptor agonist report nausea at the initiation of therapy. Because the GI side effects of these drugs wane over time, most affected patients are able to continue a course of therapy. The activation of the GLP-1 receptor can delay gastric emptying; thus exenatide and other drugs of this class should be used with caution with other compounds that affect gastric emptying. Moreover, GLP-1 agonists may alter the pharmacokinetics of drugs that require rapid GI absorption, such as oral contraceptives and antibiotics.

In the absence of other diabetes drugs that cause low blood glucose, hypoglycemia associated with GLP-1 agonist treatment is rare. The combination of exenatide or liraglutide with sulfonylurea drugs causes an increased rate of hypoglycemia compared to sulfonylurea treatment alone. Because of the high degree of renal clearance, exenatide should not be given to persons with moderate to severe renal failure (creatinine clearance <30 mL/minute). There is no current recommendation for dose adjustments of other GLP-1 receptor agonists for decreased renal function. Exenatide has also been rarely associated with acute renal failure. Based on surveillance data, there is a possible association of exenatide treatment with pancreatitis, including fatal and nonfatal hemorrhagic or necrotizing pancreatitis. There is currently no mechanism to explain this association, and cases linking exenatide to pancreatitis are rare.

Mechanism of Action. DPP-4 is a serine protease that is widely distributed throughout the body, expressed as an ectoenzyme on endothelial cells, on the surface of T-lymphocytes, and in a circulating form. DPP-4 cleaves the two N-terminal amino acids from peptides with a proline or alanine in the second position. Although there are many potential substrates for this enzyme, it seems to be especially critical for the inactivation of GLP-1 and GIP (*glucose-dependent insulinotropic polypeptide; gastric inhibitory peptide*) (Drucker, 2007). DPP-4 inhibitors increase the AUC of GLP-1 and GIP when their secretion is by a meal (Figure 43-10).

Dosage Forms. Several agents provide nearly complete and long-lasting inhibition of DPP-4, thereby increasing the proportion of active GLP-1 from 10-20% of total circulating GLP-1 immunoreactivity to nearly 100%. Two of these, sitagliptin (JANUVIA) and saxagliptin (ONGLYZA), are now available in the U.S.; a third, vildagliptin, is available in the E.U.; a fourth compound, alogliptin, is in advanced stages of clinical trials. Sitagliptin and alogliptin are competitive inhibitors of DPP-4, whereas vildagliptin and saxagliptin bind the enzyme covalently. Despite these differences, all four drugs can be given in doses that lower measurable activity of DPP-4 by >95% for 12 hours. This causes a greater than 2-fold elevation of plasma concentrations of active GIP and GLP-1 and is associated with increased insulin secretion, reduced glucagon levels, and improvements in both fasting and postprandial hyperglycemia. Inhibition of DPP-4 does not appear to have direct effects on insulin sensitivity, gastric motility, or satiety, nor does chronic treatment with DPP-4 inhibitors affect body weight. DPP-4 inhibitors, used as monotherapy in type 2 diabetic patients, reduced HbA_{1c} levels by an average ~0.8%. These compounds are also effective for chronic glucose control when added to the treatment of diabetic patients receiving metformin, thiazolidinediones, sulfonylureas, and insulin. The effects of DPP-4 inhibitors in combination regimens appear to be additive. The recommended dose of sitagliptin is 100 mg once daily. The recommended dose of saxagliptin is 5 mg once daily.

Absorption, Distribution, Metabolism, and Excretion. DPP-4 inhibitors are absorbed effectively from the small intestine. They circulate in primarily in unbound form and are excreted mostly unchanged in the urine. DPP-4 inhibitors do not bind to albumin, nor do they affect the hepatic cytochrome oxidase system. Both sitagliptin and saxagliptin are excreted renally, and lower doses should be used in patients with reduced renal function. Sitagliptin has minimal metabolism by hepatic microsomal enzymes. Saxagliptin is metabolized by CYP 3A4/5 to an active metabolite. The dose saxagliptin should be lowered to 2.5 mg daily when co-administered with strong CYP3A4 inhibitors (e.g., ketoconazole, atazanavir, clarithromycin, indinavir, itraconazole, nefazodone, nelfinavir, ritonavir, saquinavir, and telithromycin).

Adverse Effects and Drug Interactions. There are no consistent adverse effects that have been noted in clinical trials with any of the DPP-4 inhibitors. With few exceptions the incidence of adverse

effects in drug-treated and placebo-treated patients has been similar. DPP-4 is expressed on lymphocytes; in the immunology literature, the enzyme is referred to as CD26. Although there is some evidence of minor effects on *in vitro* lymphocyte function with DPP-4 inhibitors, there is no evidence from clinical studies of major adverse effects in humans. This area bears scrutiny as more patients are treated with these compounds.

OTHER HYPOGLYCEMIC AGENTS

Alpha Glucosidase Inhibitors

Mechanism of Action. α -Glucosidase inhibitors reduce intestinal absorption of starch, dextrin, and disaccharides by inhibiting the action of α -glucosidase in the intestinal brush border. Inhibition of this enzyme slows the absorption of carbohydrates from the GI tract and blunts the rate of rise of postprandial plasma glucose. These drugs also increase the release of the glucoregulatory hormone GLP-1 into the circulation, which may contribute to their glucose-lowering effects.

Dosage Forms. The drugs in this class are acarbose (PRECOSE, others), miglitol (GLYSET), and voglibose; only acarbose and miglitol are available in the U.S. Dosing of acarbose and miglitol are similar. Both are provided as 25, 50, or 100 mg tablets that are taken before meals. It is recommended that treatment start with lower doses and be titrated as indicated by balancing postprandial glucose, A1C, and GI symptoms. Acarbose and miglitol are most effective when given with a starchy, high-fiber diet with restricted amounts of glucose and sucrose.

Absorption, Distribution, Metabolism, Excretion, and Dosing. Acarbose is minimally absorbed and the small amount of drug reaching the systemic circulation is cleared by the kidney. Miglitol absorption is saturable, with 50-100% of any dose taken into the circulation. Miglitol is cleared almost entirely by the kidney, and dose reductions are recommended for patients with creatinine clearance <30 mL/minute.

Adverse Effects and Drug Interactions. The most prominent adverse effects related to α -glucosidase inhibitors are malabsorption, flatulence, diarrhea, and abdominal bloating. These side effects are dose dependent and related to the mechanism of action of the drugs, with greater amounts of carbohydrate available in the lower intestinal tract for metabolism by bacteria. Mild to moderate elevations of hepatic transaminases have been reported with acarbose, but symptomatic liver disease is very rare. Cutaneous hypersensitivity has been described but is also rare. α -Glucosidase inhibitors do not stimulate insulin release and therefore do not result in hypoglycemia when given alone. Hypoglycemia has been described when α -glucosidase inhibitors are added to insulin or an insulin secretagogue. For hypoglycemia in the setting of α -glucosidase use, glucose rather than sucrose or more complex carbohydrates should be used for treatment. Acarbose can decrease the absorption of digoxin and miglitol can decrease the absorption of propranolol and ranitidine. Alpha glucosidase inhibitors are contraindicated in patients with stage 4 renal failure.

Therapeutic Uses. α -Glucosidase inhibitors are indicated as adjuncts to diet and exercise in type 2 diabetic patients not reaching glycemic targets. They can also be used in combination with other oral antidiabetic agents and/or insulin. In clinical studies α -glucosidase inhibitors reduce A1C by 0.5-0.8%, fasting glucose by \sim 1 mM and postprandial glucose by 2.0-2.5 mM. These agents do not cause weight gain or have significant effects on plasma lipids. α -Glucosidase inhibitors have been demonstrated to reduce the progression from impaired glucose tolerance to type 2 diabetes.

Pramlintide

Mechanism of Action. Islet amyloid polypeptide (amylin), is a 37-amino acid peptide produced in the pancreatic β cell and secreted with insulin. A synthetic form of amylin with several amino acid modifications to improve bioavailability, pramlintide (SYMLIN), has been developed as a drug for the treatment of diabetes (Hoogwerf et al., 2008). It is thought to mediate its actions through specific binding to the amylin receptor in specific regions of the hindbrain. Activation of the amylin receptor cause reductions in glucagon release, delayed gastric emptying, and satiety.

Absorption, Distribution, Metabolism, Excretion, and Dosing. Pramlintide is administered as a subcutaneous injection prior to meals. Pramlintide is not extensively bound by plasma proteins and has a $t_{1/2}$ of 50 minutes. Metabolism and clearance is primarily by the kidney. The doses in patients with type 1 diabetes start at 15 μ g and are titrated upward to a maximum of 60 μ g; in type 2 diabetes the starting dose is 60 μ g and the maximum is 120 μ g. Because of differences in the pH of the solution, pramlintide should not be administered in the same syringe as insulin.

Adverse Effects and Drug Interactions. The most common adverse events associated with pramlintide therapy are nausea and hypoglycemia. Although pramlintide alone does not lower blood glucose, addition to insulin at mealtimes has been noted to cause increased rates of hypoglycemia, occasionally severe. It is currently recommended that prandial insulin doses be reduced 30-50% at the time of pramlintide initiation and then retitrated. Because of its effects on GI motility, pramlintide is contraindicated in patients with gastroparesis or other disorders of motility. Because pramlintide can delay gastric emptying, it should be used with caution when combined with other compounds that affect GI motility. Moreover, the pharmacokinetics of drugs that require rapid GI absorption may be altered. Pramlintide is a pregnancy Category C drug. Pramlintide can be used in persons with moderate renal disease (creatinine clearance >20 mL/minute).

Therapeutic Uses. Pramlintide is approved for treatment of types 1 and 2 diabetes as an adjunct in patients who take insulin with meals. In clinical trials of type 2 diabetic subjects, pramlintide reduced A1C by 0.5%, low-

ered insulin requirements, and caused weight loss of 1.0-2.5 kg over 3-6 months. Results in studies of type 1 diabetic subjects were similar, with reductions in A1C of 0.3-0.5%, weight loss of 1-2 kg, and insulin sparing. Pramlintide is now being evaluated as a drug for weight loss in nondiabetic persons.

Bile Acid Binding Resins

Mechanism of Action. Bile acid metabolism is abnormal in patients with type 2 diabetes, and there have been intermittent reports that bile acid binding resins lower plasma glucose in diabetic patients. The mechanism by which bile acid binding and removal from enterohepatic circulation lowers blood glucose has not been established. Bile acid sequestrants could reduce intestinal glucose absorption, although there is no direct evidence of this. Bile acids also act as signaling molecules through nuclear receptors, some of which may act as glucose sensors. The only bile acid sequestrant specifically approved for the treatment of type 2 diabetes is colesevelam (WELCHOL); other bile acid sequestrants likely are also effective.

Absorption, Distribution, Metabolism and Excretion. Colesevelam is provided as a powder for oral solution and as 625-mg tablets; typical usage is three tablets twice a day before lunch and dinner or six tablets prior to the patient's largest meal. The drug is absorbed from the intestinal tract only in trace amounts, so that its distribution is limited to the GI tract.

Adverse Effects and Drug Interactions. The most common side effects of colesevelam are gastrointestinal, with constipation, dyspepsia, abdominal pain, and nausea affecting up to 10% of treated patients. Intestinal obstruction has been reported in persons with previous intestinal surgery or obstruction. Like other bile acid binding resins, colesevelam can increase plasma triglycerides in persons with an inherent tendency to hypertriglyceridemia. In \sim 400 patient-year exposures in clinical trials, plasma triglycerides in treated patients did not exceed 1000 mg/dL, and no associated pancreatitis was documented; nonetheless, colesevelam should be used cautiously in patients with plasma triglycerides >200 mg/dL. Colesevelam has no effects on systemic drug metabolism but can interfere with the absorption of commonly used drugs like phenytoin, warfarin, verapamil, glyburide, L-thyroxine, and ethinyl estradiol; these medications should be given 4 hours prior to colesevelam. The drug may also interfere with the absorption of fat-soluble vitamins. Colesevelam is a pregnancy Category B drug that has no contraindications in patients with renal or liver disease.

Therapeutic Uses. The bile acid binding resin colesevelam, approved for treatment of hypercholesterolemia, may be used for treatment of type 2 diabetes as an adjunct to diet and exercise (Sonnett et al., 2009). In clinical trials, colesevelam reduced A1C by 0.5% when added to metformin, sulfonylurea, or insulin treatment in type 2 diabetic patients. A new bile acid binding resin, col-

istilan (not available in the U.S.), also reduced blood glucose in diabetic subjects. This supports the idea that beneficial effects on glucose metabolism are a shared effect among bile acid binding resins.

Miscellaneous Agents.

Bromocriptine. A formulation of bromocriptine (CYCLOSET), a dopamine receptor agonist, was approved by the FDA in 2009 for the treatment of type 2 diabetes but is not yet available in the U.S. Bromocriptine is an established treatment for Parkinson disease and hyperprolactinemia (see Chapters 22 and -38). Studies to elucidate the mechanism of bromocriptine to improve blood glucose have not been definitive. In humans, DA agonists do not improve insulin sensitivity, and in cultured islet cells they do not enhance insulin secretion. Effects of bromocriptine on blood glucose may reflect an action in the CNS. The effectiveness of bromocriptine to improve glycemic control is modest (A1C reduction of 0.1-0.4%). The dose range for CYCLOSET is 1.6 mg to 4.8 mg, taken with food in the morning within two hours of awakening. Side effects include nausea, fatigue, dizziness, orthostatic hypotension, vomiting, and headache. The role of this agent in the treatment of type 2 diabetes is uncertain.

COMBINED PHARMACOLOGICAL APPROACHES TO TYPE 2 DIABETES

Progressive Management of Type 2 Diabetes

There are several useful algorithms or flow charts for the treatment of type 2 diabetes (Figure 43-11; Nathan et al., 2009). There are a number of pathways or combination of drugs that are used for treatment of type 2 diabetes if the glucose control does not reach the therapeutic target (Inzucchi, 2002; Monami et al., 2008). For example, the addition of a second oral agent, such as an insulin sensitizer, either alone or in combination with an oral insulin secretagogue, also may provide good therapeutic results. Another approach is to introduce basal insulin (often at bedtime) in combination with oral hypoglycemic agents. This combination allows the oral agents to provide postprandial glycemic control while the basal insulin provides the foundation for normalizing fasting or basal glucose levels. Insulin can be combined with various oral antihyperglycemic agents. Combination of glargine with sulfonylureas and/or metformin can reduce both fasting (basal) and postprandial glucose levels. The exact combination of therapies can be guided by an estimation of the β cell secretory reserve in each patient (i.e., a measurement of circulating C peptide level). The progressive insulin deficiency in type 2 diabetes often makes it increasingly difficult to achieve tight glycemic control solely with oral antihyperglycemic agents (Bretzel et al.,

2008; Lasserson et al., 2009). Table 43-9 summarizes available pharmacological agents for the treatment of diabetes.

Emerging Therapies for Diabetes

A number of immunomodulatory approaches are being investigated to prevent or block the autoimmune process that is central to type 1 diabetes. Interventions with immune modifying agents, such as monoclonal antibodies against the lymphocyte receptors CD3, CD20 and CD 25, and immunosuppressant mycophenolate (Chapter 35), are currently ongoing. The use of immunosuppressive agents, such as cyclosporine, glucocorticoids and azathioprine, has been tested in small numbers of patients with new-onset type 1 diabetes. Although some of these studies have demonstrated that immunosuppression can slow β cell loss, this approach has not been widely accepted because of the acute and long-term toxicities of these drugs.

Drugs in Development for Type 2 Diabetes. Inhibitors of the sodium glucose co-transporter 2 (SGLT2) are designed to reduce hyperglycemia by increasing urinary clearance of glucose. SGLT2 is expressed in the proximal renal tubule and functions to reabsorb filtered glucose from the tubule lumen to epithelial cells; glucose subsequently is returned to the circulation through the actions of the glucose transporters 1 and 2. SGLT2 is a low-affinity, high-capacity co-transporter that shuttles sodium and glucose in a 1:1 ratio and accounts for most of the recovery of filtered glucose in the nephron; SGLT1 located in the distal tubule plays a lesser role. Loss-of-function mutations in SGLT2 cause glucosuria. There are several orally available, highly specific SGLT2 inhibitors in clinical development. These compounds cause urinary losses of 50-100 g per day of glucose in the urine, reduce fasting glucose by 0.5-2.0 mM, lower A1C by 0.5-1.0%, and cause modest amounts of weight loss. In clinical trials, SGLT2 inhibitors have been generally well tolerated. There is a mild diuretic effect, rare instances of hypoglycemia, and a slight increase in urinary tract infection, including genital infections. Although there are yet no specific indications with this class of drugs, the novel mechanism, the general action to reduce glycemia in proportion to plasma levels and the blockade of reuptake of renally filtered solute, raise the possibility that SGLT2 inhibitors could have application as adjuncts to a wide range of other diabetes therapies.

A second area of new drug development is activators of glucokinase (GK), the principle hexokinase in islet β cells and hepatocytes. The half-maximal activity of GK is near 8 mM so that the enzyme is highly functional as blood glucose increases from fasting levels of 5 mM to postprandial levels of 7-9 mM. In mouse models engineered to delete GK specifically from the islet or liver, hyperglycemia develops; overexpression of GK leads to improved glucose tolerance. Loss-of-function mutations of GK cause the autosomal dominant form of diabetes, MODY-2. There are now orally available small molecules that are allosteric activators of GK, which lower blood glucose in hyperglycemic animals. Because GK has a

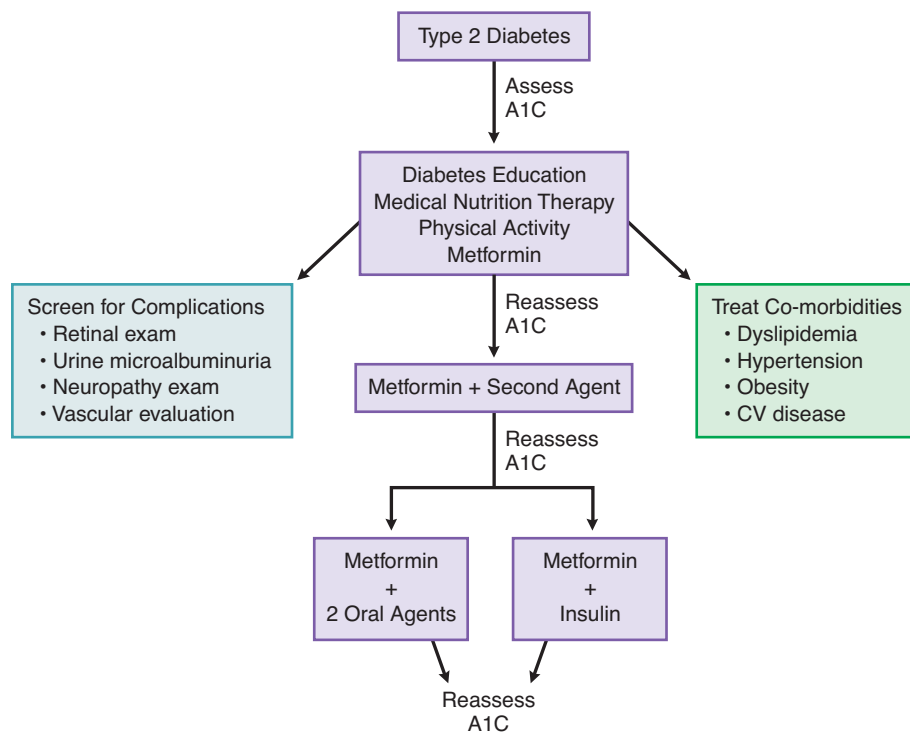

Figure 43–11. Treatment algorithm for management of type 2 diabetes mellitus. Patients diagnosed with type 2 diabetes, either by fasting glucose, oral glucose tolerance testing, or A1C, should have diabetes education that includes instruction on medical nutrition therapy and physical activity. Most patients newly diagnosed with type 2 diabetes have had subclinical or undiagnosed diabetes for many years previously and should be evaluated for diabetic complications (retinal exam, test for excess protein or albumin excretion in the urine, and clinical evaluation for peripheral neuropathy and vascular insufficiency); common comorbidities (hypertension and dyslipidemia) should be treated. Metformin is the consensus first line of therapy and should be started at the time of diagnosis. Failure to reach the glycemic target, generally a A1C $\leq 7\%$ within 3–4 months, should prompt the addition of a second oral agent. Reinforce lifestyle interventions at every visit and check A1C every 3 months. Treatment may escalate to metformin plus two oral agents or metformin plus insulin, if necessary.

relatively low affinity for glucose, the GK activators have muted action at fasting glycemia and a low risk for inducing hypoglycemia. In early phases of clinical trial, GK activators seem to lower blood glucose in diabetic humans.

The enzyme 11 β -hydroxysteroid dehydrogenase 1 (11 β -HSD1) is expressed in the liver, adipose tissue, and skeletal muscle. 11 β -HSD1 converts inactive cortisone into the active glucocorticoid cortisol (Figure 42-6). Cortisol plays an important role in normal counterregulation of insulin action, but excess activity is associated with weight gain, visceral adiposity, insulin resistance, inefficient proinsulin processing, and hyperglycemia. This has led to the strategy of inhibition of 11 β -HSD1 to reduce cortisol levels in the visceral and splanchnic beds, potentially increasing insulin sensitivity and glucose metabolism. Potent, orally available, selective inhibitors of 11 β -HSD1 that can inhibit the enzyme in liver and adipose tissue are under investigation. Inhibition of 11 β -HSD1 improves glycemic control, insulin sensitivity, and total cholesterol in patients with type 2 diabetes.

Several intracellular enzymes serve as nutrient sensors, including SIRT1, AMPK, DGAT1, and ACC2. Compounds that

stimulate the activities of these enzymes have the potential to increase glucose utilization, alter fatty acid metabolism, and increase energy expenditure, potentially resulting in improvements of both glucose and lipid metabolism as well as a decrease in body weight. A SIRT1 activator, resveratrol, has been reported to decrease glucose and insulin levels and improve glucose tolerance in subjects with type 2 diabetes. Activators of other peripheral nutrient sensors are in development.

HYPOGLYCEMIA

During prolonged fasting, the blood glucose levels may drop to 3–4 mM in healthy persons with no symptoms of hypoglycemia due to gradual shifts in fuel metabolism to increase the percentage of energy derived from stored lipids. In the absence of prolonged fasting, healthy humans almost never have blood glucose levels <3.5 mM (Cryer, 2008; Cryer et al., 2009). This is due to a highly adapted neuroendocrine counterregulatory

Table 43-9

Comparison of Agents Used for Treatment of Diabetes

	MECHANISM OF ACTION	EXAMPLES	HbA _{1c} REDUCTION (%) ^a	AGENT-SPECIFIC ADVANTAGES	AGENT-SPECIFIC DISADVANTAGES	CONTRAINDICATIONS
Oral						
Biguanides ^c	↓ Hepatic glucose production	Metformin	1-2	Weight neutral, Do not cause hypoglycemia, inexpensive	Diarrhea, nausea, lactic acidosis	GFR<50 mL/min, CHF, radiographic contrast studies, seriously ill patients, acidosis
α-Glucosidase inhibitors ^c	↓ GI glucose absorption	Acarbose, miglitol	0.5-0.8	Reduce postprandial glycemia	GI flatulence, liver function tests	Renal/liver disease
Dipeptidyl peptidase-4 inhibitors ^c	Prolong endogenous GLP-1 action	Saxagliptin, sitagliptin, vildagliptin	0.5-1.0	Do not cause hypoglycemia		Reduce dose with renal disease
Insulin secretagogues – Sulfonylureas ^c	↑ Insulin secretion	See text and Table 43-8	1-2	Inexpensive	Hypoglycemia, weight gain	Renal/liver disease
Insulin secretagogues – Non-sulfonylureas ^c	↑ Insulin secretion	See text and Table 43-8	1-2	Short onset of action, lower postprandial glucose	Hypoglycemia	Renal/liver disease
Thiazolidinediones ^c	↓ Insulin resistance, ↑ glucose utilization	Rosiglitazone, pioglitazone	0.5-1.4	Lower insulin requirements	Peripheral edema, CHF, weight gain, fractures, macular edema. Rosiglitazone may increase risk of CV disease	CHF, liver disease
Bile Acid sequestrants ^c	Bind bile acids; mechanism of glucose-lowering not known	Colesevelam	0.5		Constipation, dyspepsia, abdominal pain, nausea, ↑ triglycerides, interfere with absorption of other drugs, intestinal obstruction	

Parenteral Insulin	↑ Glucose utilization, ↓ Hepatic glucose production, and other anabolic actions	See text and Table 43-5	Not limited	Known safety profile	Injection, weight gain, hypoglycemia	
GLP-1 agonists ^c	↑ Insulin, ↓ Glucagon, slow gastric emptying, satiety	Exenatide, liraglutide	0.5-1.0	Weight loss	Injection, nausea, ↑ risk of hypoglycemia with insulin secretagogues, pancreatitis	Renal disease, agents that also slow GI motility, pancreatitis
Amylin agonists ^{b,c}	Slow gastric emptying, ↓ Glucagon	Pramlintide	0.25-0.5	Reduce postprandial glycemia; weight loss	Injection, nausea, ↑ risk of hypoglycemia with insulin	Agents that also slow GI motility
Medical nutrition therapy and physical activity ^c	↓ Insulin, resistance, ↑ insulin secretion	Low-calorie, low-fat diet, exercise	1-3	Other health benefits	Compliance difficult, long-term success low	

^aA1C reduction (absolute) depends partly on starting A1C value.
^bUsed in conjunction with insulin for treatment of type 1 diabetes
^cUsed for treatment of type 2 diabetes

1270 system that prevents acute hypoglycemia, a hazardous and potentially lethal situation. The two major clinical scenarios for hypoglycemia are:

- treatment of diabetes
- inappropriate production of endogenous insulin or an insulin-like substance by a pancreatic islet tumor (insulinoma) or a non-islet tumor

Hypoglycemia in the first scenario can occur either in the fasting or fed state, whereas in the second scenario, hypoglycemia occurs almost exclusively in the fasting or postabsorptive state. Some drugs not used for the treatment of diabetes promote hypoglycemia (Table 43–3; Murad et al., 2009). After a brief discussion of the physiological responses to hypoglycemia, agents used to treat hypoglycemia are discussed.

The most common and serious adverse event related to diabetes therapy is hypoglycemia. Although an adverse reaction to a number of oral therapies, it is most pronounced and serious with insulin therapy. Hypoglycemia may result from an inappropriately large dose, from a mismatch between the time of peak delivery of insulin and food intake, or from superimposition of additional factors that increase sensitivity to insulin (e.g., adrenal or pituitary insufficiency) or that increase insulin-independent glucose uptake (e.g., exercise). The more vigorous the attempt to achieve euglycemia, the more frequent are the episodes of hypoglycemia (Cryer, 2008; Heller, 2008). In the Diabetes Control and Complications Trial, the incidence of severe hypoglycemic reactions was three times higher in the intensive insulin therapy group than in the conventional therapy group. Milder but significant hypoglycemic episodes were much more common than were severe reactions, and their frequency also increased with intensive therapy. Hypoglycemia is the major risk that always must be weighed against benefits of efforts to normalize glucose control.

There is a hierarchy of physiological responses to hypoglycemia. The first response is a reduction of endogenous insulin secretion, which occurs at a plasma glucose level of ~70 mg/dL (3.9 mM); thereafter, the counter-regulatory hormones—epinephrine, glucagon, growth hormone, cortisol, and norepinephrine—are released. Symptoms of hypoglycemia are first discerned at a plasma glucose level of 60–80 mg/dL (3.3–4.4 mM). Sweating, hunger, paresthesias, palpitations, tremor, and anxiety, principally of autonomic origin, usually are seen first. Difficulty in concentrating, confusion, weakness, drowsiness, a feeling of warmth, dizziness, blurred vision, and loss of consciousness (i.e., most important neuroglycopenic symptoms) usually occur at lower plasma glucose levels than do autonomic symptoms.

Glucagon and epinephrine are the most important counter-regulatory hormones in acute hypoglycemia in newly diagnosed diabetes patients and normal subjects. In patients with type 1 and type 2 diabetes of longer duration, the glucagon secretory response to hypoglycemia becomes deficient, but effective glucose counter-regulation still occurs because epinephrine plays a compensatory role. Diabetic patients thus become dependent on epinephrine for counter-regulation,

and if this mechanism becomes deficient, the incidence of severe hypoglycemia increases. This occurs in patients with diabetes of long duration who may also have autonomic neuropathy. The absence of both glucagon and epinephrine can lead to prolonged hypoglycemia, particularly during the night, when some individuals can have extremely low plasma glucose levels for several hours. Severe hypoglycemia can lead to convulsions and coma. In addition to autonomic neuropathy, several related syndromes of defective counter-regulation contribute to the increased incidence of severe hypoglycemia in intensively treated type 1 diabetes patients. These include hypoglycemic unawareness, altered thresholds for release of counter-regulatory hormones, and deficient secretion of counter-regulatory hormones. With the ready availability of home glucose monitoring, hypoglycemia can be documented in most patients who experience suggestive symptoms. Hypoglycemia that occurs during sleep may be difficult to detect but should be suspected from a history of morning headaches, night sweats, or symptoms of hypothermia.

All diabetic patients who receive insulin or oral agents that can cause hypoglycemia should be aware of the symptoms of hypoglycemia, carry some form of easily ingested glucose, and carry an identification card or bracelet containing pertinent medical information. When possible, patients who suspect that they are experiencing hypoglycemia should document the glucose concentration with a measurement. Mild-to-moderate hypoglycemia may be treated simply by ingestion of glucose (15 g of carbohydrate). When hypoglycemia is severe, it should be treated with intravenous glucose or an injection of glucagon (Figure 43–10).

Agents Used to Treat Hypoglycemia

Glucagon is a single-chain polypeptide of 29 amino acids and is produced by recombinant DNA technology. Glucagon interacts with a GPCR on the plasma membrane of target cells that signals through G_s . The primary effects of glucagon on the liver are mediated by cAMP. Glucagon is used to treat severe hypoglycemia, particularly in diabetic patients when the patient cannot safely consume oral glucose and intravenous glucose is not available (Figure 43–12). For hypoglycemic reactions, 1 mg is administered intravenously, intramuscularly, or subcutaneously, usually by the patient's family member, who must be trained to administer this.

The intramuscular route is preferred in such an emergency. The hyperglycemic action of glucagon is transient and may be inadequate if hepatic stores of glycogen are depleted. After the initial response to glucagon, patients should be given glucose or urged to eat to prevent recurrent hypoglycemia. Glucagon also is sometimes used to relax the intestinal tract to facilitate radiographic examination of the upper and lower gastrointestinal tract with barium and retrograde ileography and in magnetic resonance imaging of the gastrointestinal tract. Nausea and vomiting are the most frequent adverse effects.

Diazoxide (PROGLYCEM) is an antihypertensive, antidiuretic benzothiadiazine derivative with potent hypoglycemic actions when given orally. Hypoglycemia

Figure 43-12. Treatment of hypoglycemia with glucose or glucagon. The blood glucose falls following administration of insulin (at time = 0). Following administration of oral glucose (10 or 20 g) or subcutaneous glucagon (at arrow marked “R_x”), the blood glucose rises. The blue band shows the recovery when glucose or glucagon was not administered. (Copyright 1993 American Diabetes Association. From Wiethop and Cryer. *Diabetes Care*, Vol. 16, 1993; 1131–1136. Reprinted with permission from The American Diabetes Association.)

results primarily from inhibition of insulin secretion. Diazoxide interacts with the K_{ATP} channel on the β cell membrane and either prevents its closing or prolongs the open time; this effect is opposite to that of the sulfonylureas (Figure 43-3). Diazoxide has been used to treat patients with various forms of chronic or recurring hypoglycemia.

The usual oral dose is 3–8 mg/kg per day in adults and children and 8 to 15 mg/kg per day in infants and neonates. The drug can cause nausea and vomiting and thus usually is given in divided doses with meals. Diazoxide circulates largely bound to plasma proteins and has a $t_{1/2}$ of ~48 hours. Thus the patient should be maintained at the chosen dosage for several days before evaluating the therapeutic result. Diazoxide has a number of adverse effects, including retention of Na^+ and fluid, hyperuricemia, hypertrichosis (especially in children), thrombocytopenia, and leucopenia, which sometimes limit its use. Despite these side effects, the drug may be useful in patients with inoperable insulinomas and in children with neonatal hyperinsulinism (leucine sensitivity, islet cell hyperplasia, nesidioblastosis, extrapancreatic malignancy, or islet cell adenoma).

OTHER PANCREATIC ISLET HORMONES

Somatostatin was identified as an inhibitor of GH secretion from the pituitary. Somatostatin (SST) is produced

by δ cells of the pancreatic islet, cells of the GI tract, and in the CNS. Somatostatin, produced as a 14–amino acid or a 28–amino acid peptide molecule, acts through a family of five GPCRs, $SSTR_{1-5}$. SST inhibits a wide variety of endocrine and exocrine secretions, including TSH and GH from the pituitary, gastrin, motilin, VIP, glicentin, and insulin, glucagon, and pancreatic polypeptide from the pancreatic islet. The physiological role of somatostatin has not been defined precisely, but its short $t_{1/2}$ (3–6 minutes) prevents its use therapeutically. Longer-acting analogs such as octreotide (SANDOSTATIN) and lanreotide (SOMATULINE) are useful for treatment of carcinoid tumors, glucagonomas, VIPomas, and acromegaly (Chapter 38).

A depot form of octreotide or lanreotide can be administered intramuscularly every 4 weeks. Octreotide or lanreotide successfully controls excess secretion of growth hormone in most patients, and both have been reported to reduce the size of pituitary tumors in about one-third of cases. Octreotide has been used to treat severe hypoglycemia related to sulfonylurea ingestion (Cryer et al., 2009). Because octreotide also can decrease blood flow to the GI tract, it has been used to treat bleeding esophageal varices, peptic ulcers, and postprandial orthostatic hypotension. Gallbladder abnormalities (stones and biliary sludge) occur frequently with chronic use of the somatostatin analogs, as do GI symptoms. Hypoglycemia, hyperglycemia, hypothyroidism, and goiter have been reported in patients being treated with somatostatin analogs for acromegaly.

Agents Affecting Mineral Ion Homeostasis and Bone Turnover

Peter A. Friedman

To understand why, when, and how to employ pharmacological agents that affect mineral ion homeostasis, one must first understand some basic physiology and pathophysiology of the subject. This chapter presents a primer on mineral ion homeostasis and the endocrinology of Ca^{2+} and phosphate metabolism, then some relevant pathophysiology, and, finally, pharmacotherapeutic options in treating disorders of mineral ion homeostasis.

PHYSIOLOGY OF MINERAL ION HOMEOSTASIS

Calcium

Elemental calcium is essential for a variety of micromolecular and macroscopic biological functions. Its ionized form, Ca^{2+} , is an important component of current flow across excitable membranes. Ca^{2+} is vital for muscle contraction, fusion, and release of storage vesicles. In the submicromolar range, intracellular Ca^{2+} acts as a critical second messenger (Chapter 3). In extracellular fluid, millimolar concentrations of calcium promote blood coagulation and support the formation and continuous remodeling of the skeleton.

Ca^{2+} has an adaptable coordination sphere that facilitates binding to the irregular geometry of proteins. The capacity of an ion to cross-link two proteins requires a high coordination number, which dictates the number of electron pairs that can be formed and generally is six to eight for Ca^{2+} . Unlike disulfide or sugar-peptide cross-links, Ca^{2+} linking is readily reversible. Cross-linking of structural proteins in bone matrix is enhanced by the relatively high extracellular concentration of calcium.

In the face of millimolar extracellular Ca^{2+} , intracellular free Ca^{2+} is maintained at a low level, ~ 100 nM in cells in their basal state, by active extrusion by

Ca^{2+} -ATPases and by $\text{Na}^+/\text{Ca}^{2+}$ exchange. As a consequence, changes in cytosolic Ca^{2+} (whether released from intracellular stores or entering via membrane Ca^{2+} channels) can modulate effector targets, often by interacting with the Ca^{2+} -binding protein calmodulin. The rapid association-dissociation kinetics of Ca^{2+} and the relatively high affinity and selectivity of Ca^{2+} -binding domains permit effective regulation of Ca^{2+} over the 100 nM to 1 μM range.

The body content of calcium in healthy adult men and women, respectively, is ~ 1300 and 1000 g, of which $>99\%$ is in bone and teeth. Ca^{2+} is the major extracellular divalent cation. Although the portion of calcium in extracellular fluids is small, this fraction is stringently regulated within narrow limits. In adult humans, the normal serum calcium concentration ranges from 8.5-10.4 mg/dL (4.25-5.2 mEq/L, 2.1-2.6 mM) and includes three distinct chemical forms of Ca^{2+} : ionized (50%), protein-bound (40%), and complexed (10%). Thus, whereas total plasma calcium concentration is ~ 2.54 mM, the concentration of ionized Ca^{2+} in human plasma is ~ 1.2 mM.

The various pools of calcium are illustrated schematically in Figure 44-1. Only diffusible calcium (i.e., ionized plus complexed) can cross cell membranes. Albumin accounts for some 90% of the serum calcium bound to plasma proteins. Smaller percentages are bound, albeit with greater affinity, to β -globulin, α_2 -globulin, α_1 -globulin, and γ -globulin. The remaining 10% of the serum calcium is complexed in ion pairs with small polyvalent anions, primarily phosphate and citrate. The degree of complex formation depends on the ambient pH and the concentrations of ionized calcium and complexing anions. Ionized Ca^{2+} is the physiologically relevant component, mediates calcium's biological effects, and, when perturbed, produces the characteristic signs and symptoms of hypo- or hypercalcemia.

Figure 44-1. Pools of calcium in serum. Concentrations are expressed as mg/dL on the left-hand axis and as mM on the right. The total serum calcium concentration is 10 mg/dL or 2.5 mM, divided into three pools: protein-bound (40%), complexed with small anions (10%), and ionized calcium (50%). The complexed and ionized pools represent the diffusible forms of calcium.

The total plasma calcium concentration can be interpreted only by correcting for the concentration of plasma proteins. A change of plasma albumin concentration of 1.0 g/dL from the normal value of 4.0 g/dL can be expected to alter total calcium concentration by ~ 0.8 mg/dL.

The extracellular Ca^{2+} concentration is tightly controlled by hormones that affect calcium entry at the intestine and its exit at the kidney; when needed, these same hormones regulate withdrawal from the large skeletal reservoir.

Calcium Stores. The skeleton contains 99% of total body calcium in a crystalline form resembling the mineral hydroxyapatite [$\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$]; other ions, including Na^+ , K^+ , Mg^{2+} , and F^- , also are present in the crystal lattice. The steady-state content of calcium in bone reflects the net effect of bone resorption and bone formation, coupled with aspects of bone remodeling. In addition, a labile pool of bone Ca^{2+} exchanges readily with interstitial fluid. This exchange is modulated by hormones, vitamins, drugs, and other factors that directly alter bone turnover or that influence the Ca^{2+} level in interstitial fluid.

Calcium Absorption and Excretion. In the U.S., $\sim 75\%$ of dietary calcium is obtained from milk and dairy products. The adequate intake value for calcium is 1300 mg/day in adolescents and 1000 mg/day in adults. After age 50, the adequate intake is 1200 mg/day. This contrasts with median intakes of calcium for boys and girls ≥ 9 years of age of 865 and 625 mg, respectively, and a median daily calcium intake of 517 mg for women >50 years of age.

Figure 44-2. Schematic representation of the whole body daily turnover of calcium. (Adapted with permission from Yanagawa N, Lee DBN. Renal handling of calcium and phosphorus. In: *Disorders of Bone and Mineral Metabolism* (Coe FL, Favus MJ, eds.), Raven Press, New York, 1992, pp. 3–40.)

Figure 44-2 illustrates the components of whole-body daily calcium turnover. Ca^{2+} enters the body only through the intestine. *Active vitamin D-dependent transport* occurs in the proximal duodenum, whereas *facilitated diffusion* throughout the small intestine accounts for most total Ca^{2+} uptake. This uptake is counterbalanced by an obligatory daily intestinal calcium loss of ~ 150 mg/day that reflects the calcium content of mucosal and biliary secretions and in sloughed intestinal cells.

The efficiency of intestinal Ca^{2+} absorption is inversely related to calcium intake. Thus, a diet low in calcium leads to a compensatory increase in fractional absorption owing partly to activation of vitamin D. In older persons, this response is considerably less robust. Disease states associated with steatorrhea, diarrhea, or chronic malabsorption promote fecal loss of calcium, whereas drugs such as glucocorticoids and phenytoin depress intestinal Ca^{2+} transport.

Urinary Ca^{2+} excretion is the net difference between the quantity filtered at the glomerulus and the amount reabsorbed. About 9 g of Ca^{2+} are filtered each day. Tubular reabsorption is very efficient, with $>98\%$ of filtered Ca^{2+} returned to the circulation. The efficiency of reabsorption is highly regulated by parathyroid hormone (PTH) but also is influenced by filtered Na^+ , the presence of nonreabsorbed anions, and diuretic agents (Chapter 25). Sodium intake, and therefore sodium excretion, is directly related to urinary calcium excretion. Diuretics that act on the ascending limb of the loop of Henle (e.g., furosemide) increase calcium excretion. By contrast, thiazide diuretics uncouple the relationship between Na^+ and Ca^{2+} excretion, increasing sodium excretion but diminishing calcium excretion (Friedman and Bushinsky, 1999). Urine Ca^{2+} excretion is a direct function of dietary protein intake, presumably owing to the effect of sulfur-containing amino acids on renal tubular function.

Phosphate

Phosphate is an essential component of all body tissues, present in plasma, extracellular fluid, cell membrane phospholipids, intracellular fluid, collagen, and bone tissue. More than 80% of total body phosphorus is found in bone, and ~15% is in soft tissue. Additionally, phosphate subserves roles as a dynamic constituent of intermediary and energy metabolism and as a key regulator of enzyme activity when transferred by protein kinases from ATP to phosphorylatable serine, threonine, and tyrosine residues.

Biologically, phosphorus (P) exists in both organic and inorganic (P_i) forms. Organic forms include phospholipids and various organic esters. In extracellular fluid, the bulk of phosphorus is present as inorganic phosphate in the form of NaH_2PO_4 and Na_2HPO_4 ; at pH 7.4, the ratio of disodium to monosodium phosphate is 4:1, so plasma phosphate has an intermediate valence of 1.8. Owing to its relatively low concentration in extracellular fluid, phosphate contributes little to buffering capacity. The aggregate level of inorganic phosphate (P_i) modifies tissue concentrations of Ca^{2+} and plays a major role in renal H^+ excretion. Within bone, phosphate is complexed with calcium as hydroxyapatites having the general formula $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$ and as calcium phosphate.

Absorption, Distribution, and Excretion. Phosphate is absorbed from and, to a limited extent, secreted into the GI tract. Phosphate is a ubiquitous component of ordinary foods; thus even an inadequate diet rarely causes phosphate depletion. Transport of phosphate from the intestinal lumen is an active, energy-dependent process that is regulated by several factors, primarily vitamin D, which stimulates absorption. In adults, about two-thirds of ingested phosphate is absorbed and is excreted almost entirely into the urine. In growing children, phosphate balance is positive, and plasma concentrations of phosphate are higher than in adults.

Phosphate excretion in the urine represents the difference between the amount filtered and that reabsorbed. More than 90% of plasma phosphate is freely filtered at the glomerulus, and 80% is actively reabsorbed, predominantly in the initial segment of the proximal convoluted tubule but also in the proximal straight tubule (pars recta). Renal phosphate absorption is regulated by a variety of hormones and other factors; the most important are PTH and dietary phosphate, with extracellular volume and acid-base status playing lesser roles. Dietary phosphate deficiency upregulates renal phosphate transporters and decreases excretion, whereas a high-phosphate diet increases phosphate excretion; these changes are independent of any effect on plasma P_i , Ca^{2+} , or PTH. PTH increases urinary phosphate excretion by blocking phosphate absorption. Expansion of plasma volume increases urinary phosphate excretion. Effects of vitamin D and its metabolites on proximal tubular phosphate are modest at best.

Role of Phosphate in Urine Acidification. Despite the fact that the concentration and buffering capacity of phosphate in extracellular fluid are low, phosphate is concentrated progressively in the renal tubule and

becomes the most abundant buffer system in the distal tubule and terminal nephron. The exchange of H^+ and Na^+ in the tubular urine converts disodium hydrogen phosphate (Na_2HPO_4) to sodium dihydrogen phosphate (NaH_2PO_4), permitting the excretion of large amounts of acid without lowering the urine pH to a degree that would block H^+ transport.

Actions of Phosphate. If large amounts of phosphate are introduced into the GI tract by oral administration or enema, a cathartic action will result. Thus, phosphate salts are employed as mild laxatives (Chapter 46). If excessive phosphate salts are introduced either intravenously or orally, they may reduce the concentration of Ca^{2+} in the circulation and induce precipitation of calcium phosphate in soft tissues.

HORMONAL REGULATION OF CALCIUM AND PHOSPHATE HOMEOSTASIS

A number of hormones interact to regulate extracellular calcium and phosphate balance. The most important are parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D (calcitriol), which regulate mineral homeostasis by effects on the kidney, intestine, and bone (Figure 44–3).

Figure 44–3. Calcium homeostasis and its regulation by parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D. PTH has stimulatory effects on bone and kidney, including the stimulation of 1α -hydroxylase activity in kidney mitochondria leading to the increased production of 1,25-dihydroxyvitamin D (calcitriol) from 25-hydroxycholecalciferol, the monohydroxylated vitamin D metabolite (Figure 44–6). Calcitriol is the biologically active metabolite of vitamin D.

Parathyroid hormone (PTH) is a polypeptide hormone that helps to regulate plasma Ca^{2+} by affecting bone resorption/formation, renal Ca^{2+} excretion/reabsorption, and calcitriol synthesis (thus GI Ca^{2+} absorption).

History. Sir Richard Owen, the curator of the British Museum of Natural History, discovered the parathyroid glands in 1852 while dissecting a rhinoceros that had died in the London Zoo. Credit for discovery of the human parathyroid glands usually is given to Sandstrom, a Swedish medical student who published an anatomical report in 1890. In 1891, von Recklinghausen reported a new bone disease, which he termed “osteitis fibrosa cystica,” which Askanazy subsequently described in a patient with a parathyroid tumor in 1904. The glands were rediscovered a decade later by Gley, who determined the effects of their extirpation with the thyroid. Vassale and Generali then successfully removed only the parathyroids and noted that tetany, convulsions, and death quickly followed unless calcium was given postoperatively.

MacCallum and Voegtlin first noted the effect of parathyroidectomy on plasma Ca^{2+} . The relation of low plasma Ca^{2+} concentration to symptoms was quickly appreciated, and a comprehensive picture of parathyroid function began to form. Active glandular extracts alleviated hypocalcemic tetany in parathyroidectomized animals and raised the level of plasma Ca^{2+} in normal animals. For the first time, the relation of clinical abnormalities to parathyroid hyperfunction was appreciated.

Whereas American and British investigators used physiological approaches to explore the function of the parathyroid glands, German and Austrian pathologists related the skeletal changes of osteitis fibrosa cystica to the presence of parathyroid tumors; these two investigational approaches arrived at the same conclusions, as has been recounted by Carney (1997).

Chemistry. PTH molecules of all species are all single polypeptide chains of 84 amino acids with molecular masses of ~9500 Da. Biological activity is associated with the N-terminal portion of the peptide; residues 1–27 are required for optimal binding to the PTH receptor and hormone activity. Derivatives lacking the first and second residue bind to PTH receptors but do not activate the cyclic AMP or IP_3 - Ca^{2+} signaling pathways. The PTH fragment lacking the first six amino acids inhibits PTH action.

Synthesis, Secretion, and Immunoassay. PTH is synthesized as a 115-amino-acid translation product called *preproparathyroid hormone*. This single-chain peptide is converted to proparathyroid hormone by cleavage of 25 amino-terminal residues as the peptide is transferred to the intracisternal space of the endoplasmic reticulum. Proparathyroid hormone then moves to the Golgi complex, where it is converted to PTH by cleavage of six amino acids. PTH(1-84) resides within secretory granules until it is discharged into the circulation. Neither preproparathyroid hormone nor proparathyroid hormone appears in plasma. The synthesis and processing of PTH have been reviewed (Jüppner et al., 2001).

A major proteolytic product of PTH is PTH(7–84). PTH(7–84) and other amino-truncated PTH fragments accumulate significantly during renal failure in part because they are normally cleared from the circulation predominantly by the kidneys, whereas intact PTH is also

removed by extrarenal mechanisms. Rather than competing with PTH(1–84) binding at the receptor, PTH(7–84) may cause the PTH receptor to internalize from the plasma membrane in a cell-specific manner (Sneddon et al., 2003).

During periods of hypocalcemia, more PTH is secreted and less is hydrolyzed. In this setting, PTH(7–84) release is augmented. In prolonged hypocalcemia, PTH synthesis also increases, and the gland hypertrophies.

PTH(1–84) has a $t_{1/2}$ in plasma of ~4 minutes; removal by the liver and kidney accounts for ~90% of its clearance. Proteolysis of PTH (in the storage granule and in plasma) generates smaller fragments (e.g., a 33–36 amino acid N-terminal fragment that is fully active, a larger C-terminal peptide, and PTH[7–84]). Much of what circulates in the blood and is measured by older RIAs is the inactive C-terminal fragment that has a longer $t_{1/2}$ than the active N-terminal fragment or the intact PTH(1–84). Second-generation enzyme-linked immunosorbent assays for PTH, by contrast, can distinguish among these forms, but the clinical value of such information and whether it should affect therapeutic intervention remains controversial (D’Amour, 2008; Herberth et al., 2009).

Physiological Functions. The primary function of PTH is to maintain a constant concentration of Ca^{2+} and P_i in the extracellular fluid. The principal processes regulated are renal Ca^{2+} and P_i absorption, and mobilization of bone Ca^{2+} (Figure 44–3). PTH also affects a variety of tissues not involved in mineral ion homeostasis that include cartilage, vascular smooth muscle, placenta, liver, pancreatic islets, brain, dermal fibroblasts, and lymphocytes. The actions of PTH on its target tissues are mediated by at least two receptors. The PTH_1 receptor (PTH1R or PTH/PTHrP receptor) also binds PTH-related protein (PTHrP); the PTH_2 receptor, found in vascular tissues, brain, pancreas, and placenta, binds only PTH. Both of these are GPCRs that can couple with G_s and G_q in cell-type specific manners; thus cells may show one, the other, or both types of responses. There is also evidence that PTH can activate phospholipase D through a $\text{G}_{12/13}$ -RhoA pathway (Singh et al., 2005). A third receptor, designated the CPTH receptor, interacts with forms of PTH that are truncated in the amino-terminal region, contain most of the carboxy terminus, and are inactive at the PTH_1 receptor; these CPTH receptors reportedly are expressed on osteocytes (Selim et al., 2006).

Regulation of Secretion. Plasma Ca^{2+} is the major factor regulating PTH secretion. As the concentration of Ca^{2+} diminishes, PTH secretion increases. Sustained hypocalcemia induces parathyroid hypertrophy and hyperplasia. Conversely, if the concentration of Ca^{2+} is high, PTH secretion decreases. Studies of parathyroid cells in culture show that amino acid transport, nucleic acid and protein synthesis, cytoplasmic growth, and PTH secretion are all stimulated by low concentrations of Ca^{2+} and suppressed by high concentrations. Thus, Ca^{2+} itself appears to regulate parathyroid gland growth as well as hormone synthesis and secretion.

Changes in plasma Ca^{2+} regulate PTH secretion by the plasma membrane-associated calcium-sensing receptor (CaSR) on parathyroid cells. The CaSR is a GPCR that couples with G_q and G_i . Occupancy of the CaSR by Ca^{2+} thus stimulates the G_q -PLC- IP_3 - Ca^{2+} pathway leading to activation of PKC; this results in inhibition of PTH secretion, an unusual case in which elevation of cellular Ca^{2+} inhibits secretion (another being the granular cells in the juxtaglomerular complex of the kidney, where elevation of cellular Ca^{2+}

inhibits renin secretion). Simultaneous activation of the G_i pathway by Ca^{2+} reduces cAMP synthesis and lowers the activity of PKA, also a negative signal for PTH secretion. Conversely, reduced occupancy of CaSR by Ca^{2+} reduces signaling through G_i and G_q , lessening inhibition of adenylyl cyclase and lowering activation of the G_q pathway, thereby promoting PTH secretion. Thus, the extracellular concentration of Ca^{2+} is controlled by a classical negative-feedback system, the afferent limb of which is sensitive to the ambient activity of Ca^{2+} and the efferent limb of which releases PTH. Acting via the CaSR, hypercalcemia reduces intracellular cyclic AMP content and activates PKC, whereas hypocalcemia does the reverse. The precise links between these changes and alterations in PTH secretion remain to be defined. Other agents that increase parathyroid cell cyclic AMP levels, such as β adrenergic receptor agonists and *dopamine*, also increase PTH secretion, but the magnitude of response is far less than that seen with hypocalcemia. The active vitamin D metabolite, 1,25-dihydroxyvitamin D (*calcitriol*), directly suppresses PTH gene expression. There appears to be no relation between physiological concentrations of extracellular phosphate and PTH secretion, except insofar as changes in phosphate concentration alter circulating Ca^{2+} . Severe hypermagnesemia or hypomagnesemia can inhibit PTH secretion.

Effects on Bone. PTH exerts both catabolic and anabolic effects on bone. Normally, these processes are tightly coupled. Chronically elevated PTH enhances bone resorption and thereby increases Ca^{2+} delivery to the extracellular fluid, whereas intermittent exposure to PTH promotes anabolic actions. The primary skeletal target cell for PTH is the osteoblast, although evidence points to the presence of functional PTH receptors on osteocytes (O'Brien et al., 2008). PTH also recruits osteoclast precursor cells to form new bone remodeling units. Sustained increases in circulating PTH cause characteristic histological changes in bone that include an increase in the prevalence of osteoclastic resorption sites and in the proportion of bone surface that is covered with unmineralized matrix (Martin and Ng, 1994).

Direct effects of PTH on osteoblasts *in vitro* generally are inhibitory and include reduced formation of type I collagen, alkaline phosphatase, and osteocalcin. However, the response to PTH *in vivo* reflects not only hormone action on individual cells but also the increased total number of active osteoblasts, owing to initiation of new remodeling units. Thus, plasma levels of osteocalcin and alkaline phosphatase activity actually may be increased. No simple model can fully explain the molecular basis of PTH effects on bone. PTH stimulates cyclic AMP production in osteoblasts, but there also is evidence that intracellular Ca^{2+} mediates some PTH actions.

Effects on Kidney. In the kidney, PTH enhances the efficiency of Ca^{2+} reabsorption, inhibits tubular reabsorption of phosphate, and stimulates conversion of vitamin D to its biologically active form, calcitriol (Figure 44–3). As a result, filtered Ca^{2+} is avidly retained, and its concentration increases in plasma, whereas phosphate is excreted, and its plasma concentration falls. Newly synthesized calcitriol interacts with specific high-affinity receptors in the intestine to increase the efficiency of intestinal Ca^{2+} absorption, thereby contributing to the increase in plasma (Ca^{2+}).

Calcium. PTH increases tubular reabsorption of Ca^{2+} with concomitant decreases in urinary Ca^{2+} excretion. The effect occurs at distal nephron sites. This action, along with mobilization of calcium from bone and increased absorption from the intestine, increases the

concentration of Ca^{2+} in plasma. Eventually, the increased glomerular filtration of Ca^{2+} overwhelms the stimulatory effect of PTH on tubular reabsorption, and hypercalciuria ensues. Conversely, reduction of serum PTH depresses tubular reabsorption of Ca^{2+} and thereby increases urinary Ca^{2+} excretion. When the plasma Ca^{2+} concentration falls below 7 mg/dL (1.75 mM), Ca^{2+} excretion decreases as the filtered load of Ca^{2+} reaches the point where the cation is almost completely reabsorbed despite reduced tubular capacity.

Phosphate. PTH increases renal excretion of inorganic phosphate by decreasing its reabsorption by proximal tubules. This action is mediated by retrieval of the luminal membrane $Na-P_i$ cotransport protein, NPT2a, rather than an effect on its activity. Patients with primary hyperparathyroidism therefore typically have low tubular phosphate reabsorption.

Cyclic AMP apparently mediates the renal effects of PTH on proximal tubular phosphate reabsorption. PTH-sensitive adenylyl cyclase is located in the renal cortex, and cyclic AMP synthesized in response to the hormone affects tubular transport mechanisms. A portion of the cyclic AMP synthesized at this site, so-called nephrogenous cyclic AMP, escapes into the urine. Measurement of urinary cyclic AMP is used as a surrogate for parathyroid activity and renal responsiveness.

Other Ions. PTH reduces renal Mg^{2+} excretion. This effect reflects the net result of enhanced renal Mg^{2+} reabsorption and increased mobilization of the ion from bone (Quamme, 2010). PTH increases excretion of water, amino acids, citrate, K^+ , bicarbonate, Na^+ , Cl^- , and SO_4^{2-} , whereas it decreases the excretion of H^+ . These effects are minor and generally can be seen only under tightly controlled circumstances.

Calcitriol Synthesis. The final step in the activation of vitamin D to calcitriol occurs in kidney proximal tubule cells. Three primary regulators govern the enzymatic activity of the 25-hydroxyvitamin D_3 -1 α -hydroxylase that catalyzes this step: P_i , PTH, and Ca^{2+} (see later for further discussion). Reduced circulating or tissue phosphate content rapidly increases calcitriol production, whereas hyperphosphatemia or hypercalcemia suppresses it. PTH powerfully stimulates calcitriol synthesis. Thus, when hypocalcemia causes a rise in PTH concentration, both the PTH-dependent lowering of circulating P_i and a more direct effect of the hormone on the 1 α -hydroxylase lead to increased circulating concentrations of calcitriol.

Integrated Regulation of Extracellular Ca^{2+} Concentration by PTH. Even modest reductions of serum Ca^{2+} stimulate PTH secretion. For minute-to-minute regulation of Ca^{2+} , adjustments in renal Ca^{2+} handling more than suffice to maintain plasma calcium homeostasis. With more prolonged hypocalcemia, the renal 1 α -hydroxylase is induced, enhancing the synthesis and release of calcitriol that directly stimulates intestinal calcium absorption (Figure 44–3). In addition, delivery of calcium from bone into the extracellular fluid is augmented. In the face of prolonged and severe hypocalcemia, new bone remodeling units are activated to restore circulating Ca^{2+} concentrations, albeit at the expense of skeletal integrity.

When plasma Ca^{2+} activity rises, PTH secretion is suppressed, and tubular Ca^{2+} reabsorption decreases. The reduction in circulating PTH promotes renal phosphate conservation, and both the decreased PTH and the increased phosphate depress calcitriol production and thereby decrease intestinal Ca^{2+} absorption. Finally, bone remodeling is suppressed. These integrated physiological events ensure a coherent

response to positive or negative excursions of plasma Ca^{2+} concentrations. In humans, the importance of other hormones, such as FGF23 and calcitonin, to this scheme remains unsettled. They may modulate the Ca^{2+} -parathyroid-vitamin D axis or, in the case of FGF23, serve as primary regulators (Razzaque, 2009).

Vitamin D

Vitamin D traditionally was viewed as a permissive factor in calcium metabolism because it was thought to permit efficient absorption of dietary calcium and to allow full expression of the actions of PTH. We know now that vitamin D exerts a more active role in calcium homeostasis. Vitamin D is actually a hormone rather than a vitamin; it is synthesized in mammals and, under ideal conditions, probably is not required in the diet. Receptors for the activated form of vitamin D are expressed in many cells that are not involved in calcium homeostasis, including hematopoietic cells, lymphocytes, epidermal cells, hair follicles, adipose tissue, pancreatic islets, muscle, and neurons.

History. Vitamin D is the name applied to two related fat-soluble substances, *cholecalciferol* (vitamin D_3) and *ergocalciferol* (vitamin D_2) (Figure 44–4), that share the capacity to prevent or cure rickets. Prior to the discovery of vitamin D, a high percentage of urban children living in temperate zones developed rickets. Some researchers believed that the disease was due to lack of fresh air and sunshine; others claimed a dietary factor was responsible. Mellanby and Huldschinsky showed both notions to be correct; addition of cod liver oil to the diet or exposure to sunlight prevented or cured the disease. In 1924, it was found that ultraviolet irradiation of animal rations was as efficacious at curing rickets as was irradiation of the animal itself. These observations led to the elucidation of the structures of chole- and ergocalciferol and eventually to the discovery that these compounds require further processing in the body to become active. The discovery of metabolic activation is attributable primarily to studies conducted in the laboratories of DeLuca and Kodicek (DeLuca, 1988). The biological actions of vitamin D are mediated by the vitamin D receptor (VDR), a nuclear receptor, that was cloned in 1987 (McDonnell et al., 1987).

Chemistry and Occurrence. Ultraviolet irradiation of several animal and plant sterols results in their conversion to compounds possessing vitamin D activity. The principal provitamin found in animal tissues is 7-dehydrocholesterol, which is synthesized in the skin. Exposure of the skin to sunlight converts 7-dehydrocholesterol to cholecalciferol (vitamin D_3) (Figure 44–4). Ergosterol, which is present only in plants and fungi, is the provitamin for vitamin D_2 (ergocalciferol). Ergosterol and vitamin D_2 differ from 7-dehydrocholesterol and vitamin D_3 , respectively, by the presence of a double bond between C22 and C23 and a methyl group at C24. Vitamin D_2 is the active constituent of a number of commercial vitamin preparations and is in irradiated bread and irradiated milk. In humans there is no practical difference between the antirachitic potencies of vitamin D_2 and vitamin D_3 . Therefore, “vitamin D” is used here as a collective term for vitamins D_2 and D_3 .

Human Requirements and Units. Although sunlight provides adequate vitamin D supplies in the equatorial belt, in temperate climates insufficient cutaneous solar radiation especially in winter may necessitate dietary vitamin D supplementation. It was assumed that vitamin D deficiency had been eliminated as a significant medical problem in the U.S. However, upward adjustment of estimates of normal vitamin D levels, improved analytical methodology, and more comprehensive data collection have led to an appreciation of the common finding of low circulating levels of vitamin D and a re-emergence of vitamin D-dependent rickets. Potential factors contributing to the rise of vitamin D deficiency include diminished consumption of vitamin D-fortified foods owing to concerns about fat intake; reduced intake of calcium-rich foods, including milk, in adolescents and young women of reproductive age; increased use of sunscreens and decreased exposure to sunlight to reduce the risk of skin cancer and prevent premature aging from exposure to ultraviolet radiation; and an increased prevalence and duration of exclusive breast-feeding (the combination of human milk, a poor source of vitamin D, and the high prevalence of low circulating vitamin D levels in U.S. women, particularly African-American mothers) (Bodnar et al., 2007).

There is no consensus regarding optimal vitamin D intake, and determination of vitamin D requirements is remarkably unsupported by clinical measurements. The recommended dietary allowance of vitamin D for infants and children is 400 IU, or 10 μg , daily. The basis for this dose was that it approximates that in a teaspoon (5 mL) of cod liver oil, which had long been considered safe and effective in preventing rickets (Vieth, 1999). Because adults require less vitamin D than infants, the adult dose was set arbitrarily at 200 IU.

The Food and Nutrition Board of the Institute of Medicine has developed Dietary Reference Intakes (DRI) for vitamins (Institute of Medicine, 2003). In both premature and normal infants, intake of 200 units per day of vitamin D from any source is considered adequate for optimal growth. Recently, the American Academy of Pediatrics recommended an intake of 400 IU of vitamin D per day from infants through adolescence (Wagner and Greer, 2008). Beyond adolescence, this amount probably may be sufficient, although nutritionists now recommend high daily intake, up to 4000 IU/day (Bischoff-Ferrari et al., 2009). There is some evidence that vitamin D requirements increase during pregnancy and lactation (Hollis and Wagner, 2004), where vitamin D doses of <1000 IU/day may be inadequate to maintain normal circulating 25-hydroxyvitamin D concentrations. Doses of $\leq 10,000$ IU/day of vitamin D for up to 5 months do not elevate circulating 25-hydroxyvitamin D to concentrations >90 ng/mL.

Absorption, Fate, and Excretion. Vitamins D_2 and D_3 are absorbed from the small intestine, although vitamin D_3 may be absorbed more efficiently. Most of the vitamin appears first within chylomicrons in lymph. Bile is essential for adequate absorption of vitamin D; deoxycholic acid is the major constituent of bile in this regard (Chapter 46). The primary route of vitamin D_3 excretion is the bile; with a smaller percentage found in the urine. Patients who have intestinal bypass surgery or otherwise have severe shortening or inflammation of the small intestine may fail to absorb vitamin D sufficiently to maintain normal levels; hepatic or biliary dysfunction also may seriously impair vitamin D absorption.

Absorbed vitamin D circulates in the blood in association with vitamin D-binding protein, a specific α -globulin. The vitamin

Figure 44-4. Photobiology and metabolic pathways of vitamin D production and metabolism.

disappears from plasma with a $t_{1/2}$ of 20–30 hours but is stored in fat depots for prolonged periods.

Metabolic Activation. Whether derived from diet or endogenously synthesized, vitamin D requires modification to become biologically active. The primary active metabolite of the vitamin is calcitriol

[1 α ,25-dihydroxyvitamin D, 1,25(OH)₂D], the product of two successive hydroxylations of vitamin D (Figure 44-4).

25-Hydroxylation of Vitamin D. The initial step in vitamin D activation occurs in the liver, where cholecalciferol and ergocalciferol are hydroxylated in the 25-position to generate 25-OH-cholecalciferol

(25-OHD, or calcifediol) and 25-OH-ergocalciferol, respectively. 25-OHD is the major circulating form of vitamin D₃; it has a biological $t_{1/2}$ of 19 days, and normal steady-state concentrations are 15-50 ng/mL. Reduced extracellular Ca²⁺ levels stimulate 1 α -hydroxylation of 25-OHD, increasing the formation of biologically active 1,25(OH)₂D₃. In contrast, when Ca²⁺ concentrations are elevated, 25-OHD is inactivated by 24-hydroxylation. Similar reactions occur with 25-OH-ergocalciferol. Normal steady-state concentrations of 25-OHD in human beings are 15-50 ng/mL, although concentrations <25 ng/mL may be associated with increased circulating PTH and greater bone turnover.

1 α -Hydroxylation of 25-OHD. After production in the liver, 25-OHD enters the circulation and is carried by vitamin D-binding globulin. Final activation to calcitriol occurs primarily in the kidney but also takes place in other sites, including keratinocytes and macrophages (Hewison et al., 2004). The enzyme system responsible for 1 α -hydroxylation of 25-OHD (CYP1 α , 25-hydroxyvitamin D₃-1 α -hydroxylase, 1 α -hydroxylase) is associated with mitochondria in proximal tubules.

Vitamin D 1 α -hydroxylase is subject to tight regulatory controls that result in changes in calcitriol formation appropriate for optimal calcium homeostasis. Dietary deficiency of vitamin D, calcium, or phosphate enhances enzyme activity. 1 α -Hydroxylase is potently stimulated by PTH and probably also by prolactin and estrogen. Conversely, high calcium, phosphate, and vitamin D intakes suppress 1 α -hydroxylase activity. Regulation (Figure 44-5) is both acute and chronic, the latter owing to changes in protein synthesis. PTH increases calcitriol production rapidly via a cyclic AMP-dependent pathway. Hypocalcemia can activate the hydroxylase directly in addition to affecting it indirectly by eliciting PTH secretion (Bland et al., 1999). Hypophosphatemia greatly increases 1 α -hydroxylase activity. Calcitriol controls 1 α -hydroxylase activity by a negative-feedback mechanism that involves a direct action on the kidney, as well as inhibition of PTH secretion. The plasma $t_{1/2}$ of calcitriol is estimated at 3-5 days in humans.

24-Hydroxylase. Calcitriol and 25-OHD are hydroxylated to 1,24,25(OH)₂D and 24,25(OH)₂D, respectively, by another renal enzyme, 24-hydroxylase, whose expression is induced by calcitriol and suppressed by factors that stimulate the 25-OHD-1 α -hydroxylase. Both 24-hydroxylated compounds are less active than calcitriol and presumably represent metabolites destined for excretion.

Physiological Functions and Mechanism of Action. Calcitriol augments absorption and retention of Ca²⁺ and phosphate. Although regulation of Ca²⁺ homeostasis is considered to be its primary function, accumulating evidence underscores the importance of calcitriol in a number of other processes.

Calcitriol acts to maintain normal concentrations of Ca²⁺ and phosphate in plasma by facilitating their absorption in the small intestine, by interacting with PTH to enhance their mobilization from bone, and by decreasing their renal excretion. It also exerts direct physiological and pharmacological effects on bone mineralization (Suda et al., 2003).

The mechanism of action of calcitriol is mediated by its interaction with VDR. Calcitriol binds to cytosolic

Figure 44-5. Regulation of 1 α -hydroxylase activity. Changes in the plasma levels of PTH, Ca²⁺, and phosphate modulate the hydroxylation of 25-OH vitamin D to the active form, 1,25-dihydroxyvitamin D. 25-OHD, 25-hydroxycholecalciferol; 1,25-(OH)₂-D, calcitriol; PTH, parathyroid hormone.

VDRs within target cells, and the receptor-hormone complex translocates to the nucleus and interacts with DNA to modify gene transcription. The VDR belongs to the steroid and thyroid hormone receptor superfamily. Calcitriol also exerts nongenomic effects. It is controversial whether the presence of a functional VDR is required for this action (Zanello and Norman, 2004).

Intestinal Absorption of Calcium. Calcium is absorbed predominantly in the duodenum, with progressively smaller amounts in the jejunum and ileum. Studies of Ca²⁺ uptake by isolated cells reflect these differences and suggest that elevated amounts of transport are likely due to greater transport by each duodenal cell. The colon also contributes to calcium absorption because ileostomy reduces absorption.

In the absence of calcitriol, calcium absorption is inefficient and proceeds in a thermodynamically passive manner through the lateral intercellular spaces (paracellular pathway). Calcitriol increases the transcellular movement of Ca²⁺ from the mucosal to the serosal surface of the duodenum. Transcellular Ca²⁺ movement involves three processes: Ca²⁺ entry across the mucosal surface, diffusion through the cell, and energy-dependent extrusion across the serosal cell membrane. Calcium is also secreted from serosal to

mucosal compartments. Thus, net calcium absorption is the difference between the two oppositely oriented vectorial processes. The complex mechanisms and the proteins mediating calcium absorption are still incompletely understood (Perez et al., 2008). Evidence implicates TRPV6 Ca^{2+} channels in mediating mucosal calcium entry in the intestine (Bianco et al., 2007). In humans, TRPV6 is expressed in the duodenum and proximal jejunum. A calcium-poor diet upregulates intestinal TRPV6 expression in mice (Van Cromphaut et al., 2001). This effect is greatly reduced in VDR knockout mice, suggesting that TRPV6 mediates calcium entry and is vitamin D dependent.

Ca^{2+} absorption is potently augmented by calcitriol. It is likely that calcitriol enhances all three steps involved in intestinal Ca^{2+} absorption: entry across mucosal brush border membranes, diffusion through the enterocytes, and active extrusion across serosal plasma membranes. Calcitriol upregulates the synthesis of calbindin- $\text{D}_{9\text{K}}$ and calbindin- $\text{D}_{28\text{K}}$ and the serosal plasma membrane Ca-ATPase . Calbindin- $\text{D}_{9\text{K}}$ enhances the extrusion of Ca^{2+} by the Ca-ATPase , whereas the precise function of calbindin- $\text{D}_{28\text{K}}$ is unsettled.

Mobilization of Bone Mineral. Although vitamin D-deficient animals show obvious deficits in bone mineral, there is little evidence that calcitriol directly promotes mineralization. Thus, even though VDR knockout mice exhibit severely impaired bone formation and mineralization, these deficiencies can be entirely corrected by a high-calcium diet. These results support the view that the primary role of calcitriol is to stimulate intestinal absorption of calcium, which, in turn, indirectly promotes bone mineralization. Indeed, children with rickets caused by mutations of the VDR have been treated successfully with intravenous infusions of Ca^{2+} and phosphate. In contrast, physiological doses of vitamin D promote mobilization of Ca^{2+} from bone, and large doses cause excessive bone turnover. Although calcitriol-induced bone resorption may be reduced in parathyroidectomized animals, the response is restored when hyperphosphatemia is corrected. Thus, PTH and calcitriol act independently to enhance bone resorption.

Calcitriol increases bone turnover by multiple mechanisms (Suda et al., 2003). Mature osteoclasts apparently lack the VDR. Acting by a non-VDR mechanism, calcitriol promotes the recruitment of osteoclast precursor cells to resorption sites, as well as the development of differentiated functions that characterize mature osteoclasts.

Osteoblasts, the cells responsible for bone formation, express the VDR, and calcitriol induces their production of several proteins, including osteocalcin, a vitamin K-dependent protein that contains γ -carboxyglutamic acid residues, and interleukin-1 (IL-1), a lymphokine that promotes bone resorption (Spear et al., 1988). Thus the current view is that calcitriol is a bone-mobilizing hormone but not a bone-forming hormone. Osteoporosis is a disease in which osteoclast responsiveness to calcitriol or other bone-resorbing agents is profoundly impaired, leading to deficient bone resorption.

Renal Retention of Calcium and Phosphate. The effects of calcitriol on the renal handling of Ca^{2+} and phosphate are of uncertain importance. Calcitriol increases retention of Ca^{2+} independently of phosphate. The effect on Ca^{2+} is thought to proceed in distal tubules, whereas enhanced phosphate absorption occurs in proximal tubules.

Other Effects of Calcitriol. It now is evident that the effects of calcitriol extend well beyond calcium homeostasis. Receptors for calcitriol are distributed widely throughout the body (Pike and Shevde,

2005). Calcitriol affects maturation and differentiation of mononuclear cells and influences cytokine production and immune function (Nagpal et al., 2005). One focus of research is the potential use of calcitriol to inhibit proliferation and to induce differentiation of malignant cells (van den Bemd et al., 2000). The possibility of dissociating the hypercalcemic effect of calcitriol from its actions on cell differentiation has encouraged the search for analogs that might be useful in cancer therapy. Calcitriol inhibits epidermal proliferation and promotes epidermal differentiation and therefore is a potential treatment for psoriasis vulgaris (Kragballe and Iversen, 1993) (Chapter 65). Calcitriol also affects the function of skeletal muscle, brain (Carswell, 1997), and blood pressure (Nagpal et al., 2005).

Calcitonin

Calcitonin is a hypocalcemic hormone whose actions generally oppose those of PTH.

History and Source. Copp observed in 1962 that perfusion of canine parathyroid and thyroid glands with hypercalcemic blood caused a transient hypocalcemia that occurred significantly earlier than that caused by total parathyroidectomy. He concluded that the parathyroid glands secreted a calcium-lowering hormone (calcitonin) in response to hypercalcemia and in this way normalized plasma Ca^{2+} concentrations. The physiological relevance of calcitonin has been challenged vigorously: calcitonin normally circulates at remarkably low levels; surgical removal of the thyroids has no appreciable effect on calcium metabolism; and conditions associated with profound elevations of serum calcitonin concentration are not accompanied by hypocalcemia (Hirsch and Baruch, 2003). The primary interest in calcitonin arises from its pharmacological use in treating Paget's disease and hypercalcemia and in its diagnostic use as a tumor marker for medullary carcinoma of the thyroid.

The thyroid parafollicular C cells are the site of production and secretion of calcitonin. Human C cells, which are derived from neural crest ectoderm, are distributed widely in the thyroid, parathyroid, and thymus. In non-mammalian vertebrates, calcitonin is found in ultimobranchial bodies, which are separate organs from the thyroid gland.

The calcitonin gene is localized on human chromosome 11p and contains six exons (Figure 44–6). The primary transcript is alternatively spliced in a tissue-specific manner. In thyroid C cells, the calcitonin/calcitonin gene-related peptide (CGRP) pre-mRNA is processed primarily with common exons 2 and 3 to include exon 4. This leads to production of the 32-amino-acid peptide calcitonin, along with a flanking 21-amino-acid peptide called katecalcitonin, whose physiological significance is unknown. In neuronal cells, in contrast, most of the calcitonin/CGRP pre-mRNA, is processed to exclude exon 4, resulting in inclusion of exons 5 and 6 with common exons 2 and 3, which ultimately gives rise to CGRP. This results in the production of the 37-amino-acid CGRP. Calcitonin is the most potent peptide inhibitor of osteoclast-mediated bone resorption and helps to protect the skeleton during periods of “calcium stress,” such as growth, pregnancy, and lactation. CGRP and the closely related peptide adrenomedullin are potent endogenous vasodilators.

Chemistry and Immunoreactivity. Calcitonin is a single-chain peptide of 32 amino acids with a disulfide bridge linking the cysteine residues in positions 1 and 7 (Figure 44–7). In all species, 8 of the

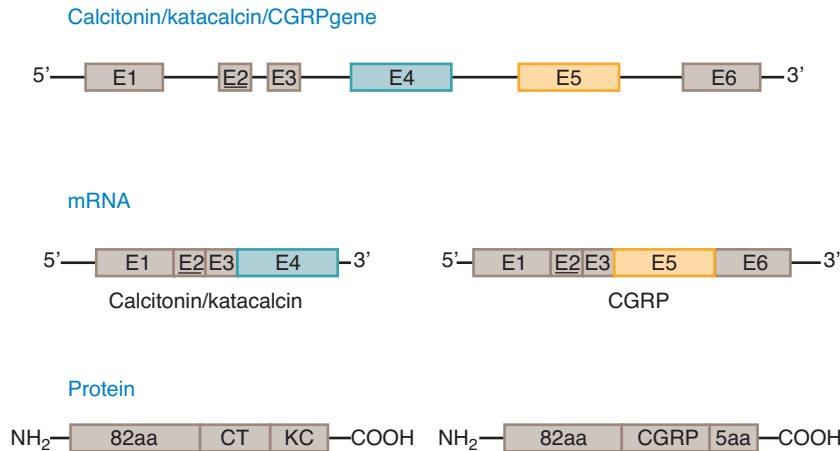

Figure 44–6. Alternative splicing of calcitonin/calcitonin gene–related peptide (CGRP).

32 residues are invariant, including the disulfide bridge and a carboxyl-terminal proline amide; both structural features are essential for biological activity. The residues in the middle portion of the molecule (positions 10–27) are more variable and apparently influence potency and/or duration of action. Calcitonins derived from salmon and eel differ from the human hormone by 13 and 16 amino acid residues, respectively, and are more potent than mammalian calcitonin. Salmon calcitonin is used therapeutically in part because it is cleared more slowly from the circulation.

Regulation of Secretion. The biosynthesis and secretion of calcitonin are regulated by the plasma Ca^{2+} concentration. Calcitonin secretion increases when plasma Ca^{2+} is high and decreases when plasma Ca^{2+} is low. Multiple forms of calcitonin are found in plasma, including high-molecular-weight aggregates or cross-linked products. Assays for the intact monomeric peptide are now available. The circulating concentrations of calcitonin are low, normally <15 and 10 pg/mL for males and females, respectively. The circulating $t_{1/2}$ of calcitonin is ~10 minutes. Abnormally elevated levels of calcitonin are characteristic of thyroid C-cell hyperplasia and medullary thyroid carcinoma.

Calcitonin secretion is stimulated by a number of agents, including catecholamines, glucagon, gastrin, and cholecystokinin, but there is little evidence for a physiological role for secretion in response to these stimuli.

Mechanism of Action. Calcitonin actions are mediated by the calcitonin receptor (CTR), which is a member of the PTH/secretin subfamily of GPCRs (Lin et al., 1991). Six human CTR subtypes occur through alternative splicing of coding and noncoding exons (Purdue et al.,

2002). These isoforms exhibit distinct ligand-binding specificity and/or signal-transduction pathways and are distributed in a tissue-specific pattern. Of the more abundant isoforms, hCTR1⁻, which lacks a 16-amino acid insert in the first intracellular loop, preferentially couples with the G_s -adenylyl cyclase pathway (Gorn et al., 1995). The hCTR1⁺ isoform, which includes this cassette, does not couple with PLC (Naro et al., 1998) and therefore does not activate PKC or trigger an increase in Ca^{2+} . Calcitonin receptors can dimerize with RAMPs (receptor-activity modifying proteins) to create receptors with high affinity for amylin (Hay et al., 2005) (Chapter 43).

The hypocalcemic and hypophosphatemic effects of calcitonin are caused predominantly by direct inhibition of osteoclastic bone resorption. Although calcitonin inhibits the effects of PTH on osteolysis, it inhibits neither PTH activation of bone cell adenylyl cyclase nor PTH-induced uptake of Ca^{2+} into bone. Calcitonin interacts directly with receptors on osteoclasts to produce a rapid and profound decrease in ruffled border surface area, thereby diminishing resorptive activity.

Depressed bone resorption reduces urinary excretion of Ca^{2+} , Mg^{2+} , and hydroxyproline. Plasma phosphate concentrations are lowered owing also to increased urinary phosphate excretion. Direct renal effects of calcitonin vary with species. Acute administration of pharmacological doses of calcitonin increases urinary calcium excretion, whereas calcitonin inhibits renal calcium excretion at physiological concentrations. In humans, calcitonin increases fractional urinary calcium excretion in a dose-dependent manner in subjects given a modest calcium load (Carney, 1997).

Figure 44–7. Comparison of calcitonins from several species. Calcitonin is a 32-amino-acid polypeptide with a disulfide bond between residues 1 and 7 and a proline-amide at the C-terminus. The figure highlights the differences in amino acid sequence between human calcitonin and calcitonins of other species; lack of an entry indicates identity with human calcitonin. Salmon calcitonin is ~20 times more potent in humans than is human calcitonin.

Fibroblast Growth Factor 23 and Klotho

Fibroblast growth factor 23 (*FGF23*) is a hypophosphatemic hormone whose actions generally parallel those of PTH but with effects restricted to regulation of renal P_i absorption and vitamin D biosynthesis. Klotho is a membrane protein that serves as an essential cofactor in the transduction of FGF23 signaling.

FGF23 was discovered by positional cloning as the gene responsible for autosomal dominant hypophosphatemic rickets (ADHR). It was simultaneously cloned as one factor causing tumor-induced osteomalacia (TIO). FGF23, a protein of 251 amino acids, is produced primarily by several bone cells including osteoblasts, osteocytes, and lining cells.

FGF23 is secreted in response to dietary phosphorus load, and its main function is the promotion of urinary phosphate excretion and the suppression of active vitamin D production by the kidney. Emerging evidence suggests that FGF23 is the principal regulator of proximal renal tubule phosphate reabsorption and of 1,25-dihydroxyvitamin D synthesis. Serum levels of FGF23 rise precipitously in patients with chronic kidney disease and are inversely correlated with the degree of hyperphosphatemia. Elevated FGF23 may contribute to impaired production of 1,25-dihydroxyvitamin D.

Klotho was originally identified as a gene mutated in mice that developed accelerated aging. Further analysis revealed a pattern of altered mineral ion metabolism and diminished bone density similar to that found in FGF23 knockout mice or patients with ADHR. The similar phenotypes of Klotho-deficient and FGF23-null mice suggested that Klotho and FGF23 function in a common signaling pathway. Klotho acts as a cofactor in FGF signaling, facilitates the interactions of FGF23 with its receptor, and determines its tissue specificity (Razzaque, 2009). Exogenous FGF23 administration reduces serum P_i and calcitriol synthesis. Vitamin D analogs are commonly used in the management of chronic kidney disease. Although no clinical agents based on FGF23 have yet been developed, bioactive fragments or FGF23 inhibitors might become useful in counterbalancing the hyperphosphatemic actions of vitamin D therapy.

BONE PHYSIOLOGY

The skeleton is the primary structural support for the body and also provides a protected environment for hematopoiesis. It contains both a large mineralized matrix and a highly active cellular compartment.

Skeletal Organization. It is useful to consider the *appendicular*, or *peripheral*, skeleton as separate from the *axial*, or *central*, skeleton because their turnover rates differ. Appendicular bones make up 80% of bone mass and are composed predominantly of compact cortical bone. Axial bones, such as the spine and pelvis, contain substantial amounts of trabecular bone within a thin cortex. Trabecular bone consists of highly connected bony plates that resemble a honeycomb. The intertrabecular interstices contain bone marrow and fat. *Alterations in bone turnover are observed first and foremost in axial bone* both because bone surfaces, where bone remodeling occurs, are more densely distributed in trabecular bone and because marrow

precursor cells that ultimately participate in bone turnover lie in close proximity to trabecular surfaces.

Bone Mass. Bone mineral density (BMD) and fracture risk in later years reflect the maximal bone mineral content at skeletal maturity (peak bone mass) and the subsequent rate of bone loss. Major increases in bone mass, accounting for ~60% of final adult levels, occur during adolescence, mainly during years of highest growth velocity. Bone acquisition is largely complete by age 17 in girls and by age 20 in boys. Inheritance accounts for much of the variance in bone acquisition; other factors include circulating estrogen and androgens, physical activity, and dietary calcium.

Bone mass peaks during the third decade, remains stable until age 50, and then declines progressively. Similar trajectories occur for men and women of all ethnic groups. The fundamental accuracy of this model has been amply confirmed for cortical bone, although trabecular bone loss at some sites probably begins prior to age 50. In women, loss of estrogen at menopause accelerates the rate of bone loss. *Primary regulators of adult bone mass include physical activity, reproductive endocrine status, and calcium intake. Optimal maintenance of BMD requires sufficiency in all three areas, and deficiency of one is not compensated by excessive attention to another.*

Bone Remodeling. Growth and development of endochondral bone are driven by a process called *modeling*. Once new bone is laid down, it is subject to a continuous process of breakdown and renewal called *remodeling*, by which bone mass is adjusted throughout adult life (Ballock and O'Keefe, 2003). Remodeling is carried out by myriad independent "bone remodeling units" throughout the skeleton (Figure 44–8). Remodeling proceeds on bone surfaces, ~90% of which are normally inactive, covered by a thin layer of lining cells. In response to physical or biochemical signals, recruitment of marrow precursor cells to the bone surface results in their fusion into the characteristic multinucleated osteoclasts that resorb, or excavate, a cavity into the bone.

Osteoclast production is regulated by osteoblast-derived cytokines such as IL-1 and IL-6. Studies have begun to clarify the mechanisms through which osteoclast production is regulated (Suda et al., 1999). The receptor for activating NF- κ B (RANK) is an osteoclast protein whose expression is required for osteoclastic bone resorption. Its natural ligand, RANK ligand (RANKL; previously called *osteoclast differentiation factor*), is a membrane-spanning osteoblast protein. On binding to RANK, RANKL induces osteoclast formation (Khosla, 2001) (Figure 44–9). RANKL initiates the activation of mature osteoclasts, as well as the differentiation of osteoclast precursors. Osteoblasts produce osteoprotegerin (OPG), which acts as a decoy ligand for RANKL. Under conditions favoring increased bone resorption, such as estrogen deprivation, OPG is suppressed, RANKL binds to RANK, and osteoclast production increases. When estrogen sufficiency is reestablished, OPG increases and competes effectively with RANKL for binding to RANK. In certain model systems, OPG is superior to bisphosphonates in suppressing bone resorption and hypercalcemia (Morony et al., 2005).

Completion of the resorption phase is followed by invasion of preosteoblasts derived from marrow stroma into the base of the resorption cavity. These cells develop the characteristic osteoblastic phenotype and begin to replace the resorbed bone by elaborating new bone matrix constituents, such as collagen and osteocalcin. Once the

Figure 44–8. *The bone remodeling cycle.* Osteoclast precursors fuse and are activated to resorb a lacuna in a previously quiescent surface. These cells are replaced by osteoblasts that deposit new bone to restore the integrity of the tissue. (Adapted with permission from Skerry TM, Gowen M. Bone cells and bone in remodelling in rheumatoid arthritis. In: *Mechanisms and Models in Rheumatoid Arthritis* [Henderson B, Edwards JCW, Pettipher ER, eds.], Academic Press, London, 1995, pp. 205–220.)

newly formed osteoid reaches a thickness of $\sim 20\ \mu\text{m}$, mineralization begins. A complete remodeling cycle normally requires ~ 6 months.

If the replacement of resorbed bone precisely matched the amount that was removed, remodeling would not change net bone mass. However, small bone deficits persist on completion of each cycle, reflecting inefficient remodeling dynamics. Consequently, life-long accumulation of remodeling deficits underlies the well-documented phenomenon of age-related bone loss, a process that begins shortly after growth stops. *Alterations in remodeling activity represent the final pathway through which diverse stimuli, such as dietary sufficiency, exercise, hormones, and drugs, affect bone balance.* Changes in the hormonal milieu often lead to an increase in the activation of remodeling units. Examples include hyperthyroidism, hyperparathyroidism, and hypervitaminosis D. Other factors that may impair osteoblast function include high doses of *corticosteroids* or *ethanol*. Finally, estrogen deficiency augments osteoclastic resorptive capacity by a proapoptotic action (Manolagas et al., 2002).

At any given time, a transient deficit in bone, the remodeling space, represents sites of bone resorption that have not yet filled in. Stimuli that alter the rate of emergence of new remodeling units either increase or decrease the remodeling space until a new steady state is established at an increased or decreased bone mass.

DISORDERS OF MINERAL HOMEOSTASIS AND BONE

Abnormal Calcium Metabolism

Hypercalcemia. Moderate elevations of the concentration of Ca^{2+} in the extracellular fluid may have no clinically detectable effects. The degree of hypercalcemia and the rate of onset of the elevation in the serum calcium concentration largely dictate the extent of symptoms.

Figure 44–9. Receptor for activating NF- κ B ligand (RANKL) and osteoclast formation. RANKL, acting on RANK, promotes osteoclast formation and subsequent resorption of bone matrix. Osteoprotegerin (OPG) binds to RANKL, reducing its binding to RANK and thereby inhibiting osteoclast differentiation.

Chronic elevation of serum Ca^{2+} to 12–14 mg/dL (3–3.5 mmol/L) generally causes few manifestations, whereas an acute rise to the same levels may cause marked neuromuscular manifestations owing to an increased threshold for excitation of nerve and muscle. Symptoms include fatigue, muscle weakness, anorexia, depression, diffuse abdominal pain, and constipation.

Hypercalcemia can result from a number of conditions. Ingestion of large quantities of calcium by itself generally does not cause hypercalcemia; exceptions are hyperthyroid subjects, who absorb Ca^{2+} with increased efficiency, and subjects with the uncommon *milk-alkali syndrome*, a condition caused by concurrent ingestion of large quantities of milk and absorbable alkali (e.g., certain antacids; Chapter 45), resulting in impaired renal Ca^{2+} excretion and attendant hypercalcemia.

In an outpatient setting, the most common cause of hypercalcemia is primary hyperparathyroidism, which results from hypersecretion of PTH by one or more parathyroid glands. Secondary hyperparathyroidism, in contrast, arises as a compensation for reductions of circulating Ca^{2+} and is not associated with hypercalcemia.

Symptoms and signs of primary hyperparathyroidism include fatigue, exhaustion, weakness, polydipsia, polyuria, joint pain, bone pain, constipation, depression, anorexia, nausea, heartburn, nephrolithiasis, and hematuria. This condition frequently is accompanied by significant hypophosphatemia owing to the effects of PTH in diminishing renal tubular phosphate reabsorption. Some patients have renal

calculi and peptic ulceration, and a few display classical parathyroid skeletal disease. However, most patients show few, if any, symptoms, and those that are present are often vague and nonspecific. Contemporary clinical assays that distinguish between full-length PTH(1–84) and “intact” PTH [PTH(1–84) + PTH(7–84)] obviate many of the difficulties with previous assays and, in conjunction with an elevated serum calcium, possess a diagnostic accuracy of >90% (Jüppner and Potts, 2002).

Familial benign hypercalcemia (or *familial hypocalciuric hypercalcemia*) is a genetic disorder generally accompanied by extremely low urinary calcium excretion. Familial benign hypercalcemia results from heterozygous mutations in the Ca^{2+} -sensing receptor (Pollak et al., 1996). Hypercalcemia usually is mild, and circulating PTH often is normal to slightly elevated. The importance of making this diagnosis lies in the fact that patients mistakenly diagnosed as having primary hyperparathyroidism may undergo surgical exploration without discovery of an adenoma and without therapeutic benefit. Patients do not experience long-term clinical consequences, except for homozygous infants, who may have severe, even lethal, hypercalcemia. Diagnosis is established by demonstrating hypercalcemia in first-degree family members and a decreased fractional excretion of calcium.

Newly diagnosed hypercalcemia in hospitalized patients is caused most often by a systemic malignancy, either with or without bony metastasis. PTH-related protein (PTHrP) is a primitive, highly conserved protein that may be abnormally expressed in malignant tissue, particularly by squamous cell and other epithelial cancers. The substantial sequence homology of the amino-terminal portion of PTHrP with that of native PTH permits it to interact with the PTH-1 receptor in target tissues, thereby causing the hypercalcemia and hypophosphatemia seen in humoral hypercalcemia of malignancy (Grill et al., 1998). Other tumors release cytokines or prostaglandins that stimulate bone resorption. In some patients with lymphomas, hypercalcemia results from overproduction of 1,25-dihydroxyvitamin D by the tumor cells owing to expression of 1α -hydroxylase. A similar mechanism underlies the hypercalcemia that is seen occasionally in sarcoidosis and other granulomatous disorders.

Hypercalcemia associated with malignancy generally is more severe than in primary hyperparathyroidism (frequently with calcium levels that exceed 13 mg/dL) and may be associated with lethargy, weakness, nausea, vomiting, polydipsia, and polyuria. Assays for PTHrP may aid diagnosis.

Vitamin D excess may cause hypercalcemia if sufficient 25-hydroxyvitamin D is present to stimulate intestinal Ca^{2+} hyperabsorption, leading to hypercalcemia and suppressing PTH and 1,25-dihydroxyvitamin D levels. Measurement of 25-hydroxyvitamin D is diagnostic. Occasional patients with *hyperthyroidism* show mild hypercalcemia, presumably owing to increased bone turnover. *Immobilization* may lead to hypercalcemia in growing children and young adults but rarely causes hypercalcemia in older individuals unless bone turnover is already increased, as in Paget’s disease or hyperthyroidism. Hypercalcemia sometimes is noted in adrenocortical deficiency, as in Addison’s disease, or following removal of a hyperfunctional adrenocortical tumor. Hypercalcemia occurs following renal transplantation owing to persistent hyperfunctioning parathyroid tissue that resulted from the previous renal failure.

The differential diagnosis of hypercalcemia may pose difficulties, but advances in serum assays for PTH, PTHrP, and

Hypocalcemia. Mild hypocalcemia (i.e., reduction in ionized serum $[Ca^{2+}]$) from normal to concentrations above 3.2 mg/dL (0.8 mM), approximately equal to a total serum (Ca^{2+}) of 8–8.5 mg/dL (2–2.1 mM), is usually asymptomatic. Again, the rapidity of change affects the clinical picture because patients exhibit greater signs and symptoms if the hypocalcemia develops acutely. The signs and symptoms of hypocalcemia include tetany and related phenomena such as paresthesias, increased neuromuscular excitability, laryngospasm, muscle cramps, and tonic-clonic convulsions. In chronic hypoparathyroidism, ectodermal changes—consisting of loss of hair, grooved and brittle fingernails, defects of dental enamel, and cataracts—are encountered; calcification in the basal ganglia may be seen on routine skull radiographs. Psychiatric symptoms such as emotional lability, anxiety, depression, and delusions often are present.

Combined deprivation of Ca^{2+} and vitamin D, as observed with malabsorption states or dietary deficiency, readily promotes hypocalcemia. When caused by malabsorption, hypocalcemia is accompanied by low concentrations of phosphate, total plasma proteins, and magnesium. Mg^{2+} deficiency may accentuate the hypocalcemia by diminishing the secretion and action of PTH. In infants with malabsorption or inadequate calcium intake, Ca^{2+} concentrations usually are depressed, with attendant hypophosphatemia resulting in rickets.

Hypoparathyroidism is most often a consequence of thyroid or neck surgery but also may be due to genetic or autoimmune disorders. In hypoparathyroidism, hypocalcemia is accompanied by hyperphosphatemia, reflecting decreased PTH action on renal phosphate transport.

Pseudohypoparathyroidism is a diverse family of hypocalcemic and hyperphosphatemic disorders. Pseudohypoparathyroidism results from resistance to PTH rather than PTH deficiency; this resistance is not due to mutations of the PTH receptor but rather to mutations in $G_s\alpha$ (*GNAS1*), which normally mediates hormone-induced adenylyl cyclase activation (Yu et al., 1999). The variable phenotypes arising from *GNAS1* defects apparently are due to differential genomic imprinting of the maternal and paternal alleles (Levine et al., 2003). Multiple hormonal abnormalities have been associated with the *GNAS1* mutation, but none is as severe as the deficient response to PTH.

Hypocalcemia is not unusual in the first several days following removal of a parathyroid adenoma. If hyperphosphatemia is also present, the condition is one of functional hypothyroidism owing to temporary failure of the remaining parathyroid glands to compensate for the missing adenomatous tissue. In patients with parathyroid bone disease, postoperative hypocalcemia associated with hypophosphatemia may reflect rapid uptake of calcium into bone, the “hungry bone” syndrome. In this setting, persistent, severe hypocalcemia may require administration of vitamin D and supplemental calcium for several months.

Neonatal tetany resulting from hypocalcemia sometimes occurs in infants of mothers with *hyperparathyroidism*; indeed, the tetany may call attention to the mother’s disorder. This problem disappears when the infant’s own parathyroid glands develop sufficiently to respond appropriately.

Hypocalcemia is associated with advanced renal insufficiency accompanied by hyperphosphatemia. Many patients with this condition do not develop tetany unless the accompanying acidosis is treated, which decreases the ionized calcium. High concentrations of phosphate in plasma inhibit the conversion of 25-hydroxycholecalciferol to 1,25-dihydroxycholecalciferol. Hypocalcemia also can occur following massive transfusions with citrated blood, which chelates calcium.

Disturbed Phosphate Metabolism

Dietary inadequacy very rarely causes phosphate depletion. Sustained use of antacids, however, can severely limit phosphate absorption and result in clinical phosphate depletion, manifest as malaise, muscle weakness, and osteomalacia (Chapter 45). *Osteomalacia*, as described later, is characterized by undermineralized bone matrix and may occur when sustained phosphate depletion is caused by inhibiting its absorption in the GI tract (as with aluminum-containing antacids) or by excess renal excretion owing to PTH action.

Hyperphosphatemia is an important component of the bone disease seen in chronic renal failure. In this condition, phosphate retention is primary and reflects the degree of renal compromise. The increased phosphate level reduces the serum Ca^{2+} concentration, which, in turn, activates the parathyroid gland calcium-sensing receptor, stimulates PTH secretion, and exacerbates the hyperphosphatemia. The continuing hyperphosphatemia may be modified by vigorous administration of aluminum hydroxide gel or calcium carbonate supplements. As discussed later, the FDA recently approved therapeutic use of the calcium-sensing receptor agonist *cinacalcet* to suppress PTH secretion.

Disorders of Vitamin D

Hypervitaminosis D. The acute or long-term administration of excessive amounts of vitamin D or enhanced responsiveness to normal amounts of the vitamin leads to derangements in calcium metabolism. The responses to vitamin D reflect endogenous vitamin D production, tissue reactivity, and vitamin D intake. Some infants may be hyperreactive to small doses of vitamin D. In adults, hypervitaminosis D results from overtreatment of *hypoparathyroidism* or secondary *hyperparathyroidism* of renal osteodystrophy and from faddist use of excessive doses. Toxicity in children also may occur following accidental ingestion of adult doses and from feeding premature infants with formula containing supplemental vitamin D.

The amount of vitamin D necessary to cause hypervitaminosis varies widely. As a rough approximation, continued daily ingestion of $\geq 50,000$ units by a person with normal parathyroid function and sensitivity to vitamin D may result in poisoning. Hypervitaminosis D is particularly dangerous in patients who are receiving digoxin because the toxic effects of the cardiac glycosides are enhanced by hypercalcemia (Chapter 28).

The initial signs and symptoms of vitamin D toxicity are those associated with hypercalcemia. Because hypercalcemia in vitamin D intoxication generally is due to very high circulating levels of 25-OHD, the plasma concentrations of PTH and calcitriol typically (but not uniformly) are suppressed. In children, a single episode of moderately severe hypercalcemia may arrest growth completely for ≥ 6 months, and the deficit in height may never be fully corrected. Vitamin D toxicity in the fetus is associated with excess maternal vitamin D intake or extreme sensitivity and may result in congenital supravalvular aortic stenosis. In infants, this anomaly frequently is associated with other stigmata of hypercalcemia.

Vitamin D Deficiency. Vitamin D deficiency results in inadequate absorption of Ca^{2+} and phosphate. The consequent decrease of plasma Ca^{2+} concentration stimulates PTH secretion, which acts to restore plasma Ca^{2+} at the expense of bone. Plasma concentrations of phosphate remain subnormal because of the phosphaturic effect of increased circulating PTH. In children, the result is a failure to mineralize newly formed bone and cartilage matrix, causing the defect in growth known as *rickets*. As a consequence of inadequate calcification, bones of individuals with rickets are soft, and the stress of weight bearing gives rise to bowing of the long bones.

In adults, vitamin D deficiency results in osteomalacia, a disease characterized by generalized accumulation of undermineralized bone matrix. Severe osteomalacia may be associated with extreme bone pain and tenderness. Muscle weakness, particularly of large proximal muscles, is typical and may reflect both hypophosphatemia and inadequate vitamin D action on muscle. Gross deformity of bone occurs only in advanced stages of the disease. Circulating 25-OHD concentrations < 8 ng/mL are highly predictive of osteomalacia.

Metabolic Rickets and Osteomalacia. These disorders are characterized by abnormalities in calcitriol synthesis or response.

Hypophosphatemic vitamin D-resistant rickets, in its most common form, is an X-linked disorder (XLH) of calcium and phosphate metabolism. Calcitriol levels are inappropriately normal for the observed degree of hypophosphatemia. Patients experience clinical improvement when treated with large doses of vitamin D, usually in combination with inorganic phosphate. Even with vitamin D treatment, calcitriol concentrations may remain lower than expected. The genetic basis for XLH has been defined. The affected protein, a phosphate-regulating gene with homologies to endopeptidases on the X chromosome (PHEX), is a neutral endoprotease. The substrate for this enzyme likely is involved in renal phosphate transport. Syndromes closely related to XLH, in which phosphate levels are altered without significant net changes in serum concentrations of calcium, PTH, or $1,25(\text{OH})_2\text{D}_3$, include *hereditary hypophosphatemic rickets with hypercalciuria* (HHRH) and *autosomal dominant hypophosphatemic rickets*. The latter disorder maps to chromosome 12p13.3 and is associated with mutations in the gene encoding fibroblast growth factor 23 (White et al., 2001; Bergwitz and Jüppner, 2010).

Vitamin D-dependent rickets (also called *vitamin D-dependent rickets type I*, *VDDR-1* or *pseudovitamin D-deficiency rickets* (PDDR) is an autosomal recessive disease caused by an inborn error of vitamin D metabolism involving defective conversion of 25-OHD to calcitriol owing to mutations in *CYP1 α* (1α -hydroxylase). The condition responds to physiological doses of calcitriol. An initial dose of 1–3 $\mu\text{g}/\text{day}$ is used to heal rickets, after which a maintenance dose of 0.25–1 $\mu\text{g}/\text{day}$ can be used. $1\alpha\text{OHD}$ is also effective at slightly higher dosages (2–5 $\mu\text{g}/\text{day}$ and 1–2 $\mu\text{g}/\text{day}$, respectively). Other vitamin D analogs upstream of the 1α -hydroxylase have little activity.

Hereditary 1,25-dihydroxyvitamin D resistance (HVDDR, also called *vitamin D-dependent rickets type II*) is an autosomal recessive disorder that is characterized by hypocalcemia, osteomalacia, rickets, and total alopecia. Multiple heterogenous mutations of the vitamin D receptor cause vitamin D-dependent rickets type II (Malloy et al., 2005). Absolute hormone resistance results from premature stop mutations, missense mutations in the zinc finger DNA-binding domain, mutations of the receptor ligand-binding domain, or mutations that affect heterodimerization of the VDR with the retinoid X receptor (RXR).

Serum abnormalities include low serum concentrations of calcium and phosphate and elevated serum alkaline phosphatase activity. The hypocalcemia leads to secondary hyperparathyroidism with elevated PTH levels and hypophosphatemia. The 25(OH)-vitamin D values are normal, whereas $1,25(\text{OH})_2$ -vitamin D levels are elevated in type II vitamin D-dependent rickets. This clinical feature distinguishes hereditary vitamin D-dependent rickets type II from *CYP1 α* deficiency (vitamin D-dependent rickets type I), where serum $1,25(\text{OH})_2$ -vitamin D values are depressed. Children affected by vitamin D-dependent rickets type II are refractory even to massive doses of vitamin D and calcitriol, and they may require prolonged treatment with parenteral Ca^{2+} . Some remission of symptoms has been observed during adolescence, but the basis of remission is unknown. Notably, missense mutations in the ligand-binding domain have been described that result only in partial hormone resistance. Thus, the use of calcitriol analogs that bind to the VDR at different amino acids may provide therapeutic opportunities not otherwise available. This represents a prime application of pharmacogenetics, where “personalized” treatment based on the specific VDR mutations can be envisioned.

Renal osteodystrophy (renal rickets) refers to the disordered bone morphology that attends chronic kidney disease. It is characterized by abnormalities of bone turnover, mineralization, volume, linear growth, or strength, as well as underlying defects in mineral ion, PTH, or vitamin D metabolism. In the early phase of chronic renal failure, physiological concentrations of $1,25(\text{OH})_2\text{D}$ in circulation may become insufficient to regulate parathyroid cell function normally. As a result, the set point of PTH secretion to plasma Ca^{2+} concentration shifts to the right, PTH synthesis becomes enhanced at the transcriptional level, and parathyroid cells begin to proliferate. This resistance of the parathyroid cells to the physiological concentration of $1,25(\text{OH})_2\text{D}$ may be partially due to decreased conversion of 25-OHD to calcitriol. Phosphate retention and diminished serum calcium also increase PTH mRNA levels but at the post-transcriptional level. In addition, calcitriol deficiency impairs intestinal Ca^{2+} absorption and mobilization from bone. Hypocalcemia commonly results (although in some patients, prolonged and severe hyperparathyroidism eventually may lead to hypercalcemia). Aluminum

Osteoporosis

Osteoporosis is a condition of low bone mass and microarchitectural disruption that results in fractures with minimal trauma. Osteoporosis is a major and growing public health problem in developed nations. Many women (30-50%) and men (15-30%) suffer a fracture related to osteoporosis. Characteristic sites of fracture include vertebral bodies, the distal radius, and the proximal femur, but osteoporotic individuals have generalized skeletal fragility, and fractures at sites such as ribs and long bones also are common. Fracture risk increases exponentially with age, and spine and hip fractures are associated with reduced survival. Fractures of distal forearm, foot, or ankle are not associated with increased mortality (Teng et al., 2008).

Osteoporosis can be categorized as *primary* or *secondary*. In 1948, Albright and Reifenstein concluded that primary osteoporosis included two separate entities: one related to menopausal estrogen loss and the other to aging. This concept was extended by the recognition that primary osteoporosis represents two fundamentally different conditions: *type I osteoporosis*, characterized by loss of trabecular bone owing to estrogen lack at menopause, and *type II osteoporosis*, characterized by loss of cortical and trabecular bone in men and women due to long-term remodeling inefficiency, dietary inadequacy, and activation of the parathyroid axis with age. It is not clear, however, that these two entities are truly distinct. Although many osteoporotic women undoubtedly have experienced excessive menopausal bone loss, it may be more appropriate to consider osteoporosis as the result of multiple physical, hormonal, and nutritional factors acting alone or in concert.

Secondary osteoporosis is due to systemic illness or medications such as glucocorticoids or phenytoin. The most successful approach to secondary osteoporosis is prompt resolution of the underlying cause or drug discontinuation. Whether primary or secondary, osteoporosis is associated with characteristic disordered bone remodeling, so the same therapies can be used.

Paget's Disease. Paget's disease is characterized by single or multiple sites of disordered bone remodeling. The etiology of the disease is uncertain but is thought to be the result of infection with the measles virus of the paramyxovirus family (Roodman and Windle, 2005). It affects up to 2-3% of the population >60 years of age. The primary pathologic abnormality is increased bone resorption followed by exuberant bone formation. However, the newly formed bone is disorganized and of poor quality, resulting in characteristic bowing, stress fractures, and arthritis of joints adjoining the involved bone. Pagetic lesions contain many abnormal multinucleated osteoclasts associated with a disordered mosaic pattern of bone formation. Pagetic bone is thickened and has abnormal microarchitecture. The altered bone structure can produce secondary problems, such as deafness, spinal cord compression, high-output cardiac failure, and pain. Malignant degeneration to osteogenic sarcoma is a rare but lethal complication of Paget's disease.

Renal Osteodystrophy. Bone disease is a frequent consequence of chronic renal failure and dialysis. Pathologically, lesions are typical of hyperparathyroidism (osteitis fibrosa), vitamin D deficiency (osteomalacia), or a mixture of both. The underlying pathophysiology reflects increased serum phosphate and decreased calcium, leading to secondary events that strive to preserve circulating levels of mineral ions at the expense of bone.

PHARMACOLOGICAL TREATMENT OF DISORDERS OF MINERAL ION HOMEOSTASIS AND BONE METABOLISM

Hypercalcemia

Hypercalcemia can be life threatening. Such patients frequently are severely dehydrated because hypercalcemia compromises renal concentrating mechanisms. Thus, fluid resuscitation with large volumes of isotonic saline must be early and aggressive (6-8 L/day). Agents that augment Ca^{2+} excretion, such as loop diuretics (Chapter 25), may help to counteract the effect of plasma volume expansion by saline but are contraindicated until volume is repleted because they otherwise will aggravate volume depletion and hypercalcemia.

Corticosteroids administered at high doses (e.g., 40-80 mg/day of prednisone) may be useful when hypercalcemia results from sarcoidosis, lymphoma, or hypervitaminosis D (Chapter 42). The response to steroid therapy is slow; from 1-2 weeks may be required before plasma Ca^{2+} concentration falls.

Calcitonin (CALCIMAR, MIACALCIN) may be useful in managing hypercalcemia. Reduction in Ca^{2+} can be rapid, although "escape" from the hormone commonly occurs within several days. The recommended starting dose is 4 units/kg of body weight administered subcutaneously every 12 hours; if there is no response within 1-2 days, the dose may be increased to a maximum of 8 units/kg every 12 hours. If the response after 2 more days still is unsatisfactory, the dose may be increased to a maximum of 8 units/kg every 6 hours. Calcitonin can lower serum calcium by 1-2 mg/dL.

Intravenous *bisphosphonates* (pamidronate, zoledronate) have proven very effective in the management of hypercalcemia (see further discussion of bisphosphonates later in the chapter). These agents potently inhibit osteoclastic bone resorption. Oral bisphosphonates are less effective for treating hypercalcemia. Therefore, pamidronate (AREDIA) is given as an intravenous infusion of 60-90 mg over 4-24 hours; the more prolonged infusion (>4 hours) is reserved primarily for patients with renal dysfunction. With pamidronate, resolution of hypercalcemia occurs over several days, and the effect usually persists for several weeks. Zoledronate (ZOMETA) has superseded pamidronate because of its more rapid normalization of serum calcium and longer duration of action.

Plicamycin (mithramycin, MITHRACIN) is a cytotoxic anti-biotic that also decreases plasma Ca^{2+} concentrations by inhibiting bone resorption. Reduction in plasma Ca^{2+} concentrations occurs within 24-48 hours when a relatively low dose of this agent is given

(15–25 $\mu\text{g}/\text{kg}$ of body weight) to minimize the high systemic toxicity of the drug; indeed, its toxicity generally precludes its use.

Oral sodium phosphate lowers plasma Ca^{2+} concentrations and may offer short-term calcemic control of some patients with primary hyperparathyroidism who are awaiting surgery. However, the risk of precipitating calcium phosphate salts in soft tissues throughout the body is of concern. In light of satisfactory responses to other agents, administration of intravenous sodium phosphate is not recommended as a treatment for hypercalcemia.

Once the hypercalcemic crisis has resolved or in patients with milder calcium elevations, therapy turns to more durable resolution of the hypercalcemic state. Parathyroidectomy remains the only definitive treatment for primary hyperparathyroidism. Specific indications for surgery have been proposed (Bilezikian et al., 2002). In the hands of a skilled parathyroid surgeon, resection of a single adenoma (~80% of cases) or of the hyperplastic glands (~15% of cases) cures hyperparathyroidism. Complications include transient postoperative hypocalcemia, which may reflect temporary disruption of blood supply to the remaining parathyroid tissue or skeletal avidity for calcium, and permanent hypoparathyroidism. As described later, a calcium mimetic that stimulates the calcium-sensing receptor is a promising new therapy for hyperparathyroidism that may be used increasingly in the future.

Therapy of hypercalcemia of malignancy ideally is directed at the underlying cancer. When this is not possible, parenteral bisphosphonates often will maintain calcium levels within an acceptable range.

Hypocalcemia and Other Therapeutic Uses of Calcium. Hypoparathyroidism is treated primarily with vitamin D. Dietary supplementation with Ca^{2+} also may be necessary.

Calcium is used in the treatment of calcium deficiency states and as a dietary supplement. Ca^{2+} salts are specific in the immediate treatment of hypocalcemic tetany regardless of etiology. In severe tetany, symptoms are best brought under control by intravenous medication. *Calcium chloride* ($\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$) contains 27% Ca^{2+} ; it is valuable in the treatment of hypocalcemic tetany and laryngospasm. The salt is given intravenously and *must never be injected into tissues*. Injections of calcium chloride are accompanied by peripheral vasodilation and a cutaneous burning sensation. The salt usually is given intravenously in a concentration of 10% (equivalent to 1.36 mEq Ca^{2+}/mL). The rate of injection should be slow (not >1 mL/minute) to prevent cardiac arrhythmias from a high concentration of Ca^{2+} . The injection may induce a moderate fall in blood pressure owing to vasodilation. Because calcium chloride is an acidifying salt, it is usually undesirable in the treatment of the hypocalcemia caused by renal insufficiency. *Calcium gluceptate* injection (a 22% solution; 18 mg or 0.9 mEq of Ca^{2+}/mL) is administered intravenously at a dose of 5–20 mL for the treatment of severe hypocalcemic tetany; the injection produces a transient tingling sensation when given too rapidly. When the intravenous route is not possible, injections may be given intramuscularly in the gluteal region at a dose of up to 5 mL. A mild local reaction may result. *Calcium gluconate* injection (a 10% solution; 9.3 mg of Ca^{2+}/mL) given intravenously is the treatment of choice for severe hypocalcemic tetany. Patients with moderate-to-severe hypocalcemia may be treated by

intravenous infusion of calcium gluconate at a dose of 10–15 mg of Ca^{2+}/kg of body weight over 4–6 hours. Because the usual 10-mL vial of a 10% solution contains only 93 mg Ca^{2+} , many vials are needed. The intramuscular route should not be employed because abscess formation at the injection site may result.

For control of milder hypocalcemic symptoms, oral medication suffices, frequently in combination with vitamin D or one of its active metabolites. Calcium salts are acidifying, and different forms can be interchanged to avoid gastric irritation. Available Ca^{2+} salts include calcium carbonate, lactate, gluconate, phosphate, citrate, and hydroxyapatite. Calcium carbonate is prescribed most frequently, whereas calcium citrate may be absorbed more efficiently than other salts. However, absorption efficiency for most commonly prescribed calcium products is reasonable, and for many patients, cost and palatability outweigh modest differences in efficacy. Average doses for hypocalcemic patients are calcium gluconate, 15 g/day in divided doses; calcium lactate, 7.7 g plus 8 g lactose with each meal; and calcium carbonate or calcium phosphate, 1–2 g with meals.

Calcium carbonate and calcium acetate are used to restrict phosphate absorption in patients with chronic renal failure and oxalate absorption in patients with inflammatory bowel disease. Acute administration of calcium may be lifesaving in patients with extreme hyperkalemia (serum $\text{K}^+ > 7$ mEq/L). Calcium gluconate (10–30 mL of a 10% solution) can reverse some of the cardiotoxic effects of hyperkalemia, providing time while other efforts are taken to lower the plasma K^+ concentration.

Additional FDA-approved uses of calcium include intravenous treatment for black widow spider envenomation and management of magnesium toxicity. Use of supplemental calcium in the prevention and treatment of osteoporosis is discussed later.

THERAPEUTIC USES OF VITAMIN D

Clinical Forms of Vitamin D. Calcitriol (1,25-dihydroxycholecalciferol; CALCIJEX, ROCALTROL) is available for oral administration or injection. Intravenous treatment regimens with high doses of calcitriol or one of its derivatives have become predominant for managing patients with chronic kidney disease and end-stage kidney disease. Its specific therapeutic uses are discussed later. Several derivatives of vitamin D (Figure 44–10) are of considerable therapeutic and experimental interest.

Doxercalciferol (1α -hydroxyvitamin D_2 , HECTOROL) is a pro-drug that first must be activated by hepatic 25-hydroxylation to generate the biologically active compound, $1\alpha,25\text{-(OH)}_2\text{D}_2$ (Figure 44–10). The FDA has approved oral and intravenous preparations of 1α -hydroxyvitamin D_2 for use in treating secondary hyperparathyroidism, starting at 10 mg three times per week.

Dihydroxycholecalciferol (DHT, ROXANE) is a reduced form of vitamin D_2 . In the liver DHT is converted to its active form, 25-hydroxydihydroxycholecalciferol. DHT is $<1\%$ as active as calcitriol in antirachitic assays but is much more effective in mobilizing bone mineral at high doses; it therefore can be used to maintain plasma Ca^{2+} in hypoparathyroidism. DHT is well absorbed from the GI tract and maximally increases serum calcium concentration after 2 weeks of daily

Figure 44–10. Vitamin D analogs.

administration. The hypercalcemic effects typically persist for 2 weeks but can last for up to 1 month. DHT is available for oral administration in doses ranging from 0.2–1 mg/day (average 0.6 mg/day).

1 α -Hydroxycholecalciferol (1-OHD₃, alphacalcidol; ONE-ALPHA) was introduced as a substitute for 1,25(OH)₂D₃; alphacalcidol is a synthetic vitamin D₃ derivative that is already hydroxylated in the 1 α position and is rapidly hydroxylated by 25-hydroxylase to form 1,25-(OH)₂D₃. It is equal to calcitriol in assays for stimulation of intestinal absorption of Ca²⁺ and bone mineralization and does not require renal activation. It therefore has been used to treat renal osteodystrophy and is available in the U.S. for experimental purposes.

Ergocalciferol (calciferol, DRISDOL) is pure vitamin D₂. It is available for oral, intramuscular, or intravenous administration. Ergocalciferol is indicated for the prevention of vitamin D deficiency and the treatment of familial hypophosphatemia, hypoparathyroidism, and vitamin D-resistant rickets type II, typically in doses of 50,000–200,000 units/day in conjunction with calcium supplements.

Analogs of Calcitriol. Several vitamin D analogs (Figure 44–10) suppress PTH secretion by the parathyroid glands but have less or negligible hypercalcemic activity. They therefore offer a safer and more effective means of controlling secondary hyperparathyroidism.

Calcipotriol (calcipotriene) is a synthetic derivative of calcitriol with a modified side chain that contains a 22–23 double bond, a 24(S)-hydroxy functional group, and carbons 25–27 incorporated into a cyclopropane ring. Calcipotriol has comparable affinity with calcitriol for the vitamin D receptor, but it is <1% as active as calcitriol in regulating calcium metabolism. This reduced calcemic activity largely reflects the pharmacokinetics of calcipotriol

(Kissmeyer and Binderup, 1991). Calcipotriol has been studied extensively as a treatment for psoriasis (Chapter 65), although its mode of action is not known; a topical preparation (DOVONEX) is available for that purpose. In clinical trials, topical calcipotriol has been found to be slightly more effective than glucocorticoids with a good safety profile.

Paricalcitol (1,25-dihydroxy-19-norvitamin D₂, ZEMPLAR) is a synthetic calcitriol derivative that lacks the exocyclic C19 and has a vitamin D₂ rather than vitamin D₃ side chain (Figure 44–10). It reduces serum PTH levels without producing hypercalcemia or altering serum phosphorus (Martin et al., 1998). In an animal model, paricalcitol prevented or reversed PTH-induced high-turnover bone disease (Slatopolsky et al., 2003). Paricalcitol administered intravenously is FDA-approved for treating secondary hyperparathyroidism in patients with chronic renal failure.

22-Oxacalcitriol (1,25-dihydroxy-22-oxavitamin D₃, OCT, maxacalcitol, OXAROL) differs from calcitriol only in the substitution of C-22 with an oxygen atom. Oxacalcitriol has a low affinity for vitamin D-binding protein; as a result, more of the drug circulates in the free (unbound) form, allowing it to be metabolized more rapidly than calcitriol with a consequent shorter t_{1/2}. Oxacalcitriol is a potent suppressor of PTH gene expression and shows very limited activity on intestine and bone. It is a useful compound in patients with overproduction of PTH in chronic renal failure. It should be borne in mind that persuasive evidence supports the use of cinacalcet for treatment of secondary hyperparathyroidism (Drueke and Ritz, 2009). Indeed, emerging findings show the clinical efficacy of cinacalcet for managing primary hyperparathyroidism (Peacock et al., 2009).

Therapeutic Indications for Vitamin D

The major therapeutic uses of vitamin D may be divided into four categories:

- prophylaxis and cure of nutritional rickets
- treatment of metabolic rickets and osteomalacia, particularly in the setting of chronic renal failure
- treatment of hypoparathyroidism
- prevention and treatment of osteoporosis (discussed in the section on osteoporosis)

Vitamin D supplementation may help prevent fractures, but the relationship between blood vitamin D concentrations and fracture risk is unclear (Cauley et al., 2008).

Nutritional Rickets. Nutritional rickets results from inadequate exposure to sunlight or deficiency of dietary vitamin D. The condition, once extremely rare in the U.S. and other countries where food fortification with the vitamin is practiced, is now increasing. Infants and children receiving adequate amounts of vitamin D–fortified food do not require additional vitamin D; however, breast-fed infants or those fed unfortified formula should receive 400 units of vitamin D daily as a supplement (Wagner and Greer, 2008). The usual practice is to administer vitamin A in combination with vitamin D. A number of balanced vitamin A and D preparations are available for this purpose. *Because the fetus acquires >85% of its calcium stores during the third trimester, premature infants are especially susceptible to rickets and may require supplemental vitamin D.*

Treatment of fully developed rickets requires a larger dose of vitamin D than that used prophylactically. One thousand units daily will normalize plasma Ca^{2+} and phosphate concentrations in ~10 days, with radiographic evidence of healing within ~3 weeks. However, a larger dose of 3000–4000 units daily often is prescribed for more rapid healing, particularly when respiration is compromised by severe thoracic rickets.

Vitamin D may be given prophylactically in conditions that impair its absorption (e.g., diarrhea, steatorrhea, and biliary obstruction). Parenteral administration also may be used in such cases.

Treatment of Osteomalacia and Renal Osteodystrophy. Osteomalacia, distinguished by undermineralization of bone matrix, occurs commonly during sustained phosphate depletion. Patients with chronic renal disease are at risk for developing osteomalacia but also may develop a complex bone disease called *renal osteodystrophy*. In this setting, bone metabolism is stimulated by an increase in PTH and by a delay in bone mineralization that is due to decreased renal synthesis of calcitriol. In renal osteodystrophy, low bone mineral density may be accompanied by high-turnover bone lesions typically seen in patients with uncontrolled hyperparathyroidism or by low bone remodeling activity seen in patients with adynamic bone disease. The therapeutic approach to the patient with renal osteodystrophy depends on its specific type. In high-turnover (hyperparathyroid) or mixed high-turnover disease with deficient mineralization, dietary phosphate restriction, generally in combination with a phosphate binder, is recommended because phosphate restriction is

limited by the need to provide adequate protein intake to maintain nitrogen balance. Although highly effective, *aluminum* is no longer used as a phosphate binder because it promotes adynamic bone disease, anemia, myopathy, and occasionally dementia. Calcium-containing phosphate binders along with calcitriol administration may contribute to oversuppression of PTH secretion and likewise result in adynamic bone disease and an increased incidence of vascular calcification. Highly effective non-calcium-containing phosphate binders have been developed. Sevelamer hydrochloride (RENAGEL), a nonabsorbable phosphate-binding polymer, effectively lowers serum phosphate concentration in hemodialysis patients, with a corresponding reduction in the calcium \times phosphate product. Sevelamer hydrochloride consists of cross-linked poly[allylamine hydrochloride] that is resistant to digestive degradation. Its partially protonated amines spaced one carbon from the polymer backbone chelate phosphate ions. Sevelamer is modestly water soluble and only trace amounts are absorbed from the GI tract. However, with continued use, progressive accumulation has been reported in experimental animals. Side effects of sevelamer include vomiting, nausea, diarrhea, and dyspepsia. Sevelamer does not affect the bioavailability of digoxin, warfarin, enalapril, or metoprolol. Lanthanum carbonate (FOSRENOL) is a poorly permeable trivalent cation that is useful in treating the hyperphosphatemia associated with renal osteodystrophy.

Renal osteodystrophy associated with low bone turnover (adynamic bone disease) is increasingly common and may be due to oversuppression of PTH with aggressive use of either calcitriol or other vitamin D analogs. Although PTH levels generally are low (<100 pg/mL), a high PTH level does not exclude the presence of adynamic bone disease, especially with PTH assays that do not distinguish between biologically active and inactive PTH fragments (Monier-Faugere et al., 2001). Current guidelines suggest that treatment with an active vitamin D preparation is indicated if serum 25-OHD levels are <30 ng/mL and serum calcium is <9.5 mg/dL (2.37 mM). However, if 25-OHD and serum calcium levels are elevated, vitamin D supplementation should be discontinued. If the serum calcium level is <9.5 mg/dL, treatment with a vitamin D analog is warranted irrespective of the 25-OHD level (Eknoyan et al., 2003).

Hypoparathyroidism. Vitamin D and its analogs are a mainstay of the therapy of hypoparathyroidism. Dihydrotachysterol (DHT) has a faster onset, shorter duration of action, and a greater effect on bone mobilization than does vitamin D and traditionally has been a preferred agent. Calcitriol also is effective in the management of hypoparathyroidism and certain forms of pseudohypoparathyroidism in which endogenous levels of calcitriol are abnormally low. However, most hypoparathyroid patients respond to any form of vitamin D. Calcitriol may be preferred for temporary treatment of hypocalcemia while awaiting effects of a slower-acting form of vitamin D.

Miscellaneous Uses of Vitamin D. Vitamin D is used to treat hypophosphatemia associated with Fanconi's syndrome. Large doses of vitamin D (>10,000 units/day) are not useful in patients with osteoporosis and even can be dangerous. However, administration of 400–800 units/day of vitamin D to frail elderly men and women has been shown to suppress bone remodeling, protect bone mass, and reduce fracture incidence (see later section on osteoporosis). Clinical trials suggest that calcitriol may become an important agent for the treatment of psoriasis (Kowalick, 2001). As such nontraditional

uses of vitamin D are discovered, it will become important to develop noncalcemic analogs of calcitriol that achieve effects on cellular differentiation without the risk of hypercalcemia.

Adverse Effects of Vitamin D Therapy

The primary toxicity associated with calcitriol reflects its potent effect to increase intestinal calcium and phosphate absorption, along with the potential to mobilize osseous calcium and phosphate. Hypercalcemia, with or without hyperphosphatemia, commonly complicates calcitriol therapy and may limit its use at doses that effectively suppress PTH secretion. As described earlier, noncalcemic vitamin D analogs provide alternative interventions, although they do not obviate the need to monitor serum calcium and phosphorus concentrations.

Hypervitaminosis D is treated by immediate withdrawal of the vitamin, a low-calcium diet, administration of glucocorticoids, and vigorous fluid support. As noted earlier under hypercalcemia, forced saline diuresis with loop diuretics is also useful. With this regimen, the plasma Ca^{2+} concentration falls to normal, and Ca^{2+} in soft tissue tends to be mobilized. Conspicuous improvement in renal function occurs unless renal damage has been severe.

CALCITONIN

Diagnostic Uses of Calcitonin. Calcitonin is a sensitive and specific marker for the presence of medullary thyroid carcinoma (MTC), a neuroendocrine malignancy originating in thyroid parafollicular C cells. MTC can be hereditary (25%) or sporadic (75%) and is present in all patients with the multiple endocrine neoplasia type 2 (MEN2) syndromes. Because one form of MEN2 is inherited as a dominant trait, relatives of patients should be examined repeatedly by calcitonin measurements from early childhood. Because calcitonin levels may be low in early tumor stages or in pre-malignant C-cell hyperplasia, pentagastrin-induced calcitonin provides greater sensitivity and increased MTC detection. The identification of discrete mutations in the *RET* protooncogene in subjects with MEN2 offers hope that genetic screening will supplant reliance on testing serum calcitonin, which can give spurious results.

Therapeutic Uses. Calcitonin lowers plasma Ca^{2+} and phosphate concentrations in patients with hypercalcemia; this effect results from decreased bone resorption and is greater in patients in whom bone turnover rates are high. Although calcitonin is effective for up to 6 hours in the initial treatment of hypercalcemia, patients become refractory after a few days. This is likely due to receptor downregulation (Takahashi et al.,

1995). Use of calcitonin does not substitute for aggressive fluid resuscitation, and the bisphosphonates are the preferred agents.

Calcitonin is effective in disorders of increased skeletal remodeling, such as Paget's disease, and in some patients with osteoporosis. In Paget's disease, chronic use of calcitonin produces long-term reductions of serum alkaline phosphatase activity and symptoms. Development of antibodies to calcitonin occurs with prolonged therapy, but this is not necessarily associated with clinical resistance. Side effects of calcitonin include nausea, hand swelling, urticaria, and, rarely, intestinal cramping. Side effects appear to occur with equal frequency with human and salmon calcitonin. *Salmon calcitonin* is approved for clinical use. The latter product also is available as a nasal spray, introduced for once-daily treatment of postmenopausal osteoporosis. For Paget's disease, calcitonin generally is administered by subcutaneous injection because intranasal delivery is relatively ineffective owing to limited bioavailability. After initial therapy at 100 units/day, the dose typically is reduced to 50 units three times a week.

BISPHOSPHONATES

Bisphosphonates are analogs of pyrophosphate (Figure 44-11) that contain two phosphonate groups attached to a geminal (central) carbon that replaces the oxygen in pyrophosphate. Because they form a three-dimensional structure capable of chelating divalent cations such as Ca^{2+} , the bisphosphonates have a strong affinity for bone, targeting especially bone surfaces undergoing remodeling. Accordingly, they are used extensively in conditions characterized by osteoclast-mediated bone resorption, including osteoporosis, steroid-induced osteoporosis, Paget's disease, tumor-associated osteolysis, breast and prostate cancer, and hypercalcemia. Calcium supplements, antacids, food or medications containing divalent cations, such as iron, may interfere with intestinal absorption of bisphosphonates. Recent evidence suggests that second- and third-generation bisphosphonates also may be effective anticancer drugs. For a review of the basic and clinical pharmacology of bisphosphonates, see Russell, 2007.

The clinical utility of bisphosphonates resides in their direct inhibition of bone resorption. First-generation bisphosphonates contain minimally modified side chains (R_1 and R_2 in Figure 44-11) (medronate, clodronate, and etidronate) or possess a chlorophenol group (tiludronate) (Figure 44-11). They are the least potent and in some instances cause bone demineralization. Second-generation aminobisphosphonates (e.g., alendronate and pamidronate) contain a nitrogen group in the side chain. They are 10-100 times more potent than first-generation compounds. Third-generation bisphosphonates (e.g., risedronate and zoledronate) contain a nitrogen atom within a heterocyclic ring and are up to 10,000 times more potent than first-generation agents.

Figure 44–11. Structures of pyrophosphate and bisphosphonates. The substituents (R_1 and R_2) on the central carbon of the bisphosphonate parent structure are shown in blue.

Bisphosphonates concentrate at sites of active remodeling. Because they are highly negatively charged, bisphosphonates are membrane impermeable but are incorporated into the bone matrix by fluid-phase endocytosis (Stenbeck and Horton, 2000). Bisphosphonates remain in the matrix until the bone is remodeled and then are released in the acid environment of the resorption lacunae beneath the osteoclast as the overlying mineral matrix is dissolved. The importance of this process for the antiresorptive effect of bisphosphonates is evidenced by the fact that calcitonin blocks the antiresorptive action.

Although bisphosphonates prevent hydroxyapatite dissolution, their antiresorptive action is due to direct inhibitory effects on osteoclasts rather than strictly physiochemical effects. The antiresorptive activity apparently involves two primary mechanisms: osteoclast apoptosis and inhibition of components of the cholesterol biosynthetic pathway.

The current model is that apoptosis accounts for the antiresorptive effect of first-generation bisphosphonates, whereas the inhibitory action of aminobisphosphonates proceeds through the

latter mechanism. Consistent with this view, the antiresorptive effect of aminobisphosphonates such as alendronate and risedronate, but not of clodronate or etidronate, persists when apoptosis is suppressed (Halasy-Nagy et al., 2001). First-generation bisphosphonates are metabolized into a nonhydrolyzable ATP analog (AppCCl₂p) that accumulates within osteoclasts and induces apoptosis (Rogers, 2003). In contrast, the aminobisphosphonates such as alendronate and ibandronate directly inhibit multiple steps in the pathway from mevalonate to cholesterol and isoprenoid lipids, such as geranylgeranyl diphosphate, that are required for the prenylation of proteins that are important for osteoclast function. The potency of aminobisphosphonates for inhibiting farnesyl synthase correlates directly with their antiresorptive activity (Dunford et al., 2001).

Available Bisphosphonates

Several bisphosphonates are available in the U.S. (Figure 44–11). Etidronate sodium (DIDRONEL) is used for treatment of Paget's disease and may be used parenterally to treat hypercalcemia. Because etidronate is the only bisphosphonate that inhibits mineralization, it

has been supplanted largely by pamidronate and zoledronate for treating hypercalcemia. Pamidronate (AREDIA) is approved for management of hypercalcemia and for prevention of bone loss in breast cancer and multiple myeloma, but it also is effective in other skeletal disorders. Pamidronate is available in the U.S. only for parenteral administration. For treatment of hypercalcemia, pamidronate may be given as an intravenous infusion of 60-90 mg over 4-24 hours.

Several newer bisphosphonates have been approved for treatment of Paget's disease. These include tiludronate (SKELID), alendronate (FOSAMAX), and risedronate (ACTONEL). Tiludronate is approved for treatment of Paget's disease of bone. Standard dosing is 400 mg/day orally for 3 months. Tiludronate in recommended doses does not interfere with bone mineralization, unlike etidronate. Zoledronate (ZOMETA) is approved for treating Paget's disease and administered as a single 5-mg infusion decreased bone turnover markers for 6 months with no loss of therapeutic effect (Reid et al., 2005). Zometa is widely used for prevention of osteoporosis in prostate and breast cancer patients receiving hormonal therapy. It is also approved for treating hypercalcemia of malignancies and for preventing fractures and skeletal complications in cancer patients with bone metastases. It is widely used to prevent osteoporosis and fractures in breast and prostate cancer patients receiving hormone-antagonist treatment.

The potent bisphosphonate ibandronate is approved for the prevention and treatment of postmenopausal osteoporosis. The recommended oral dose is 2.5 mg daily or 150 mg once monthly, which appears to be as effective as daily treatment and is well tolerated.

Absorption, Fate, and Excretion. All oral bisphosphonates are very poorly absorbed from the intestine and have remarkably limited bioavailability (<1% [alendronate, risedronate] to 6% [etidronate, tiludronate]). Hence these drugs should be administered with a full glass of water following an overnight fast and at least 30 minutes before breakfast. Oral bisphosphonates have not been used widely in children or adolescents because of uncertainty of long-term effects of bisphosphonates on the growing skeleton.

Bisphosphonates are excreted primarily by the kidneys. Adjusted doses for patients with diminished renal function have not been determined; bisphosphonates currently are not recommended for patients with a creatinine clearance of <30 mL/minute.

Adverse Effects. Oral bisphosphonates, including alendronate, ibandronate, and risedronate, can cause heartburn, esophageal irritation, or esophagitis. Other GI side effects include abdominal pain and diarrhea. Symptoms often abate when patients take the medication after an overnight fast, with tap or filtered water (not mineral water), and remain upright. Esophageal complications are infrequent when the drug is taken as described. If symptoms persist despite these precautions, use of a nonsteroidal anti-inflammatory drug or acetaminophen can diminish these symptoms; a proton pump inhibitor at bedtime may be helpful (Chapter 45). Both drugs may be better tolerated on a once-weekly regimen with no reduction of efficacy. Patients with active upper GI disease should not be given oral bisphosphonates.

Serious osteonecrosis of the jaw is associated with use of bisphosphonates (Edwards et al., 2008). In 2008 the FDA issued an alert on the use of bisphosphonates (<http://www.fda.gov/Drugs/DrugSafety/PostmarketDrugSafetyInformationforPatientsandProviders/ucm124165.htm>) and product labeling was modified to highlight

the severe musculoskeletal pain that may occur and its relation to osteonecrosis of the jaw.

Owing to cytokine release, initial parenteral infusion of pamidronate, may cause skin flushing, flu-like symptoms, muscle and joint aches and pains, nausea and vomiting, abdominal discomfort and diarrhea (or constipation) but mainly when given in higher concentrations or at faster rates than those recommended. These symptoms are short lived and generally do not recur with subsequent administration.

Zoledronate has more potent effects on calcium than some other bisphosphonates and is capable of causing severe hypocalcemia. It has been associated with renal toxicity, deterioration of renal function, and potential renal failure. Thus, the infusion should be given over at least 15 minutes, and the dose should be 4 mg. Patients who receive zoledronate should have standard laboratory and clinical parameters of renal function assessed prior to treatment and periodically after treatment to monitor for deterioration in renal function.

Other Therapeutic Uses

Hypercalcemia. The use of pamidronate in the management of malignancy-associated hypercalcemia was described earlier. Zoledronate appears to be more effective than pamidronate and at least as safe, can be infused over 15 minutes rather than 2-4 hours, and is FDA-approved for this indication.

Postmenopausal Osteoporosis. Much interest is focused on the role of bisphosphonates in the treatment of osteoporosis. Clinical trials show that treatment is associated with increased bone mineral density and protection against fracture.

Cancer. Bisphosphonates may also have direct antitumor action by inhibiting oncogene activation and through their anti-angiogenic effects. Randomized clinical trials of bisphosphonates in patients with breast cancer suggest that they delay or prevent development of metastases as a component of endocrine adjuvant therapy (Gnant et al., 2009).

PARATHYROID HORMONE

Continuous administration of parathyroid hormone (PTH) or high-circulating PTH levels achieved in primary hyperparathyroidism causes bone demineralization and osteopenia. However, *intermittent* PTH administration promotes bone growth. Selye first described the anabolic action of PTH some 80 years ago, but this observation was largely ignored and generally forgotten. Beginning in the 1970s, studies focused on the anabolic action of PTH, culminating with FDA approval of synthetic human 34-amino-acid amino-terminal PTH fragment [hPTH(1-34), teriparatide (FORTEO)] for use in treating severe osteoporosis (Hodsman et al., 2005).

Full-length human recombinant PTH(1-84) is in phase III trials for hypoparathyroidism, for which teriparatide is not approved. Intermittent PTH(1-84) may soon be approved for use in osteoporosis, but its benefits over PTH(1-34) remain to be established.

Absorption, Fate, and Excretion. Pharmacokinetics and systemic actions of teriparatide on mineral metabolism are the same as for PTH. Teriparatide is administered by once-daily subcutaneous injection of 20 μg into the thigh or abdomen. With this regimen, serum PTH concentrations peak at 30 minutes after the injection and decline to undetectable concentrations within 3 hours, whereas the serum calcium concentration peaks at 4–6 hours after administration. Based on aggregate data from different dosing regimens, teriparatide bioavailability averages 95%. Teriparatide clearance averages 62 L/hour in women and 94 L/hour in men, which exceeds normal liver plasma flow, consistent with both hepatic and extrahepatic PTH removal. The serum $t_{1/2}$ of teriparatide is ~ 1 hour when administered subcutaneously versus 5 minutes when administered intravenously. The longer $t_{1/2}$ following subcutaneous administration reflects the time required for absorption from the injection site. The elimination of PTH(1–34) and full-length PTH proceeds by nonspecific enzymatic mechanisms in the liver, followed by renal excretion.

Clinical Effects. In postmenopausal women with osteoporosis, teriparatide increases BMD and reduces the risk of vertebral and nonvertebral fractures. Several laboratories have examined the effects of intermittent PTH on BMD in patients with osteoporosis. In these studies, teriparatide increased axial bone mineral, although initial reports of effects on cortical bone were disappointing. Co-administration of hPTH(1–34) with estrogen or synthetic androgen led to impressive gains in vertebral bone mass or trabecular bone. However, in some early studies there was only maintenance or even loss of cortical bone. Vitamin D insufficiency in patients at baseline or pharmacokinetic differences involving bioavailability or circulating half-life may have contributed to observed differences on cortical bone. The most comprehensive studies to date established the value of daily hPTH(1–34) administration on total BMD, with significant elevations of BMD in lumbar spine and femoral neck and with significant reductions of vertebral and nonvertebral fracture risk in osteoporotic women (Neer et al., 2001) and men (Finkelstein et al., 2003).

Candidates for teriparatide treatment include women who have a history of osteoporotic fracture, who have multiple risk factors for fracture, or who failed or are intolerant of previous osteoporosis therapy. Men with primary or hypogonadal osteoporosis are also candidates for treatment with teriparatide. However, the effect on fracture incidence in this group has not been established.

Adverse Effects. In rats, teriparatide increased the incidence of osteosarcoma (Vahle et al., 2004). Because of these findings, a black box warning appears on the FORTEO package insert. The clinical relevance of this finding is unclear, especially because patients with primary hyperparathyroidism have marked elevation of serum PTH without a greater incidence of osteosarcoma. Nonetheless, teriparatide should not be used in patients who are at increased baseline risk for osteosarcoma (including those with Paget's disease of bone, unexplained elevations of alkaline phosphatase, open epiphyses, or prior radiation therapy involving the skeleton). The safety and efficacy of FORTEO have not been evaluated for extended use beyond 2 years of treatment and therapy should be limited to no more than 2 years. A tumor registry-based analysis of the occurrence of osteosarcoma in teriparatide-treated patients is ongoing; cases of osteosarcoma associated with the drug should be reported to the FDA. Increases in bone density acquired during therapy with teriparatide

can be maintained or extended with subsequent use of bisphosphonates (Black et al., 2005).

Full-length PTH(1–84) has been associated with osteosarcomas in rats (Jollette et al., 2006) although not in humans. The significance and interpretation of the toxicological findings has been questioned (Tashjian and Goltzman, 2008). However, adverse effects include exacerbation of nephrolithiasis and elevation of serum uric acid levels.

CALCIUM SENSOR MIMETICS: CINACALCET

Calcimimetics are drugs that mimic the stimulatory effect of calcium on the calcium-sensing receptor (CaSR) to inhibit PTH secretion by the parathyroid glands. By enhancing the sensitivity of the CaSR to extracellular Ca^{2+} , calcimimetics lower the concentration of Ca^{2+} at which PTH secretion is suppressed. Inorganic di- and trivalent cations, along with polycations such as spermine, aminoglycosides (e.g., streptomycin, gentamicin, and neomycin) and polybasic amino acids (e.g., polylysine) are full agonists and are referred to as type I calcimimetics. Phenylalkylamine derivatives that are allosteric CaSR modulators that require the presence of Ca^{2+} or other full agonists to enhance the sensitivity of activation without altering the maximal response are designated as type II calcimimetics. Cinacalcet (SENSIPAR) (Figure 44–12) is approved for the treatment of secondary hyperparathyroidism owing to chronic renal disease and for patients with hypercalcemia associated with parathyroid carcinoma. Cinacalcet lowers serum PTH levels in patients with normal or reduced renal function (Padhi and Harris, 2009).

In clinical trials, cinacalcet at 20- to 100-mg doses lowered PTH levels in a concentration-dependent manner by 15–50% and the serum calcium \times phosphate product by 7% compared with placebo (Franceschini et al., 2003). Cinacalcet also effectively reduced PTH levels in patients with primary hyperparathyroidism and provided sustained normalization of serum calcium without altering bone mineral density (Shoback et al., 2003). Long-term control of PTH levels was achieved during a 3-year study of cinacalcet, suggesting that resistance does not develop. There currently is insufficient information to know whether reducing serum PTH levels with

Figure 44–12. Structure of cinacalcet. Cinacalcet exists as optical isomers. The R-enantiomer, which is more active, is shown.

cinacalcet improves outcomes such as risk of cardiovascular events, bone disease, or mortality (Evenepoel, 2008).

Absorption, Fate, and Excretion. Cinacalcet (αR)-(-)- α -methyl-*N*-[3-[3-(trifluoromethyl)phenyl]propyl]-1-naphthalenemethanamine hydro-chloride) exhibits first-order absorption, with maximal serum concentrations achieved 2–6 hours after oral administration. Maximal effects, as defined by the nadir of serum PTH, occur 2–4 hours after administration. After absorption, plasma concentrations of cinacalcet decrease with a $t_{1/2}$ of 30–40 hours. Cinacalcet is eliminated primarily by renal excretion, with some 85% recovered in the urine after oral administration; the drug is also metabolized by multiple hepatic cytochromes, including CYPs 3A4, 2D6, and 1A2.

Cinacalcet is available in 30-, 60-, and 90-mg tablets. Optimal doses have not been defined. The recommended starting dose for treatment of secondary hyperparathyroidism in patients with chronic kidney disease on dialysis is 30 mg once daily, with a maximum of 180 mg/day. For treatment of parathyroid carcinoma, a starting dose of 30 mg twice daily is recommended, with a maximum of 90 mg four times daily. The starting dose is titrated upward every 2–4 weeks to maintain the PTH level between 150 and 300 pg/mL (secondary hyperparathyroidism) or to normalize serum calcium (parathyroid carcinoma).

Adverse Reactions. The principal adverse event with cinacalcet is hypocalcemia. Thus, the drug should not be used if the initial serum $[Ca^{2+}]$ is <8.4 mg/dL; serum calcium and phosphorus concentrations should be measured within 1 week, and PTH should be measured within 4 weeks after initiating therapy or after changing dosage.

Hypocalcemia can be diminished by initiating therapy with a low dose and gradually titrating it as necessary or adjusting the dose when vitamin D and/or phosphate binders are administered concomitantly. Patients on hemodialysis with low-calcium dialysate need to be monitored closely for hypocalcemia. Seizure threshold is lowered by significant reductions in serum Ca^{2+} , so patients with a history of seizure disorders should be monitored especially closely. Finally, adynamic bone disease may develop if the PTH level is <100 pg/mL, and the drug should be discontinued or the dose decreased if the PTH level falls below 150 pg/mL.

Drug Interactions. Potential drug interactions can be anticipated with drugs that interfere with calcium homeostasis or that hinder cinacalcet absorption. Based on these considerations, potentially interfering drugs may include vitamin D analogs, phosphate binders, bisphosphonates, calcitonin, glucocorticoids, gallium, and cisplatin. The other category of drug interactions is for compounds metabolized by CYPs. Caution is recommended when cinacalcet is co-administered with inhibitors of CYP3A4 (e.g., ketoconazole, erythromycin, or itraconazole), CYP2D6 (many β adrenergic receptor blockers, flecainide, vinblastine, and most tricyclic antidepressants), and many other drugs.

INTEGRATED APPROACH TO PREVENTION AND TREATMENT OF OSTEOPOROSIS

Osteoporosis is a major and growing public health problem in developed nations. Ten million Americans

are afflicted with osteoporosis, and an estimated 44 million individuals >50 years of age have low bone mass placing them at risk for osteoporosis. Osteoporosis is associated with a significant risk for bone fracture, especially of the hip, spine, and wrist. Approximately 50% women and 25% of men >50 years of age will experience an osteoporosis-related fracture. However, important reductions in fracture risk can be achieved with appropriate lifelong attention to prevention. Regular weight-bearing and muscle-strengthening exercise of reasonable intensity is endorsed at all ages. For children and adolescents, adequate dietary calcium and vitamin D are important if peak bone mass is to reach the level appropriate for genetic endowment. Attention to nutritional status (i.e., increased dietary calcium or calcium and/or vitamin D supplements) also may be required, particularly in elderly patients and those at risk of vitamin D deficiency. Smoking and excessive alcohol are significant risk factors and should be avoided. Although the administration of estrogen to women at menopause is a powerful intervention to preserve bone and protect against fracture, the detrimental effects of hormone-replacement therapy (HRT) have mandated a major reexamination on treatment options (see later and Chapter 40).

Pharmacological agents used to manage osteoporosis act by decreasing the rate of bone resorption and thereby slowing the rate of bone loss (antiresorptive therapy) or by promoting bone formation (anabolic therapy). Because bone remodeling is a coupled process, antiresorptive drugs ultimately decrease the rate of bone formation and therefore do not promote substantial gains in BMD. They nonetheless reduce fracture risk, particularly in the spine but also in the hip (for alendronate and risedronate). Increases in BMD during the first years of antiresorptive therapy represent a constriction of the remodeling space to a new steady-state level, after which BMD reaches a plateau (Figure 44–13). One consequence of this phenomenon is that therapeutic trials in osteoporosis must be of sufficient duration (i.e., at least 2 years) to determine whether an increase in BMD represents anything more than a simple reduction in remodeling space.

Pharmacological treatment of osteoporosis is aimed at restoring bone strength and preventing fractures. The long-standing centerpiece of this approach has been antiresorptive drugs such as the bisphosphonates, estrogen, or the selective estrogen receptor modulator (SERM) raloxifene, and, to some extent, calcitonin. These drugs inhibit osteoclast-mediated bone loss, thereby reducing bone turnover.

Figure 44-13. Relative efficacy of different therapeutic interventions on bone mineral density of the lumbar spine. Teriparatide (40 μ g) (Neer et al., 2001), PTH (25 μ g) + estradiol, alendronate (10 mg), estradiol (0.625 mg/day), raloxifene (120 mg), calcitonin (200 IU). Typical results with placebo treatment underscore the inexorable bone loss without intervention. Some of the indicated treatment interventions involved combination therapy, and absolute comparisons should not be made. For additional references, see legend to Figure 61-13 in the 11th edition of this text.

Until recently, antiresorptive drugs were the only agents approved in the U.S. for treating osteoporosis. The increase in bone density that they produce is variable and depends on the site and the particular drug; generally, the increase is <10% after 3 years (Figure 44-12). This situation changed in 2002 when the FDA approved the biologically active PTH fragment PTH(1-34) (teriparatide, FORTEO) for use in treating postmenopausal women with osteoporosis and to increase bone mass in men with primary or hypogonadal osteoporosis. For a review and proposed guidelines for teriparatide/PTH use, see Hodsman et al. (2005). This agent should be used only after consideration of the risks (potential cause of osteosarcoma) and benefits in patients refractory to bisphosphonates or at serious risk of fracture. Therapeutic approaches likely will evolve considerably as newer treatment paradigms are developed and combinations of antiresorptive agents and PTH are introduced, and as the molecular physiology of osteoblast and osteoclast function is elucidated (Grey et al., 2005).

Antiresorptive Agents. Bisphosphonates. Bisphosphonates are the most frequently used drugs for the prevention and treatment of osteoporosis. Second- and third-generation oral bisphosphonates alendronate and risendronate have sufficient potency to suppress bone resorption at doses that do not inhibit mineralization.

Alendronate (FOSAMAX), risendronate (ACTONEL), and ibandronate (BONIVA) are approved for prevention and treatment of osteoporosis and for the treatment of glucocorticoid-associated osteoporosis. Multiple appropriate formulations are available. Studies of daily treatment with alendronate established its efficacy to increase bone mineral density, decrease bone turnover, and reduce the risk of vertebral fracture among women with osteoporosis (Bone

et al., 2004; Liberman et al., 1995; Tonino et al., 2000; Tucci et al., 1996). Similar results were obtained with risendronate (Delmas et al., 2008). The results of 10-year daily treatment with 10 mg of alendronate (with 500 mg of supplemental calcium) reported a 14% increase of lumbar spine BMD, with smaller increments at the trochanter, total hip, and femoral neck (Bone et al., 2004). On reduction and discontinuation of treatment, BMD at the lumbar spine was maintained. Although significant decreases of BMD occurred at the total hip, femoral neck, and forearm, BMD at the lumbar spine, trochanter, total hip, and total body remained significantly above baseline values at year 10.

For patients in whom oral bisphosphonates cause severe esophageal distress despite countermeasures, intravenous zoledronate (RECLAST) or ibandronate offer skeletal protection without causing adverse GI effects. For treatment of osteoporosis, ibandronate (3 mg) is given intravenously every 3 months; zoledronate is administered as 5 mg once yearly. Zoledronate is the first bisphosphonate to be approved from once-yearly intravenous treatment of osteoporosis. Intravenous ibandronate significantly increased BMD of the lumbar spine. No fracture prevention data for intravenous ibandronate are available. Zoledronate reduces both vertebral and nonvertebral fractures (Black et al., 2007). Optimal duration of treatment and long-term safety remain to be established. A 4-mg formulation (ZOMETA) is available for intravenous treatment of hypercalcemia of malignancy, multiple myeloma, or bone metastasis resulting from solid tumors.

Denosumab. As described earlier, RANKL binds to its cognate receptor RANK on the surface of precursor and mature osteoclasts, and stimulates these cells to mature and resorb bone. OPG, which competes with RANK for binding to RANKL, is the physiological inhibitor of RANKL. Denosumab is an investigational human monoclonal antibody that binds with high affinity to RANKL, mimicking the effect of OPG, and thereby reducing the binding of RANKL to RANK. Denosumab blocks osteoclast formation and activation. It increases BMD and decreases bone turnover markers when given subcutaneously once every 6 months. Denosumab, administered subcutaneously at 60 mg doses every 6 months, resulted in 68%, 41%, and 20% reductions in vertebral, hip and nonvertebral fractures, respectively, in a phase III clinical trial (Cummings et al., 2008). In the 3-year Fracture Reduction Evaluation with Denosumab and Osteoporosis Every Six Months (FREEDOM) Trial, denosumab significantly reduced morphometric vertebral fractures, and decreased hip and nonvertebral fractures and changes in BMD and bone turnover markers (Cummings et al., 2008). This novel therapy may soon gain FDA approval.

Selective Estrogen Receptor Modulators (SERMs). Considerable work has been undertaken to develop estrogenic compounds with tissue-selective activities. One of these, raloxifene (EVISTA), acts as an estrogen agonist on bone and liver, is inactive on the uterus, and acts as an anti-estrogen on the breast (Chapter 40). In postmenopausal women, raloxifene stabilizes and modestly increases BMD and has been shown to reduce the risk of vertebral compression fracture (Ettinger et al., 1999). Raloxifene is approved for both the prevention and treatment of osteoporosis. With the decreased use of estrogen for treating osteoporosis, the SERM raloxifene would seem to be an ideal alternative to HRT because raloxifene reduces the risk of vertebral fractures (albeit without a positive effect on nonvertebral fractures), breast

cancer, and coronary events (coronary death, nonfatal myocardial infarction, and hospitalized acute coronary syndromes other than myocardial infarction) (Clemett and Spencer, 2000). The major drawback of raloxifene is that it can worsen vasomotor symptoms.

Estrogen. There is an unambiguous relationship between estrogen deficiency and osteoporosis. Postmenopausal status or estrogen deficiency at any age significantly increases a patient's risk for osteoporosis and fractures. Likewise, overwhelming evidence supports the positive impact of estrogen replacement on the conservation of bone and protection against osteoporotic fracture after menopause (Chapter 40). The outcome of the Women's Health Initiative (WHI) studies, however, strikingly altered the view of the therapeutic use of HRT for long-term prevention or treatment of osteoporosis. Significantly increased risks of heart disease and breast cancer were found (Anderson et al., 2004; Cauley et al., 2003). The consensus among experts now is to reserve HRT only for the short-term relief of vasomotor symptoms associated with menopause. HRT should be limited to osteoporosis prevention in women with significant ongoing vasomotor symptoms who are not at an increased risk for cardiovascular disease. An annual individualized risk-benefit reassessment should be performed on these patients.

Calcium. The physiological roles of Ca^{2+} and its use in the treatment of hypocalcemic disorders were discussed earlier. The rationale for using supplemental calcium to protect bone varies with time of life.

For preteens and adolescents, adequate substrate calcium is required for bone accretion. Controlled trials indicate that supplemental calcium promotes adolescent bone acquisition (Johnston et al., 1992), but its impact on peak bone mass is not known. Higher calcium intake during the third decade of life is positively related to the final phase of bone acquisition (Recker et al., 1992). There is controversy about the role of calcium during the early years after menopause, when the primary basis for bone loss is estrogen withdrawal. Although little effect of calcium on trabecular bone has been reported, reduction in cortical bone loss with calcium supplementation has been observed (Elders et al., 1994), even in populations with high dietary calcium intake. In elderly subjects, supplemental calcium suppresses bone turnover, improves BMD. Although some studies found a concomitant decrease in the incidence of fracture (Dawson-Hughes et al., 1997), three randomized trials found that it did not reduce fracture rate in older women (Jackson et al., 2006).

Patients who are unable or unwilling to increase calcium by dietary means alone may choose from many palatable, low-cost calcium preparations. As noted previously, numerous oral calcium preparations are available. The most frequently prescribed is carbonate, which should be taken with meals to facilitate dissolution and absorption. Traditional dosing of calcium is ~1000 mg/day, nearly the amount present in a quart of milk. Adults >50 years of age need 1200 mg of calcium daily. More may be necessary to overcome endogenous intestinal calcium losses, but daily intakes of ≥ 2000 mg frequently are reported to be constipating.

Vitamin D and Its Analogs. Modest supplementation with vitamin D (400-800 IU/day) may improve intestinal Ca^{2+} absorption, suppress bone remodeling, and improve BMD in individuals with marginal or deficient vitamin D status. A prospective study found that neither dietary calcium nor vitamin D intake was of major importance for the primary prevention of osteoporotic fractures in women (Michaelsson et al., 2003). However, supplemental vitamin D in

combination with calcium reduced fracture incidence in multiple trials (Jackson et al., 2006). Several meta-analyses reported reduction in the rate of fractures when vitamin D and calcium were taken together. Because women commonly consume less than the recommended intake of vitamin D, use of supplemental vitamin D or increased consumption of such vitamin D-rich foods as dark fish may be prudent.

The use of calcitriol to treat osteoporosis is distinct from ensuring vitamin D nutritional adequacy. Here, the rationale is to suppress parathyroid function directly and reduce bone turnover. Calcitriol and the polar vitamin D metabolite 1α -hydroxycholecalciferol are used frequently in Japan and other countries, but experience in the U.S. has been mixed. Higher doses of calcitriol appear to be more likely to improve BMD, but at the risk of hypercalciuria and hypercalcemia; therefore, close scrutiny of patients and dose modification are required. Restriction of dietary calcium may reduce toxicity during calcitriol therapy (Gallagher and Goldgar, 1990). A low incidence of hypercalciuric and hypercalcemic complications of therapy in Japan may reflect relatively poor calcium intakes in that country.

Calcitonin. Calcitonin inhibits osteoclastic bone resorption and modestly increases bone mass in patients with osteoporosis; the largest increases occurred in patients with high intrinsic rates of bone turnover. One study showed that calcitonin nasal spray (200 units/day) reduced the incidence of vertebral compression fractures by ~40% in osteoporotic women (Chesnut et al., 2000).

Thiazide Diuretics. Although not strictly antiresorptive, *thiazides* reduce urinary Ca^{2+} excretion and constrain bone loss in patients with hypercalciuria. Whether they will prove to be useful in patients who are not hypercalciuric is not clear, but data suggest that they reduce hip fracture risk. No sustained effect is observed (Schoofs et al., 2003). Hydrochlorothiazide, 25 mg once or twice daily, may reduce urinary Ca^{2+} excretion substantially. Effective doses of thiazides for reducing urinary Ca^{2+} excretion generally are lower than those necessary for blood pressure control. For a more detailed discussion of thiazide diuretics, see Chapter 25.

Anabolic Agents. Teriparatide. Teriparatide (FORTEO) is the only agent currently available that increases new bone formation. It is FDA-approved for treatment of osteoporosis for up to 2 years in both men and postmenopausal women at high risk for fractures. Teriparatide significantly decreased the incidence of vertebral (4-5% vs. 14%) and nonvertebral fractures (3% vs. 6%) compared to placebo in a prospective, randomized control study (FPT) (Neer et al., 2001). Teriparatide increases predominantly trabecular bone at the lumbar spine and femoral neck; it has less significant effects at cortical sites. Although initial studies showed dose-dependent actions, and side effects, because of concern (and black box label warning), teriparatide is approved at the 20 μg dose, administered once daily by subcutaneous injection in the thigh or abdominal wall. The most common adverse effects associated with teriparatide include injection-site pain, nausea, headaches, leg cramps, and dizziness.

Combination Therapies

Osteoporosis. Because teriparatide stimulates bone formation, whereas bisphosphonates reduce bone resorption, it was predicted that therapy combining the two would enhance the effect on BMD more than treatment with either one alone. However, addition of

alendronate to PTH treatment provided no additional benefit for BMD and reduced the anabolic effect of PTH in both women and men (Cosman, 2008). Sequential treatment with PTH(1-84) followed by alendronate increased vertebral BMD to a greater degree than alendronate or estrogen alone (Rittmaster et al., 2000). Recent work underscores the beneficial action of alendronate in consolidating the gains in lumbar spine BMD achieved by antecedent teriparatide treatment in men.

The fracture outcome 30 months after cessation of teriparatide therapy was studied in a cohort of patients included in the FPT. Approximately 50% of each group (teriparatide or control) were treated with a bisphosphonate for some period of time during the 30-month period. Patients treated with bisphosphonates after discontinuation of teriparatide showed continued increments in BMD, whereas those who received no treatment had declines (Prince et al., 2005).

Paget's Disease. Although most patients with Paget's disease require no treatment, factors such as severe pain, neural compression, progressive deformity, hypercalcemia, high-output congestive heart failure, and repeated fracture risk are considered indications for treatment. Bisphosphonates and calcitonin decrease the elevated biochemical markers of bone turnover, such as plasma alkaline phosphatase activity and urinary excretion of hydroxyproline. An initial course of bisphosphonate typically is given once daily or once weekly for 6 months. With treatment, most patients experience a decrease in bone pain over several weeks. Such treatment may induce long-lasting remission. If symptoms recur, additional courses of therapy can be effective. When etidronate is given at higher doses (10-20 mg/kg per day) or continuously for >6 months, there is a substantial risk for osteomalacia. At lower doses (5-7.5 mg/kg per day), focal osteomalacia has been observed occasionally. Defective mineralization has not been observed with other bisphosphonates or with calcitonin.

Choice of optimal therapy for Paget's disease varies among patients. Bisphosphonates are the standard therapy. Intravenous pamidronate induces long-term remission following a single infusion. Zoledronate seems to exhibit greater response rates and a longer median duration of complete response (Major et al., 2001). Compared with calcitonin, bisphosphonates have the advantage of oral administration, lower cost, lack of antigenicity, and generally fewer side effects. Resistance to calcitonin develops in most patients. However, calcitonin is highly reliable and may have a distinct skeletal analgesic property. Mithramycin (plicamycin) has been used in difficult cases of Paget's disease that do not respond to bisphosphonates or calcitonin. Therapeutic utility of this agent is limited by a high potential for hemorrhagic and other toxicities, and it is not generally recommended.

FLUORIDE

Fluoride is discussed because of its toxic properties and its effect on dentition and bone.

Absorption, Distribution, and Excretion. Human beings obtain fluoride predominantly from the ingestion of plants and water, with most absorption taking place in the intestine. The degree of fluoride absorption correlates with its water solubility. Relatively soluble compounds, such as sodium fluoride, are absorbed almost completely, whereas relatively insoluble compounds, such as cryolite

(Na_3AlF_6) and the fluoride found in bone meal (fluoroapatite) are absorbed poorly. A second route of absorption is through the lungs, and inhalation of fluoride present in dusts and gases constitutes the major route of industrial exposure.

Fluoride is distributed widely in organs and tissues but is concentrated in bone and teeth, and the skeletal burden is related to intake and age. Bone deposition reflects skeletal turnover; growing bone shows greater deposition than mature bone.

The kidneys are the major site of fluoride excretion. Small amounts of fluoride also appear in sweat, milk, and intestinal secretions; in a very hot environment, sweat can account for nearly 50% of total fluoride excretion.

Pharmacological Actions and Uses. Because it is concentrated in the bone, the radionuclide ^{18}F has been used in skeletal imaging. Sodium fluoride enhances osteoblast activity and increases bone volume. These effects may be bimodal, with low doses stimulating and higher doses suppressing osteoblasts; if true, this may account for the poorly mineralized and mechanically defective bone seen in some studies. In doses of 30-60 mg/day, fluoride increases trabecular bone mineral density in many, but not all, patients. In one controlled trial, fluoride increased lumbar spine density (cancellous bone) but decreased cortical bone mineral density; these changes were associated with a significant increase in peripheral fractures and stress fractures (Riggs et al., 1990). In one study, sustained-release fluoride, which provided lower blood fluoride levels, increased bone mineral density and decreased fractures (Pak et al., 1994). Intermittent courses of slow-release fluoride also have been evaluated. When the total fluoride dose was kept constant (Balena et al., 1998), there was no difference in outcome between continuous and intermittent fluoride treatment; notably, both regimens increased cancellous and trabecular thickness to the same extent. *Unfortunately, increased bone mass is not synonymous with increased bone strength* (Riggs et al., 1990). Thus, the apparent effects of fluoride in osteoporosis are slight compared with those achieved with PTH or other agents.

Other pharmacological actions of fluoride can be classified as toxic. Fluoride inhibits several enzyme systems and diminishes tissue respiration and anaerobic glycolysis.

Acute Poisoning. Acute fluoride poisoning usually results from accidental ingestion of fluoride-containing insecticides or rodenticides. Initial symptoms (salivation, nausea, abdominal pain, vomiting, and diarrhea) are secondary to the local action of fluoride on the intestinal mucosa. Systemic symptoms are varied and severe: increased irritability of the central nervous system consistent with the Ca^{2+} -binding effect of fluoride and the resulting hypocalcemia; hypotension, presumably owing to central vasomotor depression as well as direct cardiotoxicity; and stimulation and then depression of respiration. Death can result from respiratory paralysis or cardiac failure. The lethal dose of sodium fluoride for humans is ~5 g, although there is considerable variation. Treatment includes the intravenous administration of glucose in saline and gastric lavage with lime water (0.15% calcium hydroxide solution) or other Ca^{2+} salts to precipitate the fluoride. Calcium gluconate is given intravenously for tetany; urine volume is kept high with vigorous fluid resuscitation.

Chronic Poisoning. In humans, the major manifestations of chronic ingestion of excessive fluoride are osteosclerosis and mottled

enamel. Osteosclerosis is characterized by increased bone density secondary both to elevated osteoblastic activity and to the replacement of hydroxyapatite by the denser fluoroapatite. The degree of skeletal involvement varies from changes that are barely detectable radiologically to marked cortical thickening of long bones, numerous exostoses scattered throughout the skeleton, and calcification of ligaments, tendons, and muscle attachments. In its severest form, it is a disabling and crippling disease.

Mottled enamel, or dental fluorosis, was first described >60 years ago. In very mild mottling, small, opaque, paper-white areas are scattered irregularly over the tooth surface. In severe cases, discrete or confluent, deep brown- to black-stained pits give the tooth a corroded appearance. Mottled enamel results from a partial failure of the enamel-forming ameloblasts to elaborate and lay down enamel. Because mottled enamel is a developmental injury, fluoride ingestion following the eruption of teeth has no effect. Mottling is one of the first visible signs of excess fluoride intake during childhood. Continuous use of water containing ~1 ppm of fluoride may result in very mild mottling in 10% of children; at 4-6 ppm the incidence approaches 100%, with a marked increase in severity.

Severe dental fluorosis formerly occurred in regions where local water supplies had a very high fluoride content (e.g., Pompeii, Italy, and Pike's Peak, Colorado). Current regulations in the U.S. require lowering the fluoride content of the water supply or providing an alternative source of acceptable drinking water for affected communities. Sustained consumption of water with a fluoride content of 4 mg/L (4 ppm) is associated with deficits in cortical bone mass and increased rates of bone loss over time (Sowers et al., 1991).

Fluoride and Dental Caries. After a new water supply was established, children in Bauxite, Arkansas, had a much higher incidence of caries than those who had been exposed to the former fluoride-containing water. Subsequent studies established definitely that supplementation of water fluoride content to 1.0 ppm is a safe and practical intervention that substantially reduces the incidence of caries in permanent teeth.

There are partial benefits for children who begin drinking fluoridated water at any age; however, optimal benefits are obtained at ages before permanent teeth erupt. Topical application of fluoride solutions by dental personnel appears to be particularly effective on newly erupted teeth and can reduce the incidence of caries by 30-40%. Dietary fluoride supplements should be considered for children <12 years of age whose drinking water contains <0.7 ppm fluoride. Conflicting results have been reported from studies of fluoride-containing toothpastes.

Adequate incorporation of fluoride into teeth hardens the outer layers of enamel and increases resistance to demineralization. Fluoride deposition apparently involves exchange with hydroxyl or citrate anions in the enamel apatite crystal surface. The mechanism by which fluoride prevents caries is not completely understood. There is no convincing evidence that fluoride from any source reduces the development of caries after the permanent teeth are completely formed (usually ~14 years of age).

The fluoride salts usually employed in dentifrices are sodium fluoride and stannous fluoride. Sodium fluoride also is available in a variety of preparations for oral and topical use, including tablets, drops, rinses, and gels.

Since its inception, regulation of the fluoride concentration of community water supplies periodically has encountered vocal opposition, including allegations of putative adverse health consequences of fluoridated water. Careful examination of these issues indicates that cancer and all-cause mortalities do not differ significantly between communities with fluoridated and nonfluoridated water (Richmond, 1985).

CLINICAL SUMMARY

Increasing evidence supports the concept that regular physical activity, adequate calcium intake, and lifestyle changes have a positive impact on bone remodeling, constrain bone loss, and reduce fracture risk. Antiresorptive agents such as bisphosphonates, estrogen, selective estrogen response modulators (SERMs), and calcium slow bone resorption. Recombinant human PTH is available for the treatment of osteoporosis and provides significant intervention for restoring normal bone mass.

Cinacalcet, a drug that acts directly on the parathyroid calcium-sensing receptor, provides a novel approach to decreasing PTH secretion in secondary hyperparathyroidism and parathyroid carcinoma. Improved assays for measuring biologically active and inactive forms of PTH may facilitate the diagnosis and treatment of diseases associated with PTH resistance.

Estrogen-replacement therapy, once a mainstay treatment for osteoporosis in women, has been curtailed by the findings of the Women's Health Initiative: Despite estrogen's beneficial effects on bone and fracture risk, alone or in combination with *progestin*, estrogen promotes an array of serious adverse cardiovascular consequences. The FDA now recommends that estrogen be reserved for women at significant risk of osteoporosis who cannot take other medications.

Pharmacotherapy of Gastric Acidity, Peptic Ulcers, and Gastroesophageal Reflux Disease

John L. Wallace and
Keith A. Sharkey

The acid-peptic diseases are those disorders in which gastric acid and pepsin are necessary, but usually not sufficient, pathogenic factors. Although inherently causative, acid and pepsin in the stomach normally do not produce damage or symptoms because of intrinsic defense mechanisms. Barriers to the reflux of gastric contents into the esophagus comprise the primary esophageal defense. If these protective barriers fail and reflux occurs, dyspepsia and/or erosive esophagitis may result. Therapies are directed at decreasing gastric acidity, enhancing the lower esophageal sphincter, or stimulating esophageal motility (Chapter 46). The stomach is protected by a number of factors, collectively referred to as “mucosal defense,” many of which are stimulated by the local generation of prostaglandins and NO (Wallace, 2008). If these defenses are disrupted, a gastric or duodenal ulcer may form. The treatment and prevention of these acid-related disorders are accomplished by decreasing gastric acidity and enhancing mucosal defense. The appreciation that an infectious agent, *Helicobacter pylori*, plays a key role in the pathogenesis of acid-peptic diseases has stimulated new approaches to prevention and therapy.

PHYSIOLOGY OF GASTRIC SECRETION

Gastric acid secretion is a complex, continuous process in which multiple central and peripheral factors contribute to a common end point: the secretion of H^+ by parietal cells. Neuronal (acetylcholine, ACh), paracrine (histamine), and endocrine (gastrin) factors all regulate acid secretion (Figure 45–1). Their specific receptors (M_3 , H_2 , and CCK_2 , respectively) are on the basolateral membrane of parietal cells in the body and fundus of

the stomach. Some of these receptors are also present on enterochromaffin-like cells (ECL), where they regulate the release of histamine. The H_2 receptor is a GPCR (Chapters 3 and 32) that activates the G_s -adenylyl cyclase-cyclic AMP-PKA pathway. ACh and gastrin signal through GPCRs that couple to the G_q -PLC- IP_3 - Ca^{2+} pathway in parietal cells. In parietal cells, the cyclic AMP and the Ca^{2+} -dependent pathways activate H^+ , K^+ -ATPase (the proton pump), which exchanges hydrogen and potassium ions across the parietal cell membrane. This pump generates the largest ion gradient known in vertebrates, with an intracellular pH of ~ 7.3 and an intracanalicular pH of ~ 0.8 .

The most important structures for CNS stimulation of gastric acid secretion are the dorsal motor nucleus of the vagal nerve, the hypothalamus, and the solitary tract nucleus. Efferent fibers originating in the dorsal motor nuclei descend to the stomach via the vagus nerve and synapse with ganglion cells of the enteric nervous system. ACh release from postganglionic vagal fibers directly stimulates gastric acid secretion through muscarinic M_3 receptors on the basolateral membrane of parietal cells. The CNS predominantly modulates the activity of the enteric nervous system via ACh, stimulating gastric acid secretion in response to the sight, smell, taste, or anticipation of food (the “cephalic” phase of acid secretion). ACh also indirectly affects parietal cells by increasing the release of histamine from the ECL cells in the fundus of the stomach and of gastrin from G cells in the gastric antrum.

ECL cells, the source of gastric histamine, usually are in close proximity to parietal cells. Histamine acts as a paracrine mediator, diffusing from its site of release to nearby parietal cells, where it activates H_2 receptors. The critical role of histamine in gastric acid secretion is dramatically demonstrated by the efficacy of H_2 receptor antagonists in decreasing gastric acid secretion.

Gastrin, which is produced by antral G cells, is the most potent inducer of acid secretion. Multiple pathways stimulate gastrin release, including CNS activation, local distention, and chemical

Figure 45–1. Physiological and pharmacological regulation of gastric secretion: the basis for therapy of acid-peptic disorders. Shown are the interactions among an enterochromaffin-like (ECL) cell that secretes histamine, a ganglion cell of the enteric nervous system (ENS), a parietal cell that secretes acid, and a superficial epithelial cell that secretes mucus and bicarbonate. Physiological pathways, shown in solid black, may be stimulatory (+) or inhibitory (–). 1 and 3 indicate possible inputs from postganglionic cholinergic fibers; 2 shows neural input from the vagus nerve. Physiological agonists and their respective membrane receptors include acetylcholine (ACh), muscarinic (M), and nicotinic (N) receptors; gastrin, cholecystikinin receptor 2 (CCK₂); histamine (HIST), H₂ receptor; and prostaglandin E₂ (PGE₂), EP₃ receptor. A red — indicates targets of pharmacological antagonism. A light blue dashed arrow indicates a drug action that mimics or enhances a physiological pathway. Shown in red are drugs used to treat acid-peptic disorders. NSAIDs are nonsteroidal anti-inflammatory drugs, which can induce ulcers via inhibition of cyclooxygenase.

components of the gastric contents. Gastrin stimulates acid secretion indirectly by inducing the release of histamine by ECL cells; a direct effect on parietal cells also plays a lesser role.

Somatostatin (SST), which is produced by antral D cells, inhibits gastric acid secretion. Acidification of the gastric luminal pH to <3 stimulates SST release, which in turn suppresses gastrin release in a negative feedback loop. SST-producing cells are decreased in patients with *H. pylori* infection, and the consequent reduction of SST's inhibitory effect may contribute to excess gastrin production.

Gastric Defenses Against Acid. The extremely high concentration of H⁺ in the gastric lumen requires robust defense mechanisms to protect the esophagus and the stomach. The primary esophageal defense is the lower esophageal sphincter, which prevents reflux of acidic gastric contents into the esophagus. The stomach protects itself from acid damage by a number of mechanisms

that require adequate mucosal blood flow, perhaps because of the high metabolic activity and oxygen requirements of the gastric mucosa. One key defense is the secretion of a mucus layer that helps to protect gastric epithelial cells by trapping secreted bicarbonate at the cell surface. Gastric mucus is soluble when secreted but quickly forms an insoluble gel that coats the mucosal surface of the stomach, slows ion diffusion, and prevents mucosal damage by macromolecules such as pepsin. Mucus production is stimulated by prostaglandins E₂ and I₂, which also directly inhibit gastric acid secretion by parietal cells. Thus, drugs that inhibit prostaglandin formation (e.g., NSAIDs, ethanol) decrease mucus secretion and predispose to the development of acid-peptic disease.

Figure 45–1 outlines the rationale and pharmacological basis for the therapy of acid-peptic diseases. The proton pump inhibitors are used most commonly, followed by the histamine H₂ receptor antagonists.

PROTON PUMP INHIBITORS

Chemistry; Mechanism of Action; Pharmacology. The most potent suppressors of gastric acid secretion are inhibitors of the gastric H^+ , K^+ -ATPase (proton pump) (Figure 45–2). In typical doses, these drugs diminish the daily production of acid (basal and stimulated) by 80–95%. Six proton pump inhibitors are available for clinical use: omeprazole (PRILOSEC, others) and its S-isomer, esomeprazole (NEXIUM), lansoprazole (PREVACID) and its R-enantiomer, dexlansoprazole (KAPIDEX), rabeprazole (ACIPHEX), and pantoprazole (PROTONIX, others). These drugs have different substitutions on their pyridine and/or benzimidazole groups but are remarkably similar in their pharmacological properties (Appendix II). Omeprazole is a racemic mixture of R- and S-isomers; the S-isomer, esomeprazole (S-omeprazole), is eliminated less rapidly than R-omeprazole, which theoretically provides a therapeutic advantage because of the increased $t_{1/2}$. Despite claims to the contrary, all proton pump inhibitors have equivalent efficacy at comparable doses.

Proton pump inhibitors (PPIs) are prodrugs that require activation in an acid environment. After absorption

into the systemic circulation, the prodrug diffuses into the parietal cells of the stomach and accumulates in the acidic secretory canaliculi. Here, it is activated by proton-catalyzed formation of a tetracyclic sulfenamide (Figure 45–2), trapping the drug so that it cannot diffuse back across the canalicular membrane. The activated form then binds covalently with sulfhydryl groups of cysteines in the H^+ , K^+ -ATPase, irreversibly inactivating the pump molecule. Acid secretion resumes only after new pump molecules are synthesized and inserted into the luminal membrane, providing a prolonged (up to 24- to 48-hour) suppression of acid secretion, despite the much shorter plasma half-lives (0.5–2 hours) of the parent compounds. Because they block the final step in acid production, the proton pump inhibitors are effective in acid suppression regardless of other stimulating factors.

To prevent degradation of proton pump inhibitors by acid in the gastric lumen, oral dosage forms are supplied in different formulations:

- enteric-coated drugs contained inside gelatin capsules (omeprazole, dexlansoprazole, esomeprazole, and lansoprazole)

Figure 45–2. Proton pump inhibitors. **A.** Inhibitors of gastric H^+ , K^+ -ATPase (proton pump). **B.** Conversion of omeprazole to a sulfenamide in the acidic secretory canaliculi of the parietal cell. The sulfenamide interacts covalently with sulfhydryl groups in the proton pump, thereby irreversibly inhibiting its activity. The other three proton pump inhibitors undergo analogous conversions.

- enteric-coated granules supplied as a powder for suspension (lansoprazole)
- enteric-coated tablets (pantoprazole, rabeprazole, and omeprazole)
- powdered omeprazole combined with *sodium bicarbonate* (ZEGERID) contained in capsules and formulated for oral suspension

The delayed-release and enteric-coated tablets dissolve only at alkaline pH, whereas admixture of omeprazole with sodium bicarbonate simply neutralizes stomach acid; both strategies substantially improve the oral bioavailability of these acid-labile drugs. Until recently, the requirement for enteric coating posed a challenge to the administration of proton pump inhibitors in patients for whom the oral route of administration is not available (Freston et al., 2003). These patients and those requiring immediate acid suppression now can be treated parenterally with esomeprazole, pantoprazole, or lansoprazole, which are approved for intravenous administration in the U.S. A single intravenous bolus of 80 mg of pantoprazole inhibits acid production by 80-90% within an hour, and this inhibition persists for up to 21 hours, permitting once-daily dosing to achieve the desired degree of hypochlorhydria. The FDA-approved dose of intravenous pantoprazole for gastroesophageal reflux disease is 40 mg daily for up to 10 days. Higher doses (e.g., 160-240 mg in divided doses) are used to manage hypersecretory conditions such as the Zollinger-Ellison syndrome.

Pharmacokinetics. Because an acidic pH in the parietal cell acid canaliculi is required for drug activation and food stimulates acid production, these drugs ideally should be given ~30 minutes before meals. Concurrent administration of food may reduce somewhat the rate of absorption of proton pump inhibitors, but this effect is not thought to be clinically significant. Concomitant use of other drugs that inhibit acid secretion, such as H_2 receptor antagonists, might be predicted to lessen the effectiveness of the proton pump inhibitors, but the clinical relevance of this potential interaction is unknown.

Once in the small bowel, proton pump inhibitors are rapidly absorbed, highly protein bound, and extensively metabolized by hepatic CYPs, particularly CYP2C19 and CYP3A4. Several variants of CYP2C19 have been identified. Asians are more likely than whites or African Americans to have the CYP2C19 genotype that correlates with slow metabolism of proton pump inhibitors (23% vs. 3%, respectively), which has been suggested to contribute to heightened efficacy and/or toxicity in this ethnic group (Dickson and Stuart, 2003). Although the CYP2C19 genotype is correlated with the magnitude of gastric acid suppression by proton pump inhibitors in patients with gastroesophageal reflux disease, there is no evidence that the CYP2C19 genotype predicts clinical efficacy of these drugs (Chong and Ensom, 2003).

Because not all pumps or all parietal cells are active simultaneously, maximal suppression of acid secretion requires several doses of the proton pump inhibitors. For example, it may take 2-5 days of therapy with once-daily dosing to achieve the 70% inhibition of proton pumps that is seen at steady state (Wang and Hunt, 2008). More frequent initial dosing (e.g., twice daily) will reduce the time to achieve full inhibition but is not proven to improve patient outcome. Because the proton pump inhibition is irreversible, acid secretion will be suppressed for 24-48 hours, or more, until new proton pumps are synthesized and incorporated into the luminal membrane of parietal cells.

Chronic renal failure does not lead to drug accumulation with once-a-day dosing of the proton pump inhibitors. Hepatic disease substantially reduces the clearance of esomeprazole and lansoprazole. Thus, in patients with severe hepatic disease, dose reduction is recommended for esomeprazole and should be considered for lansoprazole.

Adverse Effects and Drug Interactions. Proton pump inhibitors generally cause remarkably few adverse effects. The most common side effects are nausea, abdominal pain, constipation, flatulence, and diarrhea. Subacute myopathy, arthralgias, headaches, and skin rashes also have been reported. As noted earlier, proton pump inhibitors are metabolized by hepatic CYPs and therefore may interfere with the elimination of other drugs cleared by this route. Proton pump inhibitors have been observed to interact with warfarin (esomeprazole, lansoprazole, omeprazole, and rabeprazole), diazepam (esomeprazole and omeprazole), and cyclosporine (omeprazole and rabeprazole). Among the proton pump inhibitors, only omeprazole inhibits CYP2C19 (thereby decreasing the clearance of disulfiram, phenytoin, and other drugs) and induces the expression of CYP1A2 (thereby increasing the clearance of imipramine, several antipsychotic drugs, tacrine, and theophylline). There is emerging evidence that omeprazole can interact adversely with the anticlotting agent, clopidogrel, at the level of CYP2C19, for which both are substrates; thus, omeprazole can inhibit conversion of clopidogrel to the active anticoagulating form. Pantoprazole is less likely to result in this interaction (Ferreiro and Angiolillo, 2009; Norgard et al., 2009); concurrent use of clopidogrel and PPIs (mainly pantoprazole) significantly reduced GI bleeding without increasing adverse cardiac events (Ray et al., 2010). For the pharmacological issues involved in the concurrent use of dual antiplatelet therapy and proton pump inhibitors, see Chapter 30, "Regulation of Blood Coagulation."

Chronic treatment with omeprazole decreases the absorption of vitamin B_{12} , but the clinical relevance of this effect is not clear. Loss of gastric acidity also may affect the bioavailability of such drugs as ketoconazole, ampicillin esters, and iron salts. Chronic use of proton pump inhibitors has been reported to be associated with an increased risk of bone fracture and with increased susceptibility to certain infections (e.g., hospital-acquired pneumonia, community-acquired *Clostridium difficile*) (Coté and Howden, 2008). Hypergastrinemia is more frequent and more severe with proton pump inhibitors than with H_2 receptor antagonists, and gastrin levels of >500 ng/L occur in ~5-10% of users with chronic omeprazole administration. This hypergastrinemia may predispose to rebound hypersecretion of gastric acid upon discontinuation of therapy and also may promote the growth of gastrointestinal (GI) tumors. In rats, long-term administration of proton pump inhibitors causes hyperplasia of enterochromaffin-like cells and the development of gastric carcinoid tumors. Although the gastrin levels observed in rats are ~10-fold higher than those seen in human beings, this finding has raised concerns about the possibility of similar complications of proton pump inhibitors in humans, for which there is no unequivocal evidence.

Therapeutic Uses. Prescription proton pump inhibitors are used to promote healing of gastric and duodenal ulcers and to treat gastroesophageal reflux disease (GERD), including erosive esophagitis, which is either complicated or unresponsive to treatment with H_2 receptor antagonists. Over-the-counter omeprazole is approved for the self-treatment of heartburn. Proton pump inhibitors also are the

mainstay in the treatment of pathological hypersecretory conditions, including the Zollinger-Ellison syndrome. Lansoprazole and esomeprazole are FDA approved for treatment and prevention of recurrence of nonsteroidal anti-inflammatory drug (NSAID)-associated gastric ulcers in patients who continue NSAID use. It is not clear if proton pump inhibitors affect the susceptibility to NSAID-induced damage and bleeding in the small and large intestine. In addition, all proton pump inhibitors are approved for reducing the risk of duodenal ulcer recurrence associated with *H. pylori* infections. Therapeutic applications of proton pump inhibitors are further discussed later under “Specific Acid-Peptic Disorders and Therapeutic Strategies.”

Use in Children. In children, omeprazole is safe and effective for treatment of erosive esophagitis and GERD. Younger patients generally have increased metabolic capacity, which may explain the need for higher dosages of omeprazole per kilogram in children compared with adults.

H₂ RECEPTOR ANTAGONISTS

The description of selective histamine H₂ receptor blockade was a landmark in the treatment of acid-peptic disease (Black, 1993). Before the availability of the H₂ receptor antagonists, the standard of care was simply acid neutralization in the stomach lumen, generally with inadequate results. The long history of safety and efficacy with the H₂ receptor antagonists eventually led to their availability without a prescription. Increasingly, however, proton pump inhibitors are replacing the H₂ receptor antagonists in clinical practice.

Chemistry; Mechanism of Action; Pharmacology. The H₂ receptor antagonists inhibit acid production by reversibly competing with histamine for binding to H₂ receptors on the basolateral membrane of parietal cells. Four different H₂ receptor antagonists, which differ mainly in their pharmacokinetics (Appendix II) and propensity to cause drug interactions, are available in the U.S. (Figure 45-3): cimetidine (TAGAMET, others), ranitidine (ZANTAC, others), famotidine (PEPCID, others), and nizatidine (AXID, others). These drugs are less potent than proton pump inhibitors but still suppress 24-hour gastric acid secretion by ~70%. The H₂ receptor antagonists predominantly inhibit basal acid secretion, which accounts for their efficacy in suppressing nocturnal acid secretion. Because the most important determinant of duodenal ulcer healing is the level of nocturnal acidity, evening dosing of H₂-receptor antagonists is adequate therapy in most instances. Ranitidine and nizatidine also may stimulate GI motility, but the clinical importance of this effect is unknown.

Figure 45-3. Histamine and H₂ receptor antagonists.

All four H₂ receptor antagonists are available as prescription and over-the-counter formulations for oral administration. Intravenous and intramuscular preparations of cimetidine, ranitidine, and famotidine also are available. When the oral or nasogastric routes are not an option, these drugs can be given in intermittent intravenous boluses or by continuous intravenous infusion (Table 45-1). The latter provides better control of gastric pH but is not proven to be more effective in preventing significant bleeding in critically ill patients.

Pharmacokinetics. The H₂ receptor antagonists are rapidly absorbed after oral administration, with peak serum concentrations

Table 45-1

Intravenous Doses of H₂ Receptor Antagonists

	CIMETIDINE	RANITIDINE	FAMOTIDINE
Intermittent bolus	300 mg every 6-8 hours	50 mg every 6-8 hours	20 mg every 12 hours
Continuous infusion	37.5-100 mg/hour	6.25-12.5 mg/hour	1.7-2.1 mg/hour

within 1-3 hours. Absorption may be enhanced by food or decreased by antacids, but these effects probably are unimportant clinically. Therapeutic levels are achieved rapidly after intravenous dosing and are maintained for 4-5 hours (cimetidine), 6-8 hours (ranitidine), or 10-12 hours (famotidine). Unlike proton pump inhibitors, only a small percentage of H₂ receptor antagonists are protein bound. Small amounts (from <10% to ~35%) of these drugs undergo metabolism in the liver, but liver disease *per se* is not an indication for dose adjustment. The kidneys excrete these drugs and their metabolites by filtration and renal tubular secretion, and it is important to reduce doses of H₂ receptor antagonists in patients with decreased creatinine clearance. Neither hemodialysis nor peritoneal dialysis clears significant amounts of the drugs.

Adverse Reactions and Drug Interactions. Like the proton pump inhibitors, the H₂ receptor antagonists generally are well tolerated, with a low (<3%) incidence of adverse effects. Side effects usually are minor and include diarrhea, headache, drowsiness, fatigue, muscular pain, and constipation. Less common side effects include those affecting the CNS (confusion, delirium, hallucinations, slurred speech, and headaches), which occur primarily with intravenous administration of the drugs or in elderly subjects. Long-term use of cimetidine at high doses—seldom used clinically today—decreases testosterone binding to the androgen receptor and inhibits a CYP that hydroxylates estradiol. Clinically, these effects can cause galactorrhea in women and gynecomastia, reduced sperm count, and impotence in men. Several reports have associated H₂ receptor antagonists with various blood dyscrasias, including thrombocytopenia. H₂ receptor antagonists cross the placenta and are excreted in breast milk. Although no major teratogenic risk has been associated with these agents, caution nevertheless is warranted when they are used in pregnancy.

All agents that inhibit gastric acid secretion may alter the rate of absorption and subsequent bioavailability of the H₂ receptor antagonists (see “Antacids” section). Drug interactions with H₂ receptor antagonists occur mainly with cimetidine, and its use has decreased markedly. Cimetidine inhibits CYPs (e.g., CYP1A2, CYP2C9, and CYP2D6), and thereby can increase the levels of a variety of drugs that are substrates for these enzymes. Ranitidine also interacts with hepatic CYPs, but with an affinity of only 10% of that of cimetidine; thus, ranitidine interferes only minimally with hepatic metabolism of other drugs. Famotidine and nizatidine are even safer in this regard, with no significant drug interactions mediated by inhibiting hepatic CYPs. Slight increases in blood-alcohol concentration may result from concomitant use of H₂ receptor antagonists, but this is unlikely to be clinically significant.

Therapeutic Uses. The major therapeutic indications for H₂-receptor antagonists are to promote healing of gastric and duodenal ulcers, to treat uncomplicated GERD, and to prevent the occurrence of stress ulcers. More information about the therapeutic applications of H₂ receptor antagonists is provided in the section “Specific Acid-Peptic Disorders and Therapeutic Strategies.”

TOLERANCE AND REBOUND WITH ACID-SUPPRESSING MEDICATIONS

Tolerance to the acid-suppressing effects of H₂ receptor antagonists is well described and may account for a

diminished therapeutic effect with continued drug administration (Sandevik et al., 1997). Tolerance can develop within 3 days of starting treatment and may be resistant to increased doses of the medications. Diminished sensitivity to these drugs may result from the effect of the secondary hypergastrinemia to stimulate histamine release from ECL cells. Proton pump inhibitors, despite even greater elevations of endogenous gastrin, do not cause this phenomenon, probably because their site of action is distal to the action of histamine on acid release. However, rebound increases in gastric acidity can occur when either of these drug classes is discontinued, possibly reflecting changes in function and justifying a gradual drug taper or the substitution of alternatives (e.g., antacids) in at-risk patients.

AGENTS THAT ENHANCE MUCOSAL DEFENSE

Prostaglandin Analogs: Misoprostol

Chemistry; Mechanism of Action; Pharmacology. Prostaglandin E₂ (PGE₂) and prostacyclin (PGI₂) are the major prostaglandins synthesized by the gastric mucosa. Contrary to their cyclic AMP-elevating effects on many cells via EP₂ and EP₄ receptors, these prostanoids bind to the EP₃ receptor on parietal cells (Chapters 33 and 34) and stimulate the G_i pathway, thereby decreasing intracellular cyclic AMP and gastric acid secretion. PGE₂ also can prevent gastric injury by cytoprotective effects that include stimulation of mucin and bicarbonate secretion and increased mucosal blood flow. Although smaller doses than those required for acid suppression can protect the gastric mucosa in laboratory animals, this has not been convincingly demonstrated in humans; acid suppression appears to be the most important effect clinically (Wolfe and Sachs, 2000).

Because NSAIDs diminish prostaglandin formation by inhibiting cyclooxygenase, synthetic prostaglandin analogs offer a logical approach to reducing NSAID-induced mucosal damage. Misoprostol (15-deoxy-16-hydroxy-16-methyl-PGE₁; CYTOTEC, others) is a synthetic analog of PGE₁. Structural modifications include an additional methyl ester group at C1 that increases potency and duration of antisecretory effect, and transfer of a hydroxyl group from C15 to C16 and addition of a methyl group that increases oral bioactivity, duration of antisecretory action, and safety. The degree of inhibition of gastric acid secretion by misoprostol is directly related to dose; oral doses of 100-200 µg significantly inhibit basal acid secretion (up to 85-95% inhibition) or food-stimulated acid secretion (up to 75-85% inhibition). The usual recommended dose for ulcer prophylaxis is 200 µg four times a day.

Pharmacokinetics. Misoprostol is rapidly absorbed after oral administration and then is rapidly and extensively de-esterified to form misoprostol acid, the principal and active metabolite of the drug. Some of this conversion may occur in the parietal cells. A single dose inhibits acid production within 30 minutes; the therapeutic effect peaks at 60-90 minutes and lasts for up to 3 hours. Food and antacids decrease the rate of misoprostol absorption, resulting in delayed and decreased peak plasma concentrations of the active metabolite. The free acid is excreted mainly in the urine, with an elimination $t_{1/2}$ of 20-40 minutes.

Adverse Effects. Diarrhea, with or without abdominal pain and cramps, occurs in up to 30% of patients who take misoprostol. Apparently dose related, it typically begins within the first 2 weeks after therapy is initiated and often resolves spontaneously within a week; more severe or protracted cases may necessitate drug discontinuation. *Misoprostol can cause clinical exacerbations of inflammatory bowel disease* (Chapter 47) and should be avoided in patients with this disorder. *Misoprostol is contraindicated during pregnancy* because it can increase uterine contractility.

Therapeutic Use. Misoprostol is FDA-approved to prevent NSAID-induced mucosal injury. However, it rarely is used because of its adverse effects and the inconvenience of four-times-daily dosing.

SUCRALFATE

Chemistry; Mechanism of Action; Pharmacology. In the presence of acid-induced damage, pepsin-mediated hydrolysis of mucosal proteins contributes to mucosal erosion and ulcerations. This process can be inhibited by sulfated polysaccharides. Sucralfate (CARAFATE, others) consists of the octasulfate of sucrose to which $\text{Al}(\text{OH})_3$ has been added. In an acid environment ($\text{pH} < 4$), sucralfate undergoes extensive cross-linking to produce a viscous, sticky polymer that adheres to epithelial cells and ulcer craters for up to 6 hours after a single dose. In addition to inhibiting hydrolysis of mucosal proteins by pepsin, sucralfate may have additional cytoprotective effects, including stimulation of local production of prostaglandins and epidermal growth factor. Sucralfate also binds bile salts; thus some clinicians use sucralfate to treat individuals with the syndromes of biliary esophagitis or gastritis (the existence of which is controversial).

Therapeutic Uses. The use of sucralfate to treat peptic acid disease has diminished in recent years. Nevertheless, because increased gastric pH may be a factor in the development of nosocomial pneumonia in critically ill patients, sucralfate may offer an advantage over proton pump inhibitors and H_2 receptor antagonists for the prophylaxis of stress ulcers. Due to its unique mechanism of action, sucralfate also has been used in several other conditions associated with mucosal inflammation/ulceration that may not respond to acid suppression, including oral mucositis (radiation and aphthous ulcers) and bile reflux gastropathy. Administered by rectal enema, sucralfate also has been used for radiation proctitis and solitary rectal ulcers.

Because it is activated by acid, sucralfate should be taken on an empty stomach 1 hour before meals. The use of antacids within 30 minutes of a dose of sucralfate should be avoided. The usual dose of sucralfate is 1 g four times daily (for active duodenal ulcer) or 1 g twice daily (for maintenance therapy).

Adverse Effects. The most common side effect of sucralfate is constipation (~2%). Because some aluminum can be absorbed, sucralfate should be avoided in patients with renal failure who are at risk for aluminum overload. Likewise, aluminum-containing antacids should not be combined with sucralfate in these patients. Sucralfate forms a viscous layer in the stomach that may inhibit absorption of other drugs, including phenytoin, digoxin, cimetidine, ketoconazole, and fluoroquinolone antibiotics. Sucralfate therefore should be taken at least 2 hours after the administration of other drugs. The “sticky” nature of the viscous gel produced by sucralfate in the stomach also may be responsible for the development of bezoars in some patients, particularly in those with underlying gastroparesis.

ANTACIDS

Although hallowed by tradition, the antacids largely have been replaced by more effective and convenient drugs. Nevertheless, they continue to be used by patients for a variety of indications, and some knowledge of their pharmacology is important for the medical professional (Table 45-2 compares some commonly used antacid preparations).

Many factors, including palatability, determine the effectiveness and choice of antacid. Although sodium bicarbonate effectively neutralizes acid, it is very water soluble and rapidly absorbed from the stomach, and the alkali and sodium loads may pose a risk for patients with cardiac or renal failure. Depending on particle size and crystal structure, CaCO_3 rapidly and effectively neutralizes gastric H^+ , but the release of CO_2 from bicarbonate- and carbonate-containing antacids can cause belching, nausea, abdominal distention, and flatulence. Calcium also may induce rebound acid secretion, necessitating more frequent administration.

Combinations of Mg^{2+} (rapidly reacting) and Al^{3+} (slowly reacting) hydroxides provide a relatively balanced and sustained neutralizing capacity and are preferred by most experts. Magaldrate is a hydroxymagnesium aluminate complex that is converted rapidly in gastric acid to $\text{Mg}(\text{OH})_2$ and $\text{Al}(\text{OH})_3$, which are absorbed poorly and thus provide a sustained antacid effect. Although fixed combinations of magnesium and aluminum theoretically counteract the adverse effects of each other on the bowel (Al^{3+} can relax gastric smooth muscle, producing delayed gastric emptying and constipation; Mg^{2+} exerts the opposite effects), such balance is not always achieved in practice.

Simethicone, a surfactant that may decrease foaming and hence esophageal reflux, is included in many antacid preparations. However, other fixed combinations, particularly those with aspirin, that are marketed for “acid indigestion” are irrational choices, are potentially unsafe in patients predisposed to gastroduodenal ulcers, and should not be used.

Table 45–2

Composition and Acid Neutralizing Capacities of Popular Antacid Preparations

PRODUCT	Al(OH) ₃ ^a	Mg(OH) ₂ ^a	CaCO ₃ ^a	SIMETHICONE ^a	ACID NEUTRALIZING CAPACITY ^b

^aContents, milligrams per tablet or per 5 ml.

^bAcid neutralizing capacity, milliequivalents per tablet or per 5 ml.

The U.S. marketplace for antacids is fluid. The current trend of “reusing” well-known brand names to introduce new products that contain an active ingredient different from expected is a source of confusion that can present a danger to patients. Medication safety experts encourage clinical practitioners to refer to the active ingredient(s) in conjunction with the proprietary (brand) name when selecting OTC products.

The relative effectiveness of antacid preparations is expressed as milliequivalents of acid-neutralizing capacity (defined as the quantity of 1N HCl, expressed in milliequivalents, that can be brought to pH 3.5 within 15 minutes); according to FDA requirements, antacids must have a neutralizing capacity of at least 5 mEq per dose. Due to discrepancies between *in vitro* and *in vivo* neutralizing capacities, antacid doses in practice are titrated simply to relieve symptoms. For uncomplicated ulcers, antacids are given orally 1 and 3 hours after meals and at bedtime. This regimen, providing ~120 mEq of a Mg-Al combination per dose, may be almost as effective as conventional dosing with an H₂ receptor antagonist. For severe symptoms or uncontrolled reflux, antacids can be given as often as every 30–60 minutes. In general, antacids should be administered in suspension form because this probably has a greater neutralizing capacity than powder or tablet dosage forms. If tablets are used, they should be thoroughly chewed for maximum effect.

Antacids are cleared from the empty stomach in ~30 minutes. However, the presence of food is sufficient to elevate gastric pH to ~5 for ~1 hour and to prolong the neutralizing effects of antacids for ~2–3 hours.

Antacids vary in the extent to which they are absorbed, and hence in their systemic effects. In general, most antacids can elevate urinary pH by ~1 pH unit. Antacids that contain Al³⁺, Ca²⁺, or Mg²⁺ are absorbed less completely than are those that contain NaHCO₃. With normal renal function, the modest accumulations of Al³⁺ and Mg²⁺ do not pose a problem; with renal insufficiency, however, absorbed Al³⁺ can contribute to osteoporosis, encephalopathy, and proximal myopathy. About 15% of orally administered Ca²⁺ is absorbed, causing a transient hypercalcemia. Although this is not a problem in normal patients, the hypercalcemia from as little as 3–4 g of CaCO₃ per day can be problematic in patients with uremia. In the

past, when large doses of NaHCO₃ and CaCO₃ were administered commonly with milk or cream for the management of peptic ulcer, the *milk-alkali syndrome* (alkalosis, hypercalcemia, and renal insufficiency) occurred frequently. Today, this syndrome is rare and generally results from the chronic ingestion of large quantities of Ca²⁺ (five to forty 500-mg tablets per day of calcium carbonate) taken with milk. Patients may be asymptomatic or may present with the insidious onset of hypercalcemia, reduced secretion of parathyroid hormone, retention of phosphate, precipitation of Ca²⁺ salts in the kidney, and renal insufficiency.

By altering gastric and urinary pH, antacids may affect a number of drugs (e.g., thyroid hormones, allopurinol, and imidazole antifungals, by altering rates of dissolution and absorption, bioavailability, and renal elimination). Al³⁺ and Mg²⁺ antacids also are notable for their propensity to chelate other drugs present in the GI tract, forming insoluble complexes that pass through the GI tract without absorption. Thus it generally is prudent to avoid concurrent administration of antacids and drugs intended for systemic absorption. Most interactions can be avoided by taking antacids 2 hours before or after ingestion of other drugs.

Other Acid Suppressants and Cytoprotectants

The M₁ muscarinic receptor antagonists pirenzepine and telenzepine (Chapter 9) can reduce basal acid production by 40–50% and long have been used to treat patients with peptic ulcer disease in countries other than the U.S. The ACh receptor on the parietal cell itself is of the M₃ subtype, and these drugs are believed to suppress neural stimulation of acid production via actions on M₁ receptors of intramural ganglia (Figure 45–1). Because of their relatively poor efficacy, significant and undesirable anticholinergic side effects, and risk of blood disorders (pirenzepine), they rarely are used today.

In the hope of providing more rapid onset of action and sustained acid suppression, reversible inhibitors of the gastric H^+ , K^+ -ATPase (e.g., the pyrrolopyridazine derivative AKU517) are being developed for clinical use. Antagonists of the CCK2 gastrin receptor on parietal cells also are under study. The precise role that these agents will play in the therapy of acid-peptic disorders in the future is yet to be determined.

Rebamipide (2-(4-chlorobenzoylamino)-3-[2(1H)-quinolinon-4-yl]-propionic acid) is used for ulcer therapy in parts of Asia. It appears to exert a cytoprotective effect both by increasing prostaglandin generation in gastric mucosa and by scavenging reactive oxygen species. Ecabet (GASTROM; 12-sulfodehydroabietic acid monosodium), which appears to increase the formation of PGE_2 and PGI_2 , also is used for ulcer therapy, mostly in Japan. Carbenoxolone, a derivative of glycyrrhizic acid found in licorice root, has been used with modest success for ulcer therapy in Europe. Its exact mechanism of action is not clear, but it may alter the composition and quantity of mucin. Unfortunately, carbenoxolone inhibits the type I isozyme of 11β -hydroxysteroid dehydrogenase, which protects the mineralocorticoid receptor from activation by cortisol in the distal nephron; it therefore causes hypokalemia and hypertension due to excessive mineralocorticoid receptor activation (Chapter 42). Bismuth compounds (Chapter 46) may be as effective as cimetidine in patients with peptic ulcers and are frequently prescribed in combination with antibiotics to eradicate *H. pylori* and prevent ulcer recurrence. Bismuth compounds bind to the base of the ulcer, promote mucin and bicarbonate production, and have significant antibacterial effects. Bismuth compounds are an important component of many anti-*Helicobacter* regimens; however, given the availability of more effective drugs, bismuth compounds seldom are used alone as cytoprotective agents.

SPECIFIC ACID-PEPTIC DISORDERS AND THERAPEUTIC STRATEGIES

The success of acid-suppressing agents in a variety of conditions is critically dependent on their ability to keep intragastric pH above a certain target, generally pH 3–5; this target varies to some extent with the disease being treated (Figure 45–4).

Gastroesophageal Reflux Disease

In the U.S., it is estimated that one in five adults has symptoms of heartburn or gastroesophageal regurgitation at least once a week. Although most cases follow a relatively benign course, these symptoms, often referred to as “gastroesophageal reflux disease” (GERD), can be associated with severe erosive esophagitis; stricture formation and Barrett’s metaplasia (replacement of squamous by intestinal columnar epithelium), in turn, is associated with a small but significant risk of adenocarcinoma. Most of the symptoms of GERD reflect injurious effects of the refluxed acid-peptic content on the esophageal epithelium, providing

Figure 45–4. Comparative success of therapy with proton pump inhibitors and H_2 receptor antagonists. Data show the effects of a proton pump inhibitor (given once daily) and an H_2 receptor antagonist (given twice daily) in elevating gastric pH to the target ranges (i.e., pH 3 for duodenal ulcer, pH 4 for GERD, and pH 5 for antibiotic eradication of *H. pylori*).

the rationale for suppression of gastric acid. The goals of GERD therapy are complete resolution of symptoms and healing of esophagitis. Proton pump inhibitors clearly are more effective than H_2 receptor antagonists in achieving these goals. Healing rates after 4 weeks and 8 weeks of therapy with proton pump inhibitors are ~80% and 90%, respectively; the corresponding healing rates with H_2 receptor antagonists are 50% and 75%, respectively. Indeed, proton pump inhibitors are so effective that their empirical use is advocated as a therapeutic trial in patients in whom GERD is suspected to play a role in the pathogenesis of symptoms.

Because of the wide clinical spectrum associated with GERD, the therapeutic approach is best tailored to the level of severity in the individual patient (Figure 45–5). In general, the optimal dose for each patient is determined based on symptom control, and routine measurement of esophageal pH to guide dosing is not recommended. Strictures associated with GERD also respond better to proton pump inhibitors than to H_2 receptor antagonists; indeed, the use of proton pump inhibitors reduces the requirement for esophageal dilation. Unfortunately, one of the other complications of GERD, Barrett’s esophagus, appears to be more refractory to therapy because neither acid suppression nor antireflux surgery has been shown convincingly to produce regression of metaplasia or to decrease the incidence of tumors.

Regimens for the treatment of GERD with proton pump inhibitors and histamine H_2 receptor antagonists are listed in Table 45–3. Although some patients with mild GERD symptoms may be managed by nocturnal doses of H_2 receptor antagonists,

Severity of GERD

Stage I
Sporadic uncomplicated heartburn, often in setting of known precipitating factor. Often not the chief complaint. Less than 2-3 episodes per week. No additional symptoms.

Medical Management

Lifestyle modification, including diet, positional changes, weight loss, *etc.* Antacids and/or histamine H₂ receptor antagonists as needed.

Stage II
Frequent symptoms, with or without esophagitis. Greater than 2-3 episodes per week.

Proton pump inhibitors more effective than histamine H₂ receptor antagonists.

Stage III
Chronic, unrelenting symptoms; immediate relapse off therapy. Esophageal complications (*e.g.*, stricture, Barrett's metaplasia).

Proton pump inhibitor either once or twice daily.

Figure 45–5. General guidelines for the medical management of gastroesophageal reflux disease (GERD). Only medications that suppress acid production or that neutralize acid are shown. (Adapted from Wolfe and Sachs, 2000, with permission from Elsevier. Copyright © Elsevier.)

twice-daily dosing usually is required. Antacids are recommended only for the patient with mild, infrequent episodes of heartburn. In general, prokinetic agents (Chapter 46) are not particularly useful for GERD, either alone or in combination with acid-suppressant medications.

GERD is a chronic disorder that requires long-term therapy. Some experts advocate “stepdown” approaches that attempt to maintain symptomatic remission by either decreasing the dose of the

proton pump inhibitor or switching to an H₂ receptor antagonist. Other experts have advocated intermittent, “on-demand” therapy with proton pump inhibitors for symptomatic relief in patients who have responded initially but continue to have symptoms. However, many patients will maintain their requirement for proton pump inhibitors, and several studies suggest that these drugs are better than H₂ receptor antagonists for maintaining remission in GERD.

Severe Symptoms and Nocturnal Acid Breakthrough. In patients with severe symptoms or extraintestinal manifestations of GERD, twice-daily dosing with a proton pump inhibitor may be needed. However, it is difficult if not impossible to render patients achlorhydric—even on twice-daily doses of proton pump inhibitors—and two-thirds or more of subjects will continue to make acid, particularly at night. This phenomenon, called *nocturnal acid breakthrough*, has been invoked as a cause of refractory symptoms in some patients with GERD. However, decreases in gastric pH at night while on therapy generally are not associated with acid reflux into the esophagus, and the rationale for suppressing nocturnal acid secretion (even if feasible) remains to be established. Nevertheless, patients with continuing symptoms on twice-daily proton pump inhibitors are often treated by adding an H₂ receptor antagonist at night. Although this can further suppress acid production, the effect is short lived, probably due to the development of tolerance, as described earlier (Fackler et al., 2002).

Therapy for Extraintestinal Manifestations of GERD. With varying levels of evidence, acid reflux has been implicated in a variety of atypical symptoms, including noncardiac chest pain, asthma, laryngitis, chronic cough, and other ear, nose, and throat conditions. Proton pump inhibitors have been used with some success in certain patients with these disorders, generally in higher doses and for longer periods of time than those used for patients with more classic symptoms of GERD.

Table 45–3

Antisecretory Drug Regimens for Treatment and Maintenance of GERD

DRUG	DOSAGE
<i>H₂ Receptor Antagonists</i>	
Cimetidine	400*/800* mg <i>bid</i>
Famotidine	20/40 mg <i>bid</i>
Nizatidine	150*/300* mg <i>bid</i>
Ranitidine	150/300 mg <i>bid</i>
<i>Proton Pump Inhibitors</i>	
Esomeprazole	20/40 mg daily/40* mg <i>bid</i>
Lansoprazole	30*/60* mg daily/30* mg <i>bid</i>
Omeprazole	20/40* mg daily/20* mg <i>bid</i>
Pantoprazole	40/80* mg daily/40* mg <i>bid</i>
Rabeprazole	20/40* mg daily/20* mg <i>bid</i>

bid, twice daily.

*Indicates unlabeled use.

GERD and Pregnancy. Heartburn is estimated to occur in 30-50% of pregnancies, with an incidence approaching 80% in some populations (Richter, 2003). In the vast majority of cases, GERD ends soon after delivery and thus does not represent an exacerbation of a preexisting condition. Nevertheless, because of its high prevalence and the fact that it can contribute to the nausea of pregnancy, treatment often is required. Treatment choice in this setting is complicated by the paucity of data for the most commonly used drugs. In general, most drugs used to treat GERD fall in FDA Category B, with the exception of omeprazole (FDA Category C).

Mild cases of GERD during pregnancy should be treated conservatively; antacids or sucralfate are considered the first-line drugs. If symptoms persist, H₂ receptor antagonists can be used, with ranitidine having the most established track record in this setting. PPIs are reserved for women with intractable symptoms or complicated reflux disease. In these situations, lansoprazole is considered the preferred choice among the proton pump inhibitors, based on animal data and available experience in pregnant women.

PEPTIC ULCER DISEASE

The pathophysiology of peptic ulcer disease is best viewed as an imbalance between mucosal defense factors (bicarbonate, mucin, prostaglandin, NO, and other peptides and growth factors) and injurious factors (acid and pepsin). On average, patients with duodenal ulcers produce more acid than do control subjects, particularly at night (basal secretion). Although patients with gastric ulcers have normal or even diminished acid production, ulcers rarely if ever occur in the complete absence of acid. Presumably, a weakened mucosal defense and reduced bicarbonate production contribute to the injury

from the relatively lower levels of acid in these patients. *H. pylori* and exogenous agents such as NSAIDs interact in complex ways to cause an ulcer. Up to 60% of peptic ulcers are associated with *H. pylori* infection of the stomach. This infection may lead to impaired production of somatostatin by D cells and, in time, decreased inhibition of gastrin production, resulting in increased acid production and reduced duodenal bicarbonate production.

NSAIDs also are very frequently associated with peptic ulcers and bleeding. Topical injury by the luminal presence of the drug appears to play a minor role in the pathogenesis of these ulcers, as evidenced by the fact that ulcers can occur with very low doses of aspirin (10 mg) or with parenteral administration of NSAIDs (Wallace, 2008). The effects of these drugs are instead mediated systemically; the critical element is suppression of mucosal prostaglandin synthesis (particularly PGE₂ and PGI₂). Most of the mucosal prostaglandin synthesis occurs via the constitutively expressed cyclooxygenase-1 (COX-1), but COX-2, which can be very rapidly induced, also contributes significantly to the generation of mucosal-protective prostaglandins. Thus suppression of COX-1 and COX-2 by NSAIDs contributes to the induction of mucosal injury. COX-2-derived prostaglandins are particularly important in repair of mucosal injury (Wallace, 2008).

Table 45-4 summarizes current recommendations for drug therapy of gastroduodenal ulcers. Proton pump inhibitors relieve symptoms of duodenal ulcers and promote healing more rapidly than do H₂ receptor antagonists, although both classes of drugs are very effective in this setting. Peptic ulcer represents a chronic disease, and recurrence within 1 year is expected in the majority of patients who do not receive prophylactic acid suppression. With the appreciation

Table 45-4

Recommendations for Treatment of Gastroduodenal Ulcers

DRUG	ACTIVE ULCER	MAINTENANCE THERAPY
<i>H₂ Receptor Antagonists</i>		
Cimetidine	800 mg at bedtime/400 mg twice daily	400 mg at bedtime
Famotidine	40 mg at bedtime	20 mg at bedtime
Nizatidine/ranitidine	300 mg after evening meal or at bedtime/150 mg twice daily	150 mg at bedtime
<i>Proton Pump Inhibitors</i>		
Lansoprazole	15 mg (DU; NSAID risk reduction) daily 30 mg (GU including NSAID-associated) daily	
Omeprazole	20 mg daily	
Rabeprazole	20 mg daily	
<i>Prostaglandin Analog</i>		
Misoprostol	200 µg four times daily (NSAID-associated ulcer prevention)*	

DU, duodenal ulcer; GU, gastric ulcer.

*Only misoprostol 800 µg/day has been directly shown to reduce the risk of ulcer complications such as perforation, hemorrhage, or obstruction (Rostom et al., 2009).

that *H. pylori* plays a major etiopathogenic role in the majority of peptic ulcers, prevention of relapse is focused on eliminating this organism from the stomach. Chronic acid suppression, once the mainstay of ulcer prevention, now is used mainly in patients who are *H. pylori*-negative or, in some cases, for maximum prevention of recurrence in patients who have had life-threatening complications.

Intravenous pantoprazole or lansoprazole clearly is the preferred therapy in patients with acute bleeding ulcers. The theoretical benefit of maximal acid suppression in this setting is to accelerate healing of the underlying ulcer. In addition, a higher gastric pH enhances clot formation and retards clot dissolution.

Treatment of *Helicobacter pylori* Infection. *H. pylori*, a gram-negative rod, has been associated with gastritis and the subsequent development of gastric and duodenal ulcers, gastric adenocarcinoma, and gastric B-cell lymphoma (Suerbaum and Michetti, 2002). Because of the critical role of *H. pylori* in the pathogenesis of peptic ulcers, to eradicate this infection is standard care in patients with gastric or duodenal ulcers. Provided that patients are not taking NSAIDs, this strategy almost completely eliminates the risk of ulcer recurrence. Eradication of *H. pylori* also is indicated in the treatment of mucosa-associated lymphoid tissue lymphomas of the stomach, which can regress significantly after such treatment.

Many regimens for *H. pylori* eradication have been proposed. Evidence-based literature review suggests that the ideal regimen in this setting should achieve a cure rate of at least 80%. Five important considerations influence the selection of an eradication regimen (Chey and Wong, 2007; Graham, 2000) (Table 45-5). First, single-antibiotic regimens are ineffective in eradicating *H. pylori* infection and lead to microbial resistance. Combination therapy with two or three antibiotics (plus acid-suppressive therapy) is associated with the highest rate of *H. pylori* eradication. Second, a proton pump inhibitor or H₂ receptor antagonist significantly enhances the effectiveness of *H. pylori* antibiotic regimens containing amoxicillin or clarithromycin. Third, a regimen of 10-14 days of treatment appears to be better than shorter treatment regimens; in the U.S., a 14-day course of therapy generally is preferred. Fourth, poor patient compliance is linked to the medication-related side effects experienced by as many as half of patients taking triple-agent regimens, and to the inconvenience of three- or four-drug regimens administered several times per day. Packaging that combines the daily doses into one convenient unit is available and may improve patient compliance (Table 45-5). Finally, the emergence of resistance to clarithromycin and

Table 45-5

Therapy of *Helicobacter pylori* Infection

Triple therapy × 14 days: Proton pump inhibitor + clarithromycin 500 mg plus metronidazole 500 mg or amoxicillin 1 g twice a day (tetracycline 500 mg can be substituted for amoxicillin or metronidazole)

Quadruple therapy × 14 days: Proton pump inhibitor twice a day + metronidazole 500 mg three times daily plus bismuth subsalicylate 525 mg + tetracycline 500 mg four times daily

or

H₂ receptor antagonist twice a day plus bismuth subsalicylate 525 mg + metronidazole 250 mg + tetracycline 500 mg four times daily

Dosages:

Proton pump inhibitors:	H ₂ receptor antagonists:
Omeprazole: 20 mg	Cimetidine: 400 mg
Lansoprazole: 30 mg	Famotidine: 20 mg
Rabeprazole: 20 mg	Nizatidine: 150 mg
Pantoprazole: 40 mg	Ranitidine: 150 mg
Esomeprazole: 40 mg	

See Chey and Wong, 2007.

metronidazole increasingly is recognized as an important factor in the failure to eradicate *H. pylori*. Clarithromycin resistance is related to mutations that prevent binding of the antibiotic to the ribosomes of the pathogen and is an all-or-none phenomenon. In contrast, metronidazole resistance is relative rather than absolute and may involve several adaptations by the bacteria. In the presence of *in vitro* evidence of resistance to metronidazole, amoxicillin should be used instead. In areas with a high frequency of resistance to clarithromycin and metronidazole, a 14-day quadruple-drug regimen (three antibiotics combined with a proton pump inhibitor) generally is effective therapy.

NSAID-Related Ulcers. Chronic NSAID users have a 2-4% risk of developing a symptomatic ulcer, GI bleeding, or perforation. Ideally, NSAIDs should be discontinued in patients with an ulcer if at all possible. If continued therapy is needed, selective COX-2 inhibitors may be considered, although this does not eliminate the risk of subsequent ulcer formation and the possible association of these drugs with adverse cardiovascular events mandates caution (Chapter 34). Moreover, any GI benefit of selective COX-2 inhibitors is lost if the patient is also taking low-dose aspirin. Healing of ulcers despite continued NSAID use is possible with the use

of acid-suppressant agents, usually at higher doses and for a considerably longer duration than standard regimens (e.g., ≥ 8 weeks). Again, proton pump inhibitors are superior to H_2 receptor antagonists and misoprostol in promoting the healing of active ulcers (healing rates of 80-90% for proton pump inhibitors vs. 60-75% for the H_2 receptor antagonists), and in preventing recurrence of gastric and duodenal ulcers in the setting of continued NSAID administration (Lanas and Hunt, 2006; Rostom et al., 2009).

Stress-Related Ulcers. Stress ulcers are ulcers of the stomach or duodenum that occur in the context of a profound illness or trauma requiring intensive care. The etiology of stress-related ulcers differs somewhat from that of other peptic ulcers, involving acid and mucosal ischemia. Because of limitations on the oral administration of drugs in many patients with stress-related ulcers, intravenous H_2 receptor antagonists have been used extensively to reduce the incidence of GI hemorrhage due to stress ulcers. Now that intravenous preparations of proton pump inhibitors are available, it is likely that they will prove to be equally beneficial. *However, there is some concern over the risk of pneumonia secondary to gastric colonization by bacteria in an alkaline milieu.* In this setting, sucralfate appears to provide reasonable prophylaxis against bleeding without increasing the risk of aspiration pneumonia. This approach also appears to provide reasonable prophylaxis against bleeding, but it is less convenient (Cook et al., 1998).

Zollinger-Ellison Syndrome. Patients with this syndrome develop pancreatic or duodenal gastrinomas that stimulate the secretion of very large amounts of acid, sometimes in the setting of multiple endocrine neoplasia, type I. This can lead to severe gastroduodenal ulceration and other consequences of uncontrolled hyperchlorhydria. Proton pump inhibitors clearly are the drugs of choice, usually given at twice the routine dosage for peptic ulcers with the therapeutic goal of reducing acid secretion to 1-10 mmol/hour.

Nonulcer Dyspepsia. This term refers to ulcer-like symptoms in patients who lack overt gastroduodenal ulceration. It may be associated with gastritis (with or without *H. pylori*) or with NSAID use, but the pathogenesis of this syndrome remains controversial. Although empirical treatment with acid-suppressive agents is used routinely in patients with nonulcer dyspepsia, there is no convincing evidence of their benefit in controlled trials.

CLINICAL SUMMARY

The control of acid-peptic disease represents a major triumph for modern pharmacology. Proton pump inhibitors are considered superior for acid suppression in most clinically significant acid-peptic diseases, including gastroesophageal reflux disease, peptic ulcers, and NSAID-induced ulcers. Proton pump inhibitors also are employed in combination with antibiotics to eradicate infection with *H. pylori* and thereby play a role in preventing recurrent peptic ulcers. These agents largely have replaced the use of misoprostol and sucralfate, although the latter still is a low-cost alternative for prophylaxis against stress ulcers. The delay in maximal inhibition of acid secretion with the proton pump inhibitors (3-5 days) makes them less suited for use on an as-needed basis for symptom relief. In this setting, H_2 receptor antagonists, although less effective than proton pump inhibitors in suppressing acid secretion, have a more rapid onset of action that makes them useful for patient-directed management of mild or infrequent symptoms.

Treatment of Disorders of Bowel Motility and Water Flux; Anti-Emetics; Agents Used in Biliary and Pancreatic Disease

Keith A. Sharkey and
John L. Wallace

The longer I live, the more I am convinced that half the unhappiness in the world proceeds from little stoppages, from a duct choked up, from food pressing in the wrong place, from a vexed duodenum or an agitated pylorus.

—Sydney Smith (1771–1845)

INTRODUCTION TO GASTROINTESTINAL MOTILITY

The gastrointestinal (GI) tract is in a continuous contractile, absorptive, and secretory state. The control of this state is complex, with contributions by the muscle and epithelium themselves, as well as local nerves of the enteric nervous system (ENS), the autonomic nervous system (ANS), and circulating hormones (De Giorgio et al., 2007; Furness, 2006; Grundy et al., 2006; Wood, 2008). Of these, perhaps the most important regulator of physiological gut function is the ENS (Figure 46–1). The ENS is an extensive collection of nerves that constitutes the third division of the ANS. It is the only part of the ANS truly capable of autonomous function if separated from the central nervous system (CNS). The ENS lies within the wall of the GI tract organized into two connected networks of neurons and nerve fibers: the *myenteric (Auerbach's) plexus*, found between the circular and longitudinal muscle layers, and the *submucosal (Meissner's) plexus*, located in the submucosa. The former is largely responsible for motor control, whereas the latter regulates secretion, fluid transport, and blood flow. The ENS and the ANS are also involved in host defense and innervate organs and cells of the immune system (Rhee et al., 2009).

Generation and Regulation of GI Activity

The ENS is responsible for the largely autonomous nature of most GI activity. This activity is organized into relatively distinct programs that respond to input from the local environment of the gut, as well as the ANS-CNS. Each program consists of a series of complex, but coordinated, patterns of secretion and movement that show regional and temporal variation. The fasting program of the gut is called the MMC (*migrating myoelectric complex* when referring to electrical activity and *migrating motor complex* when referring to the accompanying contractions) and consists of a series of four phasic activities. The most characteristic, phase III, consists of clusters of rhythmic contractions that occupy short segments of the intestine for a period of 6–10 minutes before proceeding caudally (toward the anus). Phase II of the MMC is associated with the release of the peptide hormone motilin. Agonists of motilin stimulate motility in the proximal gut and are used clinically (Sanger, 2008). One whole MMC cycle (i.e., all four phases) takes ~80–110 minutes. The migrating motor complex occurs in the fasting state, during which it helps sweep debris caudad in the gut and serves to limit the overgrowth of luminal bacteria. The migrating motor complex cycles continually in animals that feed constantly but is interrupted by another pattern of contractions—the fed program—in intermittently feeding animals such as humans. The fed program consists of high-frequency (12–15 per minute) contractions that are either propagated for short segments (*propulsive*) or are irregular and not propagated (*mixing*).

Reflex circuits within the ENS underlie the stereotyped behaviors of the gut, such as peristalsis. Physiologically, peristalsis is a series of reflex responses to a bolus in the lumen of a given segment of the intestine; the ascending excitatory reflex results in contraction of the circular muscle on the oral side of the bolus, whereas the descending inhibitory reflex results in relaxation on the anal side. The net pressure gradient moves the bolus caudad. Three neural elements, responsible for sensory, relay, and effector functions, are required to produce these reflexes. Luminal factors stimulate sensory elements in the mucosa, leading to a coordinated pattern of

Figure 46–1. The neuronal network that initiates and generates the peristaltic response. Mucosal stimulation leads to release of serotonin by enterochromaffin cells (8), which excites the intrinsic primary afferent neurons (1), which then communicate with ascending (2) and descending (3) interneurons in the local reflex pathways. The reflex results in contraction at the oral end via the excitatory motor neuron (6) and aboral relaxation via the inhibitory motor neuron (5). The migratory myoelectric complex (see text) is shown here as being conducted by a different chain of interneurons (4). Another intrinsic primary afferent neuron with its cell body in the submucosa also is shown (7). MP, myenteric plexus; CM, circular muscle; LM, longitudinal muscle; SM, submucosa; Muc, mucosa. (Adapted from Kunze and Furness, 1999, with permission from Annual Reviews. www.annualreviews.org.)

muscle activity that is directly controlled by the motor neurons of the myenteric plexus to provide the effector component of the peristaltic reflex. Motor neurons receive input from ascending and descending interneurons (which constitute the relay and programming systems) that are of two broad types, excitatory and inhibitory. The primary neurotransmitter of the excitatory motor neurons is acetylcholine (ACh), although tachykinins, co-released by these neurons, also play a role. The principal neurotransmitter in the inhibitory motor neurons appears to be NO, although important contributions may also be made by ATP, vasoactive intestinal peptide, and pituitary adenylyl cyclase-activating peptide (PACAP), all of which are variably coexpressed with NO synthase. Substantial progress has been made in elucidating the mucosal sensor for initiating peristalsis and other reflexes. Enterochromaffin cells, scattered throughout the epithelium of the intestine, release serotonin (5-HT) to initiate many gut reflexes (Gershon and Tack, 2007) by acting locally on enteric neurons. Excessive release of 5-HT from the gut wall (e.g., by chemotherapeutic agents) leads to vomiting by actions of 5-HT on vagal nerve endings in the proximal small intestine. Compounds targeting the 5-HT system are important modulators of motility, secretion, and emesis.

This view of nerve–muscle interaction within the GI tract is in many ways oversimplified, and other cell types are important. One of these is the interstitial cell of Cajal, distributed within the gut wall and responsible for setting the electrical rhythm, and hence the pace of contractions, in various regions of the gut. These cells also

translate or modulate excitatory and inhibitory neuronal communication to the smooth muscle (Ward et al., 2004).

Excitation-Contraction Coupling in GI Smooth Muscle

Control of tension in GI smooth muscle is in large part dependent on the intracellular Ca^{2+} concentration. In general, there are two types of excitation-contraction coupling. Ionotropic receptors can mediate changes in membrane potential, which in turn activate voltage-dependent Ca^{2+} channels to trigger an influx of Ca^{2+} (electromechanical coupling); metabotropic receptors activate various signal transduction pathways to release Ca^{2+} from intracellular stores (pharmacomechanical coupling). Inhibitory receptors also exist on smooth muscle and generally act via PKA and PKG, whose kinase activities can lead to hyperpolarization, decreased cytosolic $[\text{Ca}^{2+}]$, and reduced interaction of actin and myosin. As an example, NO may induce relaxation via activation of guanylyl cyclase-cyclic GMP pathway, and the opening of several types of K^+ channels.

OVERVIEW OF FUNCTIONAL AND MOTILITY DISORDERS OF THE BOWEL

GI motility disorders are a complex and heterogeneous group of syndromes whose pathophysiology is not completely understood. Typical motility disorders include

achalasia of the esophagus (impaired relaxation of the lower esophageal sphincter associated with defective esophageal peristalsis that results in dysphagia and regurgitation), gastroparesis (delayed gastric emptying), myopathic and neuropathic forms of intestinal dysmotility, and others. These disorders can be congenital, idiopathic, or secondary to systemic diseases (e.g., diabetes mellitus or scleroderma). This term also has traditionally (and perhaps inaccurately) included disorders—such as irritable bowel syndrome (IBS) and noncardiac chest pain—in which disturbances in pain processing or sensory function may be more important than any associated motor patterns. For most of these disorders, treatment remains empirical and symptom based, reflecting our ignorance of the specific derangements in pathophysiology involved.

PROKINETIC AGENTS AND OTHER STIMULANTS OF GI CONTRACTILITY

Activation of muscarinic receptors with the older cholinomimetic agents (Chapter 9) or AChE inhibitors (Chapter 10), is not a very effective strategy for treating GI motility disorders because these agents enhance contractions in a relatively uncoordinated fashion that produces little or no net propulsive activity. The use of cholinergic agents is discussed in the previous edition of this book.

By contrast, *prokinetic* agents are medications that enhance coordinated GI motility and transit of material in the GI tract. Although ACh, when released from primary motor neurons in the myenteric plexus, is the principal immediate mediator of muscle contractility, most of the clinically useful prokinetic agents act “upstream” of ACh, at receptor sites on the motor neuron itself, or even more indirectly, on neurons or non-neuronal cells one or two orders removed from it. Although pharmacologically and chemically diverse, these agents appear to enhance the release of excitatory neurotransmitter at the nerve-muscle junction without interfering with the normal physiological pattern and rhythm of motility. Coordination of activity among the segments of the gut, necessary for propulsion of luminal contents, therefore is maintained.

Agents useful clinically in altering GI motility are considered next.

Dopamine Receptor Antagonists

Dopamine (DA) is present in significant amounts in the GI tract and has several inhibitory effects on motility,

including reduction of lower esophageal sphincter and intragastric pressures. These effects, which apparently result from suppression of ACh release from myenteric motor neurons, are mediated by D_2 dopaminergic receptors. By antagonizing the inhibitory effect of dopamine on myenteric motor neurons, DA receptor antagonists are effective as prokinetic agents; they have the additional advantage of relieving nausea and vomiting by antagonism of DA receptors in the chemoreceptor trigger zone. Examples of such agents are metoclopramide and domperidone.

Metoclopramide. Chemistry, Mechanism of Action, and Pharmacological Properties. Metoclopramide (REGLAN, others) and other substituted benzamides are derivatives of *para*-aminobenzoic acid and are structurally related to procainamide.

The mechanisms of action of metoclopramide are complex and involve $5-HT_4$ receptor agonism, vagal and central $5-HT_3$ antagonism, and possible sensitization of muscarinic receptors on smooth muscle, in addition to DA receptor antagonism. Metoclopramide is one of the oldest true prokinetic agents; its administration results in coordinated contractions that enhance transit. Its effects are confined largely to the upper digestive tract, where it increases lower esophageal sphincter tone and stimulates antral and small intestinal contractions. Despite having *in vitro* effects on the contractility of colonic smooth muscle, metoclopramide has no clinically significant effects on large-bowel motility.

Pharmacokinetics. Metoclopramide is absorbed rapidly after oral ingestion, undergoes sulfation and glucuronide conjugation by the liver, and is excreted principally in the urine, with a $t_{1/2}$ of 4-6 hours. Peak concentrations occur within 1 hour after a single oral dose; the duration of action is 1-2 hours.

Therapeutic Use. Metoclopramide has been used in patients with gastroesophageal reflux disease to produce symptomatic relief of, but not healing of, associated esophagitis. It clearly is less effective than modern acid-suppressive medications, such as proton pump inhibitors or histamine H_2 receptor antagonists, and now rarely is used in this setting. Metoclopramide is indicated more often in symptomatic patients with gastroparesis, in whom it may cause mild to modest improvements of gastric emptying (Tonini et al., 2004). Metoclopramide injection is used as an adjunctive measure in medical or diagnostic procedures such as intestinal intubation or contrast radiography of the GI tract. Although it has been used in patients with postoperative ileus, its ability to improve transit in disorders of small-bowel motility appears to be limited. *In general, its greatest utility lies in its ability to ameliorate the nausea and vomiting that often accompany GI dysmotility syndromes.* Metoclopramide has also been used in the treatment of persistent hiccups, but its efficacy in this condition is equivocal at best.

Metoclopramide is available in oral dosage forms (tablets and solution) and as a parenteral preparation for intravenous or intramuscular use. The usual initial oral dose range is 10 mg, 30 minutes before each meal and at bedtime. The onset of action is within 30-60 minutes after an oral dose. In patients with severe nausea, an initial dose of 10 mg can be given intramuscularly (onset of action 10-15 minutes) or intravenously (onset of action 1-3 minutes). For prevention of chemotherapy-induced emesis, metoclopramide can be given as an infusion of 1-2 mg/kg administered over at least 15 minutes, beginning 30 minutes before the chemotherapy is begun and repeated as needed every 2 hours for two doses, then every 3 hours for three doses.

Adverse Effects. The major side effects of metoclopramide include extrapyramidal effects, such as those seen with the phenothiazines (Chapter 16). Dystonias, usually occurring acutely after intravenous administration, and parkinsonian-like symptoms that may occur several weeks after initiation of therapy generally respond to treatment with anticholinergic or antihistaminic drugs and are reversible upon discontinuation of metoclopramide. Tardive dyskinesia also can occur with chronic treatment (months to years) and may be irreversible. Extrapyramidal effects appear to occur more commonly in children and young adults and at higher doses. Like other DA antagonists, metoclopramide also can cause galactorrhea by blocking the inhibitory effect of dopamine on prolactin release, but this adverse effect is relatively infrequent in clinical practice. Methemoglobinemia has been reported occasionally in premature and full-term neonates receiving metoclopramide.

Domperidone; D₂ Receptor Antagonists

In contrast to metoclopramide, domperidone predominantly antagonizes the D₂ receptor without major involvement of other receptors. It is not available for use in the U.S. but has been used elsewhere (MOTILUM, others) and has modest prokinetic activity in doses of 10-20 mg three times a day. Although it does not readily cross the blood-brain barrier to cause extrapyramidal side effects, domperidone exerts effects in the parts of the CNS that lack this barrier, such as those regulating emesis, temperature, and prolactin release. As is the case with metoclopramide, domperidone does not appear to have any significant effects on lower GI motility. Other D₂ receptor antagonists being explored as prokinetic agents include levosulpiride, the levo-enantiomer of sulpiride.

Serotonin Receptor Agonists

5-HT plays an important role in the normal motor and secretory function of the gut (Gershon and Tack, 2007) (Chapter 13). Indeed, >90% of the total 5-HT in the body exists in the GI tract. The enterochromaffin cell, a specialized cell found in the epithelium lining the mucosa of the gut, produces most of this 5-HT and rapidly releases 5-HT in response to chemical and mechanical stimulation (e.g., food boluses; noxious

agents such as cisplatin; certain microbial toxins; adrenergic, cholinergic, and purinergic receptor agonists). 5-HT triggers the peristaltic reflex (Figure 46-1) by stimulating intrinsic sensory neurons in the myenteric plexus (via 5-HT_{1p} and 5-HT₄ receptors), as well as extrinsic vagal and spinal sensory neurons (via 5-HT₃ receptors). Additionally, stimulation of submucosal intrinsic afferent neurons activates secretomotor reflexes resulting in epithelial secretion. 5-HT receptors also are found on other neurons in the enteric nervous system, where they can be either stimulatory (5-HT₃ and 5-HT₄) or inhibitory (5-HT_{1a}). In addition, serotonin also stimulates the release of other neurotransmitters, depending on the receptor subtype. Thus, 5-HT₁ stimulation of the gastric fundus results in release of NO and reduces smooth muscle tone. 5-HT₄ stimulation of excitatory motor neurons enhances ACh release at the neuromuscular junction, and both 5-HT₃ and 5-HT₄ receptors facilitate interneuronal signaling. Developmentally, 5-HT acts as a neurotrophic factor for enteric neurons via the 5-HT_{2B} and 5-HT₄ receptors.

Reuptake of serotonin by enteric neurons and epithelium is mediated by the same transporter (SERT; Chapters 5 and 13) as 5-HT reuptake by serotonergic neurons in the CNS. This reuptake therefore also is blocked by selective serotonin reuptake inhibitors (SSRIs, Chapter 15), which explains the common side effect of diarrhea that accompanies the use of these agents. Modulation of the multiple, complex, and sometimes opposing effects of 5-HT on gut motor function has become a major target for drug development.

The availability of serotonergic prokinetic drugs has in recent years been restricted because of serious adverse cardiac events. Tegaserod maleate (ZELNORM) was discontinued in 2007 and cisapride is available only via a restricted investigational drug protocol. A novel 5-HT₄ agonist, prucalopride (RESOLOR), is approved for use in Europe for symptomatic treatment of chronic constipation in women in whom laxatives fail to provide adequate relief.

Cisapride. Cisapride (PROPULSID) is a substituted piperidiny benza-mide (Figure 46-2) that appears to stimulate 5-HT₄ receptors and increase adenylyl cyclase activity within neurons. It also has weak 5-HT₃ antagonistic properties and may directly stimulate smooth muscle. Cisapride was a commonly used prokinetic agent, particularly for gastroesophageal reflux disease and gastroparesis. However, it no longer is generally available in the U.S. because of its potential to induce serious and occasionally fatal cardiac arrhythmias, including ventricular tachycardia, ventricular fibrillation, and torsades de pointes. These arrhythmias result from a prolonged QT interval through an interaction with pore-forming subunits of the HERG K⁺ channel. HERG K⁺ channels conduct the rapid delayed rectifier K⁺ current that is important for normal repolarization of the ventricle (Chapter 29). Cisapride-induced ventricular arrhythmias occur most

Figure 46–2. Ligands of 5-HT₃ and 5-HT₄ receptors modulating GI motility.

often when the drug is combined with other drugs that inhibit CYP3A4 (Chapter 6); such combinations inhibit the metabolism of cisapride and lead to high plasma concentrations of the drug. Due to its association with ventricular arrhythmias, cisapride is contraindicated in patients with a history of prolonged QT interval, renal failure, ventricular arrhythmias, ischemic heart disease, congestive heart failure, respiratory failure, uncorrected electrolyte abnormalities (e.g., hypokalemia and hypomagnesemia), or concomitant medications known to prolong the QT interval. At this time, cisapride is available only through an investigational, limited-access program for patients with GERD, gastroparesis, pseudo-obstruction, refractory severe chronic constipation, and neonatal enteral feeding intolerance who have failed all standard therapeutic modalities and who have undergone a thorough diagnostic evaluation, including an ECG.

Prucalopride (RESELOR; Figure 46–2) is a benzofuran derivative and a specific 5-HT₄-receptor agonist that facilitates cholinergic neurotransmission. It acts throughout the length of the intestine, increasing oral-cecal transit and colonic transit without affecting gastric emptying in healthy volunteers. In patients with chronic idiopathic constipation, prucalopride was able to improve colonic transit and stool frequency. Given in doses of 2 and 4 mg orally, once daily, there were significant normalization of bowel habits including increased stool frequency and consistency (Gale, 2009). This drug recently gained approval in Europe for use in women with chronic constipation in whom laxatives fail to provide adequate relief.

Motilides

Macrolides and Erythromycin. Motilin, a 22–amino acid peptide hormone found in the GI M cells and in some enterochromaffin cells of the upper small bowel, is a

potent contractile agent of the upper GI tract. Motilin levels fluctuate in association with the migrating motor complex and appear to be responsible for the amplification, if not the actual induction, of phase III activity. In addition, motilin receptors are found on smooth muscle cells and enteric neurons.

The effects of motilin can be mimicked by erythromycin, a discovery that arose from the frequent occurrence of GI side effects with the use of this antibiotic. This property is shared to varying extents by other macrolide antibiotics (Chapter 55), including oleandomycin, azithromycin, and clarithromycin. In addition to its motilin-like effects, which are most pronounced at higher doses (250–500 mg), erythromycin at lower doses (e.g., 40–80 mg) also may act by other poorly defined mechanisms that may involve cholinergic facilitation.

Erythromycin induces phase III migrating motor complex activity in dogs and increases smooth muscle contractility. It has multiple effects on upper GI motility, increasing lower esophageal pressure and stimulating gastric and small-bowel contractility. By contrast, it has little or no effect on colonic motility. At doses higher than 3 mg/kg, it can produce a spastic type of contraction in the small bowel, resulting in cramps, impairment of transit, and vomiting.

Therapeutic Use. The best established use of erythromycin as a prokinetic agent is in patients with diabetic gastroparesis, where it can improve gastric emptying in the short term. Erythromycin-stimulated gastric contractions can be intense and result in “dumping” of relatively

undigested food into the small bowel. This potential disadvantage can be exploited clinically to clear the stomach of undigestible residue such as plastic tubes or bezoars. Anecdotally, erythromycin also has been of benefit in patients with small-bowel dysmotility such as that seen in scleroderma, ileus, or pseudo-obstruction. Rapid development of tolerance to erythromycin, possibly by downregulation of the motilin receptor, and undesirable (in this context) anti-biotic effects have limited the use of this drug as a prokinetic agent. Several non-antibiotic synthetic analogs of erythromycin and peptide analogs of motilin have been developed; to date, the clinical results have been disappointing.

A standard dose of erythromycin for gastric stimulation is 3 mg/kg intravenously or 200-250 mg orally every 8 hours. For small-bowel stimulation, a smaller dose (e.g., 40 mg intravenously) may be more useful, as higher doses may actually retard motility of this organ. Concerns about toxicity, pseudomembranous colitis, and the induction of resistant strains of bacteria, among other things, limit the use of erythromycin to acute situations or in circumstances where patients are resistant to other medications.

Motilin Receptor Agonists. A number of these drugs have been developed for the treatment of diabetic gastroparesis. Currently, mitemcinal (GM-611), a macrolide nonantibiotic, shows promise for the treatment of gastroparesis (Gale, 2009).

Miscellaneous Agents for Stimulating Motility

The GI hormone cholecystokinin (CCK) is released from the intestine in response to meals and delays gastric emptying, causes contraction of the gallbladder, stimulates pancreatic enzyme secretion, increases intestinal motility, promotes satiety, and has a host of other actions. The C-terminal octapeptide of CCK, sincalide (KINEVAC), is useful for stimulating the gallbladder and/or pancreas and may also be used for accelerating barium transit through the small bowel for diagnostic testing of these organs. This drug is administered intravenously 0.02-0.04 µg/kg over 30-60 seconds or up to 30-45 minutes depending on the test. Administration of this agent is frequently accompanied by nausea and abdominal pain, and much less frequently dizziness. Concerns that should be noted using this agent are related to the expulsion of small gallstones into the common bile duct or cystic duct. *Dexloxiglumide* is a CCK₁ (or CCK-A)-receptor antagonist that can improve gastric emptying and was investigated as a treatment for gastroparesis and for constipation-dominant IBS, but may also have uses in feeding intolerance in critically ill individuals. Clonidine also has been reported to be of benefit in patients with gastroparesis. Octreotide acetate (SANDOSTATIN, others), a somatostatin analogue, also is used in some patients with intestinal dysmotility.

In some disorders of motility, effective treatment does not necessarily require a “neuroenteric” approach. One such example is gastroesophageal reflux disease. Acid reflux is associated with transient lower esophageal sphincter relaxations that occur in the absence of a swallow. Because the damage to the esophagus ultimately is inflicted by acid, the most effective therapy for gastroesophageal reflux disease still is the suppression of acid production by the stomach (Chapter 45). Neither metoclopramide nor cisapride by itself is particularly effective in gastroesophageal reflux disease. However, a new approach under investigation relies on suppression of the transient lower esophageal sphincter relaxations, as achieved by CCK₁-receptor antagonists (such as dexloxiglumide), GABA agonists (such as baclofen), and inhibitors of NO synthesis.

Agents that Suppress Motility

Smooth muscle relaxants such as organic nitrates and Ca²⁺ channel antagonists (Chapters 27 and 28) often produce temporary, if partial, relief of symptoms in motility disorders such as achalasia, in which the lower esophageal sphincter fails to relax, resulting in a functional obstruction to the passage of food and severe difficulty in swallowing. A more recent approach relies on the use of preparations of botulinum toxin (BOTOX, DYSPORT, MYOBLOC), injected directly into the lower esophageal sphincter via an endoscope, in doses of 80-100 units (Zhao and Pasricha, 2003). This potent agent inhibits ACh release from nerve endings (Chapter 11) and can produce partial paralysis of the sphincter muscle, with significant improvements in symptoms and esophageal clearance. However, its effects dissipate over a period of several months, requiring repeated injections; there is also some potential for post-administration “spread” of the toxin that can result in life-threatening consequences. Botulinum toxin preparations likely will be more widely used especially in the elderly and in those with other risks for pneumatic dilation. Other GI conditions in which botulinum toxin A has been used include gastroparesis, sphincter of Oddi dysfunction, and anal fissures, although currently there are not strong trial data to support its efficacy.

LAXATIVES, CATHARTICS, AND THERAPY FOR CONSTIPATION

Overview of GI Water and Electrolyte Flux. Fluid content is the principal determinant of stool volume and consistency; water normally accounts for 70-85% of total stool weight. Net stool fluid content reflects a balance between luminal input (ingestion and secretion of water and electrolytes) and output (absorption) along the length of the GI tract. The daily challenge for the gut is to extract water, minerals, and nutrients from the luminal contents, leaving behind a manageable pool of fluid for proper expulsion of waste material via the process of defecation. Normally ~8-9 L of fluid enter the small intestine daily from exogenous and endogenous sources (Figure 46-3). Net absorption of the water occurs in the small intestine in response to osmotic gradients that result from the uptake and secretion of ions and the absorption of nutrients (mainly sugars and amino acids), with only ~1-1.5 L crossing the ileocecal valve. The colon then extracts most of the remaining fluid, leaving ~100 mL of fecal water daily.

Under normal circumstances, these quantities are well within the range of the total absorptive capacity of the small bowel (~16 L) and colon (4-5 L). Neurohumoral mechanisms, pathogens, and drugs can alter these processes, resulting in changes in either secretion or absorption of fluid by the intestinal epithelium. Altered motility also contributes in a general way to this process, as the extent of absorption parallels transit time. With decreased motility and excess fluid removal,

Figure 46-3. The approximate volume and composition of fluid that traverses the small and large intestines daily. Of the 9 L of fluid typically presented to the small intestine each day, 2 L are from the diet and 7 L are from secretions (salivary, gastric, pancreatic, and biliary). The absorptive capacity of the colon is 4-5 L per day.

feces can become inspissated and impacted, leading to constipation. When the capacity of the colon to absorb fluid is exceeded, diarrhea occurs.

Constipation: General Principles of Pathophysiology and Treatment. Scientific definitions rely mostly on stool number; most surveys have found the normal stool frequency on a Western diet to be at least three times a week. However, patients use the term *constipation* not only for decreased frequency, but also for difficulty in initiation or passage, passage of firm or small-volume feces, or a feeling of incomplete evacuation. By questionnaire, 25% of the population of the U.S., more commonly women and elderly people, complain of constipation. A survey of bowel habits of adults in the U.S. showed that 18% of respondents used laxatives at least once a month, but nearly one-third of users did not have constipation. Approximately 2.5 million physician visits per year are attributed to constipation.

Constipation has many reversible or secondary causes, including lack of dietary fiber, drugs, hormonal disturbances, neurogenic disorders, and systemic illnesses. In most cases of chronic constipation, no specific cause is found. Up to 60% of patients presenting with constipation have normal colonic transit. These patients either have IBS or define constipation in terms other than stool frequency (e.g., changes in consistency, excessive straining, or a feeling of incomplete evacuation). In the rest, attempts usually are made to categorize the underlying pathophysiology either as a disorder of delayed colonic transit because of an underlying defect in colonic motility or, less commonly, as an isolated disorder of defecation or evacuation (outlet disorder) due to dysfunction of the neuromuscular apparatus of the rectoanal region. Colonic motility is responsible for mixing luminal contents to promote absorption of water and moving them from proximal to distal segments by means of propulsive contractions. Mixing in the colon is accomplished in a way similar to that in the small bowel: by short- or long-duration, stationary (nonpropulsive) contractions. Propulsive contractions in the colon include giant migrating contractions, also known as colonic mass actions or mass movements, which propagate caudally over

extended lengths in the colon and evoke mass transfer of feces from the right to the left colon once or twice a day. Disturbances in motility therefore may have complex effects on bowel movements. “Decreased motility” of the mass action type and “increased motility” of the nonpropulsive type may lead to constipation. In any given patient, the predominant factor often is not obvious. Consequently, the pharmacological approach to constipation remains empirical and is based, in most cases, on nonspecific principles.

In many cases, constipation can be corrected by adherence to a fiber-rich (20-35 g daily) diet, adequate fluid intake, appropriate bowel habits and training, and avoidance of constipating drugs. However, the association between constipation and either fluid intake or exercise has not withstood scientific scrutiny. Constipation related to medications can be corrected by use of alternative drugs where possible, or adjustment of dosage. If non-pharmacological measures alone are inadequate or unrealistic (e.g., because of elderly age or infirmity), they may be supplemented with bulk-forming agents or osmotic laxatives. When stimulant laxatives are used, they should be administered at the lowest effective dosage and for the shortest period of time to avoid abuse. In addition to perpetuating dependence on drugs, the laxative habit may lead to excessive loss of water and electrolytes; secondary aldosteronism may occur if volume depletion is prominent. Steatorrhea, protein-losing enteropathy with hypoalbuminemia, and osteomalacia due to excessive loss of calcium in the stool have been reported.

In addition to treating constipation, laxatives frequently are employed before surgical, radiological, and endoscopic procedures where an empty colon is desirable.

The terms *laxatives*, *cathartics*, *purgatives*, *aperients*, and *evacuants* often are used interchangeably. There is a distinction, however, between *laxation* (the evacuation of formed fecal material from the rectum) and *catharsis* (the evacuation of unformed, usually watery fecal material from the entire colon). Most of the commonly used agents promote laxation, but some are actually cathartics that act as laxatives at low doses.

Laxatives generally act in one of the following ways: (1) enhancing retention of intraluminal fluid by hydrophilic or osmotic mechanisms; (2) decreasing net absorption of fluid by effects on small- and large-bowel fluid and electrolyte transport; or (3) altering motility by either inhibiting segmenting (nonpropulsive) contractions or stimulating propulsive contractions. Based on their actions, laxatives can be classified as shown in Table 46–1; their known effects on motility and secretion are listed in Table 46–2. However, studies indicate considerable overlap among these traditional categories. A variety of laxatives, both osmotic agents and stimulants, increase the activity of NO synthase and the biosynthesis of platelet-activating factor in the gut. Platelet-activating factor is a phospholipid proinflammatory mediator that stimulates colonic secretion and GI motility (Izzo et al., 1998). NO also may stimulate intestinal secretion and inhibit segmenting contractions in the colon, thereby promoting laxation. Agents that reduce the expression of NO synthase or its activity can prevent the laxative effects of castor oil, cascara, and bisacodyl (but not senna), as well as magnesium sulfate.

Table 46–1

Classification of Laxatives

- 1. Luminally active agents**
 - Hydrophilic colloids; bulk-forming agents (bran, psyllium, etc.)
 - Osmotic agents (non-absorbable inorganic salts or sugars)
 - Stool-wetting agents (surfactants) and emollients (docusate, mineral oil)
- 2. Nonspecific stimulants or irritants (with effects on fluid secretion and motility)**
 - Diphenylmethanes (bisacodyl)
 - Anthraquinones (senna and cascara)
 - Castor oil
- 3. Prokinetic agents (acting primarily on motility)**
 - 5-HT₄ receptor agonists
 - Dopamine receptor antagonists
 - Motilides (erythromycin)

An alternate way to classify laxatives is by the pattern of effects produced by the usual clinical dosage (Table 46–3).

Dietary Fiber and Supplements

Under normal circumstances, the bulk, softness, and hydration of feces depend on the fiber content of the diet. Fiber is defined as that part of food that resists enzymatic digestion and reaches the colon largely unchanged. Colonic bacteria ferment fiber to varying

Table 46-3

Classification and Comparison of Representative Laxatives

LAXATIVE EFFECT AND LATENCY IN USUAL CLINICAL DOSAGE		
SOFTENING OF FECES, 1-3 DAYS	SOFT OR SEMIFLUID STOOL, 6-8 HOURS	WATERY EVACUATION, 1-3 HOURS
Bulk-forming laxatives	Stimulant laxatives	Osmotic laxatives^a
Bran	Diphenylmethane derivatives	Sodium phosphates
Psyllium preparations	Bisacodyl	Magnesium sulfate
Methylcellulose		Milk of magnesia
Calcium polycarboxiphil		Magnesium citrate
Surfactant laxatives	Anthraquinone derivatives	Castor oil
Docusates	Senna	
Poloxamers	Cascara sagrada	
Lactulose		

^aEmployed in high dosage for rapid cathartic effect and in lower dosage for laxative effect.

degrees, depending on its chemical nature and water solubility. Fermentation of fiber has two important effects:

- it produces short-chain fatty acids that are trophic for colonic epithelium
- it increases bacterial mass

Although fermentation of fiber generally decreases stool water, short-chain fatty acids also may have a prokinetic effect, and increased bacterial mass may contribute to increased stool volume. However, fiber that is not fermented can attract water and increase stool bulk. The net effect on bowel movement therefore varies with different compositions of dietary fiber (Table 46-4). In general, insoluble, poorly fermentable fibers, such as lignin, are most effective in increasing stool bulk and transit.

Bran, the residue left when flour is made from cereal grains, contains >40% dietary fiber. Wheat bran, with its high lignin content, is most effective at increasing stool weight. Fruits and vegetables contain more *pectins* and *hemicelluloses*, which are more readily fermentable and produce less effect on stool transit. *Psyllium husk*, derived from the seed of the plantago herb (*Plantago ovata*; known as ispaghula or isabgol in many parts of the world), is a component of many commercial products for constipation (METAMUCIL, others). Psyllium husk contains a hydrophilic mucilloid that undergoes significant fermentation in the colon, leading to an increase in colonic bacterial mass. The usual dose is 2.5-4 g (1-3 teaspoonfuls in 250 mL of fruit juice), titrated upward until the desired goal is reached. A variety of semisynthetic celluloses—e.g., methylcellulose (CITRUCEL, others) and the hydrophilic resin calcium polycarboxiphil (FIBERCON, FIBERALL, others), a polymer of acrylic acid resin—also are

available. These poorly fermentable compounds absorb water and increase fecal bulk. Malt soup extract (MALSTSUPEX, others), an extract of malt from barley grains that contains small amounts of polymeric carbohydrates, proteins, electrolytes, and vitamins, is another orally administered bulk-forming agent.

Fiber is contraindicated in patients with obstructive symptoms and in those with megacolon or megarectum. Fecal impaction should be treated before initiating fiber supplementation. Bloating is the most common side effect of soluble fiber products (perhaps due to colonic fermentation), but it usually decreases with time. Calcium polycarboxiphil preparations release Ca^{2+} in the GI tract and thus should be avoided by patients who must restrict their intake of calcium or who are taking tetracycline. Sugar-free bulk laxatives may contain aspartame and are contraindicated in patients with phenylketonuria. Allergic reactions to psyllium have been reported.

Osmotically Active Agents

Saline Laxatives. Laxatives containing magnesium cations or phosphate anions commonly are called *saline laxatives*: magnesium sulfate, magnesium hydroxide, magnesium citrate, sodium phosphate. Their cathartic action is believed to result from osmotically mediated water retention, which then stimulates peristalsis. Other mechanisms may contribute to their effects, including the production of inflammatory mediators. Magnesium-containing laxatives may stimulate the release of cholecystokinin, which leads to intraluminal fluid and electrolyte accumulation and to increased intestinal motility. It is estimated that for every additional mEq of Mg^{2+} in the intestinal lumen, fecal weight increases by ~7 g. The usual dose of magnesium salts contains 40-120 mEq of Mg^{2+} and produces 300-600 mL of stool within 6 hours. The intensely bitter taste of some

Table 46-4

Properties of Different Dietary Fibers

TYPE OF FIBER	WATER SOLUBILITY	% FERMENTED
Nonpolysaccharides		
Lignin	Poor	0

Noncellulose polysaccharides		
Hemicellulose	Good	56-87
Mucilages and gums	Good	85-95
Pectins	Good	90-95

preparations may induce nausea and can be masked with citrus juices.

Phosphate salts are better absorbed than magnesium-based agents and therefore need to be given in larger doses to induce catharsis. The most frequently employed preparations of sodium phosphate are an oral solution (FLEET PHOSPHO-SODA) and tablets (VISICOL, OSMOPREP). Over-the-counter oral sodium phosphate products for bowel cleansing were withdrawn from the market in 2008 following the determination by the FDA that only prescription medications should be available for this purpose. To reduce the likelihood of acute phosphate nephropathy, oral phosphates should be avoided in patients at risk (the elderly, patients with known bowel pathology or renal dysfunction, and patients on angiotensin-converting enzyme [ACE] inhibitors, angiotensin receptor blockers [ARBs], and nonsteroidal anti-inflammatory drugs [NSAIDs]) and the two-dose regimens should be split evenly with the first dose taken the evening before the exam and the second starting 3-5 hours before the exam. Adequate fluid intake (1-3 L) is essential for any oral sodium phosphate regimen used for colonic preparation.

Magnesium- and phosphate-containing preparations must be used with caution or avoided in patients with renal insufficiency, cardiac disease, or preexisting electrolyte abnormalities, and in patients on diuretic therapy. Patients taking >45 mL of oral sodium phosphate as a prescribed bowel preparation may experience electrolyte shifts that pose a risk for the development of symptomatic dehydration, renal failure, metabolic acidosis, tetany from hypocalcemia, and even death in vulnerable populations.

Nondigestible Sugars and Alcohols. *Lactulose* (CEPHULAC, CHRONULAC, others) is a synthetic disaccharide of galactose and fructose that resists intestinal disaccharidase activity. This and other non-absorbable sugars such as sorbitol and mannitol are hydrolyzed in the colon to short-chain fatty acids, which stimulate colonic propulsive motility by osmotically drawing water into the lumen. Sorbitol and lactulose are equally efficacious in the treatment of constipation caused by opioids and

vincristine, of constipation in the elderly, and of idiopathic chronic constipation.

They are available as 70% solutions, which are given in doses of 15-30 mL at night, with increases as needed up to 60 mL per day in divided doses. Effects may not be seen for 24-48 hours after dosing is begun. Abdominal discomfort or distention and flatulence are relatively common in the first few days of treatment but usually subside with continued administration. A few patients dislike the sweet taste of the preparations; dilution with water or administering the preparation with fruit juice can mask the taste.

Lactulose also is used to treat hepatic encephalopathy. Patients with severe liver disease have an impaired capacity to detoxify ammonia coming from the colon, where it is produced by bacterial metabolism of fecal urea. The drop in luminal pH that accompanies hydrolysis to short-chain fatty acids in the colon results in “trapping” of the ammonia by its conversion to the polar ammonium ion. Combined with the increases in colonic transit, this therapy significantly lowers circulating ammonia levels. The therapeutic goal in this condition is to give sufficient amounts of lactulose (usually 20-30 g, three to four times per day) to produce two to three soft stools a day with a pH of 5-5.5.

Polyethylene Glycol-Electrolyte Solutions. Long-chain polyethylene glycols (PEGs; molecular weight ~3350 Da) are poorly absorbed, and PEG solutions are retained in the lumen by virtue of their high osmotic nature. When used in high volume, aqueous solutions of PEGs with electrolytes (COLYTE, GOLYTELY, others) produce an effective catharsis and have replaced oral sodium phosphates as the most widely used preparations for colonic cleansing prior to radiological, surgical, and endoscopic procedures. Usually 240 mL of this solution is taken every 10 minutes until 4 L is consumed or the rectal

effluent is clear. To avoid net transfer of ions across the intestinal wall, these preparations contain an isotonic mixture of sodium sulfate, sodium bicarbonate, sodium chloride, and potassium chloride. The osmotic activity of the PEG molecules retains the added water and the electrolyte concentration assures little or no net ionic shifts.

PEGs (without electrolytes) are also increasingly being used in smaller doses (250-500 mL daily) for the treatment of constipation in difficult cases. A powder form of polyethylene glycol 3350 (MIRALAX, others) is now available for the short-term treatment (≤ 2 weeks) of occasional constipation, although the agent has been prescribed safely for longer periods in clinical practice. The usual dose is 17 g of powder per day in 8 ounces of water. This preparation does not contain electrolytes, so larger volumes may represent a risk for ionic shifts. As with other laxatives, prolonged, frequent, or excessive use may result in dependence or electrolyte imbalance.

Stool-Wetting Agents and Emollients

Docusate salts are anionic surfactants that lower the surface tension of the stool to allow mixing of aqueous and fatty substances, softening the stool and permitting easier defecation. However, these agents also stimulate intestinal fluid and electrolyte secretion (possibly by increasing mucosal cyclic AMP) and alter intestinal mucosal permeability. Docusate sodium (dioctyl sodium sulfosuccinate; COLACE, DOXINATE, others) and docusate calcium (dioctyl calcium sulfosuccinate; SURFAK, others), are available in several dosage forms. Despite their widespread use, these agents have marginal, if any, efficacy in most cases of constipation.

Mineral oil is a mixture of aliphatic hydrocarbons obtained from petrolatum. The oil is indigestible and absorbed only to a limited extent. When mineral oil is taken orally for 2-3 days, it penetrates and softens the stool and may interfere with resorption of water. The side effects of mineral oil preclude its regular use and include interference with absorption of fat-soluble substances (such as vitamins), elicitation of foreign-body reactions in the intestinal mucosa and other tissues, and leakage of oil past the anal sphincter. Rare complications such as lipid pneumonitis due to aspiration also can occur, so “heavy” mineral oil should not be taken at bedtime and “light” (topical) mineral oil should never be administered orally.

Stimulant (Irritant) Laxatives

Stimulant laxatives have direct effects on enterocytes, enteric neurons, and GI smooth muscle. These agents probably induce a limited low-grade inflammation in the small and large bowel to promote accumulation of water and electrolytes and stimulate intestinal motility. Proposed

mechanisms include activation of prostaglandin–cyclic AMP and NO–cyclic GMP pathways, platelet-activating factor production (see earlier), and inhibition of Na^+ , K^+ -ATPase. Included in this group are diphenylmethane derivatives, anthraquinones, and ricinoleic acid.

Diphenylmethane Derivatives. Bisacodyl (DULCOLAX, CORRECTOL, others) is the only diphenylmethane derivative available in the U.S. It is marketed as enteric-coated and regular tablets and as a suppository for rectal administration.

The usual oral daily dose of bisacodyl is 10-15 mg for adults and 5-10 mg for children ages 6-12 years old. The drug requires hydrolysis by endogenous esterases in the bowel for activation, and so the laxative effects after an oral dose usually are not produced in <6 hours; taken at bedtime, it will produce its effect the next morning. Suppositories work much more rapidly, within 30-60 minutes. Due to the possibility of developing an atonic nonfunctioning colon, bisacodyl should not be used for >10 consecutive days.

Bisacodyl is mainly excreted in the stool; $\sim 5\%$ is absorbed and excreted in the urine as a glucuronide. Overdosage can lead to catharsis and fluid and electrolyte deficits. The diphenylmethanes can damage the mucosa and initiate an inflammatory response in the small bowel and colon. To avoid drug activation in the stomach with consequent gastric irritation and cramping, patients should swallow tablets without chewing or crushing and avoid milk or antacid medications within 1 hour of the ingestion of bisacodyl.

Phenolphthalein, once among the most popular components of laxatives, has been withdrawn from the market in the U.S. because of potential carcinogenicity. Oxyphenisatin, another older drug, was withdrawn due to hepatotoxicity. Sodium picosulfate (LUBRILAX, SUR-LAX) is a diphenylmethane derivative widely available outside of the U.S. It is hydrolyzed by colonic bacteria to its active form, and hence acts locally only in the colon. Effective doses of the diphenylmethane derivatives vary as much as 4- to 8-fold in individual patients. Consequently, recommended doses may be ineffective in some patients but may produce cramps and excessive fluid secretion in others.

Anthraquinone Laxatives. These derivatives of plants such as aloe, cascara, and senna share a tricyclic anthracene nucleus modified with hydroxyl, methyl, or carboxyl groups to form monoanthrones, such as rhein and frangula. Monoanthrones are irritating to the oral mucosa; however, the process of aging or drying converts them to more innocuous dimeric (dianthrones) or glycoside forms. This process is reversed by bacterial action in the colon to generate the active forms.

Senna (SENOKOT, EX-LAX, others) is obtained from the dried leaflets on pods of *Cassia acutifolia* or *Cassia angustifolia* and contains the rhein dianthrone glycosides sennoside A and B. *Cascara sagrada* is obtained from the bark of the buckthorn tree and contains the glycosides barbaloin and chrysaloin. Barbaloin is also found in aloe. The rhubarb plant also produces anthraquinone compounds that

have been used as laxatives. Anthraquinones can also be synthesized; however, the synthetic monoanthrone danthron was withdrawn from the U.S. market because of concerns over possible carcinogenicity. In addition, all aloe and cascara sagrada products sold as laxatives have been categorized by FDA as not generally recognized as safe and effective for over-the-counter use because of a lack of scientific information about potential carcinogenicity.

Although these ingredients may still be sold over-the-counter in the U.S., legally they cannot be labeled for use as laxatives. This judgment is medically prudent but may provoke a longing for times past in Joyceans, who recall that cascara sagrada, the *sacred bark*, worked well for Leopold Bloom, in Dublin, on June 16, 1904:

Midway, his last resistance yielding, he allowed his bowels to ease themselves quietly as he read, reading still patiently that slight constipation of yesterday quite gone. Hope its not too big to bring on piles again. No, just right. So. Ah! Costive one tabloid of cascara sagrada. Life might be so. (Joyce, 1922)

Anthraquinone laxatives can produce giant migrating colonic contractions and induce water and electrolyte secretion. They are poorly absorbed in the small bowel, but because they require activation in the colon, the laxative effect is not noted until 6-12 hours after ingestion. Active compounds are absorbed to a variable degree from the colon and excreted in the bile, saliva, milk, and urine.

The adverse consequences of long-term use of these agents have limited their use. A melanotic pigmentation of the colonic mucosa (*melanosis coli*) has been observed in patients using anthraquinone laxatives for long periods (at least 4-9 months). Histologically, this is caused by the presence of pigment-laden macrophages within the lamina propria. The condition is benign and reversible on discontinuation of the laxative. These agents also have been associated with the development of “cathartic colon,” which can be seen in patients (typically women) who have a long-standing history (typically years) of laxative abuse. Regardless of whether a definitive causal relationship can be demonstrated between the use of these agents and colonic pathology, it is clear that they should not be recommended for chronic or long-term use.

Castor Oil. A bane of childhood since the time of the ancient Egyptians, castor oil (PURGE, NEOLOID, others) is derived from the bean of the castor plant, *Ricinus communis*. The castor bean is the source of an extremely toxic protein, ricin, as well as the oil (chiefly of the triglyceride of ricinoleic acid). The triglyceride is hydrolyzed in the small bowel by the action of lipases into glycerol and the active agent, ricinoleic acid, which acts primarily in the small intestine to stimulate secretion of fluid and electrolytes and speed intestinal transit. When taken on an empty stomach, as little as 4 mL of castor oil may produce a laxative effect within 1-3 hours; however, the usual dose for a cathartic effect is 15-60 mL for adults. Because of its unpleasant taste and its potential toxic effects on intestinal epithelium and enteric neurons, castor oil is seldom recommended now.

Prokinetic and Other Agents for Constipation

Although several of the agents already described stimulate motility, they do so in nonspecific or indirect ways. By contrast, the term *prokinetic* generally is reserved for agents that enhance GI transit via interaction with specific receptors involved in the regulation of motility.

Newer agents, such as the potent 5-HT₄-receptor agonist prucalopride, may be useful for the treatment of chronic constipation. Another potentially useful agent is misoprostol, a synthetic prostaglandin analog primarily used for protection against gastric ulcers resulting from the use of NSAIDs (Chapters 34 and 45). Prostaglandins can stimulate colonic contractions, particularly in the descending colon, and this may account for the diarrhea that limits the usefulness of misoprostol as a gastroprotectant. However, this property may be utilized for therapeutic gain in patients with intractable constipation. Colchicine, a microtubule formation inhibitor used for gout (Chapter 34), also has been shown to be effective in constipation (mechanism unknown), but its toxicity has limited widespread use. A novel biological agent, neurotrophin-3 (NT-3), recently was shown to be effective in improving frequency and stool consistency and decreasing straining, again by an unknown mechanism of action.

A new development in the treatment of constipation is the introduction of drugs that enhance fluid secretion by acting locally on ion channels in the colonic epithelium, to promote secretion. Lubiprostone (AMITIZA) is a prostanoid activator of Cl⁻ channels. The drug appears to bind to EP₄ receptors linked to activation of adenylyl cyclase, leading to enhanced apical Cl⁻ conductance; the identity of the Cl⁻ channel(s) involved is not certain, possibly CFTR and CIC-2. Lubiprostone was recently introduced for treatment of chronic constipation in adults and irritable bowel syndrome with constipation (IBS-C) in adult women. The drug promotes the secretion of a chloride-rich fluid and so improves stool consistency and promotes increased frequency by reflexly activating motility. A dose of 8 µg twice daily was found to be effective in IBS-C, though higher doses (24 µg twice daily) is given for chronic constipation. The drug is poorly bioavailable, acting only in the lumen of the bowel. Side effects of lubiprostone include nausea, headache, diarrhea, allergic reactions, and dyspnea.

Another class of secretory agent is represented by linaclotide, a 14-amino acid peptide agonist of guanylate cyclase C that stimulates secretion and motility. This compound shows promise in the treatment of IBS-C and chronic constipation, and it appears to have few serious side effects (Gale, 2009). Recent work in rodents suggests it may also be antinociceptive, reducing

visceral pain (Eutamene et al., 2009), a major factor in IBS-C.

Opioid-Induced Constipation

Opioids are the main class of analgesics in the treatment and palliation of cancer, as well as other chronic pain states. Opioids cause severe constipation, which significantly limits their acceptability and reduces quality of life considerably. Laxatives and dietary strategies are frequently ineffective in the management of opioid-induced constipation. A promising strategy is the prevention of opioid-induced constipation with peripherally acting μ opioid receptor antagonists that specifically target the underlying reason for this condition, without limiting centrally produced analgesia. Methylnaltrexone (RELISTOR) was approved for the treatment of opioid-induced constipation by the FDA in 2008. Approval was based on multicenter trials demonstrating good efficacy in initiating bowel movements after injection of the drug in end-stage cancer patients in a hospice setting. When methylnaltrexone (0.15-0.3 mg/kg) was administered repeatedly every other day for 2 weeks, bowel movements occurred in 50% of the patients, compared with 8–15% of patients receiving placebo (Holzer, 2009). Another μ opioid antagonist, alvimopan (ENTEREG, 0.5-1 mg twice daily for 6 weeks) has also been tested in this setting where it increased spontaneous bowel movements and improved other symptoms of opioid-induced constipation without compromising analgesia (Holzer, 2009). Opioid-induced constipation represents an off-label use for alvimopan.

Post-operative Ileus

Post-operative ileus refers to the intolerance to oral intake and non-mechanical obstruction of the bowel that occurs after abdominal and non-abdominal surgery. It generally lasts 1-3 days after surgery with some variation along the length of the bowel. The pathogenesis is complex and is a combination of activation of neural inhibitory reflexes involving enteric μ opioid receptors and the activation of local inflammatory mechanisms that reduce smooth muscle contractility. The condition is exacerbated by opioids, which are the mainstay of post-operative analgesia. The extent to which endogenous opioids are involved in post-operative ileus remains to be determined. Prolonged post-operative ileus is hard to treat, and therefore considerable efforts are made to prevent its occurrence, including use of epidural anesthetics, minimally invasive surgeries, and reduced narcotic administration. Prokinetic agents typically do not have much effect in this condition, but recently, two

new therapeutic agents have been introduced that have benefit in reducing GI recovery time after surgery.

Alvimopan (ENTEREG) is an orally active peripherally restricted μ opioid receptor antagonist that is FDA approved for limited indications following surgery (12 mg prior to surgery and then once daily for up to 7 days or until discharge; not to exceed 15 doses total). Methylnaltrexone (RELISTOR) is another peripherally restricted μ opioid receptor antagonist that lacks anti-analgesic actions. Methylnaltrexone reportedly enhanced GI transit but did not reduce time to discharge compared to standard approaches (Holzer, 2009). It is FDA approved for the treatment of opioid-induced constipation in patients receiving palliative care when laxative therapy is insufficient.

Dexpanthenol (ILOPAN, others) is the alcohol of pantothenic acid (vitamin B₅). The drug is a congener of pantothenic acid, a precursor of coenzyme A, which serves as a cofactor in the synthesis of ACh by choline acetyl transferase. It is proposed to act by enhancing ACh synthesis. ACh is the major excitatory transmitter of the gut. Dexpanthenol is used as an injection immediately postoperatively after major abdominal surgery to minimize the occurrence of paralytic ileus. It is given by intramuscular injection (200-500 mg) immediately and then 2 hours later and every 6 hours after that until the situation has resolved. It may cause mild hypotension and shortness of breath as well as local irritation.

Enemas and Suppositories

Enemas commonly are employed, either by themselves or as adjuncts to bowel preparation regimens, to empty the distal colon or rectum of retained solid material. Bowel distention by any means will produce an evacuation reflex in most people, and almost any form of enema, including normal saline solution, can achieve this. Specialized enemas contain additional substances that are either osmotically active or irritant; however, their safety and efficacy have not been studied in a rigorous manner. Repeated enemas with tap water or other hypotonic solutions can cause hyponatremia; repeated enemas with sodium phosphate-containing solution can cause hypocalcemia. Phosphate-containing enemas also are known to alter the appearance of rectal mucosa and contribute to acute phosphate nephropathy in susceptible patients.

Glycerin is a trihydroxy alcohol that is absorbed orally but acts as a hygroscopic agent and lubricant when given rectally. The resultant water retention stimulates peristalsis and usually produces a bowel movement in less than an hour. Glycerin is for rectal use only and is given in a single daily dose as a 2- or 3-g rectal suppository or as 5-15 mL of an 80% solution in enema form. Rectal glycerin may cause local discomfort, burning, or hyperemia and (minimal) bleeding. Some glycerin suppositories contain sodium stearate, which can cause local irritation.

Another agent for occasional constipation makes use of rectal distension to initiate laxation. CEO-TWO suppositories contain

1336 sodium bicarbonate and potassium bitartrate. When administered rectally, the suppository produces CO₂, which initiates a bowel movement in 5-30 minutes.

ANTI-DIARRHEAL AGENTS

Diarrhea: General Principles and Approach to Treatment. Diarrhea (Greek and Latin: *dia*, through, and *rheein*, to flow or run) does not require any definition to people who suffer from “the too rapid evacuation of too fluid stools.” Scientists usually define diarrhea as excessive fluid weight, with 200 g per day representing the upper limit of normal stool water weight for healthy adults in the Western world. Because stool weight is largely determined by stool water, most cases of diarrhea result from disorders of intestinal water and electrolyte transport.

An appreciation and knowledge of the underlying causative processes in diarrhea facilitates effective treatment. From a mechanistic perspective, diarrhea can be caused by an increased osmotic load within the intestine (resulting in retention of water within the lumen); excessive secretion of electrolytes and water into the intestinal lumen; exudation of protein and fluid from the mucosa; and altered intestinal motility resulting in rapid transit (and decreased fluid absorption). In most instances, multiple processes are affected simultaneously, leading to a net increase in stool volume and weight accompanied by increases in fractional water content.

Many patients with sudden onset of diarrhea have a benign, self-limited illness requiring no treatment or evaluation. In severe cases, dehydration and electrolyte imbalances are the principal risk, particularly in infants, children, and frail elderly patients. *Oral rehydration therapy* therefore is a cornerstone for patients with acute illnesses resulting in significant diarrhea. This is of particular importance in developing countries, where the use of such therapy saves many thousands of lives every year. This therapy exploits the fact that nutrient-linked cotransport of water and electrolytes remains intact in the small bowel in most cases of acute diarrhea. Sodium and chloride absorption is linked to glucose uptake by the enterocyte; this is followed by movement of water in the same direction. A balanced mixture of glucose and electrolytes in volumes matched to losses therefore can prevent dehydration. This can be provided by many commercial premixed formulas using glucose-electrolyte or rice-based physiological solutions.

Pharmacotherapy of diarrhea in adults should be reserved for patients with significant or persistent symptoms. Nonspecific anti-diarrheal agents typically do not address the underlying pathophysiology responsible for

the diarrhea; their principal utility is to provide symptomatic relief in mild cases of acute diarrhea. Many of these agents act by decreasing intestinal motility and should be avoided as much as possible in acute diarrheal illnesses caused by invasive organisms. In such cases, these agents may mask the clinical picture, delay clearance of organisms, and increase the risk of systemic invasion by the infectious organisms; they also may induce local complications such as toxic megacolon.

Bulk-Forming and Hydroscopic Agents. Hydrophilic and poorly fermentable colloids or polymers such as *carboxymethylcellulose* and calcium polycarbophil absorb water and increase stool bulk (calcium polycarbophil absorbs 60 times its weight in water). They usually are used for constipation but are sometimes useful in acute episodic diarrhea and in mild chronic diarrheas in patients suffering with IBS. The mechanism of this effect is not clear, but they may work as gels to modify stool texture and viscosity and to produce a perception of decreased stool fluidity. Some of these agents also may bind bacterial toxins and bile salts. Clays such as kaolin (a hydrated aluminum silicate) and other silicates such as attapulgite (magnesium aluminum disilicate; DIASORB, others) bind water avidly (attapulgite absorbs eight times its weight in water) and also may bind enterotoxins. However, binding is not selective and may involve other drugs and nutrients; hence these agents are best avoided within 2-3 hours of taking other medications. A mixture of kaolin and pectin (a plant polysaccharide) is a popular over-the-counter remedy (KAOPECTOLIN, others) and may provide useful symptomatic relief of mild diarrhea.

Bile Acid Sequestrants. Cholestyramine, colestipol, and colesevalam effectively bind bile acids and some bacterial toxins. Cholestyramine is useful in the treatment of bile salt-induced diarrhea, as in patients with resection of the distal ileum. In these patients, there is partial interruption of the normal enterohepatic circulation of bile salts, resulting in excessive concentrations reaching the colon and stimulating water and electrolyte secretion. Patients with extensive ileal resection (usually >100 cm) eventually develop net bile salt depletion, which can produce steatorrhea because of inadequate micellar formation required for fat absorption. In such patients, the use of cholestyramine aggravates the diarrhea. The drug also has had an historic role in treating mild antibiotic-associated diarrhea and mild colitis due to *Clostridium difficile*. However, its use in infectious diarrheas generally is discouraged because it may decrease clearance of the pathogen from the bowel.

In patients suspected of having bile salt–induced diarrhea, a trial of cholestyramine (QUESTRAN, QUESTRAN LIGHT, others) can be given at a dose of 4 g of the dried resin (four times a day). If successful, the dose may be titrated down to achieve the desired stool frequency.

Cholestyramine resin also is helpful for the relief of pruritus associated with partial biliary obstruction and in conditions such as primary biliary cirrhosis. In such conditions, excessive bile acids are thought to be deposited in the skin and cause irritation. Cholestyramine increases fecal excretion of bile acids and reduces circulating and eventually systemic levels with relief of pruritus in ~1-3 weeks.

Bismuth. Bismuth compounds have been used to treat a variety of GI diseases and symptoms for centuries, although their mechanism of action remains poorly understood. PEPTO-BISMOL (or generic formulations of bismuth subsalicylate) is an over-the-counter preparation estimated to be used by 60% of American households. It is a crystal complex consisting of trivalent bismuth and salicylate suspended in a mixture of magnesium aluminum silicate clay. In the low pH of the stomach, the bismuth subsalicylate reacts with hydrochloric acid to form bismuth oxychloride and salicylic acid. Although 99% of the bismuth passes unaltered and unabsorbed into the feces, the salicylate is absorbed in the stomach and small intestine. Thus, the product carries the same labeled warning regarding Reye's syndrome as other salicylates, and patients taking other forms of salicylates should be made aware of the overlap in adverse effect.

Bismuth is thought to have anti-secretory, anti-inflammatory, and antimicrobial effects. Nausea and abdominal cramps also are relieved by bismuth. The clay in PEPTO-BISMOL and generic formulations also may have some additional benefits in diarrhea, but this is not clear. Bismuth subsalicylate has been used extensively for the prevention and treatment of traveler's diarrhea, but it also is effective in other forms of episodic diarrhea and in acute gastroenteritis. Today, the most common antibacterial use of this agent is in the treatment of *Helicobacter pylori* (Chapter 45). A recommended dose of the bismuth subsalicylate (30 mL of regular strength liquid or two tablets) contains approximately equal amounts of bismuth and salicylate (262 mg each). For control of indigestion, nausea, or diarrhea, the dose is repeated every 30-60 minutes, as needed, up to eight times a day. Bismuth products have a long track record of safety at recommended doses, although impaction may occur in infants and debilitated patients. Dark stools (sometimes mistaken for melena) and black staining of the tongue in association with bismuth compounds are caused by bismuth sulfide formed in a reaction between the drug and bacterial sulfides in the GI tract.

Probiotics. The GI tract contains a vast commensal microflora that is necessary for health. Alterations in the balance or composition of the microflora are responsible for antibiotic-associated diarrhea, and possibly other disease conditions. The administration of nonpathogenic bacteria to recolonize the gut is an area of intense investigation (Sartor, 2005). Probiotic preparations containing a variety of bacterial strains have shown some degree of benefit in acute diarrheal

conditions, antibiotic-associated diarrhea, and infectious diarrhea, but most clinical studies have been small and conclusions are therefore limited. Because these agents are generally safe, their use continues despite mainly anecdotal evidence of efficacy.

Anti-Motility and Anti-Secretory Agents

Opioids. Opioids continue to be widely used in the treatment of diarrhea. They act by several different mechanisms, mediated principally through either μ - or δ -opioid receptors on enteric nerves, epithelial cells, and muscle (Chapter 18). These mechanisms include effects on intestinal motility (μ receptors), intestinal secretion (δ receptors), or absorption (μ and δ receptors). Commonly used anti-diarrheals such as diphenoxylate, loperamide, and loperamide act principally via peripheral μ opioid receptors and are preferred over opioids that penetrate the CNS.

Loperamide. Loperamide (IMODIUM, IMODIUM A-D, others), a piperidine butyramide derivative with μ receptor activity, is an orally active anti-diarrheal agent. The drug is 40-50 times more potent than morphine as an anti-diarrheal agent and penetrates the CNS poorly. It increases small intestinal and mouth-to-cecum transit times. Loperamide also increases anal sphincter tone, an effect that may be of therapeutic value in some patients who suffer from anal incontinence. In addition, loperamide has anti-secretory activity against cholera toxin and some forms of *Escherichia coli* toxin, presumably by acting on G_i -linked receptors and counteracting the increase in cellular cyclic AMP generated in response to the toxins.

Because of its effectiveness and safety, loperamide is marketed for over-the-counter distribution and is available in capsule, solution, and chewable tablet forms. It acts quickly after an oral dose, with peak plasma levels achieved within 3-5 hours. It has a $t_{1/2}$ of ~11 hours and undergoes extensive hepatic metabolism. The usual adult dose is 4 mg initially followed by 2 mg after each subsequent loose stool, up to 16 mg per day. If clinical improvement in acute diarrhea does not occur within 48 hours, loperamide should be discontinued. Recommended maximum daily doses for children are 3 mg for ages 2-5 years, 4 mg for ages 6-8 years, and 6 mg for ages 8-12 years. Loperamide is not recommended for use in children <2 years of age.

Loperamide has been shown to be effective against traveler's diarrhea, used either alone or in combination with antimicrobial agents (trimethoprim, trimethoprim-sulfamethoxazole, or a fluoroquinolone). Loperamide also has been used as adjunct treatment in almost all forms of chronic diarrheal disease, with few adverse effects. Loperamide lacks significant abuse potential and is more effective in treating diarrhea than diphenoxylate. Overdosage, however, can result in CNS depression (especially in children) and paralytic ileus. In patients with active inflammatory bowel disease involving the colon (Chapter 47), loperamide should be used with great caution, if at all, to prevent development of toxic megacolon.

Loperamide N-oxide, an investigational agent, is a site-specific prodrug; it is chemically designed for controlled release of loperamide in the intestinal lumen, thereby reducing systemic absorption.

Diphenoxylate and Difenoxin. Diphenoxylate and its active metabolite difenoxin (diphenoxylate acid) are piperidine derivatives that are related structurally to meperidine. As anti-diarrheal agents, diphenoxylate and difenoxin are somewhat more potent than morphine.

Both compounds are extensively absorbed after oral administration, with peak levels achieved within 1-2 hours. Diphenoxylate is rapidly deesterified to difenoxin, which is eliminated with a $t_{1/2}$ of ~12 hours. Both drugs can produce CNS effects when used in higher doses (40-60 mg per day) and thus have a potential for abuse and/or addiction. They are available in preparations containing small doses of atropine (considered subtherapeutic) to discourage abuse and deliberate overdosage: 25 μ g of atropine sulfate per tablet with either 2.5 mg diphenoxylate hydrochloride (LOMOTIL) or 1 mg of difenoxin hydrochloride (MOTOFEN). The usual dosage is two tablets initially, then one tablet every 3-4 hours, not to exceed eight tablets per day. With excessive use or overdose, constipation and (in inflammatory conditions of the colon) toxic megacolon may develop. In high doses, these drugs cause CNS effects as well as anticholinergic effects from the atropine (dry mouth, blurred vision, etc.) (Chapter 9).

Other opioids used for diarrhea include codeine (in doses of 30 mg given three or four times daily) and opium-containing compounds. Paregoric (camphorated opium tincture) contains the equivalent of 2 mg of morphine per 5 mL (0.4 mg/mL); deodorized tincture of opium, which is 25 times stronger, contains the equivalent of 50 mg of morphine per 5 mL (10 mg/mL). The two tinctures sometimes are confused in prescribing and dispensing, resulting in dangerous overdoses. The anti-diarrheal dose of opium tincture for adults is 0.6 mL (equivalent to 6 mg morphine) four times daily; the adult dose of paregoric is 5-10 mL (equivalent to 2-4 mg morphine) one to four times daily. Paregoric is used in children at a dose of 0.25-0.5 mL/kg (equivalent to 0.1-0.2 mg morphine/kg) one to four times daily.

Enkephalins are endogenous opioids that are important enteric neurotransmitters. Enkephalins inhibit intestinal secretion without affecting motility. Racecadotril (acetorphan), a dipeptide inhibitor of enkephalinase, reinforces the effects of endogenous enkephalins on the δ -opioid receptor to produce an anti-diarrheal effect.

α_2 Adrenergic Receptor Agonists. α_2 Adrenergic receptor agonists such as clonidine can interact with specific receptors on enteric neurons and enterocytes, thereby stimulating absorption and inhibiting secretion of fluid and electrolytes and increasing intestinal transit time. These agents may have a special role in diabetics with chronic diarrhea, in whom autonomic neuropathy can lead to loss of noradrenergic innervation. Oral clonidine (beginning at 0.1 mg twice a day) has been used in these patients; the use of a topical preparation (e.g., CATAPRES TTS, two patches a week) may result in more steady plasma levels of the drug. Clonidine also may be useful in patients with diarrhea caused by opiate withdrawal. Side effects such as hypotension, depression, and perceived fatigue may be dose limiting in susceptible patients.

Octreotide and Somatostatin. Octreotide (SANDOSTATIN, others) (Chapter 43) is an octapeptide analog of somatostatin (SST) that is effective in inhibiting the severe secretory diarrhea brought about by hormone-secreting tumors of the pancreas and the GI tract. Its mechanism of action appears to involve inhibition of hormone secretion, including 5-HT and various other GI peptides (e.g., gastrin, vasoactive intestinal polypeptide (VIP), insulin, secretin, etc.). Octreotide has been used off label, with varying success, in other forms of secretory diarrhea such as chemotherapy-induced diarrhea, diarrhea associated with human immunodeficiency virus (HIV), and diabetes-associated diarrhea. Its greatest utility, however, may be in the “dumping syndrome” seen in some patients after gastric surgery and pyloroplasty. In this condition, octreotide inhibits the release of hormones (triggered by rapid passage of food into the small intestine) that are responsible for distressing local and systemic effects.

Octreotide has a $t_{1/2}$ of 1-2 hours and is administered either subcutaneously or intravenously as a bolus dose. Standard initial therapy with octreotide is 50-100 μ g, given subcutaneously two or three times a day, with titration to a maximum dose of 500 μ g three times a day based on clinical and biochemical responses. A long-acting preparation of octreotide acetate enclosed in biodegradable microspheres (SANDOSTATIN LAR DEPOT) is available for use in the treatment of diarrheas associated with carcinoid tumors and VIP-secreting tumors, as well as in the treatment of acromegaly (Chapter 44). This preparation is injected intramuscularly once per month in a dose of 20 or 30 mg. Side effects of octreotide depend on the duration of therapy. Short-term therapy leads to transient nausea, bloating, or pain at sites of injection. Long-term therapy can lead to gallstone formation and hypo- or hyperglycemia. Another long-acting SST analog, lanreotide (SOMATULIN, others), is available in Europe but not in the U.S.; another, vapreotide, is under development. SST (STILAMIN) also is available in Europe.

Variceal Bleeding. Vasoactive agents have been used to control variceal bleeding. Traditionally, vasopressin has been used (Chapter 26), but its significant side effects—such as myocardial ischemia, peripheral vascular disease, and the release of plasminogen activator and factor VIII—have led to its decline. SST and octreotide are effective in reducing hepatic blood flow, hepatic venous wedge pressure, and azygos blood flow. These agents constrict the splanchnic arterioles by a direct action on vascular smooth muscle and by inhibiting the release of peptides contributing to the hyperdynamic circulatory syndrome of portal hypertension. Octreotide also may act through the autonomic nervous system. These agents can control bleeding acutely and decrease bleeding-related mortality, with an efficacy comparable to endoscopic therapy or balloon tamponade. The major advantage of somatostatin and octreotide over vasopressin is their safety. Because of its short $t_{1/2}$ (1-2 minutes), SST can be given only by intravenous infusion (a 250 μ g bolus dose followed by 250 μ g hourly for 5 days). Higher doses (up to 500 μ g/hour) are more efficacious and can be used for patients who continue to bleed on the lower dose (Moitinho

et al., 2001). For patients with variceal bleeding, therapy with octreotide usually is initiated while the patient is awaiting endoscopy.

Intestinal Dysmotility. Octreotide has complex and apparently conflicting effects on GI motility, including inhibition of antral motor activity and colonic tone. However, octreotide also can rapidly induce phase III activity of the migrating motor complex in the small bowel to produce longer and faster contractions than those occurring spontaneously. Its use has been shown to result in improvement in selected patients with scleroderma and small-bowel dysfunction.

Pancreatitis. Both SST and octreotide inhibit pancreatic secretion and have been used for the prophylaxis and treatment of acute pancreatitis. The rationale for their use is to “put the pancreas to rest” so as to not aggravate inflammation by the continuing production of proteolytic enzymes, to reduce intraductal pressures, and to ameliorate pain. Octreotide probably is less effective than SST in this regard because it may cause an increase in sphincter of Oddi pressure and perhaps also have a deleterious effect on pancreatic blood flow. Although some studies have suggested that these agents improve mortality in patients with acute pancreatitis, definitive data are lacking.

Other Agents

Calcium channel blockers such as verapamil and nifedipine (Chapters 25 and 27) reduce motility and may promote intestinal electrolyte and water absorption. Constipation, in fact, is a significant side effect of these drugs. However, because of their systemic effects and the availability of other agents, they seldom if ever are used for diarrheal illnesses.

Berberine is a plant alkaloid that has been used for millennia in traditional Indian and Chinese medicine. It is produced by several genera of the families Ranunculaceae and Berberidaceae (e.g., *Berberis*, *Mahonia*, and *Coptis*) and has complex pharmacological actions that include antimicrobial actions, stimulation of bile flow, inhibition of ventricular tachyarrhythmias, and possible antineoplastic activity. It is used most commonly in bacterial diarrhea and cholera, but is also apparently effective against intestinal parasites. The anti-diarrheal effects in part may be related to its antimicrobial activity, as well as its ability to inhibit smooth muscle contraction and delay intestinal transit by antagonizing the effects of ACh (by competitive and noncompetitive mechanisms) and blocking the entry of Ca^{2+} into cells. In addition, it inhibits intestinal secretion.

Chloride channel blockers are effective anti-secretory agents *in vitro* but are too toxic for human use and have not proven to be effective anti-diarrheal agents *in vivo*. Calmodulin inhibitors, which include chlorpromazine, also are anti-secretory. Zaldaride maleate, an investigational drug in this class, may be effective in traveler’s diarrhea by reducing secretion without affecting intestinal motility.

IRRITABLE BOWEL SYNDROME (IBS)

IBS, a condition that affects up to 15% of the population in the U.S., is perhaps one of the more challenging nonfatal illnesses seen by gastroenterologists (Mertz, 2003). Patients may complain of a variety of symptoms, the most characteristic of which is recurrent abdominal

pain associated with altered bowel movements. The pathophysiology of this condition is not clear; it appears to result from a varying combination of disturbances in visceral motor and sensory function, often associated with significant affective disorders. The disturbances in bowel function, which can be either constipation or diarrhea or both at different times, have led to the classical interpretation of IBS as being a “motility disorder,” but motor disturbances cannot explain the entire clinical picture. Recently, more emphasis has been devoted to the pathogenesis of pain in these patients, and there now is considerable evidence to suggest a specific enhancement of visceral (as opposed to somatic) sensitivity to noxious, as well as physiological stimuli in this syndrome. The etiopathogenesis of this visceral hypersensitivity probably is multifactorial; a popular hypothesis is that transient visceral injury in genetically predisposed individuals leads to long-lasting sensitization of the neural pain circuit despite complete resolution of the initiating event. Increasingly, this concept is being extended to other so-called functional disorders of the gut characterized by unexplained pain, including noncardiac chest pain and nonulcer dyspepsia. These disorders, also considered for many years to arise from motor disturbances, may in fact represent part of a spectrum of a new syndrome of “visceral hyperalgesia.”

Many patients can be managed satisfactorily with a strong patient-physician relationship, simple counseling, and adjunctive measures, including dietary restrictions and fiber supplementation; overt psychological abnormalities should be treated appropriately. Despite these measures, a significant proportion of patients remain plagued by severe symptoms, and drug therapy is attempted almost invariably. However, there are very few effective pharmacological options for these patients, a situation that in part reflects our limited understanding of the pathogenesis of this syndrome.

The pharmacological approach to IBS reflects its multifaceted nature. Treatment of bowel symptoms (either diarrhea or constipation) is predominantly symptomatic and nonspecific. Patients with mild symptoms often are started on fiber supplements; this approach may work for constipation and diarrhea (by binding water). Patients with episodic, discrete pain episodes often are treated with agents that may reduce smooth muscle contractility in the gut. These so-called antispasmodics include anticholinergic agents, Ca^{2+} channel antagonists, and peripheral opioid receptor antagonists. The use of most such drugs is hallowed by years of tradition but seldom has been subjected to critical assessment; however, these drugs may be modestly effective in a subset of patients and are useful adjuncts.

In recent years, an increasing emphasis is being placed on the pharmacological treatment of visceral sensitivity. Although the biological basis of visceral hyperalgesia in IBS patients is not known, a possible role for serotonin has been suggested based on its known

involvement in sensitization of nociceptor neurons in inflammatory conditions. This has led to the development of specific receptor modulators, such as the 5-HT₃ antagonist alosetron (Figure 46–2). Buspirone and sumatriptan are 5-HT₁ receptor agonists (Chapter 13) that can reduce gastric and colonic sensitivity to distention and are being evaluated in clinical trials.

The most effective class of agents in this regard has been the tricyclic anti-depressants (Chapter 15), which can have neuromodulatory and analgesic properties independent of their anti-depressant effect. Tricyclic anti-depressants have a proven track record in the management of chronic “functional” visceral pain. Effective analgesic doses of these drugs (e.g., 25–75 mg per day of nortriptyline) are significantly lower than those required to treat depression. Although changes in mood usually do not occur at these doses, there may be some diminution of anxiety and restoration of sleep patterns, which can be considered desirable effects in this group of patients. Selective serotonin reuptake inhibitors have fewer side effects and have been advocated particularly for patients with functional constipation because they can increase bowel movements and even cause diarrhea. However, they probably are not as effective as tricyclic anti-depressants in the management of visceral pain.

α_2 Adrenergic agonists, such as clonidine (Chapter 12), also can increase visceral compliance and reduce distention-induced pain. The SST analog octreotide has selective inhibitory effects on peripheral afferent nerves projecting from the gut to the spinal cord in healthy human beings and has been shown to blunt the perception of rectal distention in patients with IBS. Fedotozine, an investigational opioid that appears to be a peripherally active, selective κ receptor antagonist, produces marginal improvement in symptoms in patients with IBS and functional dyspepsia. The lack of CNS effects is an advantage in such patients in whom chronic medication use is anticipated. Other agents of unproven value include leuprolide, a gonadotropin-releasing hormone analog (Chapter 42).

Alosetron and Other 5-HT₃ Antagonists

The 5-HT₃ receptor participates in several important processes in the gut, including sensitization of spinal sensory neurons, vagal signaling of nausea, and peristaltic reflexes. Some of these effects in experimental models are potentially conflicting, with release of excitatory and inhibitory neurotransmitters. However, the clinical effect of 5-HT₃ antagonism is a general reduction in GI contractility with decreased colonic transit, along with an increase in fluid absorption. In general, therefore, these antagonists produce the opposite effects seen with 5-HT₄ agonists. Although they also may blunt visceral sensation, a direct effect on spinal afferents has not been fully established. Alosetron (LOTRONEX) was the first agent in this class specifically approved for the treatment of diarrhea-predominant IBS in women. Alosetron is a much more potent antagonist of the 5-HT₃ receptor than ondansetron and causes significant (although modest) improvements in abdominal pain as well as stool frequency, consistency, and urgency in these patients. Shortly after its initial release, alosetron was withdrawn from the U.S. market because of an unusually high incidence of ischemic colitis (up to 3 per 1000 patients), leading to surgery and even death in a small number of cases. The mechanism of this effect is not fully established but may result from the drug’s ability to suppress intestinal relaxation, thereby causing severe spasm in segments of the colon in susceptible individuals. It is not clear whether this is a nonspecific

effect or involves serotonergic mechanisms. Nevertheless, the FDA has reapproved this drug for diarrhea-predominant IBS under a limited distribution system. However, concerns about the consequences of prescribing this drug are important, and the manufacturer requires a prescription program that includes physician certification and an elaborate patient education and consent protocol before dispensing.

Alosetron is rapidly absorbed from the GI tract; its duration of action (~10 hours) is longer than expected from its $t_{1/2}$ of 1.5 hours. It is metabolized by hepatic CYPs. The drug should be started at 1 mg per day for the first 4 weeks and advanced to a maximum of 1 mg twice daily if an adequate response is not achieved.

Other 5-HT₃ antagonists currently available in the U.S. are approved for nausea and vomiting (see later in this chapter and Chapter 13).

ANTI-SPASMODICS AND OTHER AGENTS

Anticholinergic agents (“spasmolytics” or “anti-spasmodics”) often are used in patients with IBS. The most common agents of this class available in the U.S. are nonspecific antagonists of the muscarinic receptor (Chapter 9) and include the tertiary amines dicyclomine (BENTYL, others) and hyoscyamine (LEVSIN, others) and the quaternary ammonium compounds glycopyrrolate (ROBINUL, others) and methscopolamine (PAMINE, others). The advantage of the latter two compounds is that they have a limited propensity to cross the blood-brain barrier and hence a lower risk for neurological side effects such as lightheadedness, drowsiness, or nervousness. These agents typically are given either on an as-needed basis (with the onset of pain) or before meals to prevent the pain and fecal urgency that predictably occur in some patients with IBS (with presumed exaggerated gastrocolic reflex).

Dicyclomine is given in doses of 20 mg orally every 6 hours initially and increased to 40 mg every 6 hours unless limited by side effects. Doses <160 mg/day are not usually effective and should be discontinued after a 2-week trial period. Hyoscyamine is available as immediate-release oral capsules, tablets, elixir, drops, and a nonaerosol spray (all administered as 0.125–0.25 mg every 4 hours as needed), and extended-release forms for oral use (0.25–0.375 mg every 12 hours as needed). An injectable is available for subcutaneous, intravenous, or intramuscular administration. Regardless of the formulation, the adult dose of hyoscyamine usually should not exceed 1.5 mg in 24 hours. Glycopyrrolate is available as immediate-release tablets; the dose is 1–2 mg two or three times daily, not to exceed 8 mg/day. Methscopolamine is provided as 2.5-mg and 5-mg tablets; the dose is 2.5 mg a half hour before meals and 2.5–5 mg at bedtime.

Other Drugs. Cimetropium, an antimuscarinic compound that reportedly is effective in patients with IBS, is not available in the U.S. Otilonium bromide is a quaternary ammonium salt with antimuscarinic effects that also appears to block Ca²⁺ channels and neurokinin

NK₂ receptors; it is not available in the U.S. but has been used extensively for patients with IBS in other parts of the world. Mebeverine hydrochloride is a derivative of hydroxybenzamide that appears to have a direct effect on the smooth muscle cell, blocking K⁺, Na⁺, and Ca²⁺ channels. It is widely used outside of the U.S. as an anti-spasmodic agent for patients with IBS.

ANTI-NAUSEANTS AND ANTI-EMETIC AGENTS

Nausea and Vomiting

The act of emesis and the sensation of nausea that accompanies it generally are viewed as protective reflexes that serve to rid the stomach and intestine of toxic substances and prevent their further ingestion. Vomiting is a complex process that consists of a pre-ejection phase (gastric relaxation and retroperistalsis), retching (rhythmic action of respiratory muscles preceding vomiting and consisting of contraction of abdominal and intercostal muscles and diaphragm against a closed glottis), and ejection (intense contraction of the abdominal muscles and relaxation of the upper esophageal sphincter). This is accompanied by multiple autonomic phenomena including salivation, shivering, and vasomotor changes. During prolonged episodes, marked behavioral changes including lethargy, depression, and withdrawal may occur. The process appears to be coordinated by a central emesis center in the lateral reticular formation of the midbrainstem adjacent to both the chemoreceptor trigger zone (CTZ) in the area postrema (AP) at the bottom of the fourth ventricle and the solitary tract nucleus (STN). The lack of a blood-brain barrier allows the CTZ to monitor blood and cerebrospinal fluid constantly for toxic substances and to relay information to the emesis center to trigger nausea and vomiting. The emesis center also receives information from the gut, principally by the vagus nerve (via the STN) but also by splanchnic afferents via the spinal cord. Two other important inputs to the emesis center come from the cerebral cortex (particularly in anticipatory nausea or vomiting) and the vestibular apparatus (in motion sickness). In turn, the center sends out efferents to the nuclei responsible for respiratory, salivary, and vasomotor activity, as well as to striated and smooth muscle involved in the act. The CTZ has high concentrations of receptors for serotonin (5-HT₃), dopamine (D₂), and opioids; the STN is rich in receptors for enkephalin, histamine, and ACh, and also contains 5-HT₃ receptors. A variety of these

neurotransmitters are involved in nausea and vomiting (Figure 46–4), and an understanding of their nature has allowed a rational approach to the pharmacological treatment of nausea and vomiting (Hornby, 2001; Scuderi, 2003).

Anti-emetics generally are classified according to the predominant receptor on which they are proposed to act (Table 46–5). However, considerable overlap among these mechanisms exists, particularly for the older agents (Table 46–6). For treatment and prevention of the nausea and emesis associated with cancer chemotherapy, several anti-emetic agents from different pharmacological classes may be used in combination (Table 46–7). The individual classes of agents are presented next.

5-HT₃ Receptor Antagonists

Chemistry, Pharmacological Effects, and Mechanism of Action.

Ondansetron (ZOFTRAN, others) is the prototypical drug in this class. Since their introduction in the early 1990s, the 5-HT₃ receptor antagonists have become the most widely used drugs for chemotherapy-induced emesis. Other agents in this class include granisetron (KYTRIL, others), dolasetron (ANZEMET), palonosetron (ALOXI), and tropisetron (available in some countries but not in the U.S.). The differences among these agents are related mainly to their chemical structures, 5-HT₃ receptor affinities, and pharmacokinetic profiles (Table 46–8). Alosetron was discussed separately earlier.

There is evidence that effects at peripheral and central sites contribute to the efficacy of these agents. 5-HT₃ receptors are present in several critical sites involved in emesis, including vagal afferents, the STN (which receives signals from vagal afferents), and the area postrema itself (Figure 46–4). Serotonin is released by the enterochromaffin cells of the small intestine in response to chemotherapeutic agents and may stimulate vagal afferents (via 5-HT₃ receptors) to initiate the vomiting reflex. Experimentally, vagotomy has been shown to prevent cisplatin-induced emesis. However, the highest concentrations of 5-HT₃ receptors in the CNS are found in the STN and CTZ, and antagonists of 5-HT₃ receptors also may suppress nausea and vomiting by acting at these sites.

Pharmacokinetics. The anti-emetic effects of these drugs persist long after they disappear from the circulation, suggesting their continuing interaction at the receptor level. In fact, all of these drugs can be administered effectively just once a day.

These agents are absorbed well from the GI tract. Ondansetron is extensively metabolized in the liver by CYP1A2, CYP2D6, and CYP3A4, followed by glucuronide or sulfate conjugation. Patients with hepatic dysfunction have reduced plasma clearance, and some adjustment in the dosage is advisable. Although ondansetron clearance also is reduced in elderly patients, no adjustment in dosage for age is recommended. Granisetron also is metabolized predominantly by the liver, a process that appears to involve

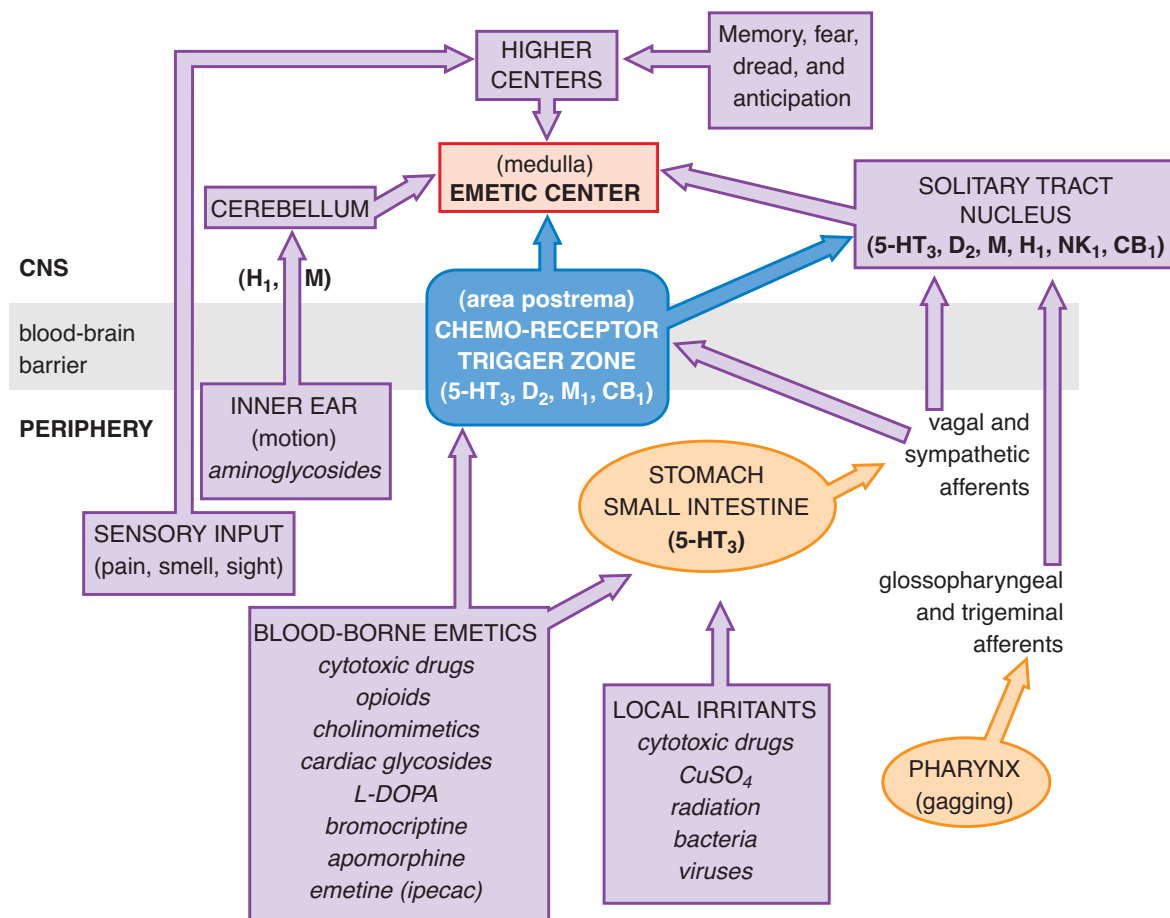

Figure 46–4. *Pharmacologist’s view of emetic stimuli.* Myriad signaling pathways lead from the periphery to the emetic center. Stimulants of these pathways are noted in *italics*. These pathways involve specific neurotransmitters and their receptors (**bold** type). Receptors are shown for dopamine (D_2), acetylcholine (muscarinic, M), histamine (H_1), cannabinoids (CB_1), substance P (NK_1), and 5-hydroxytryptamine ($5-HT_3$). Some of these receptors also may mediate signaling in the emetic center.

Table 46–5

General Classification of Anti-emetic Agents

ANTI-EMETIC CLASS	EXAMPLES	TYPE OF VOMITING MOST EFFECTIVE AGAINST
5-HT ₃ receptor antagonists ^a	Ondansetron	Cytotoxic drug induced emesis
Centrally acting dopamine receptor antagonists	Metoclopramide ^b	Cytotoxic drug induced emesis
Histamine H ₁ receptor antagonists	Promethazine ^c	
Muscarinic receptor antagonists	Cyclizine	Vestibular (motion sickness)
Neurokinin receptor antagonists	Hyoscine (scopolamine)	Motion sickness
Cannabinoid receptor agonists	Aprepitant	Cytotoxic drug induced emesis (delayed vomiting)
	Dronabinol	Cytotoxic drug induced emesis

^aThe most effective agents for chemotherapy-induced nausea and vomiting are the 5-HT₃ antagonists and metoclopramide. In addition to their use as single agents, they are often combined with other drugs to improve efficacy as well as reduce the incidence of side effects.

^bAlso has some peripheral activity at 5-HT₃ receptors.

^cAlso has some antihistaminic and anticholinergic activity.

Steroids				
Betamethasone, dexamethasone	–	–	–	–

For details, see Scuderi, 2003. Plus signs indicate some (+) to considerable (++++) interaction. (–) indicates no effect.

the CYP3A family, as it is inhibited by ketoconazole. Dolasetron is converted rapidly by plasma carbonyl reductase to its active metabolite, hydrodolasetron. A portion of this compound then undergoes subsequent biotransformation by CYP2D6 and CYP3A4 in the liver while about one-third of it is excreted unchanged in the urine. Palonosetron is metabolized principally by CYP2D6 and excreted in the urine as the metabolized and the unchanged forms in about equal proportions.

Therapeutic Use. These agents are most effective in treating chemotherapy-induced nausea and in treating nausea secondary to upper abdominal irradiation, where all three agents appear to be equally efficacious. They also are effective against hyperemesis of pregnancy, and to a lesser degree, postoperative nausea, but not against motion sickness. Unlike other agents in this class, palonosetron also may be helpful in delayed emesis, perhaps a reflection of its long $t_{1/2}$.

These agents are available as tablets, oral solution, and intravenous preparations for injection. For patients on cancer chemotherapy, these drugs can be given in a single intravenous dose (Table 46–8) infused over 15 minutes, beginning 30 minutes before chemotherapy, or in 2–3 divided doses, with the first usually given 30 minutes before

and subsequent doses at various intervals after chemotherapy. The drugs also can be used intramuscularly (ondansetron only) or orally. Granisetron is available as a transdermal formulation that is applied 24–48 hours before chemotherapy and worn for up to 7 days.

Adverse Effects. In general, these drugs are very well tolerated, with the most common adverse effects being constipation or diarrhea, headache, and lightheadedness. As a class, these agents have been shown experimentally to induce minor electrocardiographic changes, but these are not expected to be clinically significant in most cases.

Dopamine-Receptor Antagonists

Phenothiazines such as prochlorperazine, thiethylperazine (discontinued in the U.S.), and chlorpromazine (Chapter 16) are among the most commonly used “general-purpose” anti-nauseants and antiemetics. Their effects in this regard are complex, but their principal mechanism of action is D₂ receptor antagonism at the CTZ. Compared with metoclopramide or ondansetron, these drugs do not appear to be as uniformly effective in cancer chemotherapy–induced emesis. But they also possess antihistaminic and anticholinergic activities, which are of value in other forms of nausea, such as motion sickness.

Table 46-7

A. Some Anti-emetic Regimens Used in Cancer Chemotherapy

ANTI-EMETIC AGENT	INITIAL DOSE
For Severe Chemotherapy-Induced Emesis (Several Anti-emetic Agents Used in Combination)	
Dexamethasone	20 mg IV
Metoclopramide	3 mg/kg body weight IV every 2 h × 2
Diphenhydramine	25-50 mg IV every 2 h × 2
Lorazepam	1-2 mg IV
Dexamethasone	20 mg IV
Ondansetron	32 mg IV daily, in divided doses
For Moderate Chemotherapy-Induced Emesis (Anti-emetic Agents Used Singly)	
Prochlorperazine	5-10 mg orally or IV, or 25 mg by rectal suppository
Thiethylperazine	10 mg orally, IM, or by rectal suppository
Dexamethasone	10-20 mg IV
Ondansetron	8 mg orally or 10 mg IV
Dronabinol	10 mg orally

B. Useful Combinations of Anti-emetic Agents for Improved Anti-emetic Effect

PRIMARY AGENT	SUPPLEMENTAL AGENT
5-HT ₃ receptor antagonist	Corticosteroid, phenothiazine, butyrophenone, NK ₁ antagonist
Substituted benzamide	Corticosteroid ± muscarinic receptor antagonist
Phenothiazine/butyrophenone	Corticosteroid
Corticosteroid	Benzodiazepine
Cannabinoid	Corticosteroid

C. Useful Combinations of Anti-emetic Agents Providing Decreased Toxicity of the Primary Agent

PRIMARY AGENT	SUPPLEMENTAL AGENT
Substituted benzamide	H ₁ receptor antagonist, corticosteroid, benzodiazepine
Phenothiazine/butyrophenone	H ₁ receptor antagonist
Cannabinoid	Phenothiazine

H, histamine, 5-HT, serotonin; IV, intravenous; IM, intramuscular.

Antihistamines

Histamine H₁ antagonists are primarily useful for motion sickness and postoperative emesis. They act on vestibular afferents and within the brainstem. Cyclizine, hydroxyzine, promethazine, and diphenhydramine are examples of this class of agents. Cyclizine has additional anticholinergic effects that may be useful for patients with abdominal cancer. For a detailed discussion of these drugs, see Chapter 32.

Anticholinergic Agents

The most commonly used muscarinic receptor antagonist is scopolamine (hyoscine), which can be injected as the hydrobromide, but usually is administered as the free base in the form of a transdermal patch (TRANSDERM-SCOP). Its principal utility is in the prevention and treatment of motion sickness, although it has been shown to have some activity in postoperative nausea and vomiting tool. In general, anticholinergic agents have no role in chemotherapy-induced nausea. For a detailed discussion of these drugs, see Chapter 9.

Substance P Receptor Antagonists

The nausea and vomiting associated with cisplatin (Chapter 61) have two components: an acute phase that universally is experienced (within 24 hours after chemotherapy) and a delayed phase that affects only some patients (on days 2-5). 5-HT₃ receptor antagonists are not very effective against delayed emesis. Antagonists of the NK₁ receptors for substance P, such as aprepitant (and its parenteral formulation, fosaprepitant; EMEND), have anti-emetic effects in delayed nausea and improve the efficacy of standard anti-emetic regimens in patients receiving multiple cycles of chemotherapy.

After absorption, aprepitant is bound extensively to plasma proteins (>95%); it is metabolized avidly, primarily by hepatic CYP3A4, and is excreted in the stools; its $t_{1/2}$ is 9-13 hours. Aprepitant has the potential to interact with other substrates of CYP3A4, requiring adjustment of other drugs, including dexamethasone, methylprednisolone (whose dose may need to be reduced by 50%), and warfarin. Aprepitant is contraindicated in patients on cisapride or pimozide, in whom life-threatening QT prolongation has been reported.

Aprepitant is supplied in 40-, 80- and 125-mg capsules and is administered for 3 days in conjunction with highly emetogenic chemotherapy, along with a 5-HT₃ antagonist and a corticosteroid. The recommended adult dosage of aprepitant is 125 mg administered 1 hour before chemotherapy on day 1, followed by 80 mg once daily in the morning on days 2 and 3 of the treatment regimen.

Cannabinoids

Dronabinol (Δ -9-tetrahydrocannabinol; marinol) is a naturally occurring cannabinoid that can be synthesized chemically or

Table 46–8

5-HT₃ Antagonists in Chemotherapy-Induced Nausea/Emesis

DRUG	CHEMICAL NATURE	RECEPTOR INTERACTIONS	t _{1/2}	DOSE (IV)
Ondansetron	Carbazole derivative	5-HT ₃ antagonist and weak 5-HT ₄ antagonist	3.9 h	0.15 mg/kg
Granisetron	Indazole	5-HT ₃ antagonist	9–11.6 h	10 µg/kg
Dolasetron	Indole moiety	5-HT ₃ antagonist	7–9 h	1.8 mg/kg
Palonosetron	Isoquinoline	5-HT ₃ antagonist; highest affinity for 5-HT ₃ receptor in this class	40 h	0.25 mg

IV, intravenous.

extracted from the marijuana plant, *Cannabis sativa*. The exact mechanism of the anti-emetic action of dronabinol is not known but probably relates to stimulation of the CB₁ subtype of cannabinoid receptors on neurons in and around the vomiting center in the brainstem (Van Sickle et al., 2001).

Pharmacokinetics. Dronabinol is a highly lipid-soluble compound that is absorbed readily after oral administration; its onset of action occurs within an hour, and peak levels are achieved within 2–4 hours. It undergoes extensive first-pass metabolism with limited systemic bioavailability after single doses (only 10–20%). Active and inactive metabolites are formed in the liver; the principal active metabolite is 11-OH-delta-9-tetrahydrocannabinol.

These metabolites are excreted primarily via the biliary-fecal route, with only 10–15% excreted in the urine. Both dronabinol and its metabolites are highly bound (>95%) to plasma proteins. Because of its large volume of distribution, a single dose of dronabinol can result in detectable levels of metabolites for several weeks.

Therapeutic Use. Dronabinol is a useful prophylactic agent in patients receiving cancer chemotherapy when other anti-emetic medications are not effective. It also can stimulate appetite and has been used in patients with acquired immunodeficiency syndrome (AIDS) and anorexia. As an anti-emetic agent, it is administered at an initial dose of 5 mg/m² given 1–3 hours before chemotherapy and then every 2–4 hours afterward for a total of four to six doses. If this is not adequate, incremental increases can be made up to a maximum of 15 mg/m² per dose. For other indications, the usual starting dose is 2.5 mg twice a day; this can be titrated up to a maximum of 20 mg per day.

Adverse Effects. Dronabinol has complex effects on the CNS, including a prominent central sympathomimetic activity. This can lead to palpitations, tachycardia, vasodilation, hypotension, and conjunctival injection (bloodshot eyes). Patient supervision is necessary because marijuana-like “highs” (e.g., euphoria, somnolence,

detachment, dizziness, anxiety, nervousness, panic, etc.) can occur, as can more disturbing effects such as paranoid reactions and thinking abnormalities. After abrupt withdrawal of dronabinol, an abstinence syndrome (irritability, insomnia, and restlessness) can occur. Because of its high affinity for plasma proteins, dronabinol can displace other plasma protein-bound drugs, whose doses may have to be adjusted as a consequence. Dronabinol should be prescribed with great caution to persons with a history of substance abuse (alcohol, drugs) because it also may be abused by these patients.

Nabilone (CESAMET) is a synthetic cannabinoid with a mode of action similar to that of dronabinol.

Pharmacokinetics. Nabilone, like dronabinol, is a highly lipid-soluble compound that is rapidly absorbed after oral administration; its onset of action occurs within an hour, and peak levels are achieved within 2 hours. The t_{1/2} is ~2 hours for the parent compound and 35 hours for metabolites. The metabolites are excreted primarily via the biliary-fecal route (60%), with only ~25% excreted in the urine.

Therapeutic Use. Nabilone is a useful prophylactic agent in patients receiving cancer chemotherapy when other anti-emetic medications are not effective. A dose (1–2 mg) can be given the night before chemotherapy; usual dosing starts 1–3 hours before treatment and then every 8–12 hours during the course of chemotherapy and for 2 days following its cessation.

Adverse Effects. The adverse effects are largely the same as for dronabinol, with significant CNS actions in >10% of patients. Cardiovascular, GI, and other side effects are also common and together with the CNS actions limit the usefulness of this agent.

Glucocorticoids and Anti-Inflammatory Agents

Glucocorticoids such as dexamethasone can be useful adjuncts (Table 46–7) in the treatment of nausea in patients with widespread cancer, possibly by suppressing peritumoral inflammation and prostaglandin production. A similar mechanism has been invoked to explain beneficial effects of NSAIDs in the nausea and vomiting induced by systemic irradiation. For a detailed discussion of these drugs, see Chapters 34 and 42.

Benzodiazepines

Benzodiazepines, such as lorazepam and alprazolam, by themselves are not very effective anti-emetics, but their sedative, amnesic, and anti-anxiety effects can be helpful in reducing the anticipatory

Phosphorated Carbohydrate Solutions

Aqueous solutions of glucose, fructose, and phosphoric acid (EMETROL, NAUSETROL) are available over the counter to relieve nausea. Their mechanism of action is not well established. They may be safely taken for a short period (1 hour with a dose every 15 minutes).

AGENTS USED FOR MISCELLANEOUS GI DISORDERS

Chronic Pancreatitis and Steatorrhea

Pancreatic Enzymes. Chronic pancreatitis is a debilitating syndrome that results in symptoms from loss of glandular function (exocrine and endocrine) and inflammation (pain). Because there is no cure for chronic pancreatitis, the goals of pharmacological therapy are prevention of malabsorption and palliation of pain. The cornerstone of therapy for malabsorption is the use of pancreatic enzymes. Although also used for pain, these agents are much less effective for this symptom.

Enzyme Formulations. In the past, two preparations (and many brands thereof) of pancreatic enzymes were available for replacement therapy, pancreatin and pancrelipase. As of 2009, only pancrelipase (CREON, ZENPEP) is licensed for sale in the U.S. Pancreatic enzymes are typically prescribed on the basis of the lipase content. Pancrelipase products contain various amounts of lipase, protease, and amylase and thus may not be interchangeable. Excess lipase administration has been implicated in the development of fibrosing colonopathy and adherence to published dosing guidelines is thought to minimize this risk (Borowitz et al., 2002).

Replacement Therapy for Malabsorption. Fat malabsorption (steatorrhea) and protein maldigestion occur when the pancreas loses >90% of its ability to produce digestive enzymes. The resultant diarrhea and malabsorption can be managed reasonably well if 30,000 USP units of pancreatic lipase are delivered to the duodenum during a 4-hour period with and after meals; this represents ~10% of the normal pancreatic output. Alternatively, one can titrate the dosage to the fat content of the diet, with ~8000 USP units of lipase activity required for each 17 g of dietary fat. Available preparations of pancreatic enzymes contain up to 20,000 units of lipase and 76,000 units of protease, and the typical dose of pancrelipase is one to three capsules or tablets with or just before meals and snacks, adjusted until a satisfactory symptomatic response is obtained. The loss of pancreatic amylase does not present a problem because of other sources of this enzyme (e.g., salivary glands). The commercially available products are formulated as delayed-release capsules to overcome the need to control gastric acid pharmacologically.

Enzymes for Pain. Pain is the other cardinal symptom of chronic pancreatitis. The rationale for its treatment with pancreatic enzymes is based on the principle of negative feedback inhibition of the pancreas by the presence of duodenal proteases. The release of cholecystokinin (CCK), the principal secretagogue for pancreatic enzymes,

is triggered by CCK-releasing monitor peptide in the duodenum, which normally is denatured by pancreatic trypsin. In chronic pancreatitis, trypsin insufficiency leads to persistent activation of this peptide and an increased release of CCK, which is thought to cause pancreatic pain because of continuous stimulation of pancreatic enzyme output and increased intraductal pressure. Delivery of active proteases to the duodenum (which can be done reliably only with uncoated preparations) therefore is important for the interruption of this loop. Although enzymatic therapy has become firmly entrenched for the treatment of painful pancreatitis, the evidence supporting this practice is equivocal at best.

In general, pancreatic enzyme preparations are tolerated extremely well by patients. Hyperuricosuria in patients with cystic fibrosis can occur, and malabsorption of folate and iron has been reported.

Medium-chain triglycerides. Medium-chain triglycerides (MCTs) may provide an additional source of calories in patients with weight loss and a poor response to diet and pancreatic enzyme therapy. MCTs are readily degraded by gastric and pancreatic lipase, and they do not require bile for digestion. In addition, they can be directly absorbed in the intestine. Oral administration of an enteral formula such as PEPTAMEN, which is enriched in MCTs and hydrolyzed peptides, may be of benefit.

Octreotide. Octreotide (Chapter 38) also has been used, with questionable efficacy, to decrease refractory abdominal pain in patients with chronic pancreatitis.

Enzyme Deficiencies

Congenital or acquired deficiencies in digestive enzymes may lead to malabsorption and diarrhea as well as other GI symptoms. Most commonly seen are lactose intolerance, which occurs in the West (10-20%) but in some Asian populations may exceed 90%. Clinically, diarrhea, pain and flatulence occur. Treatment consists of reducing dietary intake of lactose, primarily by reducing consumption of milk and dairy products. Enzyme replacements are over the counter and can be added to meals. They are bacterial or yeast-derived β -galactosidases, with varying efficacy (LACTAID, LACTRASE, DAIRYEASE, others). Because of considerable individual variation and the uncertain degree of efficacy of these preparations, patients must establish an effective dosing regime empirically. Because of the essential requirements to maintain protein, calcium, and vitamin D intake, these must be supplemented or alternative sources provided in the diet if dairy products are limited.

Congenital sucrase-isomaltase deficiency is less common. The symptoms include diarrhea, abdominal pain, and weight loss. This is a congenital disease and may be diagnosed in children who are failing to thrive and are susceptible to repeated infections. Treatment with enzyme replacement therapy is effective. Sacrosidase (SUCRAID) taken with meals reduces or attenuates symptoms in most cases. Elimination of sugars and carbohydrates from the diet is not practical.

BILE ACIDS

Bile acids and their conjugates are essential components of bile that are synthesized from cholesterol in the liver. The major bile acids in human adults are depicted in Figure 46-5. Bile acids induce bile flow,

Bile Acid	R3	R7	R12	R24
Cholic acid	-OH	-OH	-OH	glycine (75%) taurine (24%) -OH (<1%)
Chenodeoxycholic acid	-OH	-OH	-H	
Deoxycholic acid	-OH	-H	-OH	
Lithocholic acid	-SO ₂ ⁻ / -OH	-H	-H	
Ursodeoxycholic acid	-OH	-OH	-H	

Figure 46–5. Major bile acids in adults.

feedback-inhibit cholesterol synthesis, promote intestinal excretion of cholesterol, and facilitate the dispersion and absorption of lipids and fat-soluble vitamins. After secretion into the biliary tract, bile acids are largely (95%) reabsorbed in the intestine (mainly in the terminal ileum), returned to the liver, and then again secreted in bile (enterohepatic circulation). Cholic acid, chenodeoxycholic acid, and deoxycholic acid constitute 95% of bile acids; lithocholic acid and ursodeoxycholic acid are minor constituents. The bile acids exist largely as glycine and taurine conjugates, the salts of which are called bile salts. Colonic bacteria convert primary bile acids (cholic and chenodeoxycholic acid) to secondary acids (mainly deoxycholic and lithocholic acid) by sequential deconjugation and dehydroxylation. These secondary bile acids also are absorbed in the colon and join the primary acids in the enterohepatic pool.

Dried bile from the Himalayan bear (Yutan) has been used for centuries in China to treat liver disease. Ursodeoxycholic acid (UDCA; ursodiol, ACTIGALL, others) (Figure 46–5) is a hydrophilic, dehydroxylated bile acid that is formed by epimerization of the bile acid chenodeoxycholic acid (CDCA; chenodiol) in the gut by intestinal bacteria; it comprises ~1-3% of the total bile acid pool in human beings but is present at much higher concentrations in bears. When administered orally, litholytic bile acids such as chenodiol and ursodiol can alter relative concentrations of bile acids, decrease biliary lipid secretion, and reduce the cholesterol content of the bile so that it is less lithogenic. Ursodiol also may have cytoprotective effects on hepatocytes and effects on the immune system that account for some of its beneficial effects in cholestatic liver diseases.

Bile acids were first used therapeutically for gallstone dissolution; use for this indication requires a functional gallbladder

because the modified bile must enter the gallbladder to interact with gallstones. To be amenable to dissolution, the gallstones must be composed of cholesterol monohydrate crystals and generally must be <15 mm in diameter to provide a favorable ratio of surface to size. For these reasons, the overall efficacy of litholytic bile acids in the treatment of gallstones has been disappointing (partial dissolution occurs in 40-60% of patients completing therapy and is complete in only 33-50% of these). Although a combination of chenodiol and ursodiol probably is better than either agent alone, ursodiol is preferred as a single agent because of its greater efficacy and less-frequent side effects (e.g., hepatotoxicity).

Primary biliary cirrhosis is a chronic, progressive, cholestatic liver disease of unknown etiology that typically affects middle-aged to elderly women. Ursodiol (administered at 13-15 mg/kg per day in two divided doses) reduces the concentration of primary bile acids and improves biochemical and histological features of primary biliary cirrhosis, especially in early disease. Patients with advanced primary biliary cirrhosis and complications such as ascites do not benefit from this treatment. Ursodiol also has been used in a variety of other cholestatic liver diseases, including primary sclerosing cholangitis, and in cystic fibrosis; in general, it is less effective in these conditions than in primary biliary cirrhosis.

ANTI-FLATULENCE AGENTS

“Gas” is a common but relatively vague GI complaint, used in reference not only to flatulence and eructation but also bloating or fullness. Although few symptoms can be directly attributable to excessive intestinal gas, over-the-counter and herbal preparations that are touted as anti-flatulent are very popular. One of these is simethicone (MYLICON, GAS-X, others), a mixture of siloxane polymers stabilized with silicon dioxide.

Simethicone is an inert, non-toxic insoluble liquid. Because of its ability to collapse bubbles by forming a thin layer on their surface, it is an effective anti-foaming agent. Although it may be effective in diminishing gas volumes in the GI tract, it is not clear whether this accomplishes a therapeutic effect. Simethicone is available in chewable tablets, liquid-filled capsules, suspensions, and orally disintegrating strips, either by itself or in combination with other over-the-counter medications including antacids and other digestants. The usual dosage in adults is 40-25 mg four times daily. Activated charcoal may also be used alone or in combination with simethicone, but has not been shown conclusively to have much benefit.

An alpha-galactosidase preparation (BEANO) is available over-the-counter to reduce gas from baked beans.

CLINICAL SUMMARY

GI Motility Disorders. As a group, these are difficult disorders to treat because of a lack of effective therapeutic

options. For patients with gastroparesis, first-line therapy consists of metoclopramide, which accelerates gastric emptying and also has anti-emetic effects. Erythromycin, a motilin agonist, also has been employed, but is most effective for short-term use. For patients with small-bowel dysmotility, the choices are even more limited: Metoclopramide and erythromycin generally do not work; therapy with octreotide may benefit a subset of patients.

Constipation. Although many choices exist for this condition, most therapies are empirical and non-specific. Constipation often can be addressed by simple measures such as increasing fiber intake, avoiding constipating medications, and the judicious use of osmotic laxatives on an as-needed basis. For more persistent symptoms, a specific prokinetic 5-HT₄ receptor agonist or Cl⁻ channel agonist may be effective in some patients. Stimulant laxatives, although effective, should be avoided for long-term use. Patients with chronic constipation who do not respond to simple measures should undergo further testing to discover uncommon but specific disorders of colonic or anorectal motility.

Diarrhea. In most cases, an attempt should be made to find the underlying cause and to target it specifically. If no such cause is found, chronic diarrhea can be treated empirically, with the simplest approach being bulk-forming and hygroscopic agents, followed by opioids such as loperamide for diarrhea associated with inflammatory bowel disease or diphenoxylate/difenoxin can be used to manage acute exacerbations of chronic functional diarrhea.

Irritable Bowel Syndrome. IBS consists of abdominal pain and discomfort associated with diarrhea, constipation, or alternating bouts of diarrhea and constipation. This common syndrome requires a combination of pharmacological and behavioral approaches that include dietary modifications and psychological counseling. No one therapy will work for all patients and currently there are no therapies focused on IBS that treat both the pain and GI symptoms. Anti-spasmodics are useful by themselves in mild cases and as adjuncts in a regimen that includes tricyclic anti-depressants for more persistent pain.

Nausea and Vomiting. The development of the 5-HT₃ receptor antagonists has led to a major advances in the treatment of nausea and vomiting, especially in the post-chemotherapy and post-operative settings. Anticholinergics are most effective in motion sickness. Antihistamines and related drugs still are useful for empirical treatment of nausea from a variety of causes.

Dronabinol or nabilone may be an effective agent for some refractory cases. The clinical utility of newer agents such as aprepitant in situations other than post-chemotherapy nausea will be tested in coming years.

Pharmacotherapy of Inflammatory Bowel Disease

John L. Wallace and
Keith A. Sharkey

Inflammatory bowel disease (IBD) is a spectrum of chronic, idiopathic, inflammatory intestinal conditions. IBD causes significant gastrointestinal (GI) symptoms that include diarrhea, abdominal pain, bleeding, anemia, and weight loss. IBD also is associated with a variety of extraintestinal manifestations, including arthritis, ankylosing spondylitis, sclerosing cholangitis, uveitis, iritis, pyoderma gangrenosum, and erythema nodosum.

IBD conventionally is divided into two major subtypes: ulcerative colitis and Crohn's disease. Ulcerative colitis is characterized by confluent mucosal inflammation of the colon starting at the anal verge and extending proximally for a variable extent (e.g., proctitis, left-sided colitis, or pancolitis). Crohn's disease, by contrast, is characterized by transmural inflammation of any part of the GI tract but most commonly the area adjacent to the ileocecal valve. The inflammation in Crohn's disease is not necessarily confluent, frequently leaving "skip areas" of relatively normal mucosa. The transmural nature of the inflammation may lead to fibrosis and strictures or, alternatively, fistula formation.

Medical therapy for IBD is problematic. Because no unique abnormality has been identified, current therapy for IBD seeks to dampen the generalized inflammatory response; however, no agent can reliably accomplish this, and the response of an individual patient to a given medicine may be limited and unpredictable. Based on this variable response, clinical trials generally employ standardized quantitative assessments of efficacy that take into account both clinical and laboratory parameters (e.g., the Crohn's Disease Activity Index). The disease also exhibits marked fluctuations in activity—even in the absence of therapy—leading to a significant "placebo effect" in therapeutic trials.

Specific goals of pharmacotherapy in IBD include controlling acute exacerbations of the disease, maintaining remission, and treating specific complications such as fistulas. Specific drugs may be better suited for one or the other of these aims (Table 47–1). For example, glucocorticoids remain the treatment of choice for moderate to severe flares but are inappropriate for long-term use because of side effects and their inability to maintain remission. Other immunosuppressive agents, such as azathioprine, that require several weeks to achieve their therapeutic effect, have a limited role in the acute setting but are preferred for long-term management.

For many years glucocorticoids, sulfasalazine and 5-aminosalicylic acid were the mainstays of pharmacotherapy for IBD. More recently, agents used in other immune/inflammatory conditions, such as azathioprine and cyclosporine, have been adapted for IBD therapy. Advances in the understanding of the inflammatory response and improved biotechnology have led to the development of biological agents that can target single steps in the immune cascade, a successful and widely accepted strategy. Drug delivery to the appropriate site(s) along the GI tract also has been a major challenge, and second-generation agents have improved drug delivery, increased efficacy, and decreased side effects.

PATHOGENESIS OF INFLAMMATORY BOWEL DISEASE

Crohn's disease and ulcerative colitis are chronic idiopathic inflammatory disorders of the GI tract; a summary of proposed pathogenic events and potential sites of therapeutic intervention is shown in Figure 47–1.

Table 47-1

Figure 47–1. Proposed pathogenesis of inflammatory bowel disease and target sites for pharmacological intervention. Shown are the interactions among bacterial antigens in the intestinal lumen and immune cells in the intestinal wall. If the epithelial barrier is impaired, bacterial antigens can gain access to antigen-presenting cells (APC) such as dendritic cells in the lamina propria. These cells then present the antigen(s) to CD4⁺ lymphocytes and also secrete cytokines such as interleukin (IL)-12 and IL-18, thereby inducing the differentiation of T_H1 cells in Crohn's disease (or, under the control of IL-4, type 2 helper T cells [T_H2] in ulcerative colitis). The balance of pro-inflammatory and anti-inflammatory events is also governed by regulatory T_H17 and T_{Reg} cells, both of which serve to limit immune and inflammatory responses in the GI tract. Transforming growth factor (TGF)β and IL-6 are important cytokines that drive the expansion of the regulatory T cell subsets. The T_H1 cells produce a characteristic array of cytokines, including interferon (IFN)γ and TNFα, which in turn activate macrophages. Macrophages positively regulate T_H1 cells by secreting additional cytokines, including IFNγ and TNFα. Recruitment of a variety of leukocytes is mediated by activation of resident immune cells including neutrophils. Cell adhesion molecules such as integrins are important in the infiltration of leukocytes and novel biological therapeutic strategies aimed at blocking leukocyte recruitment are effective at reducing inflammation. General immunosuppressants (e.g., glucocorticoids, thioguanine derivatives, methotrexate, and cyclosporine) affect multiple sites of inflammation. More site-specific intervention involve intestinal bacteria (antibiotics, prebiotics, and probiotics) and therapy directed at TNFα or IL-12 (see text for further details).

Although Crohn's disease and ulcerative colitis share a number of GI and extraintestinal manifestations and can respond to a similar array of drugs, emerging evidence suggests that they result from fundamentally distinct pathogenetic mechanisms (Xavier and Podolsky, 2007). Histologically, the transmural lesions in Crohn's disease exhibit marked infiltration of lymphocytes and

macrophages, granuloma formation, and submucosal fibrosis, whereas the superficial lesions in ulcerative colitis have lymphocytic and neutrophilic infiltrates. Within the diseased bowel in Crohn's disease, the cytokine profile includes increased levels of interleukin (IL)-12, IL-23, interferon-γ, and tumor necrosis factor-α (TNFα), findings characteristic of T-helper 1 (T_H1)–

1354 mediated inflammatory processes. In contrast, the inflammatory response in ulcerative colitis resembles aspects of that mediated by the T_H2 pathway. Recently, this relatively simplistic classification has been revised in the light of the description of regulatory T cells and pro-inflammatory T_H17 cells, a novel T-cell population that expresses IL-23 receptor as a surface marker and produces, among others, the pro-inflammatory cytokines IL-17, IL-21, IL-22, and IL-26. Several studies have demonstrated an important role of T_H17 cells in intestinal inflammation, particularly in Crohn's disease (Cho, 2008; Strober et al., 2007).

Important insights into pathogenesis have emerged from genetic analyses of Crohn's disease. Mutations in the gene *NOD2* (*nucleotide-binding oligomerization domain-2*; also called *CARD15*) are associated with both familial and sporadic Crohn's disease in whites (Hugot et al., 2001; Ogura et al., 2001). *NOD2* is expressed in monocytes, granulocytes, dendritic cells, Paneth cells, and epithelial cells. It is proposed to function as an intracellular sensor for bacterial infection by recognizing peptidoglycans, thereby playing an important role in the natural immunity to bacterial pathogens. Consistent with this model, other studies have identified bacterial antigens, including pseudomonal protein I2 (Dalwadi et al., 2001) and a flagellin protein (Lodes et al., 2004), as dominant superantigens that induce the T_H1 response in Crohn's disease (shown as bacterial products in Figure 47-1). More recently, genome-wide studies have revealed other genes associated with IBD, whose identification may lead to the development of novel therapeutics (Cho, 2008)

Thus, these converging experimental approaches are generating novel insights into the pathogenesis of Crohn's disease that soon may translate into novel therapeutic approaches to IBD. The major therapeutic agents available for IBD are described next.

MESALAMINE (5-ASA)-BASED THERAPY

Chemistry, Mechanism of Action, and Pharmacological Properties. First-line therapy for mild to moderate ulcerative colitis generally involves mesalamine (5-aminosalicylic acid, or 5-ASA). The archetype for this class of medications is sulfasalazine (AZULFIDINE), which consists of 5-ASA linked to sulfapyridine by an azo bond (Figure 47-2). Although this drug was developed originally as therapy for rheumatoid arthritis, clinical trials serendipitously demonstrated a beneficial effect on the GI symptoms of subjects with concomitant ulcerative colitis. Sulfasalazine is a prime example of an oral drug that is delivered effectively to the distal GI tract. Given individually, either 5-ASA or sulfapyridine is absorbed in the upper GI tract; the azo linkage in sulfasalazine prevents absorption in the stomach and small intestine, and the individual components are not liberated for absorption until colonic bacteria cleave the

Figure 47-2. Structures of sulfasalazine and related agents. The red N atoms indicate the diazo linkage that is cleaved to generate the active moiety.

bond. 5-ASA is now regarded as the therapeutic moiety, with little, if any, contribution by sulfapyridine.

Mesalamine is a salicylate, but its therapeutic effect does not appear to relate to cyclooxygenase inhibition; indeed, traditional nonsteroidal anti-inflammatory drugs and selective inhibitors of cyclooxygenase-2 ("coxibs") may exacerbate IBD. Many potential sites of action have been demonstrated *in vitro* for either sulfasalazine or mesalamine: inhibition of the production of IL-1 and $TNF\alpha$, inhibition of the lipoxygenase pathway, scavenging of free radicals and oxidants, and inhibition of NF- κ B, a transcription factor pivotal to production of inflammatory mediators. Specific mechanisms of action of these drugs have not been identified.

Although not active therapeutically, sulfapyridine causes many of the adverse effects observed in patients taking sulfasalazine. To preserve the therapeutic effect of 5-ASA without the adverse effects of sulfapyridine, several second-generation 5-ASA compounds have been developed (Figures 47-2, 47-3, and 47-4). They are divided into two groups: prodrugs and coated drugs. Prodrugs contain the same azo bond as sulfasalazine but replace the linked sulfapyridine with either another 5-ASA (olsalazine, DIPENTUM) or an inert compound

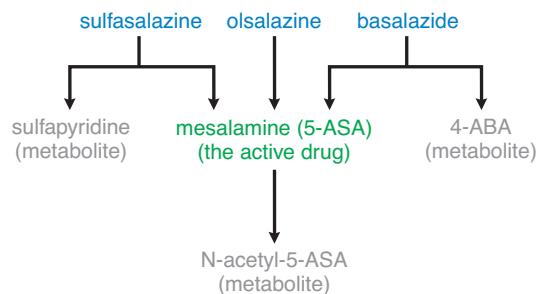

Figure 47–3. Metabolic fates of the different oral formulations of mesalamine (5-ASA). Chemical structures are in Figure 47–2.

(balsalazide, COLAZIDE). Thus, these compounds act at sites along the GI tract similar to those of sulfasalazine. The alternative approaches employ either a delayed-release formulation (PENTASA) or a pH-sensitive coating (ASACOL; LIALDA/MEZAVANT). Delayed-release mesalamine is released throughout the small intestine and colon, whereas pH-sensitive mesalamine is released in the terminal ileum and colon. These different distributions of drug delivery have potential therapeutic implications.

Oral sulfasalazine is effective in patients with mild or moderately active ulcerative colitis, with response rates in the range of 60–80% (Prantera et al., 1999). The usual dose is 4 g/day in four divided doses with food; to avoid adverse effects, the dose is increased gradually from an initial dose of 500 mg twice a day. Doses as high as 6 g/day can be used but cause an increased incidence of side effects. For patients with severe colitis, sulfasalazine is of less certain value, even though it is often added as an adjunct to systemic glucocorticoids. Regardless of disease severity, the drug plays a useful role in preventing relapses once remission has been achieved. In general, newer 5-ASA preparations have similar therapeutic efficacy in ulcerative colitis with fewer side effects. Because they lack the dose-related side effects of sulfapyridine, the newer formulations can be used to provide higher doses of mesalamine with some improvement in disease control. The usual doses to treat active disease are 800 mg three times a day for ASACOL and 1 g four times

a day for PENTASA. Lower doses are used for maintenance (e.g., ASACOL, 800 mg twice a day). Although some studies have suggested that a given preparation may be superior in treating colonic disease, there is no consensus on this issue.

The efficacy of 5-ASA preparations (e.g., sulfasalazine) in Crohn's disease is less striking, with modest benefit at best in controlled trials. Sulfasalazine has not been shown to be effective in maintaining remission and has been replaced by newer 5-ASA preparations. Some studies have reported that both ASACOL and PENTASA are more effective than placebo in inducing remission in patients with Crohn's disease (particularly colitis), although higher doses than those typically used in ulcerative colitis are required. The role of mesalamine in maintenance therapy for Crohn's disease is controversial, and there is no clear benefit of continued 5-ASA therapy in patients who achieve medical remission (Camma et al., 1997). Because they largely bypass the small intestine, the second-generation 5-ASA prodrugs such as olsalazine and balsalazide do not have a significant effect in small-bowel Crohn's disease.

Topical preparations of mesalamine suspended in a wax matrix suppository (ROWASA) or in a suspension enema (CANASA) are effective in active proctitis and distal ulcerative colitis, respectively. They appear to be superior to topical hydrocortisone in this setting, with response rates of 75–90%. Mesalamine enemas (4 g/60 mL) should be used at bedtime and retained for at least 8 hours; the suppository (500 mg) should be used two to three times a day with the objective of retaining it for at least 3 hours. Response to local therapy with mesalamine may occur within 3–21 days; however, the usual course of therapy is from 3–6 weeks. Once remission has occurred, lower doses are used for maintenance.

Pharmacokinetics. Approximately 20–30% of orally administered sulfasalazine is absorbed in the small intestine. Much of this is taken up by the liver and excreted unmetabolized in the bile; the rest (~10%) is excreted unchanged in the urine. The remaining 70% reaches the colon, where, if cleaved completely by bacterial enzymes, it generates 400 mg mesalamine for every gram of the parent compound. Thereafter, the individual components of sulfasalazine follow different metabolic pathways. Sulfapyridine, which is highly lipid soluble, is absorbed rapidly from the colon. It undergoes extensive hepatic metabolism, including acetylation and hydroxylation, conjugation with glucuronic acid, and excretion in the urine. The acetylation phenotype of the patient determines plasma levels of sulfapyridine and the probability of side effects;

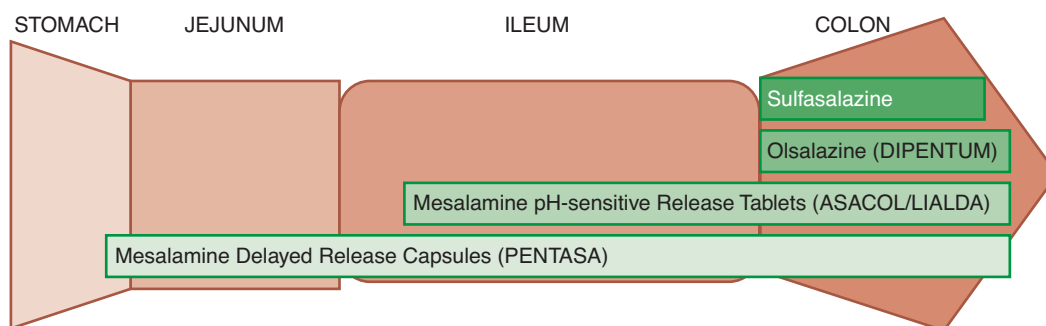

Figure 47–4. Sites of release of mesalamine (5-ASA) in the GI tract from different oral formulations.

rapid acetylators have lower systemic levels of the drug and fewer adverse effects. By contrast, only 25% of mesalamine is absorbed from the colon, and most of the drug is excreted in the stool. The small amount that is absorbed is acetylated in the intestinal mucosal wall and the liver and then excreted in the urine. Intraluminal concentrations of mesalamine therefore are very high (~1500 µg/mL or 10 mM in patients taking a typical dose of 3 g/day).

The pH-sensitive coatings (methyl-methacrylate methacrylic acid copolymer) of ASACOL (EUDAGRIT) and LIALDA/MEZAVANT limit gastric and small intestinal absorption of 5-ASA, as assessed by urinary, ileostomal, and fecal measurements of the various metabolites. The pharmacokinetics of PENTASA differ somewhat. The ethylcellulose-coated micro-granules are released in the upper GI tract as discrete prolonged-release units of mesalamine. Acetylated mesalamine can be detected in the circulation within an hour after ingestion, indicating some rapid absorption, but some intact micro-granules also can be detected in the colon. Because it is released in the small bowel, a greater fraction of PENTASA is absorbed systemically compared with the other 5-ASA preparations.

Adverse Effects. Side effects of sulfasalazine occur in 10-45% of patients with ulcerative colitis and are related primarily to the sulfa moiety. Some are dose related, including headache, nausea, and fatigue. These reactions can be minimized by giving the medication with meals or by decreasing the dose. Allergic reactions include rash, fever, Stevens-Johnson syndrome, hepatitis, pneumonitis, hemolytic anemia, and bone marrow suppression. Sulfasalazine reversibly decreases the number and motility of sperm but does not impair female fertility. Sulfasalazine inhibits intestinal folate absorption and is usually administered with folate.

The newer mesalamine formulations generally are well tolerated, and side effects are relatively infrequent and minor. Headache, dyspepsia, and skin rash are the most common. Diarrhea appears to be particularly common with olsalazine (occurring in 10-20% of patients); this may be related to its ability to stimulate chloride and fluid secretion in the small bowel. Nephrotoxicity, although rare, is a more serious concern. Mesalamine has been associated with interstitial nephritis; although its pathogenic role is controversial, renal function should be monitored in all patients receiving these drugs. Both sulfasalazine and its metabolites cross the placenta but have not been shown to harm the fetus. Although less well studied, the newer formulations appear to be safe in pregnancy. The risks to the fetus from the consequences of uncontrolled IBD in pregnant women are believed to outweigh the risks associated with the therapeutic use of these agents.

GLUCOCORTICOIDS

The effects of glucocorticoids on the inflammatory response are numerous and well documented (Chapters 38 and 42). Although glucocorticoids are universally recognized as effective in acute exacerbations, their use in either ulcerative colitis or Crohn's disease involves considerable challenges and pitfalls, and they are indicated only for moderate to severe IBD.

The response to glucocorticoids in individual patients with IBD divides them into three general classes:

responsive, dependent, and unresponsive. Glucocorticoid-responsive patients improve clinically, generally within 1-2 weeks and remain in remission as the steroids are tapered and then discontinued. Glucocorticoid-dependent patients also respond to glucocorticoids but then experience a relapse of symptoms as the steroid dose is tapered. Glucocorticoid-unresponsive patients do not improve even with prolonged high-dose steroids. Approximately 40% of patients are glucocorticoid responsive, 30-40% have only a partial response or become glucocorticoid dependent, and 15-20% of patients do not respond to glucocorticoid therapy.

Glucocorticoids sometimes are used for prolonged periods to control symptoms in corticosteroid-dependent patients. However, the failure to respond to steroids with prolonged remission (i.e., a disease relapse) should prompt consideration of alternative therapies, including immunosuppressive agents and anti-TNF α therapies. Glucocorticoid are not effective in maintaining remission in either ulcerative colitis or Crohn's disease (Steinhart et al., 2003); their significant side effects have led to increased emphasis on limiting the duration and cumulative dose of corticosteroids in IBD.

The approach to glucocorticoid therapy in IBD differs somewhat from that in diseases such as asthma or rheumatoid arthritis. Initial doses are 40-60 mg of prednisone or equivalent per day; higher doses generally are no more effective. The glucocorticoid dose in IBD is tapered over weeks to months. Even with these slow tapers, however, efforts should be made to minimize the duration of therapy. Glucocorticoids induce remission in most patients with either ulcerative colitis or Crohn's disease (Faubion et al., 2001). Oral prednisone is the preferred agent for moderate to severe disease, and the typical dose is 40-60 mg once a day. Most patients improve substantially within 5 days of initiating treatment; others require treatment for several weeks before remission occurs. For more severe cases, glucocorticoids are given intravenously. Generally, *methylprednisolone* or *hydrocortisone* is used for intravenous therapy, although some experts believe that corticotropin (ACTH) is more effective in patients who have not previously received any steroids.

Topically acting agents (i.e., given by enema) have fewer adverse effects than systemic steroids but are also less effective in reducing remission. Glucocorticoid enemas are useful mainly in patients whose disease is limited to the rectum and left colon. Hydrocortisone is available as a retention enema (100 mg/60 mL), and the usual dose is one 60-mL enema per night for 2 or 3 weeks. When administered optimally, the drug can reach up to or beyond the descending colon. Patients with distal disease usually respond within 3-7 days. Absorption, although less than with oral preparations, is still substantial (up to 50-75%). Hydrocortisone also can be given once or twice daily as a 10% foam suspension (CORTIFOAM) that delivers 80 mg hydrocortisone per application; this formulation can be useful in patients with very short areas of distal proctitis and difficulty retaining fluid.

Budesonide (ENTOCORT ER) is an enteric-release form of a synthetic steroid that is used for ileocecal Crohn's disease

(Greenberg et al., 1994; McKeage and Goa, 2002). It is proposed to deliver adequate steroid therapy to a specific portion of inflamed gut while minimizing systemic side effects owing to extensive first-pass hepatic metabolism to inactive derivatives. Topical therapy (e.g., enemas and suppositories) also is effective in treating colitis limited to the left side of the colon. Although the topical potency of budesonide is 200 times higher than that of hydrocortisone, its oral systemic bioavailability is only 10%. In some studies, budesonide was associated with a lower incidence of systemic side effects than prednisone, although data also indicate that systemic steroids are more effective in patients with higher Crohn's Disease Activity Index scores. Budesonide (9 mg/day for up to 8 weeks followed by 6 mg/day for maintenance of remission for up to 3 months) is effective in the acute management of mild-to-moderate exacerbations of Crohn's disease, but its role in maintaining remission has not been fully delineated (Hofer, 2003).

A significant number of patients with IBD fails to respond adequately to glucocorticoids and are either steroid-resistant or steroid-dependent. The reasons for this failure are poorly understood but may involve complications such as fibrosis or strictures in Crohn's disease, which will not respond to anti-inflammatory measures alone; local complications such as abscesses, in which case the use of glucocorticoids may lead to uncontrolled sepsis; and intercurrent infections with organisms such as cytomegalovirus and *Clostridium difficile*. Steroid failures also may be related to specific pharmacogenomic factors such as upregulation of the multidrug resistance (*mdr*) gene (Farrell et al., 2000) or altered levels of corticosteroid-binding globulin.

IMMUNOSUPPRESSIVE AGENTS

Several drugs developed initially for cancer chemotherapy or as immunosuppressive agents in organ transplants have been adapted for treatment of IBD. Although their initial use in IBD was based on their immunosuppressive effects, their specific mechanisms of action are unknown. Increasing clinical experience has defined specific roles for each of these agents as mainstays in the pharmacotherapy of IBD. However, their potential for serious adverse effects mandates a careful assessment of risks and benefits in each patient.

Thiopurine Derivatives

The cytotoxic thiopurine derivatives *mercaptopurine* (6-MP, PURINETHOL) and *azathioprine* (IMMURAN) (Chapters 51 and 52) are used to treat patients with severe IBD or those who are steroid resistant or steroid dependent (Prefontaine et al., 2009). These thiopurine antimetabolites impair purine biosynthesis and inhibit cell proliferation. Both are prodrugs: azathioprine is converted to mercaptopurine, which is subsequently metabolized to 6-thioguanine nucleotides that are the presumed active moiety (Figure 47–5).

These drugs generally are used interchangeably with appropriate dose adjustments, typically azathioprine (2–2.5 mg/kg) or

Figure 47–5. Metabolism of azathioprine and 6-mercaptopurine. HGPRT, hypoxanthine–guanine phosphoribosyl transferase; TPMT, thiopurine methyltransferase; XO, xanthine oxidase. The activities of these enzymes vary among humans because genetic polymorphisms are expressed differentially, explaining responses and side effects when azathioprine–mercaptopurine therapy is employed (see text for details).

mercaptopurine (1.5 mg/kg). As discussed later, the pathways by which they are metabolized are clinically relevant, and specific assays can be used to assess clinical response and to avoid side effects. Because of concerns about side effects, these drugs were used initially only in Crohn's disease, which lacks a surgical curative option. They now are considered equally effective in Crohn's disease and ulcerative colitis. These drugs effectively maintain remission in both diseases; they also may prevent (or, more typically, delay) recurrence of Crohn's disease after surgical resection. Finally, they are used successfully to treat fistulas in Crohn's disease. The clinical response to azathioprine or mercaptopurine may take weeks to months, such that other drugs with a more rapid onset of action (e.g., mesalamine, glucocorticoids, or infliximab) are preferred in the acute setting.

The decision to initiate immunosuppressive therapy depends on an accurate assessment of the risk/benefit ratio. In general, physicians who treat IBD believe that the long-term risks of azathioprine–mercaptopurine are lower than those of steroids. Thus these purines are used in glucocorticoid-unresponsive or glucocorticoid-dependent disease and in patients who have had recurrent flares of disease requiring repeated courses of steroids. Additionally, patients who have not responded adequately to mesalamine but are not acutely ill may benefit by conversion from glucocorticoids to immunosuppressive drugs. Immunosuppressives therefore may be viewed as steroid-sparing agents.

Adverse effects of azathioprine–mercaptopurine can be divided into three general categories: idiosyncratic, dose related, and possible. Although the therapeutic effects of azathioprine–mercaptopurine often are delayed, their adverse effects occur at any time after initiation of treatment and can affect up to 10% of patients. The most serious idiosyncratic reaction is pancreatitis, which affects ~5% of patients treated with these drugs. Fever, rash, and arthralgias are seen occasionally, whereas nausea and vomiting are somewhat more frequent. The major dose-related adverse effect is bone marrow suppression, and circulating blood counts should be monitored closely when therapy is initiated and at less frequent intervals during maintenance therapy (e.g., every 3 months). Elevations in

liver function tests also may be dose related. Although keeping drug levels in the appropriate range diminishes these adverse effects, they can occur even with therapeutic serum levels of 6-thioguanine nucleotides. The serious adverse effect of cholestatic hepatitis is relatively rare. Although the increased risk of infection is a significant concern with immunosuppressives, especially if pancytopenia occurs, infections are linked more closely to concomitant glucocorticoid therapy than to the immunosuppressives (Abera et al., 2003).

Immunosuppressive regimens given in the setting of cancer chemotherapy or organ transplants have been associated with an increased incidence of malignancy, particularly non-Hodgkin's lymphoma. Definitive conclusions about the causative roles of azathioprine–mercaptopurine in lymphomas are complicated by the possible increased incidence of lymphomas in IBD per se and by the relative rarity of these cancers. The increased risk, if any, must be relatively small.

Metabolism and Pharmacogenetics. Favorable responses to azathioprine–mercaptopurine are seen in up to two-thirds of patients. Recent insights into the metabolism of the thiopurine agents and appreciation of genetic polymorphisms in these pathways have provided new insights into variability in response rates and adverse effects. As shown in Figure 47–4, mercaptopurine has three metabolic fates:

- conversion by xanthine oxidase to 6-thiouric acid
- metabolism by thiopurine methyltransferase (TPMT) to 6-methyl-mercaptopurine (6-MMP)
- conversion by hypoxanthine–guanine phosphoribosyl transferase (HGPRT) to 6-thioguanine nucleotides and other metabolites

The relative activities of these different pathways may explain, in part, individual variations in efficacy and adverse effects of these immunosuppressives.

The plasma $t_{1/2}$ of mercaptopurine is limited by its relatively rapid (i.e., within 1–2 hours) uptake into erythrocytes and other tissues. Following this uptake, differences in TPMT activity determine the drug's fate. Approximately 80% of the U.S. population has what is considered “normal” metabolism, whereas 1 in 300 individuals has minimal TPMT activity. In the latter setting, mercaptopurine metabolism is shifted away from 6-methyl-mercaptopurine and driven toward 6-thioguanine nucleotides, which can severely suppress the bone marrow. About 10% of people have intermediate TPMT activity; given a similar dose, these individuals will tend to have higher 6-thioguanine levels than the normal metabolizers. Finally, ~10% of the population is considered rapid metabolizers. In these individuals, mercaptopurine is shunted away from 6-thioguanine nucleotides toward 6-MMP, which has been associated with abnormal liver function tests. In addition, relative to normal metabolizers, the 6-thioguanine levels of these rapid metabolizers are lower for an equivalent oral dose, possibly reducing therapeutic response. Given this variability, some experts evaluate an individual's TPMT activity status prior to initiating treatment with thiopurines and also measure

6-thioguanine/6-MMP levels in individuals not responding to therapy. To avoid these complexities, treatment with 6-thioguanine was explored; unfortunately, 6-thioguanine is associated with a high incidence of an uncommon liver abnormality, hepatic nodular regeneration, and associated portal hypertension; 6-thioguanine therapy of IBD therefore has been abandoned.

Xanthine oxidase in the small intestine and liver converts mercaptopurine to thiouric acid, which is inactive as an immunosuppressant. Inhibition of xanthine oxidase by allopurinol diverts mercaptopurine to more active metabolites such as 6-thioguanine and increases both immunosuppressant and potential toxic effects. Thus, patients on mercaptopurine should be warned about potentially serious interactions with medications used to treat gout or hyperuricemia, and the dose should be decreased to 25% of the standard dose in subjects who are already taking allopurinol.

Methotrexate

Methotrexate was engineered to inhibit dihydrofolate reductase, thereby blocking DNA synthesis and causing cell death. First used in cancer treatment, methotrexate subsequently was recognized to have beneficial effects in autoimmune diseases such as rheumatoid arthritis and psoriasis (Chapter 62 discusses the use of methotrexate in dermatological disorders). The anti-inflammatory effects of methotrexate may involve mechanisms in addition to inhibition of dihydrofolate reductase.

As with azathioprine–mercaptopurine, methotrexate generally is reserved for patients whose IBD is either steroid-resistant or steroid-dependent. In Crohn's disease, it both induces and maintains remission, generally with a more rapid response than that seen with mercaptopurine or azathioprine (Feagan et al., 1995). Its use in ulcerative colitis has not been thoroughly investigated.

Therapy of IBD with methotrexate differs somewhat from its use in other autoimmune diseases. Most important, higher doses (e.g., 15–25 mg/week) are given parenterally. The increased efficacy with parenteral administration may reflect the unpredictable intestinal absorption at higher doses of methotrexate. For unknown reasons, the incidence of methotrexate-induced hepatic fibrosis in patients with IBD is lower than that seen in patients with psoriasis. Use of methotrexate for treatment of IBD has largely been supplanted by biological therapies (such as anti-TNF α antibodies).

Cyclosporine

The calcineurin inhibitor cyclosporine is a potent immunomodulator used most frequently after organ transplantation (Chapter 35). It is effective in specific clinical settings in IBD, but the high frequency of significant adverse effects limits its use as a first-line medication.

Cyclosporine is effective in patients with severe ulcerative colitis who have failed to respond adequately to glucocorticoid therapy. Between 50% and 80% of these severely ill patients

improve significantly (generally within 7 days) in response to intravenous cyclosporine (2–4 mg/kg per day), sometimes avoiding emergent colectomy. Careful monitoring of cyclosporine levels is necessary to maintain a therapeutic level in whole blood between 300 and 400 ng/mL.

Oral cyclosporine is less effective as maintenance therapy in Crohn's disease, perhaps because of its limited intestinal absorption. In this setting, long-term therapy with NEORAL or GENGRAF (formulations of cyclosporine with increased oral bioavailability) may be more effective, but this has not been studied fully. The calcineurin inhibitors can be used to treat fistulous complications of Crohn's disease. A significant rapid response to intravenous cyclosporine has been observed; however, frequent relapses accompany oral cyclosporine therapy, and other medical strategies are required to maintain fistula closure. Thus, the calcineurin inhibitors generally are used to treat specific problems over a short term while providing a bridge to longer-term therapy (Sandborn, 1995).

Other immunomodulators that are being evaluated in IBD include the calcineurin inhibitor tacrolimus (FK 506, PROGRAF), mycophenolate mofetil and mycophenolate (CELLCEPT, MYFORTIC), inhibitors of inosine monophosphate dehydrogenase to which lymphocytes are especially susceptible (Chapter 35).

BIOLOGICAL THERAPIES

Infliximab (REMICADE, cA2) is a chimeric immunoglobulin (25% mouse, 75% human) that binds to and neutralizes TNF α . Although many, both pro- and anti-inflammatory cytokines, are generated in the inflamed gut in IBD (Figure 47–1), there is some rationale for targeting TNF- α because it is one of the principal cytokines mediating the T_H1 immune response characteristic of Crohn's disease (Targan et al., 1997).

Although infliximab was designed specifically to target TNF α , it may have more complex actions. Infliximab binds membrane-bound TNF α and may cause lysis of these cells by antibody-dependent or cell-mediated cytotoxicity. Thus, infliximab may deplete specific populations of subepithelial inflammatory cells. These effects, together with its mean terminal plasma $t_{1/2}$ of 8–10 days, may explain the prolonged clinical effects of infliximab.

Infliximab (5 mg/kg infused intravenously at intervals of several weeks to months) decreases the frequency of acute flares in approximately two-thirds of patients with moderate to severe Crohn's disease and also facilitates the closing of enterocutaneous fistulas associated with Crohn's disease (Present et al., 1999). Its longer-term role in Crohn's disease is evolving, but emerging evidence supports its efficacy in maintaining remission (Rutgeerts et al., 2004) and in preventing recurrence of fistulas (Sands et al., 2004). The combination of infliximab and azathioprine is more effective than infliximab alone in induction of remission and mucosal healing in steroid-resistant patients (Rutgeerts et al., 2009). In contrast, there appears to be no synergistic benefit of the combination of methotrexate and infliximab. Infliximab has also proven to be an effective treatment for refractory ulcerative colitis (Rutgeerts et al., 2009).

The use of infliximab as a biological response modifier raises several important considerations. Both acute (fever, chills, urticaria,

or even anaphylaxis) and subacute (serum sickness–like) reactions may develop after infliximab infusion, but a frank lupus-like syndrome occurs only rarely. Antibodies to infliximab can decrease its clinical efficacy. Each year, at least 10% of patients on infliximab have to stop therapy because of loss of response or intolerance (Rutgeerts et al., 2009). Strategies to minimize the development of these antibodies (e.g., treatment with glucocorticoids or other immunosuppressives) may be critical to preserving infliximab efficacy for either recurrent or chronic therapy (Farrell et al., 2003). Other proposed strategies to overcome the problem of “antibody resistance” include increasing the dose of infliximab or decreasing the interval between infusions.

Infliximab therapy is associated with increased incidence of respiratory infections; of particular concern is potential reactivation of tuberculosis or other granulomatous infections with subsequent dissemination. The FDA recommends that candidates for infliximab therapy be tested for latent tuberculosis with purified protein derivative, and patients who test positive should be treated prophylactically with isoniazid. However, anergy with a false-negative skin test has been noted in some patients with Crohn's disease, and some experts routinely perform chest radiographs to look for active or latent pulmonary disease. Infliximab also is contraindicated in patients with severe congestive heart failure (New York Heart Association classes III and IV) and should be used cautiously in class I or II patients. As with the immunosuppressives, there is concern about the possible increased incidence of non-Hodgkin's lymphoma, but a causal role has not been established. Finally, the significant cost of biological therapies such as infliximab is an important consideration.

Adalimumab (HUMIRA) is a humanized recombinant human IgG₁ monoclonal antibody against TNF α . It is effective in inducing remission in mild to moderate, severe, and fistulizing Crohn's disease (Rutgeerts et al., 2009). Unfortunately, adalimumab cannot be used to rescue patients who have lost responsiveness to another anti-TNF α antibody, such as infliximab. Certolizumab pegol (CIMZIA) is a pegylated humanized fragment antigen binding (Fab) that binds TNF α . It is approved in the U.S. for the treatment of Crohn's disease. It appears to have comparable efficacy to that of adalimumab and infliximab for the treatment of Crohn's disease, although direct comparative studies have not been performed (Rutgeerts et al., 2009). With both adalimumab and certolizumab pegol, immunogenicity appears to be less of a problem than that associated with infliximab.

Another anti-TNF α agent, Etanercept (ENBREL), is a fusion protein of the ligand-binding portion of the TNF α receptor and the Fc portion of human IgG₁. This construct binds to TNF α and blocks its biologic effects but is ineffective in Crohn's disease.

Natalizumab (TYSABRI) is a humanized monoclonal antibody against α 4-integrin (also known as VLA-4). Binding of the antibody to this adhesion molecule will reduce extravasation of certain leukocytes (e.g., lymphocytes), preventing them from migrating to sites of inflammation where they may exacerbate tissue injury. In 2008, natalizumab was approved in the U.S. for induction and maintenance of remission of moderate to severe Crohn's disease. Natalizumab had previously been withdrawn from the market and carries a black box warning because it appears to interact with other immunomodulating drugs to increase the risk of progressive multifocal leukoencephalopathy (PML). Thus, natalizumab is contraindicated for use with other immunomodulators. Because of the capacity of corticosteroids to produce immunosuppression, patients taking natalizumab

1360 for the treatment of Crohn's disease should have their doses reduced before starting natalizumab treatment.

The role of anti-TNF therapies for steroid-refractory or steroid-dependent ulcerative colitis is less clear. The rationale for their use is based on finding elevated levels of TNF α in the mucosa of patients. Large controlled clinical trials have demonstrated that anti-TNF agents significantly reduce the severity of the inflammation. The rates of clinical remission range from 26-34%, with endoscopic healing in about half the treated patients. Unlike Crohn's disease, ulcerative colitis is cured with surgery; thus the cost and serious adverse events associated with anti-TNF therapy need to be balanced with the effectiveness of the drug at preventing the need for colectomy. Currently, it is not known how effective anti-TNF therapies are for prevention, as opposed to delay, of colectomy.

ANTIBIOTICS AND PROBIOTICS

An emerging concept is that a balance in the GI tract normally exists among the mucosal epithelium, the normal gut flora, and the immune response (Preidis & Versalovic, 2009). Moreover, there are experimental and clinical data that colonic bacteria may either initiate or perpetuate the inflammation of IBD (Salzmann and Bevins, 2008), and, as mentioned earlier ("Pathogenesis of Inflammatory Bowel Disease"), recent studies have implicated specific bacterial antigens in the pathogenesis of Crohn's disease. Thus, certain bacterial strains may be either pro- (e.g., *Bacteroides*) or anti-inflammatory (e.g., *Lactobacillus*), prompting attempts to manipulate the colonic flora in patients with IBD. Traditionally, antibiotics have been used to this end, most prominently in Crohn's disease. More recently, probiotics have been used to treat specific clinical situations in IBD.

Antibiotics can be used as:

- adjunctive treatment along with other medications for active IBD
- treatment for a specific complication of Crohn's disease
- prophylaxis for recurrence in postoperative Crohn's disease

Metronidazole (Sutherland et al., 1991), ciprofloxacin (Arnold et al., 2002), and clarithromycin are the antibiotics used most frequently. They are more beneficial in Crohn's disease involving the colon than in disease restricted to the ileum. Specific Crohn's disease-related complications that may benefit from antibiotic therapy include intra-abdominal abscess and inflammatory masses, perianal disease (including fistulas and perirectal abscesses), small-bowel bacterial overgrowth secondary to partial small-bowel obstruction, secondary infections with organisms such as *C. difficile*, and post-operative complications. Metronidazole may be particularly effective for the treatment of perianal disease. Post-operatively, metronidazole and related compounds have been shown to delay the recurrence of Crohn's disease. In one study, a 3-month course of metronidazole (20 mg/kg per day) prolonged the time to both endoscopic and clinical recurrence

(Rutgeerts et al., 1995). The significant side effects of prolonged systemic antibiotic use must be balanced against their potential benefits, and definitive data to support their routine use are lacking.

Probiotics are mixtures of putatively beneficial lyophilized bacteria given orally. Several studies have provided evidence for beneficial effects of probiotics in ulcerative colitis and pouchitis (Hedin et al., 2007). However, the studies have involved relatively small numbers of patients and the various studies had different end points. Thus, the utility of probiotics as a primary therapy for IBD remains unclear.

SUPPORTIVE THERAPY IN INFLAMMATORY BOWEL DISEASE

Analgesic, anticholinergic, and antidiarrheal agents play supportive roles in reducing symptoms and improving quality of life. These drugs should be individualized based on a patient's symptoms and are supplementary to anti-inflammatory medications. Oral iron, folate, and vitamin B₁₂ should be administered as indicated. Loperamide or diphenoxylate (Chapter 46) can be used to reduce the frequency of bowel movements and relieve rectal urgency in patients with mild disease; these agents are contraindicated in patients with severe disease because they may predispose to the development of toxic megacolon. Cholestyramine can be used to prevent bile salt-induced colonic secretion in patients who have undergone limited ileocolic resections. Anticholinergic agents (dicyclomine hydrochloride, etc.; Chapter 9) are used to reduce abdominal cramps, pain, and rectal urgency. As with the antidiarrheal agents, they are contraindicated in severe disease or when obstruction is suspected. Care should be taken to differentiate exacerbation of IBD from symptoms that may be related to coexistent functional bowel disease (Chapter 46).

THERAPY OF INFLAMMATORY BOWEL DISEASE DURING PREGNANCY

IBD is a chronic disease that affects women in their reproductive years; thus, the issue of pregnancy often has a significant impact on medical management. The effects of IBD on pregnancy and the effects of pregnancy on IBD are beyond the scope of this chapter. In general, decreased disease activity increases fertility and improves pregnancy outcomes. At the same time, limiting medication during pregnancy is always desired but sometimes conflicts with the goal of controlling the disease.

Mesalamine and glucocorticoids are FDA Category B drugs that are used frequently in pregnancy and generally are considered safe, whereas methotrexate is clearly contraindicated in pregnant patients. The use of thiopurine immunosuppressives is more controversial. Because these medications are given long term, both their initiation and discontinuation are major management decisions. Although there are no controlled trials of these medications in pregnancy, considerable experience has emerged over the last several years. There does not appear to be an increase in adverse outcomes in pregnant patients maintained on thiopurine-based immunosuppressives (Francella et al., 2003). Nonetheless, decisions regarding the use of these medications in patients contemplating pregnancy are complex and necessarily must involve consideration of the risks and benefits involved.

CLINICAL SUMMARY

The treatment of IBD in any given patient may have several different goals, such as relief of symptoms, induction of remission in patients with active disease, prevention of relapse (i.e., maintenance therapy), healing of fistulas, and avoidance of emergent surgery. Further, therapy may be tailored to some extent to the severity and location of disease. Acute exacerbations of ulcerative colitis are treated with colonic-release preparations of 5-ASA and, in most patients with significant inflammation, with glucocorticoids. For milder cases involving only the rectum, these drugs may be given topically (by enema). Maintenance therapy for patients with ulcerative colitis is principally in the form of 5-ASA compounds, which generally are effective and safe. In patients who relapse on these preparations, purine metabolites (e.g., azathioprine–mercaptopurine) may be used. Other approaches being tested in this setting include the use of probiotic bacteria.

Drugs used in mild to moderately active Crohn's disease include sulfasalazine, budesonide, and oral corticosteroids. In contrast to their use in ulcerative colitis, the role of 5-ASA preparations in maintenance therapy of Crohn's disease is limited. Patients who relapse frequently may be treated with immunosuppressive agents (azathioprine–mercaptopurine or methotrexate). Glucocorticoid-dependent patients may be treated with long-term budesonide. Infliximab is particularly useful in closing fistulas associated with Crohn's disease; increasingly, along with other biological agents, it is used in acute flares of this condition. The efficacy of the biological agents in maintaining patients in remission must be balanced against the risk of adverse

effects. Antibiotics, particularly metronidazole, may be useful adjuncts for the acute treatment of complications associated with Crohn's disease (including perianal disease) but are not established as a routine therapy in this disorder.

General Principles of Antimicrobial Therapy

Tawanda Gumbo

SCIENTIFIC BASIS OF ANTIMICROBIAL CHEMOTHERAPY

An important revolution in human understanding of nature was the germ theory of disease based on the work of Louis Pasteur and Robert Koch, which linked specific microorganisms to specific diseases (Koch, 1876; Pasteur, 1861). Modern chemotherapy is predicated on this idea, radical in its time. The germ theory developed considerably in the 20th century, with identification and characterization of many microbial pathogens and their pathogenic mechanisms and the introduction of antimicrobial drugs. With the use of these drugs came issues of appropriate regimens, drug resistance, drug interactions, and toxicity.

Although the antimicrobials are a large group of diverse structures with myriad mechanisms of actions against bacteria, viruses, fungi, and parasites, we can, nonetheless, develop generalizations about important issues surrounding the use of antimicrobial agents. This chapter reviews the general classes of antimicrobial drugs, their mechanisms of action, mechanisms of resistance, and patterns of kill by different classes of the drugs. It also discusses principles for the selection of an appropriate antibiotic, dose, dose schedule, and type of antibiotic therapy. The pharmacological properties and uses of individual classes of antimicrobials are discussed in Chapters 49 through 59.

Classes and Actions of Antimicrobial Agents. Microorganisms of medical importance fall into four categories: bacteria, viruses, fungi, and parasites. The first broad classification of antibiotics follows this classification closely, so that we have (1) antibacterial, (2) antiviral, (3) antifungal, and (4) antiparasitic agents. Within each of these major categories, drugs are further categorized by their biochemical properties.

Antimicrobial molecules should be viewed as ligands whose receptors are microbial proteins. The term *pharmacophore*, first introduced by Ehrlich, defines that active chemical moiety of the drug that binds to the microbial receptor. The microbial proteins targeted by the antibiotic are essential components of biochemical reactions in the microbes, and interference with these physiological pathways kills the microorganisms. To the extent that an antimicrobial agent targets a protein that is not widely expressed in other bacteria, the drug will be relatively selective in its antimicrobial effect. The biochemical processes commonly inhibited include cell wall synthesis in bacteria and fungi, cell membrane synthesis, synthesis of 30s and 50s ribosomal subunits, nucleic acid metabolism, function of topoisomerases, viral proteases, viral integrases, viral envelope fusion proteins, folate synthesis in parasites, and parasitic chemical detoxification processes. Classification of an antibiotic is based on:

- the class and spectrum of microorganisms it kills
- the biochemical pathway it interferes with
- the chemical structure of its pharmacophore

Because antimicrobial agents are ligands that bind to their targets to produce effects, the relationship between drug concentration and effect on a population of organisms is still modeled using the standard Hill-type curve for receptor and agonist (Chapters 2 and 3), characterized by three parameters: the inhibitory concentration 50, or IC_{50} (also termed EC_{50}), a measure of the antimicrobial agent's potency; the maximal effect, E_{max} ; and H , the slope of the curve, or Hill factor. In antimicrobial therapy, the relationship is often expressed as an inhibitory sigmoid E_{max} model, to take into account the control bacterial population without treatment (E_{con}) as a fourth parameter (Equation 48–1 and

Figure 48–1. Inhibitory sigmoid E_{max} curve. CFU, colony-forming units.

Figure 48–1), where E is effect as measured by microbial burden.

$$E = E_{con} - E_{max} \times [IC]^H / ([IC]^H + [IC_{50}]^H) \quad (\text{Equation 48-1})$$

THE PHARMACOKINETIC BASIS OF ANTIMICROBIAL THERAPY

Penetration of Antimicrobial Agents into Anatomic Compartments. In many infections, the pathogen causes disease not in the whole body, but in specific organs. Moreover, only specific pathological compartments may be infected within these organs. Antibiotics are often administered far away from these sites of infection. To be effective, each antibiotic has to get to where the pathogen is, to penetrate into the infected compartment. Therefore, in choosing an antimicrobial agent for therapy, a crucial consideration is whether the drug can penetrate to the site of infection.

For example, the antibiotic levofloxacin achieves skin tissue/plasma peak concentration ratio of 1.4, epithelial lining fluid to plasma ratio of 2.8, and urine to plasma ratios of 67 (Chow et al., 2002; Conte et al., 2006; Wagenlehner et al., 2006). In a clinical trial on patients treated with levofloxacin, the two most important factors in predicting successful clinical and microbiological outcomes in the patients were a sufficient maximal plasma concentration of the drug (C_{pmax}), which needed to achieve a level of 12 times the minimum inhibitory concentration (MIC) ($C_{pmax}/MIC \geq 12$), and the site of infection. The failure rate of therapy was 0% in patients with urinary tract infections, 3% in

patients with pulmonary infections, and 16% in patients with skin and soft tissue infections (Preston et al., 1998). Clearly, the poorer the penetration into the anatomical compartment, the higher the likelihood of failure.

The penetration of a drug into an anatomical compartment depends on the physical barriers that the molecule must traverse, the chemical properties of the drug, and the presence of multidrug transporters. The physical barriers are usually due to layers of epithelial and endothelial cells, and the type of junctions formed between these cells. Penetration across this physical barrier generally correlates with the octanol-water partition coefficient of the antimicrobial agent, a measure of the hydrophilicity or hydrophobicity of a chemical. Hydrophobic molecules get concentrated in the bi-lipid cell membrane bi-layer, whereas hydrophilic molecules tend to concentrate in the blood, the cytosol, and other aqueous compartments. Thus, the higher the octanol-water partition coefficient (P), the greater the likelihood that an antimicrobial agent will cross physical barriers erected by layers of cells. Conversely, the more charged a molecule is, and the larger it is, the poorer its penetration across membranes and other physical barriers (see Figure 2–3).

Another barrier is due to membrane transporters, which actively export drugs from the cellular or tissue compartment back into the blood (Chapter 5). A well-known example is the P-glycoprotein. Although the octanol-water partition coefficient would favor lipophilic molecules to transverse across cell barriers, P-glycoprotein exports structurally unrelated amphiphilic and lipophilic molecules of 3–4 kDa, reducing their effective penetration. Examples of antimicrobial agents that are P-glycoprotein substrates include HIV protease inhibitors, the antiparasitic agent ivermectin, the antibacterial agent telithromycin, and the antifungal agent itraconazole.

The central nervous system (CNS) is guarded by the blood-brain barrier. The movement of antibiotics across the blood-brain barrier is restricted by tight junctions that connect endothelial cells of cerebral microvessels to one another in the brain parenchyma, as well as by protein transporters (Miller et al., 2008). Antimicrobial agents that are polar at physiological pH generally penetrate poorly; some, such as *penicillin G*, are actively transported out of the cerebrospinal fluid (CSF) and achieve CSF concentrations of only 0.5–5% of that achieved in plasma. However, the integrity of the blood-brain barrier is diminished during active bacterial infection; tight junctions in cerebral capillaries open, leading to a marked increase in the penetration

of even polar drugs (Quagliarello and Scheld, 1997). As the infection is eradicated and the inflammatory reaction subsides, penetration diminishes to normal. Because this may occur while viable microorganisms persist in the CSF, drug dosage should not be reduced as the patient improves.

Drug penetration into the eye is especially pertinent in the treatment of endophthalmitis (infection and inflammation of ocular cavity and surrounding tissue) and infections of the retina. There is generally poor penetration of drug from plasma to this compartment, so that the standard therapy is direct instillation of antibiotics into the ocular cavity. In fungal endophthalmitis, however, systemic administration of amphotericin B and triazole is recommended (Pappas et al., 2009) because these agents, especially the triazoles, have sufficient penetration ratios into the vitreous space.

In patients with pulmonary infections such as pneumonia, drugs must penetrate into the epithelial lining fluid, where the pathogens are found. Among antibacterial agents, many β -lactam antibiotics have poor epithelial lining fluid-to-plasma ratios (0.1-0.4:1); macrolides have ratios of 2-40:1, fluoroquinolones have ratios $\geq 1:1$; pyrazinamide has ratios of $\sim 20:1$; isoniazid, $>1:1$; and linezolid, 2.4-4.2:1 (Kiem and Schentag, 2008).

Other important compartments requiring special drug penetration are endocardial vegetations and the biofilm formed by bacteria and fungi on prosthetic devices such as artificial heart valves, long-dwelling intravascular catheters, artificial hips, and devices for internal fixation of bone fractures. Bacterial and fungal biofilms are colonies of slowly growing cells that are enclosed within an exopolymer matrix. The exopolysaccharide is negatively charged, which restricts positively charged antibiotics from reaching their target. This physical barrier restricts the diffusion of antimicrobial molecules and sometimes binds them (Lewis, 2001). To be effective against infections in these compartments, antibiotics have to be able to penetrate the biofilm and endothelial barriers.

Pharmacokinetic Compartments. Once an antibiotic has penetrated to the site of infection, it may be subjected to processes of elimination and distribution that differ from those in the blood. These sites where the concentration-time profiles differ from each other are considered separate pharmacokinetic compartments, thus, the human body is viewed as multicompartmental. The concentration of antibiotic within each compartment is assumed to be homogeneous. If two compartments have similar concentration profiles, then they may be considered a single compartment. Antibiotic concentrations can be analyzed using any number of such compartments, with the best number of compartments chosen based on the least number of compartments that can adequately explain the findings. The model is also defined as *open* or *not open*; an open model is one in which the drug is eliminated out of the body from the compartment (e.g., kidneys). The order of the process must also be specified (Chapter 2): a

first-order process is directly correlated to concentration of drug D, or $[D]^1$, as opposed to zero order, which is independent of $[D]$ and reflects a process that is saturated at ambient levels of D (such as the elimination of ethanol; Chapter 23).

Suppose a patient has pneumonia with the pathogen in the lung epithelial lining fluid (ELF). The patient ingests an antibiotic that is absorbed via the GI tract (g) into blood or central compartment (compartment 1), as a first-order input. In this process, the transfer constant from the GI tract to central compartment is termed the *absorption constant* and is designated k_a . The antibiotic in the central compartment is then delivered to the lungs where it penetrates into the ELF (compartment 2). However, it also penetrates into other tissues of the body peripheral to the site of infection, termed the *peripheral compartment* (compartment 3). Thus, we have four compartments (including g), each with its own concentration-time profile, as shown in Figure 48-2. The penetration of drug from compartment 1 to 2 is based on the penetration factors discussed earlier and is defined by the transfer constant k_{12} . However, the drug also redistributes from compartment 2 back to 1, defined by transfer constant k_{21} . A similar process between the blood and peripheral tissues leads to transfer constants k_{13} and k_{31} . The drug may also be lost from the body (i.e., open system) via the lungs and other peripheral tissues (e.g., kidneys or liver) at a rate proportional to the concentration.

Antibiotic concentrations within each compartment change with time. The changes in the amount of antibiotic in each compartment with time are described using standard differential equations (Gibaldi and Perrier, 1975). If X is the amount of antibiotic in a compartment, SCL the drug clearance, and V_c the volume of central compartment, then equations for absorption compartment (Equation 48-2), central compartment (Equation 48-3), site of infection or compartment 2 (Equation 48-4), and peripheral compartment (Equation 48-5) are as follows:

$$dX_g/dt = -K_a \cdot X_g \quad (\text{Equation 48-2})$$

$$dX_1/dt = K_a \cdot X_g - [(SCL/V_c) + K_{12} + K_{13}] \cdot X_1 + K_{21} \cdot X_2 + K_{31} \cdot X_3 \quad (\text{Equation 48-3})$$

$$dX_2/dt = K_{12} \cdot X_1 - K_{21} \cdot X_2 \quad (\text{Equation 48-4})$$

$$dX_3/dt = K_{13} \cdot X_1 - K_{31} \cdot X_3 \quad (\text{Equation 48-5})$$

Such models have been used in conjunction with population pharmacokinetics to describe and model a plethora of antimicrobials used to treat bacteria, fungi, viruses, and parasites (Hope et al., 2007; Tarning et al., 2008; Wilkins et al., 2008; Zhou et al., 1999).

In recent years, semi-mechanistic models have related pathogen response to drug concentrations within these pharmacokinetic compartments in preclinical disease models and in patients (Gumbo et al., 2006; Jumbe et al., 2003; Neumann et al., 1998; Pukrittayakamee et al., 2003; Talal et al., 2006). Pathogens within one or more of these compartments are exposed to dynamic drug concentrations within the compartments, as described by Equations 48-2 to 48-5. A pathogen population (N) may be described as consisting of at least two subpopulations, drug-susceptible (N_S) and drug-resistant (N_R) organisms. The organisms are either killed,

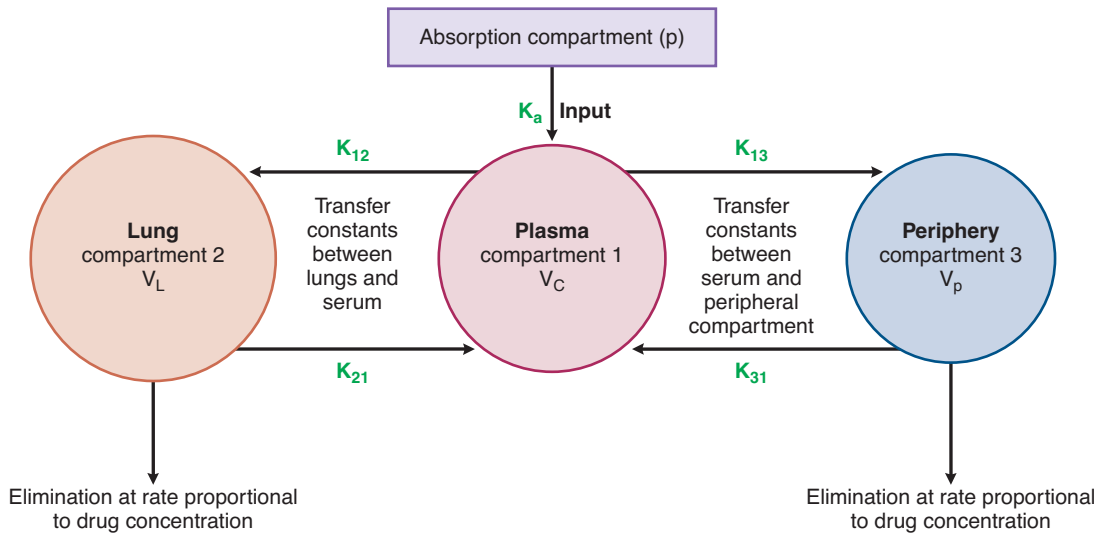

Figure 48–2. Diagrammatic depiction of a multi-compartment model.

inhibited, or continued to grow in response to the antibiotic concentration. For some pathogens such as fungi and bacteria, it is assumed they are in logarithmic growth phase in the absence of drug, exhibiting an exponential density-limited growth rate so that they will reach a stationary phase at a maximal pathogen density, POPMAX. E is a logistic carrying function, so that

$$E = 1 - (N/POPMAX) \quad (\text{Equation 48–6})$$

where N is the pathogen burden in a particular compartment. For replications rates of parasites and viruses, unique models may be specified. The drug will affect the growth rate either independent of kill or via killing the pathogen. The drug effect that is independent of kill is through a saturable Michaelis-Menten-type kinetic event (L).

$$L = (X_1/V_c)^H / [(X_1/V_c)^H + IC_{50}^H], \text{ where } H = H_{g-s} \text{ or } H_{g-r} \quad (\text{Equation 48–7})$$

where H and IC_{50} are as described in Equation 48–1. Microbial kill is based on the concentrations within the compartment, and is modeled as a sigmoid E_{\max} effect model M :

$$M = K_{\max} * (X_1/V_c)^H / [(X_1/V_c)^H + IC_{50}^H], \text{ where } H = H_{k-s} \text{ or } H_{k-r} \quad (\text{Equation 48–8})$$

where K_{\max} is the maximal kill rate. Because the microbial density (N) is in fact a balance between growth (maximal growth rate = $K_{g\max}$) and microbial kill, the change in pathogen density as a function of time is described by Equation 48–9:

$$dN/dt = K_{g\max} \cdot N \cdot E - K_{k\max} \cdot M \cdot N \quad (\text{Equation 48–9})$$

The changes in drug-susceptible subpopulation of pathogen with time and the drug-resistant subpopulation are described by:

$$dN_s/dt = K_{g\max-s} \cdot (1 - L_s) \cdot N_s \cdot E - K_{k\max-s} \cdot M_s \cdot N_s \quad (\text{Equation 48–10})$$

$$dN_R/dt = K_{g\max-R} \cdot (1 - L_R) \cdot N_R \cdot E - K_{k\max-R} \cdot M_R \cdot N_R \quad (\text{Equation 48–11})$$

This can be made more complex and predictive adding parameters describing the effect of inoculum, delay in microbial effect, or splitting the drug-resistant population to smaller subpopulations based on molecular mechanism of resistance (Bulitta et al., 2009).

Population Pharmacokinetics and Variability in Drug Response. The framework for the models central to population pharmacokinetics evolved from a series of publications by Lewis Sheiner (Sheiner et al., 1977). What are population pharmacokinetics? Consider a simple example. When multiple patients are treated with the same dose of a drug, each patient will achieve pharmacokinetic parameters that differ from others. This is termed *between-patient variability*. Even when the same dose is administered to the same patient on two separate occasions, the patient may achieve a different concentration-time profile of the drug between the two occasions. This is termed *inter-occasion* or *within-patient variability*. The variability is reflected at the level of the compartmental pharmacokinetic parameters such as k_a , k_{12} , k_{21} , SCL , V_c , and so on. Even when a recommended dose is administered, the drug may fail to reach a therapeutic concentration in some patients. In other patients, the drug may reach high and toxic concentrations. Such variability could be due to factors that can be explained, such as genetic variability. In addition, anthropometric measures such as weight, height, and age also lead to variability. Furthermore, patients may have comorbid conditions such as renal

and liver dysfunction, which may lead to variability. Drug interactions are an important source of variability with potentially dangerous consequences. These interactions usually occur when one drug inhibits or induces uptake or clearance mechanisms affecting another drug (i.e., modulation of the activities of xenobiotic metabolic enzymes, drug transporters, and excretion mechanisms; Chapters 5 and 6).

Even when such factors are accounted for, there remains residual variability due to computational noise, assay variability, and unexplainable factors. The common practice of using an “average” value of data or “naïve pooling,” has implications of smoothing out data and failing to recognize subgroups of patients at risk for therapeutic failure or increased toxicity of antibiotic. Thus the variability itself, the extent of such variability, and any factors that may explain part of the variability of drug response are more important to understand than measures of central tendency and dispersion for a hypothetical average patient. Such variability reflects the fact that pathogens within patients given the same dose of antibiotic will be exposed to different antibiotic concentrations from patient to patient, leading to effective kill in some and resistance emergence in others. Knowledge of covariates associated with pharmacokinetic variability leads to better dose adjustments, or switching therapy from one antibiotic to another, or changing concomitant medications.

IMPACT OF SUSCEPTIBILITY TESTING ON SUCCESS OF ANTIMICROBIAL AGENTS

The microbiology laboratory plays a central role in the decision to choose a particular antimicrobial agent over others. First, identification and isolation of the culprit organism takes place when the patients’ specimens are sent to the microbiology laboratory. Once the microbial species causing the disease has been identified, a rational choice of the class of antibiotics likely to work in the patient can be made. The microbiology laboratory then plays a second role, which is to perform susceptibility testing. This step is crucial in narrowing down the list of possible antimicrobials that could be used.

Millions of individuals across the globe get infected by many different isolates of the same species of pathogen. Evolutionary processes cause each isolate to be slightly different from the next, so that each will have a unique susceptibility to antimicrobial agents. As the microorganisms divide within the patient, they may

undergo further evolution between the time of infection and when the disease is diagnosed. As an example, a relatively narrow range of variants are transmitted when patients become infected with HIV. However, HIV replication has poor fidelity and has replication rates that result in up to 10^{10} viral particles each day. Moreover, viral recombination occurs commonly. Over many months, under immune pressure, numerous variants arise. The emergence of a quasi species that harbors a mutation associated with drug resistance to at least one drug is high, based on probability factors in the context of high replication rates and the massive numbers of viral particles. Therefore, we expect that there will be a wide distribution of concentrations of antimicrobial agents that can kill pathogens. Often, this distribution is Gaussian, with a skew that depends on where the patient lives. These factors will affect the shape of the inhibitory sigmoid E_{\max} model curve described by Equation 48–1.

With changes in susceptibility, the sigmoid E_{\max} curve shifts in one of two basic ways. The first is a shift to the right, an increase in IC_{50} , as shown in Figure 48–3A. This means that much higher concentrations than before are now needed to show specific effect. Susceptibility tests for bacteria, fungi, parasites, and viruses have been developed to determine whether these shifts have occurred at a sufficient magnitude to warrant higher doses of drug to achieve particular effect. The change in IC_{50} may become so large that it is not possible to overcome the concentration deficit by increasing the antimicrobial dose without causing toxicity to the patient. At that stage, the organism is now “resistant” to the particular antibiotic. A second possible change in the curve is decrease in E_{\max} (Figure 48–3B), such that increasing the dose of the antimicrobial agent beyond a certain point will achieve no further effect; i.e., changes in the microbe are such that eradication of the microbe by the particular drug can never be achieved. This occurs because the available target proteins have been reduced or the microbe has developed an alternative pathway to overcome the biochemical inhibition. As an example, maraviroc is an allosteric, noncompetitive antagonist that binds to the CCR5 receptor of patient’s CD4 cells to deny HIV entry into the cell. Viral resistance occurs by a mechanism that involves HIV adapting to use of the maraviroc-bound CCR5, which results in decrease of E_{\max} in phenotypic susceptibility assays (Hirsch et al., 2008).

Bacteria. For bacteria, dilution tests employ antibiotics in serially diluted concentrations on solid agar or in

Figure 48-3. Changes in sigmoid E_{max} model with increases in drug resistance. Increase in resistance may show changes in IC_{50} (panel A: the IC_{50} increases from 70 (orange line) to 100 (green line), to 140 (blue line)) or decrease in E_{max} (panel B: efficacy decreases from full response (orange line) to 70% (green line))

broth medium that contains a culture of the test microorganism. The lowest concentration of the agent that prevents visible growth after 18-24 hours of incubation is known as the *minimum inhibitory concentration* (MIC).

Automated systems also use a broth-dilution method. The optical density of a broth culture of the clinical isolate incubated in the presence of drug is determined. If the density of the culture exceeds a threshold optical density, then growth has occurred at that concentration of drug. The MIC is the concentration at which the optical density remains below the threshold.

The disk-diffusion technique provides only qualitative or semi-quantitative information on antimicrobial susceptibility. The test is performed by applying commercially available filter-paper disks impregnated with a specific amount of the drug onto an agar surface, over which a culture of the microorganism has been streaked. After 18-24 hours of incubation, the size of the clear zone of inhibition around the disk is measured. The diameter of the zone depends on the activity of the drug against the test strain. Standardized values for zone sizes for each bacterial species and antibiotic permit classification of the clinical isolate as either resistant

or susceptible. A variant of the disk diffusion tests is the Epsilon test, or E-test. A rectangular test strip impregnated with changing concentrations of antimicrobial agent, usually across 15 dilutions, is placed on an agar plate that has a heavy inoculum of test organism. The drug concentrations are printed along this long test strip. The cultures are then incubated under favorable conditions for 24 hours, 48 hours, or 5 days, depending on the test organism. There is no growth with higher concentrations and heavy microbial growth where there is lower drug concentration, so that a clear elliptical zone is formed that bisects the test strip at the MIC. This test has the virtue of determining an actual MIC value, rather than the dichotomous categorization of “susceptible” or “resistant.” There are test strips for hundreds of antibacterial agents as well as for some antifungal agents active against *Candida* species.

Sometimes, a biochemical or immunological reaction that leads to a color change is used to detect susceptibility. As an example, methicillin resistance in *Staphylococcus aureus* (methicillin-resistant *S. aureus*, or MRSA) occurs because of acquisition of a low-affinity penicillin-binding protein 2' (2a), or PBP2' (PBP2a). The PBP2' is extracted from isolates of the MRSA, and supernatant mixed with a latex reagent with monoclonal antibody against PBP2'. Visible clumping within 3 minutes indicates presence of PBP2', indicating MRSA.

Fungi. For fungi that are yeasts (i.e., *Candida*), susceptibility testing methods are similar to those used for bacteria. However, the definitions of MIC differ based on drug and the type of yeast, so there are cutoff points of 50% decrease in turbidity compared to controls at 24 hours, or 80% at 48 hours, or total clearance of the turbidity. Susceptibility tests and MICs for triazoles have been extensively shown to correlate with clinical outcomes.

Standardized tests for echinocandin antifungals and amphotericin B-based compounds are available. However, the correlation of these tests with clinical outcomes is still weak. Susceptibility tests for molds have also been developed, but the clinical correlations are still being examined. Different terminology from MICs has been adopted when evaluating echinocandins against molds because the fungal burden can not be measured by counting discrete cells in molds, given that hyphae will break up into unpredictable numbers of discrete fungi when under antifungal pressure. Furthermore, echinocandins often do not completely inhibit mold growth, but instead cause damage reflected by morphological changes in hyphae. Thus, the minimum effective concentration (MEC) for echinocandins is the lowest drug concentration at which short, stubby, and highly branched hyphae are observed on microscopic examination.

Viruses. In HIV phenotypic assays, the patient's HIV-RNA is extracted from plasma, and genes for targets of antiretroviral drugs such as reverse transcriptase and protease are amplified. The genes are then inserted into a standard HIV vector that lacks analogous gene sequences to produce a recombinant virus, which is co-incubated with drug of interest in a mammalian cell

viability assay (Hanna and D'Aquila, 2001; Hertogs et al., 1998; Petropoulos et al., 2000). Growth is compared to a standardized wild-type control virus. For HIV reverse transcriptase, e.g., <4-fold increase in IC_{50} is defined as “sensitive,” 4- to 10-fold increase in IC_{50} is “intermediate,” and >10-fold increase is “resistant” (Hanna and D'Aquila, 2001). Further use has been made of the viral IC_{50} to establish the inhibitory quotient (IQ). The IQ is the ratio of plasma concentration of antiviral drug to the IC_{50} . The phenotypic IQ is the ratio of plasma trough concentration to the IC_{50} .

Genotypic tests are now a standard part of HIV care in many parts of the world, although the tests are rarely used in clinical practice in resource-poor settings. The simplest tests measure presence of mutations associated with loss of function of a drug. This loss of function means that the organism is “resistant” to drug and the drug should not be used to treat that patient. The absence of mutation means the drug has an increased likelihood of working against the pathogen. There are some situations with antiretroviral therapy, however, when presence of such mutations may paradoxically lead to choice of the drug to be part of combination therapy. A famous example is that of the reverse transcriptase inhibitors zidovudine (AZT) and lamivudine (3TC) in the treatment of HIV-1, in which an M184V mutation that causes resistance to 3TC increases viral sensitivity to AZT up to 10-fold. Therefore, although presence of a mutation in a genotype assay may strongly argue for exclusion of some drugs in a regimen, the interpretation can be complex. Indeed, this is one of the limitations of this method in that the true meaning of a mutation may be unclear and interpreted differently by health-care practitioners.

Parasites. Susceptibility testing for parasites, especially malaria, has been performed in the laboratory. The tests are similar to the broth tests for bacteria, fungi, and viruses. *Plasmodium* species in the patient's blood are cultured *ex vivo* in the presence of different dilutions of antimalarial drug (Stepniewska et al., 2007). A sigmoid E_{max} curve for effect versus drug concentration is used to identify IC_{50} and E_{max} . These susceptibility tests are usually field tests at sentinel sites that are used to determine if there is drug resistance in a particular area or not, and they are not used as a routine test for clinical decision making for individual patients. In general, susceptibility tests for parasitic infections are not standardized. These tests are primarily used in the research setting and not for individualization of therapy.

BASIS FOR SELECTION OF DOSE AND DOSING SCHEDULE

Even though susceptibility testing is central to decision making, it does not completely predict patient response. Unlike in susceptibility tests in the laboratory where

drug concentrations are static by design, microorganisms in patients are exposed to dynamic concentrations of drug. In addition, the antibiotics are prescribed at a certain schedule (e.g., three times a day) so that there is a periodicity in the fluctuations of drug at the site of infection. Therefore, the microbe is exposed to a particular shape of the concentration-time curve. Harry Eagle performed studies on penicillin and discovered that the shape of the concentration-time profile was an important determinant of the efficacy of the antibiotic (Eagle et al., 1950). This important observation was forgotten until William Craig and colleagues rediscovered it and performed systematic studies on several classes of antibiotics (Craig, 1998, 2007; Vogelman et al., 1988), initiating the era of antimicrobial pharmacokinetics-pharmacodynamics (PK/PD) (Ambrose et al., 2007; Craig, 1998).

The first basic lesson is based on susceptibility (MIC or EC_{90}) of the organism to the antimicrobial agent. The response of the microbe to a fixed dose of antibiotic differs based on susceptibility of the organism. As an example, vancomycin resistance is said to be present when MIC >2.0 mg/L. When patients with MRSA infection were treated with vancomycin, the success rate was 61% in patients infected with isolates that had an MIC of 0.5 mg/L, 28% for MIC of 1.0 mg/L, and only 11% for MIC of 2.0 mg/L (Moise-Broder et al., 2004). As expected, outcomes were poorer with increasing MIC. This is not a surprise because the IC_{50} shifts to the right with decrease in susceptibility (Figure 48–3A). *The important point is that in determining therapeutic outcomes, it is important to index drug exposure to MIC.*

Second, dose itself is a poor measure of drug exposure, given between-patient and within-patient pharmacokinetic variability. Rather, actual drug concentration achieved at site of infection is the important measure. The shape of the relationship between non-protein-bound antibiotic concentration (exposure) versus microbial kill is the inhibitory sigmoid E_{max} curve of Figure 48–1 (Craig, 2007; Craig and Kunin, 1976). Maximal kill is actually on an asymptote, so that non-protein-bound antimicrobial exposures associated with 80-90% of E_{max} are termed “optimal” concentrations. *The optimal dose of the antibiotic for a patient is the dose that achieves IC_{80} to IC_{90} exposures at the site of infection.* This exposure can often be easily identified in preclinical models and directly applied to patient populations, provided interspecies differences in protein binding and pharmacokinetic variability are taken into account.

Third, *optimal microbial kill by the antibiotic may be best achieved by maximizing certain shapes of the concentration-time curve.* Certain dose schedules maximize antimicrobial effect. As an example, consider an antibiotic with a serum $t_{1/2}$ of 3 hours that is being used to treat a bloodstream infection by a pathogen with an MIC of 0.5 mg/L, administered with a dosing interval of 24 hours (that is, a once-daily schedule). Figure 48–4A depicts the concentration-time curve of the antibiotic, with definitions of peak concentration (C_{pmax}), area under the curve (AUC), and the fraction of the dosing interval for which the drug concentration remains above the MIC ($T > MIC$), as shown. The AUC is a measure of the total concentration of drug and is calculated by taking an integral between two time points, 0–24 hours (AUC_{0-24}) in this case. Now, if one were to change the dosing schedule of

Figure 48–4. Effect of different dose schedules on shape of concentration-time curve. The total AUC for the fractionated dose in **curve B** is determined by adding AUC_{0-8h} , AUC_{8-16h} and AUC_{16-24h} which adds up to the same AUC_{0-24h} in **curve A**. The time that the drug concentration exceeds MIC in **curve B** is also determined by adding up $T_1 > MIC$, $T_2 > MIC$, and $T_3 > MIC$, which results in a fraction greater than that for curve A.

the same antibiotic amount by splitting it into three equal doses administered at 0, 8, and 16 hours, the shape of the concentration-time curves changes to that shown in Figure 48–4B. Because the same cumulative dose has been given for the dosing interval of 24 hours, the AUC_{0-24} will be similar whether it was given once a day or three times a day. For the same pathogen, therefore, the change in dose schedule does not change the AUC_{0-24}/MIC (or AUC_{0-24}/EC_{90}). However, the C_{pmax} will decrease by a third when the total dose is split into thirds and administered more frequently (Figure 48–4B). Thus, when a dose is fractionated and administered more frequently, the C_{pmax}/MIC ratio *decreases*. In contrast, the time that the drug concentration persists above MIC ($T > MIC$) will *increase* with the more frequent dosing schedule, despite the same cumulative dose being administered. Which of the three indices (AUC/MIC , or C_{pmax}/MIC or $T > MIC$) is the most important to the outcome being assessed (i.e., microbial kill)? A common simple approach to the answer is to determine which of these patterns best approximates a perfect inhibitory sigmoid E_{max} curve (based on various statistical assessments of goodness of fit).

Some classes of antimicrobial agents kill best when concentration persists above MIC for longer durations of the dosing interval while kill is decreased by reducing the time above MIC. Indeed, increasing the drug concentration beyond 4–6 times the MIC does not increase microbial kill. Two good examples are β -lactam antibacterials (e.g., penicillin) and the antifungal agent 5-fluorocytosine (5-FC) (Ambrose et al., 2007; Andes and van Ogtrop, 2000). In fact, there are usually good biochemical explanations for this pattern for the drugs. The clinical implication, however, is that a drug optimized by $T > MIC$ should be dosed more frequently, or if possible should have its $t_{1/2}$ prolonged by other drugs, so that drug concentrations persist above MIC (or EC_{95}) as long as possible. Thus the effectiveness of penicillin is enhanced when it is given as a continuous infusion. HIV protease inhibitors are often “boosted” with ritonavir. This “boosting” inhibits the metabolism of the protease inhibitors by CYPs 3A4 and 2D6, thereby prolonging time above EC_{95} .

However, the peak concentration is what matters for some antimicrobial agents. Persistence of concentration above MIC has less relevance for these drugs, meaning that these drugs can be dosed more intermittently. Aminoglycosides are a prime example of this class as they used to be given three times a day but are highly effective when given once a day. These C_{pmax}/MIC -linked drugs are often able to be administered less frequently due to their long duration of *post-antibiotic* effect (PAE). In other words, effect continues long after antibiotic concentrations decline below the MIC. An example of such a drug is rifampin (Gumbo et al., 2007a). The entry of rifampin into *Mycobacterium tuberculosis* increases with increased concentration in the bacillus microenvironment, likely because of a saturable transport process. Once inside the bacteria, the drug’s macrocyclic ring binds the β -subunit of DNA-dependent RNA polymerase (*rpoB*) to form a very stable drug-enzyme complex within 10 minutes, a process not enhanced by longer incubation of drug and

enzyme (Harshey and Ramakrishnan, 1976; Wehrli et al., 1968). The PAE of the rifampin is long and concentration dependent (Gumbo et al., 2007a). This means that administering combined doses on a more intermittent basis (i.e., once a day) will maximize effect for these drugs. Toxicity generated by intermittent dosing may preclude such use for some drugs such as rifampin, whereas for others (i.e., aminoglycosides) such infrequent dosing may actually decrease toxicity.

There is a third group of drugs for which dosing schedule has no effect on efficacy, but where it is the cumulative dose that matters. Thus, it is more the total concentration (AUC) to MIC ratio that matters and not the time that concentration persists above a certain threshold. Antibacterial agents such as daptomycin fall into this class (Louie et al., 2001). These agents also have a good PAE. The AUC/IC_{50} explains why the nucleoside analogue reverse transcriptase inhibitors tenofovir and emtricitabine have been combined into one pill, administered once a day for the treatment of AIDS.

The shape of concentration-time curve that optimizes resistance suppression is often different from that which optimizes microbial kill. In many instances, the drug exposure associated with resistance suppression is much higher than for optimal kill. It should actually be this higher exposure that should be achieved by each dose in patients for optimal effect, rather than the EC_{80} as discussed earlier. However, this is often precluded by increased drug toxicity when doses are increased. Second, although the relationship between kill and exposure is based on the inhibitory sigmoid E_{max} model, experimental work with preclinical models demonstrates that this model does not apply to resistance suppression (Gumbo, 2007b; Tam et al., 2007).

The optimal dose should be designed to achieve a high probability of exceeding the EC_{80} microbial PK/PD index, or index associated with suppression of resistance, given the population pharmacokinetic variability and the MIC distribution of clinical microbe isolates. The population pharmacokinetic variability enables integration of pharmacogenetics, anthropometric measures, and residual variability into the decision to choose optimal dose (Gumbo, 2008). Once that has been achieved, the dose schedule is chosen according to whether efficacy is driven by AUC/MIC (or AUC/EC_{95}), C_{Pmax}/MIC , or $T > MIC$. Duration of therapy is then chosen, based on best available evidence.

TYPES AND GOALS OF ANTIMICROBIAL THERAPY

When an infection occurs, the numbers of microorganisms are often small in the beginning. Pathogen burden eventually increases with replication of the organism. Sometimes, the immune system manages to eliminate the infection before it causes any further damage. In other instances, the organism is not entirely eliminated but hides inside the patient's own cells and become dormant, only to reactivate when immune function is compromised in the future. In some patients, the organism may overcome immune defenses and then cause disease. In a subset of such patients, the disease is self-limited. For example, many viral upper respiratory infections are self-limited and should not be treated with antimicrobial agents. Other diseases, however, require antimicrobial therapy. In these patients, therapy should be discontinued after resolution of disease. In special cases where the immune or anatomical defect that led to the infection is still present, suppressive or "maintenance" therapy may be required. A useful way to organize the types and goals of antimicrobial therapy is to consider where along the disease progression timetable therapy is initiated (Figure 48–5); therapy can be prophylactic, preemptive, empirical, definitive, or suppressive.

Prophylactic Therapy. Prophylaxis involves treating patients who are not yet infected or have not yet developed disease. The goal of prophylaxis is to prevent infection in some patients or to prevent development of a potentially dangerous disease in those who already have evidence of infection. Ideally, a single, effective, nontoxic drug is successful in preventing infection by a specific microorganism or eradicating an early infection. The main principle behind prophylaxis is targeted therapy. However, prophylaxis to prevent

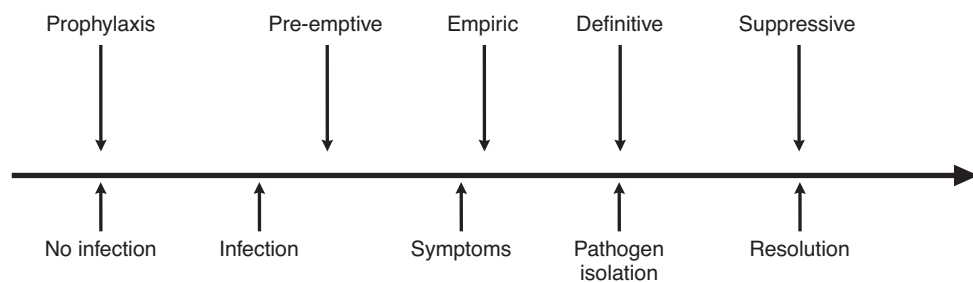

Figure 48–5. Antimicrobial therapy-disease progression timeline. Stages of disease progression are below the horizontal arrow; categories of antimicrobial therapy are above the arrow.

colonization or infection by any or all microorganisms present in the environment of a patient often fails.

Prophylaxis is used in immunosuppressed patients such as those with HIV-AIDS or are post-transplantation on anti-rejection medications. The efficacy of prophylaxis in these patients is based on excellent evidence (Anonymous, 2000; DHHS Panel on Guidelines for the Prevention and Treatment of Opportunistic Infections in HIV-Infected Adults and Adolescents, 2008). In these groups of patients, specific antiparasitic, antibacterial, antiviral, and antifungal therapy is administered based on the well-defined pattern of pathogens that are major causes of morbidity during immunosuppression. A risk-benefit analysis is used to determine choice and duration of prophylaxis. Prophylaxis of opportunistic infections in patients with AIDS is started when the CD4 count falls below 200 cells per mm³. In post-transplant patients, prophylaxis depends on time since the transplant procedure, which is related to intensity of use and type of immunosuppressive therapy. Prophylaxis should be discontinued in patients who are doing well at certain time points, such as 1 year post-transplant. In AIDS patients, prophylaxis is discontinued when the CD4 count climbs above 200 cells/mm³. Infections for which prophylaxis is given include *Pneumocystis jiroveci*, *Mycobacterium avium-intracellulare*, *Toxoplasma gondii*, *Candida* species, *Aspergillus* species, *Cytomegalovirus*, and other Herpesviridae. In general, lower doses of prophylactic agent are given compared to when the same drug is used for treatment.

Chemoprophylaxis is also used to prevent wound infections after various surgical procedures. Wound infection results when a critical number of bacteria are present in the wound at the time of closure. Antimicrobial agents directed against the invading microorganisms may reduce the number of viable bacteria below the critical level and thus prevent infection. Several factors are important for the effective and judicious use of antibiotics for surgical prophylaxis. First, antimicrobial activity must be present at the wound site at the time of its closure. Thus, infusion of the first antimicrobial dose should begin within 60 minutes before surgical incision and should be discontinued within 24 hours of the end of surgery (Bratzler and Houck, 2004). Second, the antibiotic must be active against the most likely contaminating microorganisms for that type of surgery. A number of studies indicate that chemoprophylaxis can be justified in dirty or contaminated surgical procedures (e.g., resection of the colon), where the incidence of wound infections is high. These include <10% of all surgical procedures. In clean surgical procedures, which account for ~75% of the total, the expected incidence of wound infection is <5%, and antibiotics should not be used routinely. When the surgery involves insertion of a prosthetic implant (e.g., prosthetic valve, vascular graft, prosthetic joint), cardiac surgery, or neurosurgical procedures, the complications of infection are so drastic that most authorities currently agree to chemoprophylaxis for these indications.

Patients at the highest risk for infective endocarditis for which prophylaxis is recommended fall into four groups (Wilson et al., 2007):

- those with a prosthetic material used for heart valve repair or replacement
- previous infective endocarditis

- congenital heart disease such as unrepaired cyanotic heart disease, or within 6 months of repair of the heart disease with prosthetic material, or those with residual defects adjacent to prosthetic material
- postcardiac transplant patients with heart valve defects

Chemoprophylaxis is reasonable in these patients when undergoing dental procedures if there is manipulation of gingival tissue or periapical region of teeth, or perforation of oral mucosa, but not for other dental procedures. Recommended therapy is a single dose of oral amoxicillin 30 minutes to 1 hour before the procedure or intravenous ampicillin or ceftriaxone in those unable to take oral medication. A macrolide or clindamycin may be administered for patients who are allergic to β -lactam agents. Therapy may be administered no more than 2 hours after the procedure for patients who failed to receive the prophylaxis prior to the procedure (Wilson et al., 2007). Prophylaxis is also reasonable for procedures that will involve infected skin and soft tissues as well as infected respiratory tract, but not in routine genitourinary and GI tract procedures. If the organism causing the infection is known, then the prophylactic antibiotic for patients undergoing these procedures should be tailored toward that particular organism.

Prophylaxis may be used to protect healthy persons from acquisition of or invasion by specific microorganisms to which they are exposed. This is termed *post-exposure prophylaxis*. Successful examples of this practice include rifampin administration to prevent meningococcal meningitis in people who are in close contact with a case, prevention of gonorrhea or syphilis after contact with an infected person, and macrolides after contact with confirmed cases of pertussis. Post-exposure prophylaxis is recommended in those patients inadvertently exposed to HIV infection. Currently, combination therapy from one of the classes of antiretrovirals, nucleoside reverse transcriptase inhibitors, nucleotide reverse transcriptase inhibitors, non-nucleoside reverse transcriptase inhibitors, protease inhibitors, and fusion inhibitors is administered for 4 weeks (Panlilio et al., 2005). For influenza, the neuraminidase inhibitor oseltamivir has been recommended for prevention of influenza A and B in healthy adults and children with close contact of laboratory-confirmed cases (Hayden and Pavia, 2006).

Mother-to-child transmission of HIV and syphilis are important public health problems for which specific chemotherapeutic regimens have been devised, based on locality. Anti-retroviral therapy is administered for HIV prophylaxis during the pregnancy and peripartum periods. Prophylactic therapy for syphilis during pregnancy is effective in reducing neonatal death and infant neurological, auditory, and bone malformations.

Pre-emptive therapy. Pre-emptive therapy is used as a substitute for universal prophylaxis and as early targeted therapy in high-risk patients who already have a laboratory or other test indicating that an asymptomatic patient has become infected. The principle is that delivery of therapy prior to development of symptoms (presymptomatic) aborts impending disease, and the therapy is for a short and defined duration (Singh, 2001). This has been applied in the clinic to therapy for cytomegalovirus (CMV) after both hematopoietic stem cell transplants and after solid organ transplantation. It is unclear whether this method is superior to keeping all at-risk patients on ganciclovir. Recent evidence in liver transplant patients

suggest this approach may be as efficacious as universal prophylaxis while using far less antiviral medications (Gerna et al., 2008; Singh et al., 2008).

Empirical Therapy in the Symptomatic Patient. Once a patient is symptomatic, should the patient be treated immediately? The first consideration in selecting an antimicrobial is to determine if the drug is indicated. *The reflex action to associate fever with treatable infections and prescribe antimicrobial therapy without further evaluation is irrational and potentially dangerous.*

The diagnosis may be masked if therapy is started and appropriate cultures are not obtained. Antimicrobial agents are potentially toxic and may promote selection of resistant microorganisms. For some diseases, the cost of waiting a few days is low. These patients can wait for microbiological evidence of infection without empirical treatment. In a second group of patients, the risks of waiting are high, based either on the patient's immune status or other known risk factors for poor outcome with therapy delay. Initiation of optimal empirical antimicrobial therapy should rely on the clinical presentation, which may suggest the specific microorganism, and knowledge of the microorganisms most likely to cause specific infections in a given host. In addition, simple and rapid laboratory techniques are available for the examination of infected tissues.

The most valuable and time-tested method for immediate identification of bacteria is examination of the infected secretion or body fluid with Gram stain. In malaria-endemic areas, or in travelers returning from such an area, a simple thick and thin blood smear may mean the difference between a patient's receiving appropriate therapy and surviving or death while on wrong therapy for presumed bacterial infection. Such tests help to narrow the list of potential pathogens and permit more rational selection of initial antibiotic therapy. Similarly, neutropenic patients with fever have high risks of mortality, and, when febrile, they are presumed to have either a bacterial or fungal infection; thus a broad-spectrum combination of antibacterial and antifungal agents that cover common infections encountered in granulocytopenic patients are given. Performance of cultures is still mandatory with a view to modify antimicrobial therapy with culture results.

Definitive Therapy with Known Pathogen. Once a pathogen has been isolated and susceptibilities results are available, therapy should be streamlined to a narrow targeted antibiotic. Monotherapy is preferred to decrease the risk of antimicrobial toxicity and selection of antimicrobial-resistant pathogens. Proper antimicrobial doses and dose schedules are crucial to maximizing efficacy and minimizing toxicity. In addition, the duration of therapy should be as short as is necessary. The practice of keeping a patient indefinitely on antimicrobial therapy without a particular reason is discouraged. In fact, both experimental and clinical evidence have shown that unnecessarily prolonged therapies lead to the emergence of resistance.

Combination therapy is an exception, rather than a rule. Once a pathogen has been isolated, there should be no reason to use multiple antibiotics, except when evidence overwhelmingly suggests otherwise. Using two antimicrobial agents where one is required leads to increased toxicity and unnecessary damage to the patient's otherwise protective fungal and bacterial flora. This is true, even when intuition suggests use of two agents. As an example, Cosgrove and colleagues recently demonstrated increased nephrotoxicity of low-dose gentamicin administered only for 4 days as "synergistic therapy" with vancomycin or an antistaphylococcal penicillin for *S. aureus* bacteremia and endocarditis, without improving efficacy (Cosgrove et al., 2009).

However, there are special circumstances where evidence is unequivocal in favor of combination therapy. The principles behind such antimicrobial use include:

- preventing resistance to monotherapy
- accelerating the rapidity of microbial kill
- enhancing therapeutic efficacy by use of synergistic interactions or enhancing kill by a drug based on a mutation generated by resistance to another drug
- paradoxically, reducing toxicity (i.e., when full efficacy of a standard antibacterial agent can only be achieved at doses that are toxic to the patient, and a second drug is co-administered to exert additive effects)

Clinical situations for which combination therapy is advised are discussed in the relevant chapters but include antiretroviral therapy for AIDS, antiviral therapy for hepatitis B and C, the treatment of tuberculosis, *Mycobacterium avium-intracellulare* and leprosy, fixed-dose combinations of antimalarial drugs, the treatment of *Cryptococcus neoformans* with flucytosine and amphotericin B, during empirical therapy for patients with febrile neutropenia, and advanced AIDS with fever. The combination of a sulfonamide and an inhibitor of dihydrofolate reductase, such as trimethoprim, is synergistic owing to the blocking of sequential steps in microbial folate synthesis. A fixed combination of sulfamethoxazole and trimethoprim is active against organisms that may be resistant to sulfonamides alone, is effective for many infections, and is rarely given as its separate components.

Post-treatment suppressive therapy. In some patients, after the initial disease is controlled by the antimicrobial agent, therapy is continued at a lower dose. This is because in these patients the infection is not completely eradicated and the immunological or anatomical defect that led to the original infection is still present. This is common in AIDS patients and post-transplant patients, for example. The goal is more as secondary prophylaxis. Nevertheless, risks of toxicity from long durations of the therapy are still real. In this group of patients, the suppressive therapy is eventually discontinued if the patient's immune system improves.

MECHANISMS OF RESISTANCE TO ANTIMICROBIAL AGENTS

Antimicrobial agents were viewed as miracle cures when first introduced into clinical practice. However, it became evident rather soon after the discovery of

penicillin that resistance developed quickly, terminating the miracle. This serious development is ever present with each new antimicrobial agent and threatens the end of the antimicrobial era. Today, every major class of antibiotic is associated with the emergence of significant resistance. *Two major factors are associated with emergence of antibiotic resistance: evolution and clinical/environmental practices.* A species that is subjected to pressure, chemical or otherwise, that threatens its extinction often evolves mechanisms to survive under that stress. Pathogens will evolve to develop resistance to the chemical warfare to which we subject them. This evolution is mostly aided by poor therapeutic practices by healthcare workers, as well as indiscriminant use of antibiotics for agricultural and animal husbandry purposes. Poor clinical practices that fail to incorporate the pharmacological properties of antimicrobials amplify the speed of development of drug resistance.

Antimicrobial resistance can develop at any one or more of steps in the processes by which a drug reaches and combines with its target. Thus, resistance development may develop due to:

- reduced entry of antibiotic into pathogen
- enhanced export of antibiotic by efflux pumps
- release of microbial enzymes that destroy the antibiotic
- alteration of microbial proteins that transform pro-drugs to the effective moieties
- alteration of target proteins
- development of alternative pathways to those inhibited by the antibiotic

Mechanisms by which such resistance develops can include acquisition of genetic elements that code for the resistant mechanism, mutations that develop under antibiotic pressure, or constitutive induction.

Resistance Due to Reduced Entry of Drug into Pathogen. The outer membrane of gram-negative bacteria is a permeable barrier that excludes large polar molecules from entering the cell. Small polar molecules, including many antibiotics, enter the cell through protein channels called *porins*. Absence of, mutation in, or loss of a favored porin channel can slow the rate of drug entry into a cell or prevent entry altogether, effectively reducing drug concentration at the target site. If the target is intracellular and the drug requires active transport across the cell membrane, a mutation or phenotypic change that slows or abolishes this transport mechanism can confer resistance. As an example, *Trypanosoma brucei* is treated with suramin and pentamidine during early stages, but with melarsoprol and eflornithine when CNS disease (sleeping sickness) is present. Melarsoprol is actively taken up by trypanosome P2 protein transporter. When the parasite either lacks the P2 transporter, or has a mutant form, resistance to melarsoprol and cross resistance to pentamidine occur due to reduced uptake (Ouellette, 2001).

Resistance Due to Drug Efflux. Microorganisms can overexpress efflux pumps and then expel antibiotics to which the microbes would otherwise be susceptible. There are five major systems of efflux pumps that are relevant to antimicrobial agents:

- the multidrug and toxic compound extruder (MATE)
- the major facilitator superfamily (MFS) transporters
- the small multidrug resistance (SMR) system
- the resistance nodulation division (RND) exporters
- ATP binding cassette (ABC) transporters

Efflux pumps are a prominent mechanism of resistance for parasites, bacteria, and fungi. One of the tragic consequences of resistance emergence has been the development of drug resistance by *Plasmodium falciparum*. Drug resistance to most antimalarial drugs, specifically chloroquine, quinine, mefloquine, halofantrine, lumefantrine, and the artemether-lumefantrine combination is mediated by an ABC transporter encoded by *Plasmodium falciparum* multidrug resistance gene 1 (*Pfmdr1*) (Happi et al., 2009). Point mutations in the *Pfmdr1* gene lead to drug resistance and failure of chemotherapy. Drug efflux sometimes works in tandem with chromosomal resistance, as is seen in *Streptococcus pneumoniae*, and perhaps, *Mycobacterium tuberculosis*. In these situations, induction of efflux pumps occurs early, which increases the MIC only modestly. However, this MIC increase is enough to allow further microbial replication and an increased mutation frequency, which enable the development of resistance via more robust chromosomal mutations (Gumbo et al., 2007b; Jumbe et al., 2006).

Resistance Due to Destruction of Antibiotic. Drug inactivation is a common mechanism of drug resistance. Bacterial resistance to aminoglycosides and to β -lactam antibiotics usually is due to production of an aminoglycoside-modifying enzyme or β -lactamase, respectively.

Resistance Due to Reduced Affinity of Drug to Altered Target Structure. A common consequence of either single point or multiple point mutations is change in amino acid composition and conformation of target protein. This change leads to a reduced affinity of drug for its target, or of a prodrug for the enzyme that converts the prodrug to active drug. Such alterations may be due to mutation of the natural target (e.g., fluoroquinolone resistance), target modification (e.g., ribosomal protection type of resistance to macrolides and tetracyclines), or acquisition of a resistant form of the native, susceptible target (e.g., staphylococcal methicillin resistance caused by production of a low-affinity penicillin-binding protein) (Hooper, 2002; Lim and Strynadka, 2002; Nakajima, 1999). Similarly, in HIV resistance mutations associated with reduced affinity are encountered in protease inhibitors, integrase inhibitors, fusion inhibitors, and non-nucleoside reverse transcriptase inhibitors (Nijhuis et al., 2009). Similarly, benzimidazoles are used against myriad worms and protozoa and work by binding to the parasite's tubulin; point mutations in the β -tubulin gene lead to modification of the tubulin and drug resistance (Ouellette, 2001).

Incorporation of Drug. An uncommon situation occurs when an organism not only becomes resistant to an antimicrobial agent but subsequently starts requiring it for growth. Enterococcus, which easily develops vancomycin resistance, can, after prolonged exposure to the antibiotic, develop vancomycin-requiring strains.

Resistance Due to Enhanced Excision of Incorporated Drug. Nucleoside reverse transcriptase inhibitors such as zidovudine are 2'-deoxyribonucleoside analogs that are converted to their 5'-triphosphate form and compete with natural nucleotides. These drugs are incorporated into the viral DNA chain and cause chain termination. When resistance emerges via mutations at a variety of points in the reverse transcriptase gene, phosphorolytic excision of the incorporated chain-terminating nucleoside analog is enhanced (Arion et al., 1998).

Hetero-resistance and Viral Quasi Species. Hetero-resistance is said to be present when a subset of the total microbial population is resistant, despite the total population being considered susceptible on testing (Falagas et al., 2008; Rinder, 2001). In a way, this should not be a surprise given that chromosomal mutations are a stochastic process and there is a baseline mutation rate for each gene. Therefore, a subclone that has alterations in genes associated with drug resistance is expected to reflect the normal mutation rates and occur at between 10^{-6} and 10^{-5} colonies. In bacteria, hetero-resistance has been described especially for vancomycin in *S. aureus*, vancomycin in *Enterococcus faecium*, colistin in *Acinetobacter baumannii-calcoaceticus*, rifampin, isoniazid, and streptomycin in *M. tuberculosis*, and penicillin in *S. pneumoniae* (Falagas et al., 2008; Rinder, 2001). Increased therapeutic failures and mortality have been reported in patients with hetero-resistant staphylococci and *M. tuberculosis* (Falagas et al., 2008; Hofmann-Thiel et al., 2009). For fungi, hetero-resistance leading to clinical failure has been described for fluconazole in *Cryptococcus neoformans* and *Candida albicans* (Marr et al., 2001; Mondon et al., 1999).

Viral replication is more error prone than replication in bacteria and fungi. Viral evolution under drug and immune pressure occurs relatively easily, commonly resulting in variants or quasi species that may contain drug-resistant subpopulations. This is not often termed hetero-resistance, but the principle is the same as described for bacteria and fungi: A virus may be considered susceptible to a drug because either phenotypic or genotypic tests reveal “lack” of resistance, when there is a resistant subpopulation just below the limit of assay detection. These minority quasi species that are resistant to antiretroviral agents have been associated with failure of antiretroviral therapy (Metzner et al., 2009).

EVOLUTIONARY BASIS OF RESISTANCE EMERGENCE

Development of Resistance via Mutation Selection. Mutation and antibiotic selection of the resistant mutant are the molecular basis for resistance for many bacteria, viruses, and fungi. Mutations may occur in the gene encoding (1) the target protein, altering its structure so that it no longer binds the drug; (2) a protein involved in drug transport; (3) a protein important for drug activation or inactivation; or (4) in a regulatory gene or promoter affecting expression of the target, a transport protein, or an inactivating enzyme. Mutations are not caused by drug exposure per se. They are random events that confer a survival advantage when drug is present. Any large population of drug susceptible bacteria is likely to contain rare

mutants that are only slightly less susceptible than the parent. However, suboptimal dosing strategies lead to selective kill of the more susceptible population, which leaves the resistant isolates to flourish.

In some instances, a single-step mutation results in a high degree of resistance. Examples include *M. tuberculosis katG* Ser315 mutations that cause resistance to isoniazid; the M814V mutation in the reverse transcriptase gene of HIV-1, causing resistance to lamivudine; a cytochrome-b gene mutation causing resistance to the anti-malaria drug atovaquone; and *Candida albicans fks1* Ser645 mutations causing resistance to echinocandins.

In other circumstances, however, it is the sequential acquisition of more than one mutation that leads to clinically significant resistance. As an example, the combination of pyrimethamine and sulfadoxine inhibits *Plasmodium falciparum*'s folate biosynthetic pathway via inhibition of dihydrofolate reductase (DHFR) by the pyrimethamine and inhibition of dihydropteroate synthetase (DHPS) by sulfadoxine. Clinically meaningful resistance occurs when there is a single point mutation in the *DHPS* gene accompanied by at least a double mutation in the *DHFR* gene.

Hypermutable Phenotypes. The ability to protect genetic information from disintegrating and also to be flexible enough to allow genetic changes that lead to adaptation to the environment is essential to all living things. This is accomplished principally by the insertion of the correct base pair by DNA polymerase III, proof-reading by the polymerase, and postreplicative repair. The development of a defect in one of these repair mechanisms leads to a high degree of mutations in many genes; such isolates are termed *mutator (Mut) phenotypes* and may include mutations in genes causing antibiotic resistance (Giraud et al., 2002). This second-order selection of hypermutable (mutator) alleles based on alterations in DNA repair genes has been implicated in the emergence of multidrug resistant strains of *M. tuberculosis* Beijing genotype (Rad et al., 2003).

Resistance by External Acquisition of Genetic Elements. Drug resistance may be acquired by mutation and selection, with passage of the trait *vertically* to daughter cells. For mutation and selection to be successful in generating resistance, the mutation cannot be lethal and should not appreciably alter virulence. For the trait to be passed on, the original mutant or its progeny also must disseminate and replicate; otherwise, the mutation will be lost until it is “rediscovered” by some other mutant arising from within a wild-type population.

Drug resistance more commonly is acquired by *horizontal transfer* of resistance determinants from a donor cell, often of another bacterial species, by transduction, transformation, or conjugation. Resistance acquired by horizontal transfer can disseminate rapidly and widely either by clonal spread of the resistant strain

or by subsequent transfers to other susceptible recipient strains. Horizontal transfer of resistance offers several advantages over mutation selection. Lethal mutation of an essential gene is avoided; the level of resistance often is higher than that produced by mutation, which tends to yield incremental changes; the gene, which still can be transmitted vertically, can be mobilized and rapidly amplified within a population by transfer to susceptible cells; and the resistance gene can be eliminated when it no longer offers a selective advantage.

Horizontal Gene Transfer. Horizontal transfer of resistance genes is greatly facilitated by and is largely dependent on mobile genetic elements. Mobile genetic elements include plasmids and transducing phages. Other mobile elements—transposable elements, integrons, and gene cassettes—also participate in the process. *Transposable elements* are of three general types: insertion sequences, transposons, and transposable phages. Only insertion sequences and transposons are important for resistance.

Insertion sequences (Mahillon and Chandler, 1998) are short segments of DNA encoding enzymatic functions (e.g., transposase and resolvase) for site-specific recombination with inverted repeat sequences at either end. They can copy themselves and insert themselves into a chromosome or a plasmid. Insertion sequences do not encode resistance, but they function as sites for integration of other resistance-encoding elements (e.g., plasmids or transposons). *Transposons* are insertion sequences that also code for other functions, one of which can be drug resistance. Because transposons move between chromosome and plasmid, the resistance gene can “hitchhike” with a transferable element out of the host and into a recipient. Transposons are mobile elements that excise and integrate in the bacterial genomic or plasmid DNA (i.e., from plasmid to plasmid, from plasmid to chromosome, or from chromosome to plasmid). *Integrons* (Fluit and Schmitz, 2004) are not formally mobile and do not copy themselves, but they encode an integrase and provide a specific site into which mobile gene cassettes integrate. *Gene cassettes* encode resistance determinants, usually lacking a promoter, with a downstream repeat sequence. The integrase recognizes this repeat sequence and directs insertion of the cassette into position behind a strong promoter that is present on the integron. Integrons may be located within transposons or in plasmids, and therefore may be mobilizable, or located on the chromosome.

Transduction is acquisition of bacterial DNA from a phage (a virus that propagates in bacteria) that has incorporated DNA from a previous host bacterium within its outer protein coat. If the DNA includes a gene for drug resistance, the newly infected bacterial cell may acquire resistance. Transduction is particularly important in the transfer of antibiotic resistance among strains of *S. aureus*. *Transformation* is the uptake and incorporation into the host genome by homologous recombination of free DNA released into the environment by other bacterial cells. Transformation is the molecular basis of penicillin resistance in pneumococci and *Neisseria* (Spratt, 1994). *Conjugation*, as the name implies, is gene transfer by direct

cell-to-cell contact through a sex pilus or bridge. This complex and fascinating mechanism for the spread of antibiotic resistance is extremely important because multiple resistance genes can be transferred in a single event. The transferable genetic material consists of two different sets of plasmid-encoded genes that may be on the same or different plasmids. One set encodes the actual resistance; the second encodes genes necessary for the bacterial conjugation process. Conjugation with genetic exchange between nonpathogenic and pathogenic microorganisms probably occurs in the GI tracts of humans and animals. The efficiency of transfer is low; however, antibiotics can exert a powerful selective pressure to allow emergence of the resistant strain. Genetic transfer by conjugation is common among gram-negative bacilli, and resistance is conferred on a susceptible cell as a single event. Enterococci also contain a broad range of host-range conjugative plasmids that are involved in the transfer and spread of resistance genes among gram-positive organisms.

CLINICAL SUMMARY

Antimicrobial agents work by targeting specific biochemical properties of pathogens, and therefore have a narrow spectrum of organisms that they can kill. Infection is usually in a particular anatomical compartment. Important determinants of success of antimicrobial therapy include proper selection of antimicrobial therapy based on microbiology results and susceptibility testing, knowledge of drug penetration into the infected compartment, and knowledge of compartmental pharmacokinetics. The proper dose and dosing schedule are chosen by integrating microbial pharmacokinetic-pharmacodynamic information, expected pharmacokinetic variability, and the minimum inhibitory concentration of the pathogen. The goals of therapy should be clear. Prophylaxis, pre-emptive therapy, empirical therapy, and definitive therapy should have treatment goals and duration of therapy clearly spelled out in the beginning, based on proper evidence. The general rule is monotherapy, except in select situations where combination therapy has been shown to be superior. Poor dosing strategies lead to catastrophic outcomes such as drug-resistant pathogens and untoward toxicity to the patients.

Chemotherapy of Malaria

Joseph M. Vinetz, Jérôme Clain,
Viengngeun Bounkeua, Richard T. Eastman, and
David Fidock

Malaria affects about a quarter of a billion people and leads to almost 900,000 deaths annually (World Health Organization, 2009). This disease is caused by infection with single-celled protozoan parasites of the genus *Plasmodium*. Five *Plasmodium* spp. are known to infect humans: *P. falciparum*, *P. vivax*, *P. ovale*, *P. malariae*, and *P. knowlesi*. *P. falciparum* and *P. vivax* cause most of the malarial infections worldwide. Of these, *P. falciparum* accounts for the majority of the burden of malaria in sub-Saharan Africa and is associated with the most severe disease. *P. vivax* accounts for half of the malaria burden in South and East Asia and >80% of the malarial infections in the Americas. Malaria due to *P. ovale* and *P. malariae* is relatively uncommon but requires identification both for treatment (*P. ovale*, like *P. vivax*, forms hypnozoites with the potential for relapse) and for epidemiological purposes (malarial infection, due mostly to *P. malariae*, can arise from blood transfusion). *P. knowlesi*, previously thought to infect only nonhuman primates, has emerged as a zoonotic malarial parasite and now is an important, sometimes lethal, cause of human malaria in parts of Southeast Asia (including Malaysia, Indonesia, Thailand, Singapore, and the Philippines; Cox-Singh et al., 2008). *P. knowlesi* should therefore be considered as a potential cause of malaria among travelers returning from this region. The vast majority of malaria cases occur via infection from *Anopheles* mosquitoes in endemic regions. Infections acquired congenitally or via transfusions or contaminated needles are known to occur but are rare. Screening of blood donors has reduced the risk of transfusion-transmitted malaria to 1:4,000,000 in the U.S.

Research on malaria has entered the genomic era; the complete genome sequence has been determined for multiple *Plasmodium* species, including *P. falciparum*,

P. vivax, *P. knowlesi*, and other species infecting rodents and non-human primates. The availability of a robust culture system for *P. falciparum* erythrocytic stages, combined with methods to experimentally infect mosquitoes and generate sporozoite and liver stage parasites, has generated key platforms for drug discovery. These platforms include genetic modifications by gene knock-out, heterologous expression and complementation, allelic replacement, high throughput screening of the pathogenic asexual blood stage parasites, and lower throughput assays against other stages of the parasite life cycle (Hayton and Su, 2008; Winzeler, 2008). Similar laboratory approaches have not yet been successful for *P. vivax*. Methods for sustained *in vitro* culture of blood stage forms of *P. vivax* are not yet available but are being developed for *P. knowlesi* and *P. cynomolgi*, which share important biological similarities with *P. vivax*.

BIOLOGY OF MALARIAL INFECTION

Plasmodium sporozoites, which initiate infection in humans, are inoculated into the dermis and enter the bloodstream following the bite of a *Plasmodium*-infected female anopheline mosquito. Within minutes, sporozoites travel to the liver, where they infect hepatocytes via cell surface receptor-mediated events. This process initiates the *asymptomatic prepatent period*, or *exoerythrocytic stage* of infection, which typically lasts ~1 week. During this period, the parasite undergoes asexual replication within hepatocytes, resulting in production of liver stage schizonts. Upon rupture of the infected hepatocytes, tens of thousands of merozoites are released into the bloodstream and infect red blood cells. After the initial exoerythrocytic stage, *P. falciparum* and *P. malariae* are no longer found in the liver. *P. vivax* and *P. ovale*, however, can maintain a quiescent

hepatocyte infection as a dormant form of the parasite known as the hypnozoite. Consequently, *P. vivax* and *P. ovale* can reinstate symptomatic disease long after the initial symptoms of malaria are recognized and treated. Erythrocytic forms cannot reestablish infection of hepatocytes.

Transmission of human-infecting malarial parasites is maintained in human populations both by the extended persistence of hypnozoites (lasting from months to no more than a few years for *P. vivax* and *P. ovale*), by antigenic variation in *P. falciparum* (probably months), and presumably by antigen variation in *P. malariae* (for as long as several decades) (Vinetz et al., 1998).

The asexual erythrocytic stages of malarial parasites are responsible for the clinical manifestations of malaria. This part of the *Plasmodium* life cycle is initiated by merozoite recognition of red blood cells, mediated by cell surface receptors, followed by red blood cell invasion. Once inside a red blood cell, the merozoite develops into a ring form, which becomes a trophozoite that matures into an asexually dividing blood stage schizont. Upon rupture of the infected erythrocyte, these schizonts release 8-32 merozoites that can establish new infections in nearby red blood cells. The erythrocytic replication cycle lasts for 24 hours (for *P. knowlesi*), 48 hours (for *P. falciparum*, *P. vivax*, and *P. ovale*), and 72 hours (for *P. malariae*). As such, infections due to *P. vivax* and *P. ovale* can produce tertian fever patterns (48 hours), whereas those due to *P. malariae* can result in quartan fever (72 hours, as classically described in Hippocrates' *Epidemics*). Although most invading merozoites develop into schizonts, a small proportion become gametocytes, the form of the parasite that is infective to mosquitoes. Gametocytes are ingested into the mosquito midgut during an infectious blood meal and then transform into gametes that can fertilize to become zygotes. Zygotes mature into ookinetes, which penetrate the mosquito midgut wall and develop into oocysts. Numerous rounds of asexual replication occur in the oocyst to generate sporozoites over 10-14 days. Fully developed sporozoites rupture from oocysts and invade the mosquito salivary glands, from which they can initiate a new infection during subsequent mosquito blood meals (Figure 49-1). Understanding the subtleties of the life cycles of *Plasmodium* parasites is important for tailoring drug therapies to the various species and geographic contexts.

Mechanisms of erythrocyte invasion include initial binding by merozoites to specific red blood cell surface ligands. *P. falciparum*

Figure 49-1. Life cycle of malaria parasites.

has a family of binding proteins that can recognize a variety of host cell molecules. *P. falciparum* invades all stages of erythrocytes and therefore can achieve high parasitemias. *P. vivax* selectively binds to the Duffy chemokine receptor protein as well as reticulocyte-specific proteins. Thus, *P. vivax* does not establish infection in Duffy-negative individuals and only invades reticulocytes. (However, *P. vivax* has reportedly mutated in Madagascar to enable infection of Duffy-negative individuals [Ménard et al., 2010].) Because of this restricted subpopulation of suitable erythrocytes, *P. vivax* rarely exceeds 1% parasitemia in the bloodstream. *P. ovale* is similar to *P. vivax* in its predilection for young red blood cells, but the mechanism of its erythrocyte recognition is unknown. *P. malariae* parasitizes senescent red blood cells, maintains a very low parasitemia, and typically causes an indolent infection.

P. falciparum assembles cytoadherence proteins (PfEMP1s, encoded by a highly variable family of *var* genes) into structures called knobs that are presented on the erythrocyte surface. Knobs allow the *P. falciparum*-parasitized erythrocyte to bind to postcapillary vascular endothelium, so as to avoid spleen-mediated clearance and allow the parasite to grow in a low oxygen, high carbon dioxide

microenvironment. For the patient, the consequences are microvascular blockage in the brain and organ beds, and local release of cytokines and direct vascular intermediates such as nitric oxide. These lead to severe complications such as cerebral malaria, pulmonary edema, acute renal failure, and placental malaria. These can result in low birthweight and translocation of bacteria from the gastrointestinal (GI) tract to the blood (septic complications, so-called algid malaria).

Attention is increasingly being focused on measures to prevent parasite transmission from a human host to a mosquito vector. Bed nets and residual indoor insecticide treatment are the mainstay of malaria prevention in endemic areas. Drugs are being used to prevent transmission, but this strategy presents special problems related to toxicity. Whereas some antimalarials, such as 4-aminoquinolines and sulfadoxine-pyrimethamine, promote increased gametocytemia, others, including 8-aminoquinolines and artemisinins, can reduce gametocyte levels and thus reduce transmission. Although the gametocytocidal activity of primaquine and tafenoquine is potentially important, these agents cannot be used for mass treatment without first assessing glucose-6-phosphate dehydrogenase (G6PD) levels, because of the potential for hemolytic anemia in G6PD-deficient individuals.

Clinical Manifestations of Malaria

The cardinal signs and symptoms of malaria are high, spiking fevers (with or without periodicity), chills, headaches, myalgias, malaise, and GI symptoms. Severe headache, a characteristic early symptom in malaria caused by all *Plasmodium* spp., often heralds the onset of infection, before fever and chills. *P. falciparum* causes the most severe disease and may lead to organ failure and death. Placental malaria, of particular danger for primigravidae, is due to *P. falciparum* adherence to chondroitin sulfate A (CSA) in the placenta. This often leads to severe complications, including miscarriage. When treated early, symptoms of malarial infection usually improve within 24–48 hours.

Acute illness due to *P. vivax* infection may appear severe due to high fever and prostration. Indeed, the pyrogenic threshold of this parasite (i.e., parasite burden associated with fever) is lower than that of *P. falciparum*. Nonetheless, *P. vivax* malaria generally has a low mortality rate. *P. vivax* malaria is characterized by relapses caused by the reactivation of latent tissue forms. Clinical manifestations of relapse are the same as those of primary infection. In recent years, severe *P. vivax* malaria from Oceania (Papua New Guinea, Indonesia) and India possess important similarities to severe malaria caused by *P. falciparum*. These include neurological symptoms (diminished consciousness, seizure) and pulmonary edema. Rare but life-threatening complications can occur, including splenic rupture, acute lung injury, and profound anemia.

P. ovale causes a clinical syndrome similar to that of *P. vivax* but may be milder with lower levels of parasitemia. It shares with *P. vivax* the ability to form the hypnozoite (dormant liver stage) that may relapse after months to 2 years later. *P. ovale* is more common in sub-Saharan Africa and some islands in Oceania.

P. malariae causes a generally indolent infection with very low levels of parasitemia and often does not produce clinical symptoms. This parasite can be found in all malaria-endemic areas but is most common in sub-Saharan Africa and the southwest Pacific. Interestingly, *P. malariae* prevalence increases during the dry season and can be found as a co-infection with *P. falciparum*. Although uncommon, a potentially fatal complication of *P. malariae* is a glomerulonephritis syndrome that does not respond to antimalarial treatment.

P. knowlesi infection is often misdiagnosed as *P. malariae* by light microscopy. This infection is distinguished by a shorter erythrocytic cycle (24 hours compared with 72 hours for *P. malariae*) and higher levels of parasitemia. Like *P. malariae*, *P. knowlesi* is generally sensitive to chloroquine, but patients presenting with advanced disease nonetheless may progress to death despite adequate drug dosing.

Asymptomatic *P. falciparum* and *P. vivax* infections are common in endemic regions, and they represent important potential reservoirs for malaria transmission. Although different studies are not entirely consistent in the definition of “asymptomatic,” generally this state implies a lack of fever, headache, and other systemic complaints, within a defined time period prior to a positive test for malaria parasitemia. Migration of asymptomatic individuals, to areas where malaria is not present but vector mosquitoes are (i.e., anophelism without malaria), is an important mechanism for the introduction or reintroduction of malaria, in addition to facilitating the spread of drug-resistant isolates. Novel approaches to preventing transmission from asymptomatic reservoirs—whether through new drugs or vaccines—will be essential for future malaria control, elimination, and eradication strategies.

CLASSIFICATION OF ANTIMALARIAL AGENTS

The various stages of the malarial parasite life cycle that occur in humans differ from one another in their morphology, metabolism, and drug sensitivity. Thus, antimalarial drugs can be classified based on their activities during this life cycle as well as by their intended use for either chemoprophylaxis or treatment.

The spectrum of antimalarial drug activity (Table 49–1) leads to several generalizations. The first relates to chemoprophylaxis: *Because no antimalarial drug kills sporozoites, it is not truly possible to prevent infection; drugs can only prevent the development of symptomatic malaria caused by the asexual erythrocytic forms.*

The second relates to the treatment of an established infection: *No single antimalarial is effective against all liver and intra-erythrocytic stages of the life cycle that may co-exist in the same patient. Complete elimination of the parasite infection, therefore, may require more than one drug.*

The patterns of clinically useful activity fall into three general categories (Table 49–1). The first group

Table 49–1

Malarial Parasite Developmental Stages Targeted by Antimalarial Drugs

GROUP	DRUGS	EFFECT OF DRUG ON PARASITE VIABILITY				
		SPOROZOITE	LIVER STAGES		BLOOD STAGES	
			PRIMARY	HYPNOZOITE	ASEXUAL	GAMETOCYTE
1	Artemisinins	–	–	–	+	+
	Chloroquine	–	–	–	+	+/-
	Mefloquine	–	–	–	+	–
	Quinine/Quinidine	–	–	–	+	+/-
	Pyrimethamine	–	–	–	+	–
	Sulfadoxine	–	–	–	+	–
	Tetracycline	–	–	–	+	–
2	Atovaquone/ Proguanil	–	+	–	+	+/-
3	Primaquine	–	+	+	–	+

–, no activity; +/-, low to moderate activity; +, important activity.

of agents (artemisinins, chloroquine, mefloquine, quinine and quinidine, pyrimethamine, sulfadoxine, and tetracycline) are not reliably effective against primary or latent liver stages. Instead, their action is directed against the asexual blood stages responsible for disease. These drugs will treat, or prevent, clinically symptomatic malaria. When used as chemoprophylaxis, these drugs must continue to be taken for several weeks after exposure, until parasites complete their intrahepatic stage of development and become susceptible to therapy.

The spectrum is somewhat expanded for a second category of drugs (typified by atovaquone and proguanil), which target not only the asexual erythrocytic forms but also the primary liver stages of *P. falciparum*. This additional activity shortens to several days the required period for postexposure chemoprophylaxis.

The third category, currently comprised solely of primaquine, is effective against primary and latent liver stages as well as gametocytes. Primaquine has no place in the treatment of symptomatic malaria but rather is used most commonly to eradicate the intrahepatic hypnozoites of *P. vivax* and *P. ovale* that are responsible for relapsing infections. Primaquine also has anti-gametocytic activity.

Aside from their antiparasitic activity, the utility of antimalarials for chemoprophylaxis or therapy depends on their pharmacokinetics and their safety. Thus quinine and primaquine, which have significant

toxicity and relatively short half-lives, generally are reserved for the treatment of established infection and are not used for chemoprophylaxis in a healthy traveler. In contrast, chloroquine is relatively free from toxicity and has a long $t_{1/2}$ that is convenient for chemoprophylactic dosing (in those few areas still reporting chloroquine-sensitive malaria).

Regimens currently recommended for chemoprophylaxis in travelers are given in Table 49–2, whereas regimens for the treatment and presumptive self-treatment (based on symptom presentation) of malaria in travelers are provided in Table 49–3 and Table 49–4, respectively. Individual agents are discussed in greater detail later in this chapter, listed alphabetically.

ARTEMISININ AND DERIVATIVES

History. Artemisinin is a sesquiterpene lactone endoperoxide derived from *qing hao* (*Artemisia annua*), also called *sweet wormwood* or *annual wormwood*. The Chinese have ascribed medicinal value to this plant for >2000 years (White, 2008). As early as 340 A.D., Ge Hong prescribed tea made from *qing hao* as a remedy for fevers, and in 1596, Li Shizhen recommended it to relieve malarial symptoms. By 1972, Chinese scientists had identified the major antimalarial ingredient, *qinghaosu*, now known as *artemisinin*.

Chemistry. The structures of artemisinin and its three major semi-synthetic derivatives in clinical use, dihydroartemisinin, artemether, and artesunate, are as follows:

Table 49-2

Regimens for the Prevention of Malaria in Non-immune Individuals

DRUG	USAGE	ADULT DOSE	PEDIATRIC DOSE	COMMENTS
Atovaquone/ proguanil (MALARONE)	Prophylaxis in all areas	Adult tablets contain 250 mg atovaquone and 100 mg proguanil hydrochloride. 1 adult tablet orally, daily	Pediatric tablets (62.5 mg atovaquone/25 mg proguanil HCl). 5-8 kg: 1/2 ped tab/day >8-10 kg: 3/4 ped tab/day >10-20 kg: 1 ped tab/day >20-30 kg: 2 ped tab/day >30-40 kg: 3 ped tab/day >40 kg: 1 adult tablet daily	Begin 1-2 days before travel to malarious areas. Take daily at the same time each day while in the malarious area and for 7 days after leaving such areas. Contraindicated in persons with severe renal impairment (creatinine clearance <30 mL/minute). Atovaquone/proguanil should be taken with food or a milky drink. Not recommended for prophylaxis for children <5 kg, pregnant women, and women breast- feeding infants weighing <5 kg.
Chloroquine phosphate (ARALEN and generic)	Prophylaxis only in areas with chloroquine- sensitive malaria	300 mg base (500 mg salt) orally, once/week	5 mg/kg base (8.3 mg/kg salt) orally, once/week, up to max adult dose (300 mg base)	Begin 1-2 weeks before travel to malarious areas. Take weekly on the same day of the week while in the malarious area and for 4 weeks after leaving such areas. May exacerbate psoriasis.
Doxycycline	Prophylaxis in all areas	100 mg orally, daily	≥8 years of age: 2 mg/kg up to adult dose of 100 mg/day	Begin 1-2 days before travel to malarious areas. Take daily at the same time each day while in the malarious area and for 4 weeks after leaving such areas. Contraindicated in children <8 years of age and pregnant women.
Hydroxy- chloroquine sulfate (PLAQUENIL)	An alternative to chloroquine for prophylaxis only in areas with chloroquine- sensitive malaria	310 mg base (400 mg salt) orally, once/week	5 mg/kg base (6.5 mg/kg salt) orally, once/week, up to max adult dose (310 mg base)	Begin 1-2 weeks before travel to malarious areas. Take weekly on the same day of the week while in the malarious area and for 4 weeks after leaving such areas.

(Continued)

Table 49–2

Regimens for the Prevention of Malaria in Non-immune Individuals (*Continued*)

DRUG	USAGE	ADULT DOSE	PEDIATRIC DOSE	COMMENTS
Mefloquine (LARIAM and generic)	Prophylaxis in areas with mefloquine-sensitive malaria	228 mg base (250 mg salt) orally, once/week	≤9 kg: 4.6 mg/kg base (5 mg/kg salt) orally, once/week; >9-19 kg: 1/4 tablet once/week; >19-30 kg: 1/2 tablet once/week; >31-45 kg: 3/4 tablet once/week; ≥45 kg: 1 tablet once/week	Begin 1-2 weeks before travel to malarious areas. Take weekly on same day of the week while in malarious area and for 4 weeks after leaving such areas. Contraindicated in persons allergic to mefloquine or related compounds (e.g., quinine, quinidine) and in persons with active depression, a recent history of depression, generalized anxiety disorder, psychosis, schizophrenia, other major psychiatric disorders, or seizures. Use with caution in persons with psychiatric disturbances or a previous history of depression. Not recommended for persons with cardiac conduction abnormalities.
Primaquine	Prophylaxis for short-duration travel to areas with principally <i>P. vivax</i>	30 mg base (52.6 mg salt) orally, daily	0.5 mg/kg base (0.8 mg/kg salt) up to adult dose orally, daily	Begin 1-2 days before travel to malarious areas. Take daily at same time each day while in malarious area and for 7 days after leaving such areas. Contraindicated in persons with G6PD ^a deficiency, and during pregnancy and lactation unless the infant being breastfed has documented normal G6PD level.
Primaquine	For presumptive anti-relapse therapy (terminal prophylaxis) to decrease the risk of relapses (<i>P. vivax</i> , <i>P. ovale</i>)	30 mg base (52.6 mg salt) orally, once/day for 14 days after departure from the malarious area.	0.5 mg/kg base (0.8 mg/kg salt) up to adult dose orally, once/day for 14 days after departure from the malarious area	Indicated for persons who have had prolonged exposure to <i>P. vivax</i> and <i>P. ovale</i> or both. Contraindicated in persons with G6PD ^a deficiency. Also contraindicated during pregnancy and lactation unless the infant being breastfed has a documented normal G6PD level.

^aGlucose-6-phosphate dehydrogenase. All persons who take primaquine should have a documented normal G6PD level before starting the medication. These regimens are based on published recommendations of the United States Centers for Disease Control and Prevention (CDC). These recommendations may change over time. Up-to-date information should be obtained from www.cdc.gov/travel. Recommendations and available treatment differ among countries in the industrialized world, developing world, and malaria-endemic regions; in the latter, some antimalarial treatments may be available without prescription, but the most effective drugs usually are controlled by governmental agencies.

Table 49-3

Regimens for the Treatment of Malaria (Continued)

DRUG	INDICATION	ADULT DOSAGE	PEDIATRIC DOSAGE ^a	POTENTIAL ADVERSE EFFECTS	COMMENTS
Chloroquine phosphate	<i>P. falciparum</i> from chloroquine sensitive areas <i>P. vivax</i> from chloroquine sensitive areas All <i>P. ovale</i> All <i>P. malariae</i> All <i>P. knowlesi</i>	600 mg base (1000 mg salt) orally immediately, followed by 300 mg base (500 mg salt) orally at 6, 24, and 48 h Total dose: 1500 mg base (2500 mg salt)	10 mg base/kg orally immediately, followed by 5 mg base/kg orally at 6, 24, and 48 h Total dose: 25 mg base/kg	Nausea, vomiting, rash, headache, dizziness, urticaria, abdominal pain, pruritus	Safe in children and pregnant women Give for chemoprophylaxis (500 mg salt orally every week) in pregnant women with chloroquine-sensitive <i>P. vivax</i> Contraindicated if retinal or visual field change; hypersensitivity to 4-aminoquinolines Use with caution in those with impaired liver function since the drug is concentrated in the liver
Clindamycin (oral or IV)	<i>P. falciparum</i> from chloroquine-resistant areas <i>P. vivax</i> from chloroquine-resistant areas	Oral: 20 mg base/kg/d orally divided 3 times daily × 7 d IV: 10 mg base/kg loading dose IV followed by 5 mg base/kg IV every 8 h; switch to oral clindamycin (as above) as soon as patient can take oral meds; duration = 7 d	Oral: 20 mg base/kg/d orally divided 3 times daily × 7 d IV: 10 mg base/kg loading dose IV followed by 5 mg base/kg IV every 8 h; switch to oral clindamycin (oral dose as above) as soon as patient can take oral medication; treatment course = 7 d	Diarrhea, nausea, rash	Always use in combination with quinine-quinidine Safe in children and pregnant women

Doxycycline (oral or IV)	<i>P. falciparum</i> from chloroquine-resistant areas <i>P. vivax</i> from chloroquine-resistant areas	Oral: 100 mg orally twice daily × 7 d IV: 100 mg IV every 12 h and then switch to oral doxycycline (as above) as soon as patient can take oral medication; treatment course = 7 d	Oral: 2.2 mg/kg orally every 12 h × 7 d IV: IV only if patient is not able to take oral medication; for children <45 kg, give 2.2 mg/kg IV every 12 h and then switch to oral doxycycline (dose as above) as soon as patient can take oral medication; for children >45 kg, use same dosing as for adults; duration = 7 d	Nausea, vomiting, diarrhea, abdominal pain, dizziness, photosensitivity, headache, esophagitis, odynophagia Rarely hepatotoxicity, pancreatitis, and benign intracranial hypertension seen with tetracycline class of drugs	Always use in combination with quinine or quinidine Contraindicated in children < 8 y, pregnant women, and persons with known hypersensitivity to tetracyclines Food and milk decrease absorption of doxycycline, will decrease GI disturbances To prevent esophagitis, take tetracyclines with large amounts of fluids, (patients should not lie down for 1 h after taking the drugs) Barbiturates, carbamazepine, or phenytoin may cause reduction in C _p of doxycycline
Hydroxychloroquine (oral)	Second-line alternative for treatment of: <i>P. falciparum</i> and <i>P. vivax</i> from chloroquine-sensitive areas All <i>P. ovale</i> All <i>P. malariae</i>	620-mg base (= 800 mg salt) orally immediately, followed by 310 mg base (= 400 mg salt) orally at 6, 24, and 48 h Total dose: 1550-mg base (= 2000 mg salt)	10-mg base/kg orally immediately, followed by 5-mg base/kg orally at 6, 24, and 48 h Total dose: 25-mg base/kg	Nausea, vomiting, rash, headache, dizziness, urticaria, abdominal pain, pruritus ^b	Safe in children and pregnant women Contraindicated if retinal or visual field change; hypersensitivity to 4-aminoquinolines Use with caution in those with impaired liver function

Tetracycline (oral or IV)	<i>P. falciparum</i> (chloroquine-resistant areas) <i>P. vivax</i> from chloroquine-resistant areas (with quinine/quinidine)	Oral: 250 mg 4 times daily × 7 d IV: dosage same as for oral	25 mg/kg/d orally divided 4 times daily × 7 d IV: dosage same as for oral	See doxycycline	See doxycycline

G6PD, glucose-6-phosphate dehydrogenase; IV, intravenous.

^aPediatric dosage should never exceed adult dosage.

^bExtrapolated from chloroquine literature.

^cMefloquine should not be used to treat *P. falciparum* infections acquired in the following areas: borders of Thailand with Burma (Myanmar) and Cambodia, western provinces of Cambodia, eastern states of Burma (Myanmar), border between Burma and China, Laos along borders of Laos and Burma (and adjacent parts of Thailand-Cambodia border), and southern Vietnam due to resistant strains.

^dQuinine sulfate capsule manufactured in the U.S. is in a 324-mg dose; therefore, two capsules should be sufficient for adult dosing.

^eNausea, vomiting, headache, tinnitus, deafness, dizziness, and visual disturbances.

^fRefer to quinine sulfate, package insert (Mutual Pharmaceutical Inc, Philadelphia, PA, Rev 08, November 2009).

^gAlternative dosing hypoglycemia optic neuritis regimen for quinidine gluconate (IV): 15 mg base/kg (24 mg salt/kg) loading dose IV infused over 4 h, followed by 7.5 mg base/kg (= 12 mg salt/kg) infused over 4 h every 8 h, starting 8 h after the loading dose (see package insert); once parasite density <1% and patient can take oral medication, complete treatment with oral quinine, dose as above Quinidine or quinine course = 7 d in SE Asia (3 d in Africa or South America)

^hRefer to quinidine gluconate, package insert (Eli Lilly Co, Indianapolis, IN, February 2002).

These regimens are based on published recommendations of the U.S. Centers for Disease Control and Prevention (CDC). Although current at the time of writing, these recommendations may change over time. Up-to-date information should be obtained from the CDC website at www.cdc.gov/travel. Recommendations and available treatment differ among countries in the industrialized world, developing world, and malaria-endemic regions; in the latter, some anti-malarial treatments may be available without prescription, but the most effective drugs usually are controlled by governmental agencies.

Table 49–4

Regimen for Presumptive Self-Treatment of Malaria

DRUG	ADULT DOSE	PEDIATRIC DOSE	COMMENTS
Atovaquone/proguanil (MALARONE) Self-treatment drug to be used if professional medical care is not available within 24 hours. Medical care should be sought immediately after treatment.	4 tablets (each dose contains 1000 mg atovaquone and 400 mg proguanil) orally as a single daily dose for 3 consecutive days.	Daily dose to be taken for 3 consecutive days: 5–8 kg: 2 pediatric tablets; 9–10 kg: 3 pediatric tablets; 11–20 kg: 1 adult tablet; 21–30 kg: 2 adult tablets; 31–40 kg: 3 adult tablets; >41 kg: 4 adult tablets	Contraindicated in persons with severe renal impairment (creatinine clearance <30 mL/min). Not recommended for self-treatment in persons on atovaquone/proguanil prophylaxis. Not currently recommended for children <5 kg, pregnant women, and women breast-feeding infants weighing <5 kg

These regimens are based on published recommendations of the United States Centers for Disease Control and Prevention (CDC). These recommendations may change over time. Up-to-date information should be obtained from www.cdc.gov/travel. Recommendations and available treatment differ among countries in the industrialized world, developing world, and malaria-endemic regions; in the latter, some antimalarial treatments may be available without prescription but the most effective drugs usually will be controlled by governmental agencies.

The derivatives display improved potency and bioavailability and have largely replaced the use of artemisinin. *Dihydroartemisinin* is a reduced product, *artesunate* is the water-soluble hemisuccinate ester of dihydroartemisinin, and *artemether* is a lipophilic methyl ether. Extensive structure-activity studies have confirmed the requirement for an endoperoxide moiety for antimalarial activity.

Mechanisms of Antimalarial Action and Resistance. As a class, the artemisinins are very potent and fast-acting antimalarials, inducing more rapid parasite clearance and fever resolution than any other currently licensed antimalarial drug. They are particularly well suited for the treatment of severe *P. falciparum* malaria and are also effective against the asexual erythrocytic stages of *P. vivax*. Increasingly, the standard treatment of malaria employs artemisinin-based combination therapies (ACTs) to increase treatment efficacy and reduce selection pressure for the emergence of drug resistance. Artemisinins cause a significant reduction of the parasite burden, with a four- \log_{10} reduction in the parasite population for each 48-hour cycle of intraerythrocytic invasion, replication, and egress. As such, only three to four cycles (6–8 days) of treatment are required to remove all the parasites from the blood (White, 2008). Additionally, artemisinins possess some gametocytocidal activity, leading to a decrease in malarial parasite transmission. ACTs have low toxicity and are considered safe for use in nonpregnant adults and children. Of concern, however, is the widespread distribution of counterfeit or clinically substandard drugs that contain

small quantities of the artemisinin derivative, a practice that threatens the effective administration of ACTs.

The mechanisms by which ACTs exert their antimalarial activity remain contentious (Golenser et al., 2006). Nevertheless, most studies concur that the activity of artemisinin and its potent derivatives results from reductive scission of the peroxide bridge by reduced heme-iron, which is produced inside the highly acidic digestive vacuole (DV) of the parasite as it digests hemoglobin. In addition to the formation of potentially toxic heme-adducts, activated artemisinin (for which the site of action remains unclear) might in turn generate free radicals that alkylate and oxidize proteins and possibly lipids in parasitized erythrocytes (Eastman and Fidock, 2009).

Artemisinins do not display significant clinical cross-resistance with other drugs. Indeed, sensitivity to artemisinins may even be increased in at least some strains of chloroquine-resistant parasites. Recent evidence has nonetheless suggested the emergence of *P. falciparum* isolates with an increased tolerance to artemisinins, manifesting as longer parasite clearance times (Dondorp et al., 2009). This has triggered significant efforts to elucidate the mechanistic basis of resistance and implement means to limit its spread. The World Health Organization (WHO) and most authorities strenuously recommend using artemisinins only in combination therapy, both to increase treatment efficacy and prevent the emergence of drug resistance.

Absorption, Fate, and Excretion. The semisynthetic artemisinins have been formulated for oral (dihydroartemisinin, artesunate, and artemether), intramuscular (artesunate and artemether), intravenous (artesunate), and rectal (artesunate) routes. Bioavailability after oral dosing typically is $\leq 30\%$. Although artemisinins rapidly achieve peak serum levels; intramuscular administration of the lipid-soluble artemether peaks in 2–6 hours, due to a depot effect at the injection

site. Both artesunate and artemether have modest levels of plasma protein binding, ranging from 43% to 82%. These derivatives are extensively metabolized and converted to dihydroartemisinin, which has a plasma $t_{1/2}$ of 1-2 hours (German and Aweeka, 2008). Rectal administration of artesunate has emerged as an important administration route, especially in tropical countries where it can be lifesaving. However, drug bioavailability via rectal administration is highly variable among individual patients (Medhi et al., 2009).

With repeated dosing, artemisinin and artesunate induce their own CYP-mediated metabolism, primarily via CYPs 2B6 and 3A4. This may enhance clearance by up to 5-fold. Recent studies have found no clinically significant pharmacokinetic or toxic interactions between artemisinins and its partner drugs.

Therapeutic Uses. Given their rapid and potent activity against even multidrug-resistant parasites, the artemisinins are valuable for the treatment of severe *P. falciparum* malaria. Intravenous artesunate is more than comparable to a standard quinine regimen, likely possessing higher efficacy and a better safety profile in many patient populations (Rosenthal, 2008). The artemisinins generally are not used alone because of their limited ability to eradicate infection completely. In numerous studies in Africa, South America, and Asia, artemisinins have proven highly effective, when combined with other antimalarials, for the first-line treatment of malaria (Sinclair et al., 2009). Artemisinins should not be used for chemoprophylaxis because of their short $t_{1/2}$, which translates into high recrudescence rates. In the U.S., the Food and Drug Administration (FDA) has approved the use of artemether-lumefantrine for oral treatment of uncomplicated *P. falciparum* malaria. Although useful in treating presumptively chloroquine-resistant *P. vivax*, artemether-lumefantrine does not have a formal FDA-approved indication for this infection. Under an investigational new drug (IND) application, intravenous artesunate is now indicated for the treatment of severe malaria; this drug currently can be obtained through the Centers for Disease Control and Prevention (CDC) Drug Service or CDC Quarantine Stations.

Toxicity and Contraindications. The increasing usage of ACTs has focused attention on the safety profile of artemisinins, especially with regard to potential toxic effects in infants and during the first trimester of pregnancy. In pregnant rats and rabbits, artemisinins can cause increased embryo lethality or malformations early postconception. Preclinical toxicity studies have identified the brain (and brainstem), liver, bone marrow, and fetus as the principal target organs. In patients, the many neurological changes that accompany severe malaria confound the evaluation of drug neurotoxicity; however, no systematic neurological changes were attributable to treatment in patients >5 years of age. As in small animals, patients may develop dose-related and reversible decreases in reticulocyte and neutrophil counts and increases in transaminase levels in patients.

About 1 in 3000 patients develops an allergic reaction. Studies of artemisinin treatment during the first trimester have found no evidence of adverse effects on fetal development (Eastman and Fidock, 2009). Nonetheless, out of general concern, it is recommended that ACTs not be used for the treatment of children ≤ 5 kg or during the first trimester of pregnancy.

ACT Partner Drugs. The short plasma $t_{1/2}$ of artemisinin and its derivatives translates into substantial treatment failure rates when artemisinins are used as monotherapy. Combining an artemisinin derivative with a longer-lasting partner drug assures sustained antimalarial activity. Current ACT regimens that are well tolerated in adults and children ≥ 5 kg include artemether-lumefantrine, artesunate-mefloquine, artesunate-amodiaquine, artesunate-sulfoxadine-pyrimethamine, and dihydroartemisinin-piperazine. Artesunate-pyronaridine has also recently completed phase III clinical trials. Combination with mefloquine or sulfadoxine-pyrimethamine is discussed in a separate section. Properties of other partner drugs are discussed later.

Lumefantrine shares structural similarities with the arylaminoalcohol drugs mefloquine and halofantrine (Figure 49–2) and is formulated with artemether (COARTEM).

This combination has proven to be highly effective for the treatment of uncomplicated malaria and is the most widely used first-line antimalarial across Africa. The pharmacokinetic properties of lumefantrine include a large apparent volume of distribution and a terminal elimination $t_{1/2}$ of 4-5 days. Human pharmacokinetic and pharmacodynamic studies correlate the risk of clinical failure (the likelihood to recrudescence) with plasma lumefantrine concentrations falling below 280 ng/mL. These findings, combined with a report of up to 15-fold variability in lumefantrine plasma concentrations in clinical trial volunteers, highlight the importance of appropriate dosing with lumefantrine-containing combinations (Checchi et al., 2006). Administration with a high-fat meal is recommended because it significantly increases absorption. Recently a sweetened dispersible formulation of artemether-lumefantrine (COARTEM *Dispersible*) has been approved for treatment of children. This formulation has comparable pharmacokinetics to crushed tablets and provides substantially improved ease of administration.

Amodiaquine is a congener of chloroquine (Figure 49–2) that is no longer recommended in the U.S. for chemoprophylaxis of *P. falciparum* malaria because of its toxicity (hepatic and agranulocytosis). These adverse events, however, were generally associated with its prophylactic use. A meta-analysis of clinical studies found that therapeutic amodiaquine regimens, with a total dose of up to 35 mg/kg body weight administered over 3 days, were as well tolerated as chloroquine for the treatment of uncomplicated *P. falciparum* malaria (Olliaro and Mussano, 2003). recent study reported an increased risk of neutropenia with amodiaquine therapy in HIV patients receiving antiretroviral therapy (Gasasira et al., 2008).

In vivo, amodiaquine is rapidly converted by hepatic CYPs into monodesethyl-amodiaquine. This metabolite, which retains substantial antimalarial activity, has a plasma $t_{1/2}$ of 9-18 days and reaches a peak concentration of ~500 nM 2 hours after oral administration. By contrast, amodiaquine has a $t_{1/2}$ of ~3 hours, attaining a peak concentration of ~25 nM within 30 minutes of oral administration (Eastman and Fidock, 2009). *In vivo* clearance rates of amodiaquine, however, display a variation between individuals that ranges from 78 to 943 mL/min/kg.

Piperaquine, a potent and well-tolerated bisquinoline compound (Figure 49–2) structurally related to chloroquine, became the primary antimalarial in China during the 1970s and 1980s in response to increasing rates of chloroquine resistance.

Piperaquine has a large volume of distribution and reduced rates of excretion after multiple doses. This lipophilic drug is rapidly absorbed, with a T_{max} (time to reach the highest concentration) of 2 hours after a single dose. In clinical trials, the combination of piperaquine and dihydroartemisinin produced cure rates and cleared fever and parasites in a time frame similar to artesunate-mefloquine (Wells et al., 2009). Piperaquine has the longest plasma $t_{1/2}$ (5 weeks) of all ACT partner drugs, suggesting that piperaquine-dihydroartemisinin might also be effective in reducing rates of reinfection following treatment.

Pyronaridine, an antimalarial structurally related to amodiaquine (Figure 49–2), was developed by the Chinese in the 1970s.

Pyronaridine is well tolerated and highly potent against both *P. falciparum* and *P. vivax*, causing fever to subside in 1-2 days and parasite clearance in 2-3 days. Clinical data from trials of artesunate-pyronaridine should soon be available (Wells et al., 2009).

ATOVAQUONE

History. Based on the antiprotozoal activity of hydroxynaphthoquinones, atovaquone (MEPRON) was developed as a promising synthetic derivative with potent activity against *Plasmodium* species and the opportunistic pathogens *Pneumocystis jiroveci* (previously called *Pneumocystis carinii*) and *Toxoplasma gondii* (Schlitzer, 2007). The FDA approved this compound in 1992 for treatment of mild-to-moderate *P. jiroveci* pneumonia in patients intolerant of trimethoprim-sulfamethoxazole. Subsequent clinical studies in patients with uncomplicated *P. falciparum* malaria revealed that atovaquone produced good initial responses, but parasites recrudesced and were highly atovaquone resistant. In contrast, the combination of atovaquone and proguanil produced

high cure rates with minimal toxicity. A fixed combination of atovaquone with proguanil hydrochloride (MALARONE) is available in the U.S. for malaria chemoprophylaxis and for the treatment of uncomplicated *P. falciparum* malaria in adults and children (Boggild et al., 2007).

Chemistry. Atovaquone is a highly lipophilic analog of ubiquinone.

Mechanisms of Antimalarial Action and Resistance.

Atovaquone is highly active against *P. falciparum* asexual blood stage parasites *in vitro* (with low nanomolar activity) and *in vivo* in humans and the *Aotus* primate model. This drug is effective against liver stages of *P. falciparum* but not against *P. vivax* liver stage hypnozoites. Atovaquone acts selectively on the mitochondrial cytochrome bc_1 complex to inhibit electron transport and collapse the mitochondrial membrane potential (Vaidya and Mather, 2009). The primary function of mitochondrial electron transport in *P. falciparum* is to regenerate ubiquinone, which is the electron acceptor for parasite dihydroorotate dehydrogenase, an enzyme essential for pyrimidine biosynthesis in the parasite (Painter et al., 2007). Synergy between proguanil and atovaquone results from the ability of nonmetabolized proguanil to enhance the mitochondrial toxicity of atovaquone (Fivelman et al., 2004; Srivastava et al., 1999).

Resistance to atovaquone alone in *P. falciparum* develops easily *in vitro* and *in vivo*, and it is conferred by single non-synonymous nucleotide polymorphisms in the cytochrome *b* gene located in the mitochondrial genome (Kessl et al., 2007). In the *Saccharomyces cerevisiae* cytochrome bc_1 complex, atovaquone binding is inhibited by the introduction of resistance mutations found in *P. falciparum*. Similar mutations have been reported in resistant isolates of rodent malarial species, as well as in *T. gondii* and perhaps *P. jiroveci*. Addition of proguanil markedly reduces the frequency of appearance of atovaquone resistance, as based on *in vivo* treatment cure rate. However, once atovaquone resistance is present, the synergy of the partner drug proguanil diminishes. In the key mutation associated with clinical atovaquone-proguanil resistance, tyrosine is replaced by serine, cysteine, or asparagine at codon 268 (Y268S/C/N) of the cytochrome *b* gene. Reports of atovaquone-proguanil treatment

failures are rare. However, when atovaquone-proguanil treatment fails because of parasite resistance, the recurrent malarial attack commonly occurs ~20-30 days after treatment initiation. Treatment with different drugs should then be started. Earlier treatment failures (during the first 2 weeks after treatment initiation) are more likely related to lack of compliance or inadequate drug levels (Musset et al., 2006; Rose et al., 2008).

Absorption, Fate, and Excretion. Atovaquone absorption after a single oral dose is slow, erratic, and variable due to its highly lipophilic nature and low aqueous solubility. Absorption improves when the drug is taken with a fatty meal (Boggild et al., 2007). More than 99% of the drug is bound to plasma protein, and cerebrospinal fluid levels are <1% of those in plasma. Profiles of drug concentration versus time often show a double peak, albeit with considerable variability. The first peak appears in 1-8 hours, whereas the second occurs 1-4 days after a single dose. This pattern suggests an enterohepatic circulation. In the absence of a CYP-inducing second medication, humans do not metabolize atovaquone significantly. The drug is excreted in bile, and >94% of the drug is recovered unchanged in feces; only traces appear in the urine. Atovaquone has a reported elimination $t_{1/2}$ from plasma of 2-3 days in adults and 1-2 days in children. Clearance is unaffected by dose or co-administration of proguanil (Boggild et al., 2007).

Therapeutic Uses. Atovaquone-proguanil is used for malaria chemoprophylaxis in adults and children ≥ 11 kg and for treatment of uncomplicated *P. falciparum* malaria in adults and children ≥ 5 kg.

A tablet containing a fixed dose of 250 mg atovaquone and 100 mg proguanil hydrochloride, taken orally, is highly effective and safe in a 3-day regimen for treating mild-to-moderate attacks of chloroquine- or sulfadoxine-pyrimethamine-resistant *P. falciparum* malaria (Looareesuwan et al., 1999). Although the same regimen followed by a primaquine course is effective in treatment of *P. vivax* malaria (Lacy et al., 2002), evidence for atovaquone-proguanil efficacy as treatment of non-*P. falciparum* malaria is limited (Boggild et al., 2007). The CDC does not recommend the combination for non-*P. falciparum* treatment, except for malaria caused by chloroquine-resistant *P. vivax*. Atovaquone-proguanil is a standard agent for malaria chemoprophylaxis. It can be discontinued 1 week after leaving the endemic area because both components are active against liver stage parasites. Experience in prevention of non-*P. falciparum* malaria is also limited (Ling et al., 2002). *P. vivax* infection may occur after drug discontinuation, indicating imperfect activity against exo-erythrocytic stages of this parasite.

Toxicity. Atovaquone may cause side effects (abdominal pain, nausea, vomiting, diarrhea, headache, rash) that require cessation of therapy. Vomiting and diarrhea may decrease drug absorption, resulting in therapeutic failure. However, readministration of this drug within an hour of vomiting may still be effective in patients with *P. falciparum* malaria. Atovaquone occasionally causes transient elevations of serum transaminase or amylase.

Precautions and Contraindications. Although atovaquone is generally considered to be safe, it needs further evaluation in children <11 kg, pregnant women, and lactating mothers. Accordingly, although the drug is not formally recommended for these individuals, the risks and

benefits of its use (both as chemoprophylaxis and treatment) should be considered carefully for individual patients, taking known toxicities into account. Preclinical evaluations for carcinogenicity, mutagenicity, and teratogenicity have been negative. Atovaquone may compete with certain drugs for binding to plasma proteins, and therapy with rifampin, a potent inducer of CYP-mediated drug metabolism, can reduce plasma levels of atovaquone substantially, whereas atovaquone may raise plasma levels of rifampin. Co-administration with tetracycline is associated with a 40% reduction in plasma concentration of atovaquone.

DIAMINOPYRIMIDINES

History. Based on their structural analogy with the anti-malarial proguanil (see section on proguanil), large numbers of 2,4-diaminopyrimidines were tested for inhibitory activity against malarial parasites, leading to the identification of the potent antimalarial agent pyrimethamine. Studies also observed marked antimalarial synergy between sulfonamides and proguanil. Accordingly, pyrimethamine was formulated and marketed as a fixed combination with sulfadoxine, a sulfonamide with pharmacokinetics that match those of pyrimethamine. For several decades sulfadoxine-pyrimethamine (FANSIDAR) has been a primary treatment for uncomplicated *P. falciparum* malaria, especially against chloroquine-resistant strains, but widespread resistance now seriously compromises its efficacy and it is no longer recommended for the treatment of uncomplicated malaria.

Mechanisms of Antimalarial Action and Resistance. Pyrimethamine is a slow-acting blood schizonticide with antimalarial effects *in vivo* similar to those of proguanil, resulting from inhibition of folate biosynthesis in *Plasmodium*. However, pyrimethamine has greater antimalarial potency, and its $t_{1/2}$ is much longer than that of cycloguanil, the active metabolite of proguanil. The efficacy of pyrimethamine against hepatic forms of *P. falciparum* is less than that of proguanil, and at therapeutic doses pyrimethamine fails to eradicate *P. vivax* hypnozoites or gametocytes of any *Plasmodium* species. It increases the number of circulating *P. falciparum* mature infecting gametocytes, likely leading to increased transmission to mosquitoes during the period of treatment.

The 2,4-diaminopyrimidines more potently inhibit the *Plasmodium* dihydrofolate reductase compared to the mammalian enzyme. Unlike its counterpart in human cells, the malarial dihydrofolate reductase resides on the same polypeptide chain as thymidylate synthase and, importantly, protein production is not increased in response to inhibition. The latter property favors the selective anti-plasmodial toxicity of pyrimethamine (Zhang and Rathod, 2002).

Synergy of pyrimethamine and the sulfonamides or sulfones results from inhibition of two key metabolic steps in folate biosynthesis in the parasite:

- the utilization of *p*-aminobenzoic acid for the synthesis of dihydropteroic acid, which is catalyzed by dihydropteroate synthase and inhibited by sulfonamides
- the reduction of dihydrofolate to tetrahydrofolate, which is catalyzed by dihydrofolate reductase and inhibited by pyrimethamine (Figure 52–2).

Dietary *p*-aminobenzoic acid or folate may affect the therapeutic response to antifolates. Both of these metabolites can be imported by the malarial parasite and can reduce drug efficacy substantially (Hyde, 2007). Resistance to pyrimethamine has developed in regions of prolonged or extensive drug use and can be attributed to mutations in dihydrofolate reductase that decrease the binding affinity of pyrimethamine (Gregson and Plowe, 2005). Interestingly, the pattern of amino acid substitutions is different in parasites resistant to cycloguanil, even though cross-resistance can occur between these structurally related inhibitors of plasmodial dihydrofolate reductase. The key mutation associated with pyrimethamine resistance is the substitution of asparagine for serine at codon 108 (S108N). The stepwise accumulation of additional single-amino-acid changes at codons 51, 59, and 164 is associated with progressively increasing resistance, as determined with *P. falciparum* isolates and with recombinant proteins. The triple mutant N51I/C59R/S108N (predominant in Africa) and the quadruple mutant N51I/C59R/S108N/I164L (predominant in Southeast Asia) exhibit high levels of pyrimethamine resistance and contribute to pyrimethamine-sulfadoxine therapeutic failure. Remarkably, studies exploring the mutational trajectories leading to the most resistant quadruple mutant N51I/C59R/S108N/I164L suggest a specific ordering of mutational events that balance the acquisition of resistance with the maintenance of pathogen fitness (Lozovsky et al., 2009). These studies also suggest that this quadruple mutant is substantially less fit in the absence of drugs when compared to its wild-type counterpart. Compensatory mechanisms might therefore be necessary to alleviate this fitness cost. An increase in the number of copy of the GTP cyclohydrolase I gene, which encodes the first enzyme in the *Plasmodium* folate biosynthesis pathway, is closely associated with the dihydrofolate reductase I164L mutation, suggesting a potential compensatory function (Nair et al., 2008).

Absorption, Fate, and Distribution. After oral administration, pyrimethamine is slowly but completely absorbed, reaching peak plasma levels in 2–6 hours. The compound is significantly distributed

in the tissues and is ~90% bound to plasma proteins (German and Aweeka, 2008). Pyrimethamine is slowly eliminated from plasma with a $t_{1/2}$ of 85–100 hours. Concentrations that are suppressive for responsive *Plasmodium* strains remain in the blood for ~2 weeks, but levels are lower in patients with active infection. Several metabolites of pyrimethamine appear in the urine; however, their identities and antimalarial properties have not been fully characterized. Pyrimethamine also enters the milk of nursing mothers.

Therapeutic Uses. Pyrimethamine-sulfadoxine is no longer recommended for the treatment of uncomplicated malaria or for chemoprophylaxis due to increasing drug resistance. However, for those living in malaria-endemic areas, some still recommend it for the intermittent preventive treatment of malaria in pregnancy, and it is being evaluated for intermittent preventive treatment in infants (Aponte et al., 2009). Pyrimethamine is typically administered with either a sulfonamide or sulfone to enhance its antifolate activity. Most malaria-endemic areas currently have a high prevalence of pyrimethamine-resistant parasites.

Toxicity, Precautions, and Contraindications. Antimalarial doses of pyrimethamine alone cause minimal toxicity except for occasional skin rashes and reduced hematopoiesis. Excessive doses can produce a megaloblastic anemia, resembling that of folate deficiency, which responds readily to drug withdrawal or treatment with folic acid. At high doses, pyrimethamine is teratogenic in animals, and in humans the related combination, trimethoprim-sulfamethoxazole, may cause birth defects (Hernandez-Diaz et al., 2000).

Sulfonamides or sulfones, rather than pyrimethamine, usually account for the toxicity associated with coadministration of these antifolate drugs. The combination of pyrimethamine and sulfadoxine is no longer recommended for malaria chemoprophylaxis because in ~1 in 5000 to 1 in 8000 individuals, this combination causes severe and even fatal cutaneous reactions, such as erythema multiforme, Stevens-Johnson syndrome, or toxic epidermal necrolysis. It has also been associated with serum sickness-type reactions, urticaria, exfoliative dermatitis, and hepatitis. Pyrimethamine-sulfadoxine is contraindicated for individuals with previous reactions to sulfonamides, for lactating mothers, and for infants <2 months of age. Administration of pyrimethamine with dapsone (MALOPRIM), a drug combination unavailable in the U.S., has occasionally been associated with agranulocytosis.

PROGUANIL

History. Proguanil is the common name for chloroguanide, a biguanide derivative that emerged in 1945 as a product of British antimalarial research. The antimalarial activity of proguanil eventually was ascribed to cycloguanil, a cyclic triazine metabolite and selective inhibitor of the bifunctional plasmodial dihydrofolate reductase-thymidylate synthetase that is crucial for parasite *de novo*

purine and pyrimidine synthesis. Indeed, investigation of compounds bearing a structural resemblance to cycloguanil resulted in the development of antimalarial dihydrofolate reductase inhibitors such as pyrimethamine. Accrued evidence also indicates that proguanil itself has intrinsic antimalarial activity independent of its metabolite's effect on parasite dihydrofolate reductase–thymidylate synthetase (Fidock and Wellems, 1997).

Chemistry. Proguanil and its triazine metabolite cycloguanil have the following chemical structures:

Proguanil has the widest margin of safety of a large series of antimalarial biguanide analogs examined. Dihalogen substitution in positions 3 and 4 of the benzene ring yields chlorproguanil, a more potent prodrug than proguanil. Cycloguanil, the metabolite, is structurally related to pyrimethamine.

Mechanisms of Antimalarial Action and Resistance. In drug-sensitive *P. falciparum* malaria, proguanil exerts activity against both the primary liver stages and the asexual red blood cell stages, thus adequately controlling the acute attack and usually eradicating the infection. Proguanil is also active against acute *P. vivax* malaria, but because the latent tissue stages of *P. vivax* are unaffected, relapses may occur after the drug is withdrawn. Proguanil treatment does not destroy gametocytes, but oocytes in the gut of the mosquito can fail to develop normally.

Cycloguanil selectively inhibits the bifunctional dihydrofolate reductase–thymidylate synthetase of sensitive plasmodia, causing inhibition of DNA synthesis and depletion of folate cofactors (Kamchonwongpaisan et al., 2004). As referred to earlier, a series of amino acid changes near the dihydrofolate reductase–binding site have been identified that cause resistance to cycloguanil, pyrimethamine, or

both (Gregson and Plowe, 2005). Specifically, resistance to cycloguanil (and chlorcycloguanil) can be linked to mutations leading to paired A16V/S108T substitutions in *Plasmodium* dihydrofolate reductase. In addition, cross-resistance between cycloguanil and pyrimethamine has been observed *in vitro* for both the triple (N51I/C59R/S108N) and quadruple (N51I/C59R/S108N/I164L) dihydrofolate reductase–thymidylate synthetase mutants, prevalent in Africa and South America, respectively (Peterson et al., 1990). Malarial isolates demonstrate varying degrees of cross-resistance to cycloguanil and pyrimethamine, indicating that the evolution of mutation patterns in individual organisms during treatment may be quite complex.

The presence of *Plasmodium* dihydrofolate reductase is not required for the intrinsic antimalarial activity of proguanil or chlorproguanil (Fidock and Wellems, 1997); however, the molecular basis for this alternative activity remains enigmatic. Proguanil as the biguanide accentuates the mitochondrial membrane-potential-collapsing action of atovaquone against *P. falciparum* but displays no such activity by itself (Vaidya and Mather, 2009) (see section on atovaquone). In contrast to cycloguanil, resistance to the parent drug, proguanil, either alone or in combination with atovaquone, is not well documented.

Absorption, Fate, and Excretion. Proguanil is slowly but adequately absorbed from the GI tract. After a single oral dose, peak plasma concentrations usually are attained within 5 hours. The mean plasma elimination $t_{1/2}$ is ~180-200 hours or longer (German and Aweeka, 2008).

The metabolism of proguanil in mammals cosegregates with mephenytoin oxidation polymorphisms, controlled by isoforms in the CYP2C subfamily. Only ~3% of whites are deficient in this oxidation phenotype, contrasted with ~20% of Asians and Kenyans. Proguanil is oxidized to two major metabolites, cycloguanil and an inactive 4-chlorophenylbiguanide. On a 200 mg daily dosage regimen, plasma levels of cycloguanil in extensive metabolizers exceed the therapeutic range, whereas cycloguanil levels in poor metabolizers fail to reach a therapeutic level. Proguanil itself does not accumulate appreciably in tissues during long-term administration, except in red blood cells where its concentration is about three times that in plasma. The inactive metabolite 4-chlorophenylbiguanide is not readily detected in plasma but appears in increased quantities in the urine of poor proguanil metabolizers. In humans, 40-60% of the absorbed proguanil is excreted in urine, either as the parent drug or as the active metabolite.

Therapeutic Uses. Proguanil as a single agent is not available in the U.S. but has been prescribed as chemoprophylaxis in England and Europe for individuals traveling to malarious areas in Africa. Strains of *P. falciparum* resistant to proguanil emerge rapidly in areas where the drug is used exclusively, but breakthrough infections may also result from deficient conversion of proguanil to its active antimalarial metabolite. Proguanil has been reported to be ineffective against multidrug-resistant strains of *P. falciparum* in Thailand and New Guinea. This drug can protect against

chloroquine and pyrimethamine-sulfadoxine resistant strains of *P. falciparum* found in sub-Saharan Africa.

Proguanil is effective and tolerated well in combination with atovaquone, once daily for 3 days, to treat drug-resistant strains of *P. falciparum* or *P. vivax* (see section on atovaquone). Indeed, this drug combination has been successful in Southeast Asia, where highly drug-resistant strains of *P. falciparum* prevail. *P. falciparum* readily develops clinical resistance to monotherapy with either proguanil or atovaquone; however resistance to the combination is uncommon unless the strain is initially resistant to atovaquone. In contrast, some strains resistant to proguanil do respond to proguanil plus atovaquone.

Toxicity and Side Effects. In chemoprophylactic doses of 200–300 mg daily, proguanil causes relatively few adverse effects, except occasional nausea and diarrhea. Large doses (≥ 1 g daily) may cause vomiting, abdominal pain, diarrhea, hematuria, and the transient appearance of epithelial cells and casts in the urine. Gross accidental or deliberate overdose (as much as 15 g) has failed to produce lasting sequelae. Doses as high as 700 mg twice daily have been taken for >2 weeks without serious toxicity. Proguanil is considered safe for use during pregnancy. It is remarkably safe when used in conjunction with other antimalarial drugs such as chloroquine, atovaquone, tetracyclines, and other antifolates.

QUINOLINES AND RELATED COMPOUNDS

Quinolines have been the mainstay of antimalarial chemotherapy starting with quinine nearly 400 years ago. In the last century, legions of related compounds were synthesized and tested for antimalarial activity. These efforts produced several drugs for the chemoprophylaxis and treatment of malaria. The most important of these are shown in Figure 49–2.

Chloroquine and Hydroxychloroquine

History. Chloroquine (ARALEN) is one of a large series of 4-aminoquinolines synthesized as part of the extensive cooperative program of antimalarial research in the U.S. during World War II. Chloroquine proved most promising and was released for field trial. When hostilities ceased, it was discovered that the compound had been synthesized and studied as early as 1934 under the name of Resochin at the Bayer laboratories in Germany but had been rejected because of toxicity in avian models.

Chemistry. The d-, l-, and dl- forms of chloroquine (see structure in Figure 49–2) have equal potency against *P. lophurae* malaria (a duck parasite), but the d-isomer is somewhat less toxic than the l-isomer in mammals. A chlorine atom attached to position 7 of the quinoline ring confers the most potent antimalarial activity in both avian and human malarias. Research on the structure-activity relationships of chloroquine and related alkaloid compounds continues in an effort to

find new effective antimalarials with improved safety profiles that can be used successfully against chloroquine- and multidrug-resistant strains of *P. falciparum*. One example is the synthesis of short-chain derivatives that can demonstrate full efficacy against chloroquine-resistant strains of *P. falciparum*. Another important example is piper-quine, a bisquinoline that was extensively used in China to treat chloroquine-resistant malaria. It is highly efficacious in combination with dihydroartemisinin (Davis et al., 2005); see earlier section on artemisinin-based combination therapies.

Hydroxychloroquine, in which one of the *N*-ethyl substituents of chloroquine is β -hydroxylated, is essentially equivalent to chloroquine against *P. falciparum* malaria. This analog is preferred over chloroquine for treatment of mild rheumatoid arthritis and lupus erythematosus because, in the high doses required, it may cause less ocular toxicity. Care should be taken when these compounds are administered to patients with known G6PD deficiency.

Mechanisms of Action and Resistance. Asexual malarial parasites flourish in host erythrocytes by digesting hemoglobin in their acidic digestive vacuoles, a process that generates free radicals and iron-bound heme (ferriprotoporphyrin IX) as highly reactive by-products (Goldberg, 2005). Perhaps aided by histidine-rich proteins and lipids, heme is sequestered as an insoluble, chemically inert malarial pigment termed *hemozoin*. Many theories for the mechanism of action of chloroquine have been advanced (Valderramos and Fidock, 2006). Current evidence suggests that quinolines interfere with heme detoxification. Chloroquine, a weak base, concentrates in the highly acidic digestive vacuoles of susceptible *Plasmodium*, where it binds to heme and disrupts its sequestration. Failure to inactivate heme or even enhanced toxicity of drug-heme complexes is thought to kill the parasites via oxidative damage to membranes, digestive proteases, or other critical biomolecules. Other quinolines such as quinine, amodiaquine, and mefloquine, as well as other amino alcohol analogs (lumefantrine, halofantrine) and mannich base analogs (pyronaridine), may act by a similar mechanism, although differences in their actions have been proposed (Bray et al., 2005; Eastman and Fidock, 2009).

Resistance of erythrocytic asexual forms of *P. falciparum* to antimalarial quinolines, especially chloroquine, now is common in most parts of the world (Figure 49–3). Reports of chloroquine failures in the treatment of *P. vivax* are fairly common in Indonesia, East Timor, and Papua New Guinea, in which case alternative treatments (mefloquine, or quinine plus doxycycline or tetracycline, or atovaquone-proguanil) should be considered (Price et al., 2009). Chloroquine-resistant *P. vivax* has also been recently detected in Ethiopia, where *P. vivax* is an important cause of morbidity (Yeshiwondim et al., 2010). Chloroquine-resistant *P. vivax* isolates do not appear to have significant alterations in their *pfcr* ortholog and may have a different resistance mechanism.

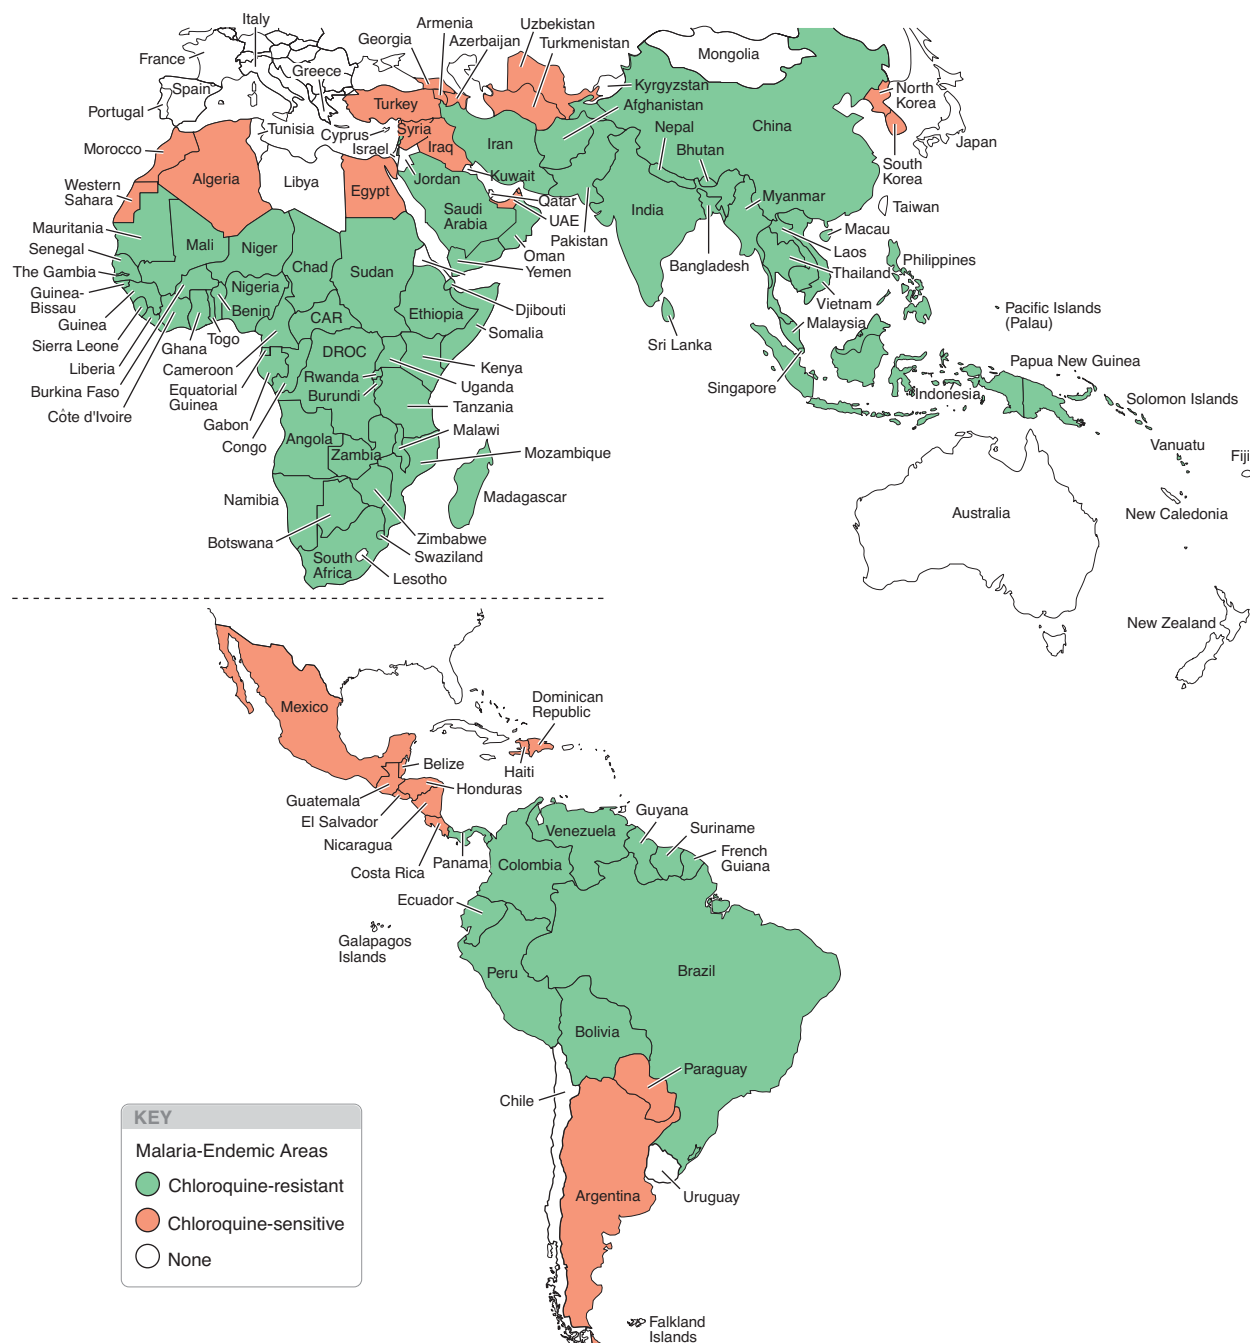

Figure 49–3. Malaria-endemic countries in the Americas (bottom) and in Africa, the Middle East, Asia, and the South Pacific (top), 2007. CAR, Central African Republic; DCOR, Democratic Republic of the Congo; UAE, United Arab Emirates. (Reproduced with permission from Anthony S. Fauci, Eugene Braunwald, Dennis L Kasper, Stephen L Hauser, Dan L Longo, J Larry Jameson, and Joseph Loscalzo, Eds. *Harrison's Principles of Internal Medicine*, 17 ed. McGraw-Hill, Inc., New York, 2008. Figure 203-2, p. 1282.)

Forty years ago, Fitch and coworkers noted that chloroquine-sensitive *P. falciparum* parasites concentrated the drug to higher levels than did chloroquine-resistant organisms (Fitch et al., 1969).

A parasite-encoded efflux mechanism may account for the reduced levels of chloroquine in the digestive vacuoles of chloroquine-resistant parasites (Martin et al., 2009; Valderramos and Fidock, 2006).

By studying the progeny of a genetic cross between a chloroquine-sensitive clone and a chloroquine-resistant clone, Wellems, Fidock, and colleagues identified a polymorphic gene (*pfcr*, for *P. falciparum* chloroquine resistance transporter) that segregates with chloroquine resistance. Geographically distinct *pfcr* alleles, possessing 4-8 point mutations compared to the invariant chloroquine-sensitive allele, were found to be highly associated with chloroquine resistance in clinical field isolates from across the malaria-endemic areas of the globe (Fidock et al., 2000). Multiple mutations are needed to confer resistance, including the K76T mutation that is ubiquitous to chloroquine-resistant strains. The *pfcr* gene encodes a putative transporter that resides in the membrane of the acidic digestive vacuole, the site of hemoglobin degradation and chloroquine action. Its physiological function, however, remains unknown. Chloroquine binding and accumulation studies, with genetically modified isogenic lines differing in their *pfcr* allele, suggest that mutant *pfcr* confers chloroquine resistance by actively effluxing chloroquine away from its heme target in the digestive vacuole, seemingly via an energy-dependent process (Sanchez et al., 2007). Heterologous expression of codon-adjusted *pfcr* alleles in *Xenopus laevis* oocytes has recently provided compelling evidence that mutant PfCRT can efflux chloroquine, and has found that this property was not solely dependent on the K76T mutation (Martin et al., 2009). Genomic studies suggest that *pfcr* has been under intense selection pressure in recent decades, consistent with its role as the primary resistance determinant and the prevalence of chloroquine use in populations exposed to parasites (Mu et al., 2010). Studies from Malawi have found that mutant *pfcr* alleles essentially disappear upon prolonged cessation of chloroquine use. This implies that mutant *pfcr* alleles can impart a significant fitness cost to the organism. This cost of fitness results in attrition of mutant forms in areas where polyclonal infections are common and subjects are sufficiently immune such that a substantial proportion of infections are not subject to the pressure of drug selection.

In addition to chloroquine, variant *pfcr* alleles may impact parasite susceptibility to other antimalarials. As an example, the 7G8 allele, representative of *pfcr* sequences from South America and the Pacific region, imparts low-level cross resistance to monodesethylamodiaquine, the active metabolite of amodiaquine (Sidhu et al., 2002). Cross-resistance to quinine has also been observed with some *pfcr* alleles in certain genetic backgrounds. In contrast, mutant *pfcr* increases parasite susceptibility to lumefantrine and artemisinin derivatives, which bodes well for the use of artemether-lumefantrine in areas where the prevalence of mutant *pfcr* is high (Sisowath et al., 2009). In addition to PfCRT, the P-glycoprotein transporter encoded by *pfmdr1*, and other transporters including PfMRP, may play a modulatory role in chloroquine resistance (Duraisingh and Cowman, 2005, Raj et al., 2009), and the glutathione system also could contribute (Ginsburg and Golenser, 2003).

Absorption, Fate, and Excretion. Chloroquine is well absorbed from the GI tract and rapidly from intramuscular and subcutaneous sites. This drug extensively sequesters in tissues, particularly liver, spleen, kidney, lung, melanin-containing tissues, and, to a lesser extent, brain and spinal cord. Chloroquine binds moderately (60%) to plasma proteins and undergoes appreciable biotransformation via hepatic CYPs to two active metabolites, desethylchloroquine and bisdesethylchloroquine (Ducharme and Farinotti, 1996). These

metabolites may reach plasma concentrations of 40% and 10% of that of chloroquine, respectively. The renal clearance of chloroquine is about half of its total systemic clearance. Unchanged chloroquine and desethylchloroquine account for >50% and 25% of the urinary drug products, respectively, and the renal excretion of both compounds is increased by acidification of the urine.

Both in adults and in children, chloroquine exhibits complex pharmacokinetics such that plasma levels of the drug shortly after dosing are determined primarily by the rate of distribution rather than the rate of elimination (Krishna and White, 1996). Because of extensive tissue binding, a loading dose is required to achieve effective concentrations in plasma. After parenteral administration, rapid entry into the bloodstream together with slow exit from this compartment can result in transiently high and potentially lethal concentrations of the drug in plasma. Hence, parenteral chloroquine is given either slowly by constant intravenous infusion or in small divided doses by the subcutaneous or intramuscular route. Chloroquine is safer when given orally because the rates of absorption and distribution are more closely matched. Peak plasma levels are achieved in ~3-5 hours after dosing by this route. The $t_{1/2}$ of chloroquine increases from a few days to weeks as plasma levels decline, reflecting release of drug from extensive tissue stores. The terminal $t_{1/2}$ ranges from 30 to 60 days, and traces of the drug can be found in the urine for years after a therapeutic regimen.

Therapeutic Uses. Chloroquine is highly effective against the erythrocytic forms of *P. vivax*, *P. ovale*, *P. malariae*, *P. knowlesi*, and chloroquine-sensitive strains of *P. falciparum*. For infections caused by *P. ovale* and *P. malariae*, it remains the agent of choice for chemoprophylaxis and treatment. Chloroquine is also widely used to treat *P. vivax*; however, as mentioned earlier, resistant strains have been detected, mostly in Asia and the Pacific region. For *P. falciparum* this drug has been largely replaced by artemisinin-based combination therapies (Eastman and Fidock, 2009). Gametocytocidal activity has been reported for the four main *Plasmodium* species infecting humans, with activity against *P. falciparum* restricted to immature gametocytes exposed to concentrations that are several fold higher than those effective against drug-sensitive asexual blood stage *P. falciparum* parasites. The drug has no activity against latent hypnozoite forms of *P. vivax* or *P. ovale*.

Chloroquine is inexpensive and safe, but its usefulness has declined across most malaria-endemic regions of the world because of the spread of chloroquine-resistant *P. falciparum*. Except in areas where resistant strains of *P. vivax* are reported, chloroquine is very effective in chemoprophylaxis or treatment of acute attacks of malaria caused by *P. vivax*, *P. ovale*, and *P. malariae* (Table 49-3). Chloroquine has no activity against primary or latent liver stages of the parasite. To prevent relapses in *P. vivax* and *P. ovale* infections, primaquine can be given either with chloroquine or used after a patient leaves an endemic area. Chloroquine rapidly controls the clinical symptoms and parasitemia of acute malarial attacks. Most patients become completely afebrile within 24-48 hours after receiving

therapeutic doses, and thick smears of peripheral blood generally are negative by 48–72 hours. If patients fail to respond during the second day of chloroquine therapy, resistant strains should be suspected and therapy instituted with quinine plus tetracycline or doxycycline, or atovaquone-proguanil, or artemether-lumefantrine, or mefloquine if the others are not available. Although chloroquine can be given safely by parenteral routes to comatose or vomiting patients, quinidine gluconate usually is given in the U.S. In comatose children, chloroquine is well absorbed and effective when given through a nasogastric tube. Tables 49–2 and 49–3 provide information about recommended chemoprophylactic and therapeutic dosage regimens involving the use of chloroquine. These regimens are subject to modification according to clinical judgment, geographic patterns of chloroquine resistance, and regional usage.

Chloroquine and its analogs are also used to treat certain non-malarial conditions, including hepatic amebiasis. Chloroquine and hydroxychloroquine have also been used as secondary drugs to treat a variety of chronic diseases because both alkaloids concentrate in lysosomes and have anti-inflammatory properties. Thus, these compounds, often together with other agents, have clinical efficacy in rheumatoid arthritis, systemic lupus erythematosus, discoid lupus, sarcoidosis, and photosensitivity diseases such as porphyria cutanea tarda and severe polymorphous light eruption.

Toxicity and Side Effects. Taken in proper doses and for recommended total durations, chloroquine is very safe. However, its safety margin is narrow, and a single dose of 30 mg/kg may be fatal (Taylor and White, 2004).

Acute chloroquine toxicity is encountered most frequently when therapeutic or high doses are administered too rapidly by parenteral routes. Toxic manifestations relate primarily to the cardiovascular system and the CNS. Cardiovascular effects include hypotension, vasodilation, suppressed myocardial function, cardiac arrhythmias, and eventual cardiac arrest. Confusion, convulsions, and coma may also result from overdose. Chloroquine doses of >5 g given parenterally usually are fatal. Prompt treatment with mechanical ventilation, epinephrine, and diazepam may be lifesaving.

Doses of chloroquine used for oral therapy of the acute malarial attack may cause GI upset, headache, visual disturbances, and urticaria. Pruritus also occurs, most commonly among dark-skinned persons. Prolonged treatment with suppressive doses occasionally causes side effects such as headache, blurring of vision, diplopia, confusion, convulsions, lichenoid skin eruptions, bleaching of hair, widening of the QRS interval, and T-wave abnormalities. These complications usually disappear soon after the drug is withheld. Rare instances of hemolysis and blood dyscrasias have been reported. Chloroquine may cause discoloration of nail beds and mucous membranes. This drug has also been reported to interfere with the immunogenicity of certain vaccines (Pappaioanou et al, 1986).

High daily doses of chloroquine or hydroxychloroquine (>250 mg) leading to cumulative total doses of >1 g/kg, such as those used for treatment of diseases other than malaria, can result in irreversible retinopathy and ototoxicity. Retinopathy presumably is related to drug accumulation in melanin containing tissues and can be avoided if the daily dose is ≤250 mg (Rennie, 1993). Prolonged therapy with high doses of chloroquine or hydroxychloroquine also can cause toxic myopathy, cardiopathy, and peripheral neuropathy.

These reactions improve if the drug is withdrawn promptly (Estes et al., 1987). Rarely, neuropsychiatric disturbances, including suicide, may be related to overdose.

Precautions and Contraindications. Chloroquine is not recommended for treating individuals who have epilepsy or myasthenia gravis. This drug should be used cautiously if at all in the presence of advanced liver disease or severe GI, neurological, or blood disorders. In individuals with decreased renal function, dosage should be adjusted to avoid elevated plasma concentrations. In rare cases, chloroquine can cause hemolysis in patients with G6PD deficiency (see later section on primaquine). Concomitant use of gold or phenylbutazone (no longer available in the U.S.) with chloroquine, in the treatment of rheumatoid arthritis, should be avoided because of the tendency of all three agents to produce dermatitis. Chloroquine should not be prescribed for patients with psoriasis or other exfoliative skin conditions because it can cause severe reactions. Because of the danger of cutaneous reactions, it should also not be used to treat malaria in patients with porphyria cutanea tarda; however it can be used in lower doses for treatment of manifestations of this form of porphyria. Chloroquine inhibits CYP2D6 and interacts with a variety of different drugs. It attenuates the efficacy of the yellow fever vaccine when administered at the same time. It should not be given with mefloquine because of increased risk of seizures and lack of added benefit. Most important, chloroquine opposes the action of anticonvulsants and increases the risk of ventricular arrhythmias when co-administered with amiodarone or halofantrine. By increasing plasma levels of digoxin and cyclosporine, chloroquine also can increase the risk of toxicity from these agents. Patients receiving long-term, high-dose therapy should undergo ophthalmological and neurological evaluations every 3–6 months.

Quinine and Quinidine

History. The medicinal use of quinine dates back >350 years (Rocco, 2003). Quinine is the chief alkaloid of cinchona, the powdered bark of the South American cinchona tree, otherwise known as Peruvian, Jesuit's, or Cardinal's bark. It had been used by indigenous Peruvians to treat shivering. In 1633, an Augustinian monk named Calancha, of Lima, Peru, first wrote that a powder of cinchona “given as a beverage, cures the fevers and tertians.” By 1640, cinchona was used to treat fevers in Europe. The Jesuit fathers were the main importers and distributors of cinchona in Europe.

For almost two centuries the bark was employed for medicine as a powder, extract, or infusion. In 1820, Pelletier and Caventou isolated quinine from cinchona. Quinine still is a mainstay for treating attacks of chloroquine- and multidrug-resistant *P. falciparum* malaria (Table 49–3). However, combination therapy (now standard artemisinin-derivative combinations) with other antimalarials is supplanting quinine regimens because of increasing resistance of *P. falciparum* to quinine in Southeast Asia and parts of the Amazon basin. Quinine toxicity, usually seen in overdose, can include pulmonary edema, immune thrombocytopenic purpura, irreversible deafness, or arrhythmias.

Oral quinine is FDA approved for the treatment of uncomplicated *P. falciparum* malaria and is currently available from one manufacturer in the U.S. Intravenous quinine is not available in the U.S. The more potent enantiomer, quinidine, is the preferred intravenous form.

Chemistry. Cinchona contains a mixture of >20 structurally related alkaloids, the most important of which are quinine and quinidine. Both compounds contain a quinoline group attached through a secondary alcohol linkage to a quinuclidine ring (Figure 49–2). A methoxy side chain is attached to the quinoline ring and a vinyl to the quinuclidine. They differ only in the steric configuration at two of the three asymmetrical centers: the carbon bearing the secondary alcohol group and at the quinuclidine junction. Although quinine and quinidine have been synthesized, the procedures are complex; hence they still are obtained from natural sources. Quinidine is both somewhat more potent as an antimalarial and more toxic than quinine (Griffith et al., 2007). Structure-activity analysis of the cinchona alkaloids provided the basis for the discovery of more recent antimalarials such as mefloquine.

Mechanisms of Action and Parasite Resistance. Quinine acts against asexual erythrocytic forms and has no significant effect on hepatic forms of malarial parasites. This drug is more toxic and less effective than chloroquine against malarial parasites susceptible to both drugs. However, quinine, along with its stereoisomer quinidine, is especially valuable for the parenteral treatment of severe illness owing to drug-resistant strains of *P. falciparum*. Of note, however, some strains from Southeast Asia and South America have become more resistant to both agents. Because of its toxicity and short $t_{1/2}$, quinine is generally not used for chemoprophylaxis.

The antimalarial mechanism of quinine is thought to share similarities to chloroquine in being able to bind heme and prevent its detoxification. The basis of *P. falciparum* resistance to quinine, nonetheless, is complex. Patterns of *P. falciparum* resistance to quinine correlate in some strains with resistance to chloroquine yet in others correlate more closely with resistance to mefloquine and halofantrine. Gene amplification of *pfmdr1* in *P. falciparum*, implicated in resistance to mefloquine and halofantrine, can contribute to reduced quinine susceptibility *in vitro*. Similarly, *pfmdr1* point mutations can also contribute to quinine resistance, in particular the N1042D mutation (Duraisingh and Cowman, 2005; Sidhu et al., 2005). Despite their close chemical similarity, quinine and quinidine sensitivity can also diverge in some strains harboring novel PfCRT haplotypes (Cooper et al., 2002). Recent evidence suggests that other transporter genes participate in conferring resistance to quinine, potentially including the sodium-hydrogen exchanger PfNH2 (Hayton and Su, 2008; Nkrumah et al., 2009).

Action on Skeletal Muscle. Quinine and related cinchona alkaloids exert effects on skeletal muscle that can have clinical implications. Quinine increases the tension response to a single maximal stimulus delivered to muscle directly or through nerves, but it also increases the refractory period of muscle so that the response to tetanic stimulation is diminished. The excitability of the motor end-plate region decreases so that responses to repetitive nerve stimulation and to acetylcholine are reduced. Thus, quinine can antagonize the actions of physostigmine on skeletal muscle as effectively as curare. Quinine may also produce alarming respiratory distress and dysphagia in patients with myasthenia gravis. The effect on skeletal muscle can be augmented by concurrent administration of gentamicin. Quinine

may also cause symptomatic relief of myotonia congenita. This disease is the pharmacological antithesis of myasthenia gravis, such that drugs effective in one syndrome aggravate the other.

Absorption, Fate, and Excretion. Quinine is readily absorbed when given orally or intramuscularly. In the former case, absorption occurs mainly from the upper small intestine and is >80% complete, even in patients with marked diarrhea. After an oral dose, plasma levels reach a maximum in 3–8 hours and, after distributing into an apparent volume of ~1.5 L/kg in healthy individuals, decline with a $t_{1/2}$ of ~11 hours. The pharmacokinetics of quinine may change according to the severity of malarial infection (Krishna and White, 1996). Values for both the apparent volume of distribution and the systemic clearance of quinine decrease, the latter more than the former, such that the average elimination $t_{1/2}$ increases to 18 hours. In patients with severe infection, standard therapeutic doses may produce peak plasma levels of quinine as high as 15–20 mg/L without causing major toxicity. In contrast, levels >10 mg/L can produce severe drug reactions. The high levels of plasma α_1 -acid glycoprotein produced in severe malaria may prevent toxicity by binding quinine and thereby reducing the free fraction of drug. Concentrations of quinine are lower in erythrocytes (33–40%) and CSF (2–5%) than in plasma, and the drug readily reaches fetal tissues.

The cinchona alkaloids are metabolized extensively, especially by hepatic CYP3A4; thus only ~20% of an administered dose is excreted in an unaltered form in the urine. These drugs do not accumulate in the body upon continued administration. However, the major metabolite of quinine, 3-hydroxyquinine, retains some antimalarial activity and can accumulate and possibly cause toxicity in patients with renal failure. Renal excretion of quinine itself is more rapid when the urine is acidic.

Therapeutic Uses. Quinine and quinidine have historically been treatments of choice for drug-resistant and severe *P. falciparum* malaria. However, the advent of artemisinin therapy is changing this situation because both oral and intravenous artemisinins have entered clinical practice (Table 49–3). In severe illness, the prompt use of loading doses of intravenous quinine (or quinidine, where intravenous quinine is not available, as is the case in the U.S.) is imperative and can be lifesaving. Oral medication to maintain therapeutic concentrations is then given as soon as tolerated and is continued for 5–7 days. Especially for treatment of infections with multidrug-resistant strains of *P. falciparum*, slower-acting blood schizonticides such as tetracyclines or clindamycin are given concurrently to enhance quinine efficacy. Formulations of quinine and quinidine and specific regimens for their use in the treatment of *P. falciparum* malaria are shown in Table 49–3.

In a series of studies over the past two decades, White and associates designed rational regimens, including the institution of loading doses, for the use of quinine and quinidine in the treatment of *P. falciparum* malaria in Southeast Asia (Krishna and White, 1996). Between 0.2 and 2.0 mg/L has been estimated as the therapeutic range for “free” quinine. Regimens needed to achieve this target may vary

based on patient age, severity of illness, and the responsiveness of *P. falciparum* to the drug. For example, lower doses are more effective in treating children in Africa than adults in Southeast Asia because the pharmacokinetics of quinine differ in the two populations, as does the susceptibility of *P. falciparum* to the drug (Krishna and White, 1996). Dosage regimens for quinidine are similar to those for quinine, although quinidine binds less to plasma proteins and has a larger apparent volume of distribution, greater systemic clearance, and shorter terminal elimination $t_{1/2}$ than quinine (Griffith et al., 2007; Miller et al., 1989). Thompson et al. (2003) suggest that the dose of quinidine currently recommended by the CDC (10 mg salt/kg initially, followed by 0.02 mg salt/kg per minute) may be too low and should be 10 mg salt/kg and 0.02 mg/kg of base/minute (60% of the salt is base). Clinical data on which to base a firm recommendation are lacking.

Treatment of Nocturnal Leg Cramps. It is commonly believed that night cramps might be relieved by quinine taken at bedtime at a dose of 200-300 mg (available until 1995 in products that did not require a prescription). Some consider this condition severe. The degree of symptomatic relief appears to vary substantially between individuals. In 1995, the FDA issued a ruling that required drug manufacturers to stop marketing over-the-counter quinine products for nocturnal leg cramps, stating that data supporting safety and efficacy of quinine for this indication were inadequate and that risks outweighed the potential benefits.

Toxicity and Side Effects. The fatal oral dose of quinine for adults is ~2-8 g. Quinine is associated with a triad of dose-related toxicities when given at full therapeutic or excessive doses. These are cinchonism, hypoglycemia, and hypotension. Mild forms of cinchonism—consisting of tinnitus, high-tone deafness, visual disturbances, headache, dysphoria, nausea, vomiting, and postural hypotension—occur frequently and disappear soon after the drug is withdrawn. Hypoglycemia is also common, mostly in the treatment of severe malaria, and can be life threatening if not treated promptly with intravenous glucose. Hypotension is rarer but also serious and most often is associated with excessively rapid intravenous infusions of quinine or quinidine. Prolonged medication or high single doses also may produce GI, cardiovascular, and skin manifestations, as discussed next.

Hearing and vision are particularly affected. Functional impairment of the eighth nerve results in tinnitus, decreased auditory acuity, and vertigo. Visual signs consist of blurred vision, disturbed color perception, photophobia, diplopia, night blindness, constricted visual fields, scotomata, mydriasis, and even blindness (Bateman and Dyson, 1986). These visual and auditory effects probably result from direct neurotoxicity, although secondary vascular changes may have a role. Marked spastic constriction of the retinal vessels leads to retinal ischemia, pale optic discs, and retinal edema, with the potential for severe optic atrophy.

GI symptoms are also prominent in cinchonism. Nausea, vomiting, abdominal pain, and diarrhea result from the local irritant action of quinine, but the nausea and emesis also have a central basis. Cutaneous manifestations may include flushing, sweating, rash, and

angioedema, especially of the face. Quinine and quinidine, even at therapeutic doses, may cause hyperinsulinemia and severe hypoglycemia through their powerful stimulatory effect on pancreatic beta cells. Despite treatment with glucose infusions, this complication can be serious and possibly life threatening, especially in pregnancy and prolonged severe infection. Hypoglycemia is seen occasionally in uninfected patients who take quinine.

Quinine rarely causes cardiac complications unless therapeutic plasma concentrations are exceeded (Krishna and White, 1996). QTc prolongation is mild and does not appear to be affected by concurrent mefloquine treatment. Acute overdose also may cause serious and even fatal cardiac dysrhythmias such as sinus arrest, junctional rhythms, AV block, and ventricular tachycardia and fibrillation (Bateman and Dyson, 1986). Quinidine is even more cardiotoxic than quinine. Cardiac monitoring of patients on intravenous quinidine is advisable where possible.

Severe hemolysis can result from hypersensitivity to these cinchona alkaloids. Hemoglobinuria and asthma from quinine may occur more rarely. “Blackwater fever”—the triad of massive hemolysis, hemoglobinemia, and hemoglobinuria leading to anuria, renal failure, and in some instances death—is a rare type of hypersensitivity reaction to quinine therapy that can occur during treatment of malaria. Quinine may cause milder hemolysis upon occasion, especially in people with G6PD deficiency. Thrombotic thrombocytopenic purpura is a rare but clinically significant adverse effect. This reaction can occur even in response to ingestion of tonic water, which has ~4% the therapeutic oral dose per 12 oz (“cocktail purpura”). Other rare adverse effects include hypoprothrombinemia, leukopenia, and agranulocytosis.

Precautions, Contraindications, and Interactions. Quinine must be used with considerable caution, if at all, in patients who manifest hypersensitivity (balanced against risks primarily of not urgently treating severe malaria in the absence of other effective antimalarial drugs). Quinine should be discontinued immediately if evidence of hemolysis appears.

This drug should be avoided in patients with tinnitus or optic neuritis. In patients with cardiac dysrhythmias, the administration of quinine requires the same precautions as for quinidine. Quinine appears to be safe in pregnancy and is used commonly for the treatment of pregnancy-associated malaria. However, glucose levels must be monitored because of the increased risk of hypoglycemia.

Because parenteral solutions of quinine and quinidine are highly irritating, the drug should not be given subcutaneously. Concentrated solutions may cause abscesses when injected intramuscularly, or thrombophlebitis when infused intravenously. Antacids that contain aluminum can delay absorption of quinine from the GI tract. Quinine and quinidine can delay the absorption and elevate plasma levels of digoxin and related cardiac glycosides. Likewise, these alkaloids may raise plasma levels of warfarin and related anticoagulants. The action of quinine at neuromuscular junctions enhances the effect of neuromuscular blocking agents and opposes the action of acetylcholinesterase inhibitors. Prochlorperazine can amplify quinine’s cardiotoxicity, as can halofantrine. The renal clearance of quinine can be decreased by cimetidine and increased by urine acidification and by rifampin.

History. Mefloquine (LARIAM) is a product of the Malaria Research Program established by the Walter Reed Institute for Medical Research in 1963 to develop promising new compounds to address the alarming growth of drug-resistant malaria. Of the many 4-quinoline methanols tested based on their structural similarity to quinine, mefloquine displayed high antimalarial activity in animal models, and emerged from clinical trials as safe and effective against drug-resistant strains of *P. falciparum*. Mefloquine was first used to treat chloroquine-resistant *P. falciparum* malaria in Thailand. However, the slow elimination of mefloquine fostered the emergence of drug-resistant parasites.

Chemistry. The structure of the mefloquine raceme is illustrated in Figure 49–2. Recent work has demonstrated that the (–)-enantiomer is associated with adverse CNS effects, whereas the (+)-enantiomer retains antimalarial activity with fewer side effects. Mefloquine can be paired with artesunate, thereby reducing the selection pressure for resistance. This combination has proved efficacious for the treatment of *P. falciparum* malaria, even in regions with high prevalence of mefloquine-resistant parasites.

Mechanisms of Action and Parasite Resistance. Mefloquine is a highly effective blood schizonticide. However, it possesses no activity against hepatic stages or mature gametocytes of *P. falciparum* or latent tissue forms of *P. vivax*.

Earlier work showed that mefloquine associates with intracellular hemozoin, suggesting similarities to the mode of action of chloroquine (Sullivan et al., 1998). However, evidence that this association might be secondary to a primarily cytosolic mode of action comes from studies with transgenic *P. falciparum* lines expressing different *pfmdr1* copy numbers. Increased *pfmdr1* copy numbers are associated with both reduced parasite susceptibility to mefloquine (and artemisinin) and increased PfMDR1-mediated solute import into the digestive vacuole of intraerythrocytic parasites (Rohrbach et al., 2006). Therefore, if the drug's target resides outside of this vacuolar compartment, increased import of mefloquine into the digestive vacuole, potentially driven by PfMDR1 activity, would be beneficial for the parasite and reduce its susceptibility to the drug.

A comprehensive clinical and molecular epidemiological study conducted with parasites from Thailand identified *pfmdr1* gene amplification as a major determinant of mefloquine treatment failure and *in vitro* mefloquine resistance (Price et al., 2004). Some individuals in that study nonetheless failed mefloquine treatment despite not having parasites with multiple *pfmdr1* copies, implying secondary mechanisms of resistance. Mefloquine susceptibility *in vitro* can also be affected by the presence of point mutations in *pfmdr1* or *pfcr* (Valderramos and Fidock, 2006).

Absorption, Fate, and Excretion. Mefloquine is taken orally because parenteral preparations cause severe local reactions. The drug is rapidly absorbed, with marked variability between individuals. Probably owing to extensive enterohepatic and enterohepatic circulation, plasma levels of mefloquine rise in a biphasic manner to their peak in ~17 hours. Mefloquine has a variable and long $t_{1/2}$, 13–24 days, reflecting its high lipophilicity, extensive tissue distribution, and

extensive binding (~98%) to plasma proteins. Mefloquine is extensively metabolized in the liver. CYP3A4 has been implicated in the metabolism of mefloquine; this CYP can be inhibited by ketoconazole and induced by rifampicin (German and Aweeka, 2008). Excretion of mefloquine is mainly by the fecal route; only ~10% of mefloquine appears unchanged in the urine. The stereoisomers of mefloquine exhibit quite different pharmacokinetic characteristics that relate to their biodisposition (Hellgren et al., 1997).

Therapeutic Uses. Mefloquine should be reserved for the prevention and treatment of malaria caused by drug-resistant *P. falciparum* and *P. vivax*, but it is no longer considered first-line treatment of malaria in most clinical contexts. The drug is especially useful as a chemoprophylactic agent for travelers spending weeks, months, or years in areas where these infections are endemic (Table 49–2). In areas where malaria is due to multiply drug-resistant strains of *P. falciparum* (particularly in Southeast Asia), mefloquine is more effective when used in combination with an artemisinin compound.

Toxicity and Side Effects. The use of mefloquine for the chemoprophylaxis or treatment of malaria must balance concerns about clinically significant risks and benefits. The major adverse effects of mefloquine have been reviewed in detail (Chen et al., 2006). Mefloquine given orally is generally well tolerated at chemoprophylactic dosages, although vivid dreams are common. Significant neuropsychiatric signs and symptoms can occur in 10% (or more) of people receiving treatment doses, although serious adverse events (psychosis, seizures) are rare. Short-term adverse effects of treatment include nausea, vomiting, and dizziness. Dividing the dose improves tolerance. The full dose should be repeated if vomiting occurs within the first hour.

Estimates for frequency of severe CNS toxicity after mefloquine treatment can be as high as 0.5%. Adverse reactions include seizures, confusion or decreased sensorium, acute psychosis, and disabling vertigo. Such symptoms generally are reversible upon drug discontinuation. At chemoprophylactic dosages, the risk of serious neuropsychiatric effects is estimated to be ~0.01% (about the same as for chloroquine). Mild-to-moderate toxicities (e.g., disturbed sleep, dysphoria, headache, GI disturbances, and dizziness) occur even at chemoprophylactic dosages. Whether these symptoms are more common than with other antimalarial regimens is debated. Adverse effects usually manifest after the first to third doses and often abate even with continued treatment. Reports of cardiac abnormalities, hemolysis, and agranulocytosis are rare.

Contraindications and Interactions. At very high doses, mefloquine is teratogenic in rodents. Studies have suggested an increased rate of stillbirths with mefloquine use, especially during the first trimester (Taylor and White, 2004). The significance of these data has been debated, but it is fair to say that the evidence for mefloquine's safety in pregnancy is not convincing, and mefloquine may be used if it is the only available treatment option. Pregnancy should be avoided

for 3 months after mefloquine use because of the prolonged $t_{1/2}$ of this agent.

This drug is contraindicated for patients with a history of seizures, depression, bipolar disorder and other severe neuropsychiatric conditions, or adverse reactions to quinoline antimalarials such as quinine, quinidine, halofantrine, mefloquine, and chloroquine. Mefloquine may counteract seizures in epileptic patients. Although this drug can be taken safely 12 hours after a last dose of quinine, taking quinine shortly after mefloquine can be very hazardous because the latter is eliminated so slowly. Treatment with or after halofantrine or within 2 months of prior mefloquine administration is contraindicated.

Recent studies do not indicate that mefloquine compromises the performance of tasks that require good motor coordination, e.g., driving or operating machinery. Although some advise against the use of mefloquine for patients in occupations that require focused concentration, dexterity and cognitive function in safety-sensitive settings, such as pilots, controlled studies suggest that mefloquine does not impair performance in persons who tolerate the drug.

Primaquine

History. The weak anti-*Plasmodium* activity of methylene blue, first discovered by Ehrlich in 1891, led to the development of the 8-aminoquinoline antimalarials, of which pamaquine was the first introduced into medicine. During World War II the search for more potent and less toxic 8-aminoquinoline antimalarials resulted in the discovery of primaquine (Figure 49–2).

Primaquine, in contrast to other antimalarials, acts on exoerythrocytic tissue stages of plasmodia in the liver to prevent and cure relapsing malaria. The striking hemolysis that may follow primaquine therapy led directly to the landmark discovery of G6PD deficiency, the first genetic disorder associated with an enzyme. Hemolysis remains notoriously identified with primaquine. Patients should be screened for G6PD deficiency prior to therapy with this drug. The pressing need for alternatives to this important drug has resulted in the evaluation of multiple 8-aminoquinoline analogs (Vale et al., 2009). These include tafenoquine, a compound under clinical evaluation that is active against relapsing liver stage forms of *P. vivax*, and multidrug resistant asexual blood stage forms of *P. falciparum* (Wells et al., 2009).

Mechanisms of Action and Parasite Resistance. Primaquine acts against primary and latent hepatic stages of *Plasmodium spp.* and prevents relapses in *P. vivax* and *P. ovale* infections. This drug and other 8-aminoquinolines also display gametocytocidal activity against *P. falciparum* and other *Plasmodium* species. However, primaquine is inactive against asexual blood stage parasites.

The mechanism of action of the 8-aminoquinolines has not been elucidated. Primaquine may be converted to electrophilic intermediates that act as oxidation-reduction mediators. Such activity could contribute to antimalarial effects by generating reactive oxygen species or by interfering with mitochondrial electron transport in the parasite (Vale et al., 2009). Some strains of *P. vivax* can exhibit partial resistance to primaquine (Baird, 2009).

Absorption, Fate, and Excretion. Absorption of primaquine from the GI tract approaches 100%. After a single dose, the plasma concentration reaches a maximum within 3 hours and then falls with a variable elimination $t_{1/2}$ averaging 7 hours.

The apparent volume of distribution is several times that of total-body water, due to extensive tissue distribution. Primaquine binds preferentially to the acute-phase reactant protein α 1-glycoprotein, which may alter the distribution of free drug depending on its concentration in the blood. Primaquine is metabolized rapidly, and only a small fraction of an administered dose is excreted as the parent drug. Importantly, primaquine induces CYP1A2. Thus, caution should be taken in administering primaquine with drugs metabolized by CYP1A2 (including warfarin) (Hill et al., 2006). The major metabolite, carboxyprimaquine, is inactive.

Therapeutic Uses. Primaquine is used primarily for terminal chemoprophylaxis and radical cure of *P. vivax* and *P. ovale* (relapsing) infections because of its high activity against the latent tissue forms (hypnozoites) of these *Plasmodium* species. The compound is given together with a blood schizonticide, usually chloroquine, to eradicate erythrocytic stages of these plasmodia and reduce the possibility of emerging drug resistance.

For terminal chemoprophylaxis, primaquine regimens should be initiated shortly before or immediately after a subject leaves an endemic area (Table 49–2). Radical cure of *P. vivax* or *P. ovale* malaria can be achieved if the drug is given either during an asymptomatic latent period of presumed infection (based on travel to or residence within an endemic region) or during an acute attack. Simultaneous administration of a schizonticidal drug plus primaquine is more effective in radical cure than sequential treatment. Limited studies have shown efficacy in prevention of *P. falciparum* and *P. vivax* malaria when primaquine is taken as chemoprophylaxis (Taylor and White, 2004). Gametocytocidal activity of primaquine should also reduce the transmission potential during drug treatment of *P. falciparum*. However, this approach to prophylaxis is not routine clinical practice. Primaquine is generally well tolerated when taken for up to 1 year.

Toxicity and Side Effects. Primaquine has few side effects when given to most whites in the usual therapeutic doses. Primaquine can cause mild to moderate abdominal distress in some individuals. Taking the drug at mealtime often alleviates these symptoms. Mild anemia, cyanosis (methemoglobinemia), and leukocytosis are less common. High doses (60–240 mg daily) worsen the abdominal symptoms and cause some degree of methemoglobinemia in most subjects. Methemoglobinemia can occur even with usual doses of primaquine and can be severe in individuals with congenital deficiency of NADH methemoglobin reductase (Coleman and Coleman, 1996). Chloroquine and dapsone may synergize with primaquine to produce methemoglobinemia in these patients. Granulocytopenia and agranulocytosis are rare complications of therapy and usually are associated with overdosage. Other rare adverse reactions are hypertension, arrhythmias, and symptoms referable to the CNS.

Therapeutic or higher doses of primaquine may cause acute hemolysis and hemolytic anemia in humans with G6PD deficiency (Vale et al., 2009). This X-linked condition, primarily owing to amino acid substitutions in the G6PD enzyme, affects >200 million people worldwide. More than 400 genetic variants of G6PD produce variable responses to oxidative stress. About 11% of African Americans have the A variant of G6PD, and are therefore vulnerable to hemolysis caused by pro-oxidant drugs such as primaquine. G6PD deficiency is uncommon in Latin America but may be present in those residents of African descent. Primaquine-induced hemolysis can be even more severe in white ethnic groups, including Sardinians, Sephardic Jews, Greeks, and Iranians; these populations have a G6PD variant in which two amino acid substitutions impair both enzyme stability and activity. Because primaquine sensitivity is inherited through an X-linked gene, hemolysis is often of intermediate severity in heterozygous females who have two populations of red blood cells, one normal and the other deficient in G6PD. Owing to “variable penetrance,” these females may be affected less frequently than predicted. Primaquine is the prototype of >50 drugs, including antimalarial sulfonamides, that cause hemolysis in G6PD-deficient individuals.

Precautions and Contraindications. G6PD deficiency should be ruled out prior to administration of primaquine. Primaquine has been used cautiously in subjects with the A form of G6PD deficiency, although benefits of treatment may not necessarily outweigh the risks. The drug should not be used in patients with more severe deficiency. If a daily dose of >30 mg primaquine base (>15 mg in potentially sensitive patients) is given, then blood counts should be followed carefully. Patients should be counseled to look for dark or blood-colored urine, which would indicate hemolysis. Primaquine should not be given to pregnant women, and, in treating lactating mothers, it should be prescribed only after ascertaining that the breast-feeding infant has a normal G6PD level (which can be difficult to assess soon after birth).

Primaquine is contraindicated for acutely ill patients suffering from systemic disease characterized by a tendency to granulocytopenia (e.g., active forms of rheumatoid arthritis and lupus erythematosus). Primaquine should not be given to patients receiving other drugs capable of causing hemolysis or depressing the myeloid elements of the bone marrow.

SULFONAMIDES AND SULFONES

History. Shortly after their introduction into clinical practice, the sulfonamides were found to have antimalarial activity, a property investigated extensively during World War II. The efficacy of sulfones was demonstrated in the first trial of dapson against *P. falciparum* in 1943. The sulfonamides combined with pyrimethamine have been used to treat chloroquine-resistant *P. falciparum* malaria, particularly in parts of Africa. The sulfonamides and sulfones are

slow-acting blood schizonticides and more active against *P. falciparum* than *P. vivax*.

Mechanism of Action. Sulfonamides are *p*-aminobenzoic acid analogs that competitively inhibit *Plasmodium* dihydropteroate synthase. These agents are combined with an inhibitor of parasite dihydrofolate reductase to enhance their antimalarial action. The synergistic “antifolate” combination of sulfadoxine, a long-acting sulfonamide, with pyrimethamine has been extensively used to treat malaria. As observed for pyrimethamine, sulfadoxine resistance appeared quickly *in vivo* after the introduction of this treatment as monotherapy.

Drug Resistance. Sulfadoxine resistance is conferred by several point mutations in the dihydropteroate synthase gene; the more widespread is the substitution Ala437Gly. These sulfadoxine-resistance mutations, when combined with mutations of dihydrofolate reductase and conferring pyrimethamine resistance, greatly increase the likelihood of sulfadoxine-pyrimethamine treatment failure. Sulfadoxine-pyrimethamine, given intermittently during the second and third trimesters of pregnancy, is a routine component of antenatal care throughout Africa. Intermittent preventive treatment strategies might also benefit infants (Aponte et al., 2009). However, there are substantial concerns about these strategies in the face of the expanding profile of resistance to pyrimethamine-sulfadoxine. A recent report found that intermittent preventive treatment in pregnancy exacerbated placental inflammation and caused increased levels of parasitemia and increased selective pressure for drug-resistant infections (Harrington et al., 2009). Thus, there is a clear need to identify alternative intermittent preventive treatment regimens. Generally, one can anticipate that, in the absence of novel antifolates effective against existing drug-resistant strains, the use of these antimalarials for either prevention or treatment will continue to decline.

TETRACYCLINES AND OTHER ANTIBIOTIC AGENTS

Tetracyclines are a group of antibiotic agents initially derived from *Streptomyces*. The pharmacological properties of tetracyclines are presented in Chapter 55. Two members of this group, tetracycline and doxycycline, are useful in malaria treatment. In addition, clindamycin, a lincosamide antibiotic (Chapter 55), is also recommended. These agents are slow-acting blood schizonticides that can be used alone for short-term chemoprophylaxis in areas with chloroquine- and mefloquine-resistant malaria (only doxycycline is recommended for malaria chemoprophylaxis). All of these antibiotics act via a delayed death mechanism resulting from their inhibition of protein translation in the parasite plastid. This effect on malarial parasites manifests as death of the progeny of drug-treated parasites, resulting in slow onset of antimalarial activity (Dahl and Rosenthal, 2008). Their relatively slow mode of action makes these drugs ineffective as single agents for malaria treatment. However, their efficacy as treatment is increased when they are used as an adjunct to quinine, quinidine, or artesunate, and in this context, they can be used to treat uncomplicated or severe *P. falciparum* malaria. These antibiotics are not clinically used to eliminate liver stage infection.

Dosage regimens for tetracyclines and clindamycin are listed in Tables 49–2 and 49–3. Because of their adverse effects on bones

and teeth, tetracyclines should not be given to pregnant women or to children <8 years of age. In these subjects, clindamycin is a reasonable alternative. Photosensitivity reactions or drug-induced superinfections may mandate discontinuation of therapy or chemoprophylaxis with tetracyclines. As an alternative antibiotic, the macrolide azithromycin also displays antimalarial activity through a similar delayed-death mechanism and is undergoing further evaluation. As with clindamycin, azithromycin is safe for use in young children and pregnant women.

PRINCIPLES AND GUIDELINES FOR CHEMOPROPHYLAXIS AND CHEMOTHERAPY OF MALARIA

Pharmacological prevention of malaria poses a difficult challenge because *P. falciparum*, which causes nearly all the deaths from human malaria, has become progressively more resistant to available antimalarial drugs. Chloroquine had been the drug of choice to prevent all forms of malaria until resistance became widespread in the past decades. Chloroquine remains effective against malaria caused by *P. ovale*, *P. malariae*, *P. knowlesi*, most strains of *P. vivax*, and chloroquine-sensitive strains of *P. falciparum* found in some geographic areas. However, chloroquine-resistant strains of *P. falciparum* are now the rule, not the exception, in most malaria-endemic regions except Mexico, Central America west of the Panama Canal Zone, the Caribbean, and parts of the Middle East (Figure 49–3). Except for parts of Africa, extensive geographic overlap also exists between chloroquine resistance and resistance to pyrimethamine-sulfadoxine. Multidrug-resistant *P. falciparum* malaria is especially prevalent and severe in Southeast Asia and Oceania. These infections may not respond adequately even to mefloquine or quinine.

Genetic studies indicate that isolates of *P. falciparum* from patients in highly endemic areas contain many parasite clones with different drug resistance phenotypes (Druilhe et al., 1998). A patient with severe malaria may have up to 10^{12} parasites. Because single point mutations occur with an estimated frequency of 10^{-9} , based on *in vitro* studies (Cooper et al., 2002), single point mutations that confer resistance could potentially arise in virtually every patient and double point mutations would arise occasionally. Most of these new mutant strains will not survive because of immunity, decreased fitness, and additional factors; nonetheless, successful drugs or drug combinations must ideally not be susceptible to resistance resulting from single point mutations. Mutations by gene amplification are expected to be even more frequent than single point mutations (Nair et al., 2008). Looking back in time, one notes that decades of intense chloroquine use preceded development of resistance to this agent. This delay was likely due to the requirement for at least four point mutations in the *pfert* gene to confer resistance (Valderramos and Fidock, 2006). Pharmacokinetics can also be a determinant in the

generation of resistance. Drugs with a long $t_{1/2}$ are thought to generally be more likely to select for resistance (White, 2004).

On a population level, the fitness of resistant parasites is another important parameter: If mutation causes a reduced ability to survive or grow, the parasites are less likely to spread. However, in the case of antifolates, treatment actually induces gametocytogenesis, which promotes transmission; this effect, together with other forces (intense selection pressure from preventive drug use; parasite migrations driven by humans), may explain the spread of particular resistance alleles across Southeast Asia and Africa. These considerations strongly argue for regimens that combine two or more anti-malarial agents with different mechanisms of action (and therefore, hopefully, with different mechanisms of resistance) to treat drug-resistant *P. falciparum* malaria (White, 2004). ACTs are the most important combination treatment currently available.

The following section presents an overview of the chemoprophylaxis and chemotherapy of malaria. For more current details about individual drugs, their clinical and chemoprophylactic applications, and about malaria risk areas, consult the latest information available from the CDC (www.cdc.gov/travel/travel). Consultation and emergency advice about treatment are available 24 hours a day from the duty officer, Division of Parasitic Diseases, CDC.

Current CDC recommendations for drugs and dosing regimens for the chemoprophylaxis and treatment of malaria in nonimmune individuals are shown in Tables 49–2 and 49–3. These will change and should serve only as general guidelines to be modified appropriately according to the status and habitat of the patient; the geographic origin, species, and drug-resistance profile of infecting parasites; and the agents used for malaria prevention.

Importantly, *drugs should not replace simple, inexpensive measures for malaria prevention*. Individuals visiting malarious areas should take appropriate steps to prevent mosquito bites. One such measure is to avoid exposure to mosquitoes at dusk and dawn, usually the times of maximal feeding. Others include using insect repellents containing at least 30% *N,N'*-diethylmetatoluamide (DEET) and sleeping in well-screened rooms or under bed nets impregnated with a pyrethrin insecticide such as permethrin (Kain and Jong, 2003).

Malaria Chemoprophylaxis. Regimens for malaria chemoprophylaxis include primarily three drugs: atovaquone-proguanil and doxycycline that can both be used in all areas, and mefloquine that can be used in areas with mefloquine-sensitive malaria. Other available options are chloroquine or hydroxychloroquine (but their use is restricted to the few areas with chloroquine-sensitive malaria), and primaquine (for short duration travel to areas with principally *P. vivax*).

In general, dosing should be started before exposure, ideally before the traveler leaves home, to establish therapeutic blood levels and to detect early signs or symptoms of intolerance so the regimen can be modified before departure. As described earlier, the duration of post-exposure dosing is dictated by the spectrum of drug action (Table 49–1).

In those few areas where chloroquine-sensitive strains of *P. falciparum* are found, chloroquine is still suitable for chemoprophylaxis. It also remains the drug of choice for chemoprophylaxis and control of infections due to *P. vivax*, *P. ovale*, *P. malariae*, and *P. knowlesi*. In areas where chloroquine-resistant malaria is endemic, mefloquine and atovaquone-proguanil are the regimens of choice for chemoprophylaxis. There is more experience with mefloquine and more evidence for its efficacy against *P. vivax*, an important consideration in areas where this species co-exists with *P. falciparum*. However, there are more contraindications to the use of mefloquine and perhaps greater toxicity than for alternative regimens. Doxycycline is an alternative chemoprophylactic agent. In cases where mefloquine, atovaquone-proguanil, and doxycycline all are contraindicated, primaquine is a possibility for chemoprophylaxis. Primaquine, like atovaquone-proguanil, is active against liver stages and can be discontinued shortly after leaving the endemic area. Attempts at radical cure of *P. vivax* malaria with primaquine should be delayed until the patient leaves an endemic area.

For chemoprophylaxis in long-term travelers, chloroquine is safe at the doses used, but some recommend yearly retinal examinations, and there is a finite dose limit for which chemoprophylaxis with chloroquine

is recommended because of ocular toxicity (Tehrani et al., 2008). Mefloquine and doxycycline are well tolerated. Mefloquine is the best documented drug for long-term travelers and, if well tolerated, can be used for prolonged periods. Atovaquone-proguanil has been studied for up to 20 weeks but probably is acceptable for years based on experience with the individual components.

The diagnosis of malaria must be considered for patients presenting with acute febrile illness after returning from a malaria-endemic region (Table 49–5). If proven to be malaria, such an illness should be considered a medical emergency, especially for vulnerable populations such as nonimmune travelers, pregnant women, and young children. Severe P. falciparum malaria is as acute as any other life-threatening illness and demands close attention and aggressive treatment. An organized, rational approach to diagnosis, parasite identification, and appropriate treatment is crucial (see Figure 49–4). Treatment with a rapidly acting blood schizonticide must be instituted promptly if P. falciparum malaria is suspected from a travel history and clinical findings. One should not wait for a definitive parasitological diagnosis to initiate therapy in such patients because their clinical status may deteriorate rapidly. Moreover, the clinical presentation may be atypical, and thick blood smears may fail to reveal malarial parasites in early stages of this infection.

Table 49–5

Criteria for the Diagnosis of Malaria

Signs and symptoms consistent with malaria, including fever, chills, headache, ± severe malaria criteria (below), *plus*

Demonstration of the presence of malaria parasite:

- Light microscope examination of stained thin or thick smear
- Rapid diagnostic test
- Molecular or biophysical-based testing

Criteria for the Diagnosis of Severe Malaria^a

Prostration	Jaundice
Impaired consciousness/coma	Severe anemia
Respiratory distress (acidotic breathing)	Acute renal failure
Multiple convulsions	Disseminated intravascular coagulation
Circulatory shock	Acidosis
Pulmonary edema	Hemoglobinuria
Acute respiratory distress syndrome	Parasitemia >5%
Abnormal bleeding

Figure 49–4. Approach to the treatment of malaria. Atovaquone-proguanil, mefloquine, artemether-lumefantrine, tetracycline, and doxycycline are not indicated during pregnancy. Tetracycline and doxycycline are not indicated in children <8 years of age. G6PD, glucose-6-phosphate dehydrogenase. (Adapted from Griffith KS, Lewis LS, Mali S, Parise ME. Treatment of malaria in the United States: A systematic review. *JAMA*, 297(20):2264–77, 2007, with permission of the American Medical Association © 2007. All rights reserved.)

Guidelines for treatment of malaria in the U.S. are provided by the CDC and are shown in Table 49–3. Updates should be checked on the CDC website. Figure 49–4 presents an overview of the general strategy for treatment of malaria in the U.S.

Treatment of Uncomplicated Malaria. Chloroquine is the drug of choice for *P. ovale*, *P. malariae*, *P. knowlesi*, and chloroquine-sensitive strains of *P. vivax* and *P. falciparum*. For *P. vivax* and *P. ovale* infections, a 2-week course of primaquine should be added to eradicate hypnozoites that may remain dormant in the liver, and thus prevent relapse. Some patients with *P. vivax* infection

may require more than one course of primaquine to obtain radical cure. Primaquine must not be given to patients with G6PD deficiency or to pregnant women. The oral route of administration should be used if feasible. Within 48–72 hours of initiating therapy, patients should show marked clinical improvement (especially clearance of fever) and a substantial decrease in parasitemia as monitored by daily thin and thick blood smears. Under controlled administration of treatment, lack of such a response or failure to clear asexual forms of the parasite from the blood by 7 days suggests the presence of drug resistance (except for atovaquone-proguanil).

For clinical classification of drug resistance, see Bloland (2001). In endemic settings, recrudescence of *P. falciparum* clinical episodes or asymptomatic parasitemia after appropriate treatment can also be due to reinfection.

For uncomplicated malaria caused by chloroquine-resistant *P. falciparum* (suspected either from travel history or lack of response to chloroquine) or by a species not yet identified, four treatment options are available:

- Artemether-lumefantrine
- Atovaquone-proguanil
- Oral quinine given along with other effective but slower-acting blood schizonticides such as tetracyclines (preferably doxycycline) or clindamycin
- Mefloquine

The oral route of drug administration is preferred, but intravenous preparations may be administered until oral medication can be taken. Malaria caused by chloroquine-resistant *P. vivax* can be treated by mefloquine, atovaquone-proguanil, or quinine (plus tetracyclines), all combined with a course of primaquine.

Treatment of Severe Malaria. For severe malaria (see Table 49–5 for diagnostic criteria), whatever the region where the infection was acquired, the recommended treatments are based on intravenous artesunate or quinidine plus a second drug (Figure 49–4). Artesunate, now available in the U.S. from the CDC under an investigational new drug protocol, should be followed by atovaquone-proguanil, clindamycin, or mefloquine. Quinidine must be substituted for quinine (no longer available) and combined with doxycycline, tetracycline, or clindamycin (reviewed in Griffith et al., 2007). Exchange transfusion may be of additional value in severe *P. falciparum* malaria with high levels of parasitemia (Griffith et al., 2007; Miller et al., 1989).

Children and pregnant women are the most susceptible to severe malaria. With appropriate dosage adjustments and safety precautions, the treatment of children generally is the same as for adults (pediatric dose should never exceed adult dose). However, tetracyclines should not be given to children <8 years of age except in an emergency, and atovaquone-proguanil as treatment has been approved only for children weighing >5 kg (for current information, see the CDC website and Boggild et al., 2007).

Chemoprophylaxis and Treatment During Pregnancy. Pregnant women should be urged not to travel to endemic areas if possible (Freedman, 2008). Chemoprophylaxis during pregnancy is complex, and women should evaluate with expert medical staff the benefits and risks of different strategies with regard to their particular situation.

Severe malaria during pregnancy should be treated with intravenous antimalarial treatment according to the general guidelines for severe malaria, taking into account the drugs that should be avoided during pregnancy.

Among the antimalarial treatments available in the U.S., many should not be used during pregnancy because of lack of sufficient formal safety data (antifolates, atovaquone-proguanil, and artemether-lumefantrine) or known potential risks for the fetus (tetracycline, doxycycline, primaquine, and mefloquine). The recommended treatment of uncomplicated malaria during pregnancy relies on chloroquine in areas with chloroquine-sensitive parasites, and quinine, alone (in *P. vivax* infections) or in combination with clindamycin (in *P. falciparum* infections), in areas with chloroquine-resistant parasites. Appropriate caution should be exercised when administering quinine, given the frequency of hypoglycemia as an adverse reaction in pregnant women. Pregnant patients with *P. vivax* or *P. ovale* infections should be kept under chloroquine chemoprophylaxis until delivery. After delivery, and after verifying that the patient is not G6PD deficient, treatment with primaquine should be initiated to eradicate hypnozoites. Atovaquone-proguanil and artemether-lumefantrine are not indicated because of lack of safety data. Mefloquine is also not indicated because of a possible association with increased risk of stillbirth. However, if recommended treatments are not available, these alternative options should be considered after balancing the potential benefits and risks for the fetus.

A recent study demonstrated better outcomes when pregnant women were treated with artesunate-atovaquone-proguanil compared with quinine; however, adequate safety data for the developing fetus are lacking (for review, see Dellicour et al., 2007). Another clinical trial recently showed that a standard six-dose oral artemether-lumefantrine regimen was well tolerated and safe in pregnant women with uncomplicated *falciparum* malaria, but efficacy was inferior to 7-day artesunate monotherapy and was unsatisfactory for general deployment along the Thai Cambodian border, probably resulting from low drug concentrations in later pregnancy (McGready et al., 2008). The use of antimalarial drugs in pregnancy has been well reviewed (Ward et al., 2007).

In lactating mothers, treatment with most compounds is acceptable, although chloroquine and hydroxychloroquine are the preferred agents. The use of atovaquone-proguanil is not recommended unless breast-feeding infants weigh >5 kg. Also, the breast-feeding infant should be shown to have a normal G6PD level before receiving primaquine (Schlagenhauf and Petersen, 2008).

New Targets, New Drugs

In the face of evolving drug resistance and the necessity to increase the useful life span of antimalarial drugs through combination therapies, novel and potent antimalarial drugs are urgently needed. The malaria research pipeline includes either compounds derived from known antimalarials through modification of their chemical structure (likely to retain activity against the original targets), drugs previously developed for other infectious organisms or diseases (and likely act on the same target in *Plasmodium*), or inhibitors of novel targets (exploiting differences in the biology of host and parasite). This latter strategy of drug discovery benefits from the genome sequencing projects of the different *Plasmodium* species and the human host. Perspectives in malaria chemotherapy (including new drug targets

and antimalarial drugs in discovery, preclinical and clinical phases) have recently been extensively discussed (Biot and Chibale, 2006; de Beer et al., 2009; Gardiner et al., 2009; Olliario and Wells, 2009; Wells et al., 2009).

Among the novel antimalarial drugs undergoing clinical development, two notable examples act on new metabolic pathways:

1. *TE3*, a prodrug of a bis-ammonium compound that acts on phospholipid metabolism through the inhibition of *de novo* phosphatidylcholine synthesis, combined with a putative activity on heme detoxification. This new class of compounds has shown potent *in vivo* antimalarial activity in the primate model *Aotus* and is not cross resistance *in vitro* with known antimalarials.
2. *Fosmidomycin*, which inhibits the 1-desoxy-D-xylulose-5-phosphate reductoisomerase in the mevalonate-independent pathway of isoprenoid synthesis in the apicoplast (Wiesner and Jomaa, 2007). The apicoplast, a specialized parasitoid organelle of algal origin, appears to be important for lipid and heme biosynthesis, and is a major focus of current drug development efforts (Wiesner et al., 2008). Fosmidomycin was initially developed as an antibacterial drug, but has shown efficacy in combination with clindamycin or azithromycin against *P. falciparum* malaria.

A nonexhaustive list of the molecular targets under current experimental or clinical investigation includes two clinically validated antimalarial drug targets (dihydrofolate reductase and cytochrome bc1 complex), for which inhibitors are being developed to overcome existing resistance (this strategy is also being explored to derive new 4-aminoquinolines and amino-alcohols) and a series of novel, experimental antimalarial drug targets: dihydro-orotate dehydrogenase (involved in pyrimidine synthesis), purine nucleoside phosphorylase (nucleotide synthesis), adenosine deaminase (regulation of intracellular nucleoside pools), subtilisin-like proteases (egress from erythrocytes), falcipains (hemoglobin proteolysis), histone deacetylase (DNA replication), protein kinases (signal transduction), and fatty acid biosynthesis (apicoplast lipid synthesis). The rationale focusing on these targets for antimalarial drug development can be found in the reviews cited.

CLINICAL SUMMARY

Agents available for the treatment of acute malaria due to *Plasmodium falciparum* in the U.S. have been expanded beyond previously used quinolines (chloroquine, quinine/quinidine, mefloquine) with or without adjunctive doxycycline and clindamycin, to include atovaquone-proguanil and artemisinin derivatives: artemether plus lumefantrine approved for oral use, and intravenous artesunate (available from the CDC under an IND protocol). Mefloquine is no longer considered first-line therapy for the treatment of any form of malaria in the U.S. because of adverse effects in the higher treatment doses and the availability of better tolerated alternatives. Sulfadoxine-pyrimethamine is no longer reliable due to widespread resistance and

diminished efficacy. Chloroquine resistance must be assumed for *P. falciparum* originating anywhere other than Mexico, Central America, and the Caribbean. Mefloquine resistance is likely for *P. falciparum* arising from border areas along Thailand and infections of similar geographic origin.

Chloroquine is the preferred drug in *P. vivax* infections originating in most geographic regions, with the exception of Papua New Guinea and Indonesia where resistance is prevalent. Radical therapy with primaquine is recommended to eradicate latent infection for both *P. vivax* and *P. ovale*, after normal erythrocyte levels of G6PD are confirmed. Primaquine is most effective if administered concurrently with the indicated therapy for acute malaria, although *P. vivax* in some regions seems to require higher or prolonged dosing to minimize the risk of relapse.

For malaria chemoprophylaxis, long-acting quinolines (chloroquine and mefloquine) are used, although they are of limited utility in specific geographic areas due to drug resistance. Because of a better side-effect profile, atovaquone-proguanil is often preferred. Doxycycline remains a viable option for malaria chemoprophylaxis, particularly in long-term travelers living in malaria-endemic regions where mefloquine resistance is present. Pregnant women should avoid travel to malaria endemic regions. If travel cannot be avoided and the risk of contracting malaria is considered to exceed the risk of adverse effects on fetus, chloroquine and mefloquine are the drugs of choice.

Atovaquone-proguanil is now the only recommended drug for the presumptive self-treatment of malaria.

Chemotherapy of Protozoal Infections: Amebiasis, Giardiasis, Trichomoniasis, Trypanosomiasis, Leishmaniasis, and Other Protozoal Infections

Margaret A. Phillips
and Samuel L. Stanley, Jr.

Humans host a wide variety of protozoal parasites that can be transmitted by insect vectors, directly from other mammalian reservoirs or from one person to another. Because protozoa multiply rapidly in their hosts and effective vaccines are unavailable, chemotherapy has been the only practical way to both treat infected individuals and reduce transmission. The immune system plays a crucial role in protecting against the pathological consequences of protozoal infections. Thus, opportunistic infections with protozoa are prominent in infants, individuals with cancer, transplant recipients, those receiving immunosuppressive drugs or extensive antibiotic therapy, and persons with advanced human immunodeficiency virus (HIV) infection. Treatment of protozoal infections in immunocompromised individuals is especially difficult, and the outcome is often unsatisfactory.

Most antiprotozoal drugs have been in use for years despite major advances in bioscience relevant to parasite biology, host defenses, and mechanisms of disease. Satisfactory agents for treating important protozoal infections such as African trypanosomiasis (sleeping sickness) and chronic Chagas' disease still are lacking. Many effective antiprotozoal drugs are toxic at therapeutic doses, a problem exacerbated by increasing drug resistance. Development of drug resistance also poses a serious threat to better tolerated antiprotozoal agents in current use. Unfortunately, many of these diseases afflict the poor in developing countries, and there is little economic incentive for pharmaceutical companies

to develop new antiparasitic drugs. Scientists and physicians working in this field must be creative and have turned to drugs developed originally for other indications (e.g., amphotericin and miltefosine for leishmaniasis), to investigational drugs made available directly from the Centers for Disease Control and Prevention (CDC), or to agents developed for veterinary use to discover new antiparasitic therapies.

This chapter describes important human protozoal infections other than malaria and the drugs used to treat them.

INTRODUCTION TO PROTOZOAL INFECTIONS OF HUMANS

Amebiasis. Amebiasis affects ~10% of the world's population, causing invasive disease in ~50 million people and death in ~100,000 of these annually (Stanley, 2003). In the U.S., amebiasis is seen most commonly in the states that border Mexico and among individuals living in poverty, crowded conditions, and areas with poor sanitation. Three morphologically identical but genetically distinct species of *Entamoeba* (i.e., *E. histolytica*, *E. dispar*, and *E. moshkovskii*) have been isolated from infected persons. Although the proportions vary worldwide, *E. dispar* and *E. moshkovskii* account for ~90% of human infections, with *E. histolytica* responsible for only 10%. However, only *E. histolytica* is capable of causing disease and thus requires treatment.

The organisms can be differentiated by antigen-detection enzyme-linked immunosorbent assays or by polymerase chain reaction (PCR)-based diagnostics. Humans are the only known hosts for these protozoa, which are transmitted almost exclusively by the fecal-oral route. Ingested *E. histolytica* cysts from contaminated food or water survive acid gastric contents and transform into *trophozoites* that reside in the large intestine. The outcome of *E. histolytica* infection is variable. Many individuals remain asymptomatic but excrete the infectious cyst form, making them a source for further infections. In other individuals, *E. histolytica* trophozoites invade into the colonic mucosa with resulting colitis and bloody diarrhea (amebic dysentery). In a smaller proportion of patients, *E. histolytica* trophozoites invade through the colonic mucosa, reach the portal circulation, and travel to the liver, where they establish an amebic liver abscess.

The cornerstone of therapy for amebiasis is the nitroimidazole compound metronidazole or its analogs tinidazole and ornidazole. Metronidazole and tinidazole are the only nitroimidazoles available in the U.S. and are the drugs of choice for the treatment of amebic colitis, amebic liver abscess, and any other extraintestinal form of amebiasis. Because metronidazole is so well absorbed in the gut, levels may not be therapeutic in the colonic lumen, and the drug is less effective against cysts. Hence patients with amebiasis (amebic colitis or amebic liver abscess) also should receive a luminal agent to eradicate any *E. histolytica* trophozoites residing within the gut lumen. Luminal agents are also used to treat asymptomatic individuals found to be infected with *E. histolytica*. The nonabsorbed aminoglycoside paromomycin and the 8-hydroxyquinoline compound iodoquinol are two effective luminal agents. Diloxanide furoate, previously considered the luminal agent of choice for amebiasis, is no longer available in the U.S. Nitazoxanide (ALINIA), a drug approved in the U.S. for the treatment of cryptosporidiosis and giardiasis, is also active against *E. histolytica*.

Giardiasis. Giardiasis, caused by the flagellated protozoan *Giardia intestinalis*, is prevalent worldwide and is the most commonly reported intestinal protozoal infection in the U.S. (Hlavsa et al., 2005). Infection results from ingestion of the cyst form of the parasite, which is found in fecally contaminated water or food. *Giardia* is a zoonosis, and cysts shed from animals or from infected humans can contaminate recreational and drinking water supplies. Human-to-human transmission via the fecal-oral route is especially common among children in day-care centers and nurseries, as well as among institutionalized individuals and male homosexuals.

Infection with *Giardia* results in one of three syndromes: an asymptomatic carrier state, acute self-limited diarrhea, or chronic

diarrhea. Asymptomatic infection is most common; these individuals excrete *Giardia* cysts and serve as a source for new infections. Most adults with symptomatic infection develop an acute self-limited illness with watery, foul-smelling stools, abdominal distension, and flatus. However, a significant proportion of these individuals go on to develop a chronic diarrhea syndrome (>2 weeks of illness) with signs of malabsorption (steatorrhea) and weight loss.

The diagnosis of giardiasis is made by identification of cysts or trophozoites in fecal specimens or of trophozoites in duodenal contents. Chemotherapy with a 5-day course of metronidazole usually is successful, although therapy may have to be repeated or prolonged in some instances. A single dose of tinidazole (TINDAMAX, others) probably is superior to metronidazole for the treatment of giardiasis. Paromomycin (HUMATIN, others) has been used to treat pregnant women to avoid any possible mutagenic effects of the other drugs. Nitazoxanide (ALINIA), N-(nitrothiazolyl) salicylamide, and tinidazole were approved recently for the treatment of giardiasis in immune-competent children <12 years of age. Furazolidone, previously used for the treatment of giardiasis, has been discontinued in the U.S.

Trichomoniasis. Trichomoniasis is caused by the flagellated protozoan *Trichomonas vaginalis*. This organism inhabits the genitourinary tract of the human host, where it causes vaginitis in women and, uncommonly, urethritis in men. Trichomoniasis is a sexually transmitted disease, with >200 million people infected worldwide and at least 3 million women infected in the U.S. annually. Infection with *Trichomonas* has been associated with an increased risk of acquiring HIV infection. Only *trophozoite* forms of *T. vaginalis* have been identified in infected secretions.

Metronidazole remains the drug of choice for the treatment of trichomoniasis. However, treatment failures owing to metronidazole-resistant organisms are becoming more frequent (Dunne et al., 2003). Tinidazole, another nitroimidazole that was approved recently by the FDA, appears to be better tolerated than metronidazole and has been used successfully at higher doses to treat metronidazole-resistant *T. vaginalis* (Sobel et al., 2001). Nitazoxanide shows activity against *T. vaginalis* *in vitro* but has not undergone clinical trials and is not licensed for the treatment of trichomoniasis.

Toxoplasmosis. Toxoplasmosis is a cosmopolitan zoonotic infection caused by the obligate intracellular protozoan *Toxoplasma gondii* (Montoya and Liesenfeld, 2004). Although cats and other feline species are the natural hosts, tissue cysts (*bradyzoites*) have been

recovered from all mammalian species examined. The four most common routes of infection in humans are:

- ingestion of undercooked meat containing tissue cysts
- ingestion of vegetable matter contaminated with soil containing infective *oocysts*
- direct oral contact with feces of cats shedding oocysts
- transplacental fetal infection with *tachyzoites* from acutely infected mothers

Primary infection with *T. gondii* produces clinical symptoms in ~10% of immunocompetent individuals. The acute illness is usually self-limiting, and treatment rarely is required. Individuals who are immunocompromised, however, are at risk of developing toxoplasmic encephalitis from reactivation of tissue cysts deposited in the brain. The vast majority of cases of toxoplasmic encephalitis are seen in patients with AIDS, in whom the disease is fatal if it is not recognized and treated appropriately. Clinical manifestations of congenital toxoplasmosis vary widely, but chorioretinitis, which may present decades after perinatal exposure, is the most commonly recognized finding.

The primary treatment for toxoplasmic encephalitis consists of the antifolates pyrimethamine (DARAPRIM) and sulfadiazine along with folinic acid (leucovorin). However, therapy must be discontinued in ~40% of cases because of toxicity owing primarily to the sulfa compound. In this instance, clindamycin can be substituted for sulfadiazine without loss of efficacy. Alternative regimens combining azithromycin, clarithromycin, atovaquone, or dapsone with either trimethoprim-sulfamethoxazole or pyrimethamine and folinic acid are less toxic but also less effective than the combination of pyrimethamine and sulfadiazine.

Spiramycin, which concentrates in placental tissue, is used for the treatment of acute acquired toxoplasmosis in pregnancy to prevent transmission to the fetus. If fetal infection is detected, the combination of pyrimethamine, sulfadiazine, and folinic acid is administered to the mother (only after the first 12-14 weeks of pregnancy) and to the newborn in the postnatal period. Spiramycin is not available in the U.S.

Cryptosporidiosis. Cryptosporidia are coccidian protozoan parasites that can cause diarrhea in a number of animal species, including humans (Ramirez et al., 2004). Their taxonomy is evolving, but *Cryptosporidium parvum* and the newly named *C. hominis* appear to account for almost all infections in humans.

Infectious *oocysts* in feces may be spread either by direct human-to-human contact or by contaminated water supplies, the latter being recognized as an established route of epidemic infection. Groups at risk include travelers, children in day-care facilities, male

homosexuals, animal handlers, veterinarians, and other healthcare personnel. Immunocompromised individuals are especially vulnerable. After ingestion, the mature oocyte is digested, releasing *sporozoites* that invade host epithelial cells, penetrating the cell membrane but not actually entering the cytoplasm. In most individuals, infection is self-limited. However, in AIDS patients and other immunocompromised individuals, the severity of voluminous, secretory diarrhea may require hospitalization and supportive therapy to prevent severe electrolyte imbalance and dehydration.

The most effective therapy for cryptosporidiosis in AIDS patients is restoration of their immune function through highly active antiretroviral therapy (HAART) (Chapter 59). Nitazoxanide has shown activity in treating cryptosporidiosis in immunocompetent children and is possibly effective in immunocompetent adults (Rossignol et al., 2001). Its efficacy in children and adults with HIV infection and AIDS is not clearly established, although some studies showed a modest benefit in a subset of adult men with AIDS and chronic cryptosporidiosis (Rossignol, 2006; Sears and Kirkpatrick, 2007). Nevertheless, nitazoxanide is currently the only drug approved for the treatment of cryptosporidiosis in the U.S.

Trypanosomiasis. African trypanosomiasis, or “sleeping sickness,” is caused by subspecies of the hemoflagellate *Trypanosoma brucei* that are transmitted by bloodsucking tsetse flies of the genus *Glossinia* (Barrett et al., 2007; Kennedy, 2008; Stuart et al., 2008). Largely restricted to sub-Saharan Africa, the infection causes serious human illness and also threatens livestock (*nagana*), leading to protein malnutrition. In humans, the infection is fatal unless treated. Owing to strict surveillance, vector control, and early therapy, the prevalence of African sleeping sickness declined to its nadir in the early 1960s. However, relaxation of these measures, together with massive population displacement and breakdowns in societal infrastructure owing to armed conflict, led to a resurgence of this disease in the 1990s. An estimated 500,000 Africans carry the infection, and >50 million people are at risk for the disease. It is extremely rare in travelers returning to the U.S. and can be difficult to diagnose in its more chronic form (Lejon et al., 2003).

The parasite is entirely extracellular, and early human infection is characterized by the finding of replicating parasites in the bloodstream or lymph without CNS involvement (stage 1); stage 2 disease is characterized by CNS involvement (Blum et al., 2006). Symptoms of early-stage disease include febrile illness, lymphadenopathy, splenomegaly, and occasional myocarditis that result from systemic dissemination of the parasites. There are two types of African trypanosomiasis, the East African (Rhodesian) and West

African (Gambian), caused by *T. brucei rhodesiense* and *T. brucei gambiense*, respectively. *T. brucei rhodesiense* produces a progressive and rapidly fatal form of disease marked by early involvement of the CNS and frequent terminal cardiac failure; *T. brucei gambiense* causes illness that is characterized by later involvement of the CNS and a more long-term course that progresses to the classical symptoms of sleeping sickness over months to years. Neurological symptoms include confusion, poor coordination, sensory deficits, an array of psychiatric signs, disruption of the sleep cycle, and eventual progression into coma and death.

Four drugs are used for the treatment of sleeping sickness, and only one, eflornithine, has been developed since the 1950s (Barrett et al., 2007; Croft, 2008; Fries and Fairlamb, 2003; Kennedy, 2008; Stuart et al., 2008). Standard therapy for early-stage disease is pentamidine for *T. brucei gambiense* and suramin for *T. brucei rhodesiense*. Both compounds must be given parenterally over long periods and are not effective against late-stage disease. The CNS phase has traditionally been treated with melarsoprol (available from the CDC), which is a highly toxic agent that causes a fatal reactive encephalopathy in 2-10% of treated patients. Moreover, lack of response to this agent is leading to increasing numbers of treatment failures (Pepin and Mpia, 2005, Robays et al., 2008b). Eflornithine, which was developed originally as an anticancer agent and approved as an orphan drug, offers the only alternative for the treatment of late-stage disease. This compound is an inhibitor of ornithine decarboxylase, a key enzyme in polyamine metabolism. It has shown marked efficacy against both early and late stages of human *T. brucei gambiense* infection; however, it is ineffective as monotherapy for infections of *T. brucei rhodesiense*. Notably, eflornithine has significantly fewer side effects than melarsoprol and is more effective than melarsoprol for treatment of late-stage Gambian trypanosomiasis, suggesting that eflornithine is the best available first-line treatment for this form of the disease (Chappuis, 2007). Although eflornithine is expensive and difficult to administer, nifurtimox-eflornithine combination therapy (NECT) allows a shorter exposure to eflornithine with good efficacy and a reduction in adverse events (Priotto et al., 2009).

Recent efforts by not-for-profit agencies have fostered significant new efforts to develop new therapies for the neglected tropical diseases including African sleeping sickness, Chagas' disease, and Leishmaniasis (Croft, 2007; Frearson et al., 2007; Nwaka and Hudson, 2006; Pink et al., 2005; Stuart et al., 2008). These efforts involve partnerships with academic and industrial groups. The recent increase in high throughput screening centers within academic groups with interest in developing drugs for these applications is also helping to fuel discovery of lead compounds. The genome data is

being exploited to develop publicly accessible databases that organize data relevant to drug discovery projects (Aguero et al., 2008). From these efforts an orally available novel diamidine, pafuramidine maleate (DB289), was recently advanced to phase IV trials for the treatment of early-stage (stage 1) sleeping sickness, representing the only new clinical candidate since the discovery of eflornithine (Mdachi et al., 2009). Although the trials were stopped due to toxicity issues (Kennedy, 2008), the discovery of pafuramidine provides hope that the current approaches and increased effort will yield new clinical entities for these diseases in the near future.

American trypanosomiasis, or *Chagas' disease*, a zoonotic infection caused by *Trypanosoma cruzi*, affects ~15 million people from Mexico to Argentina and Chile, with 50,000-200,000 new infections added each year (Bern et al., 2007; Stuart et al., 2008; Tarleton et al., 2007). The chronic form of the disease in adults is a major cause of cardiomyopathy, megaesophagus, megacolon, and death. Blood-sucking triatomid bugs infesting poor rural dwellings most commonly transmit this infection to young children; transplacental transmission also may occur in endemic areas.

Reactivation of disease also may occur in patients who are immunosuppressed after organ transplantation or because of infection (e.g., AIDS, leukemia, and other neoplasias). Occurrences of *T. cruzi* infection in transplant patients or through blood transfusions have been reported in the U.S., and as a consequence the FDA-approved diagnostic blood screening for the parasite (Bern et al., 2008). Reports of autochthonous Chagas cases are also on the rise in the U.S. Acute infection is evidenced by a raised tender skin nodule (*chagoma*) at the site of inoculation; other signs may be absent or range from fever, adenitis, skin rash, and hepatosplenomegaly to, albeit rarely, acute myocarditis, and death. Invading metacyclic *trypomastigotes* penetrate host cells, especially macrophages, where they proliferate as *amastigotes*. These then differentiate into *trypomastigotes* that enter the bloodstream. Circulating *trypomastigotes* do not multiply until they invade other cells or are ingested by an insect vector during a blood meal. After recovery from the acute infection that lasts a few weeks to months, individuals usually remain asymptomatic for years despite sporadic parasitemia. During this period, their blood can transmit the parasites to transfusion recipients and accidentally to laboratory workers. Approximately 20-30% of infected individuals eventually progress to clinically evident disease that is characterized by chronic disease of the heart and GI tract as they age. Progressive destruction of myocardial cells and neurons of the myenteric plexus results from the special tropism of *T. cruzi* for muscle cells. Recent studies with improved techniques indicate the presence of *T. cruzi* at sites of cardiac lesions, and it is now well recognized that parasite persistence is linked directly to pathology and disease outcome (Tarleton, 2003). Whether an undefined autoimmune response also contributes to the pathogenesis of Chagas' disease is unknown; however, the data indicate that immunological defenses, especially cell-mediated immunity, do modulate the course of disease.

Two nitroheterocyclic drugs, nifurtimox (available from the CDC) and benznidazole are used to treat

this infection (Bern et al., 2007; Croft, 2008; Tarleton et al., 2007). Both agents suppress parasitemia and can cure the acute phase of Chagas' disease in 60-80% of cases; however, both drugs are toxic and must be taken for long periods. A long-term clinical trial with results expected in 2011 (BENEFIT) is currently underway to provide clarification of the role of treatment in modulating disease progression and preventing death (<http://clinicaltrials.gov/show/NCT00123916>; Marin-Neto et al., 2008). Field isolates vary with respect to their susceptibility to nifurtimox and benznidazole. Moreover, cross-resistance to both compounds can be induced in the laboratory (Wilkinson et al., 2008).

Clearly, new drugs with better potency against parasites in the chronic phase and with reduced toxicities are needed. A key factor in new drug development for Chagas' disease is the need for better methods to assess parasitological cure. Several important reports documenting significant advances in this area have recently been published (Bustamante et al., 2008; Cooley et al., 2008). Additionally, some promising strides toward the development of new agents have been made. Inhibitors of an essential protease, cruzipain, have anti-parasite activity, and one (K777) is in preclinical development for the treatment of Chagas' disease (Doyle et al., 2007). In the absence of new drugs, however, alternative measures such as improved vector control and housing accommodations have been used to reduce the transmission of Chagas' disease substantially in Brazil, Chile, and Venezuela (World Health Organization, 1999).

Leishmaniasis. Leishmaniasis is a complex vector-borne zoonosis caused by ~20 different species of obligate intramacrophage protozoa of the genus *Leishmania* (Chappuis et al., 2007; Croft 2008; Stuart et al., 2008). Small mammals and canines generally serve as reservoirs for these pathogens, which can be transmitted to humans by the bites of some 30 different species of female phlebotomine sandflies.

Various forms of leishmaniasis affect people in southern Europe and many tropical and subtropical regions throughout the world. Flagellated extracellular free *promastigotes*, regurgitated by feeding flies, enter the host, where they attach to and become phagocytized by tissue macrophages. These transform into *amastigotes*, which reside and multiply within phagolysosomes until the cell bursts. Released amastigotes then propagate the infection by invading more macrophages. Amastigotes taken up by feeding sandflies transform back into promastigotes, thereby completing the transformation cycle. The particular localized or systemic disease syndrome caused by *Leishmania* depends on the species or subspecies of infecting parasite, the distribution of infected macrophages, and especially the host's immune response. In increasing order of systemic involvement and potential clinical severity, major syndromes of human leishmaniasis have been classified into *cutaneous*, *mucocutaneous*, *diffuse cutaneous*, and *visceral (kala azar)* forms. Leishmaniasis increasingly is becoming recognized as an AIDS-associated opportunistic infection.

The classification, clinical features, course, and chemotherapy of human leishmaniasis syndromes as well as the biochemistry and immunology of the parasite and host germane to chemotherapy have been recently reviewed (Chappuis et al., 2007; Croft and Coombs, 2003; Stuart et al., 2008). Cutaneous forms of leishmaniasis generally are self-limiting, with cures occurring in 3-18 months after infection. However, this form of the disease can leave disfiguring scars. The mucocutaneous, diffuse cutaneous, and visceral forms of the disease do not resolve without therapy. Visceral leishmaniasis caused by *L. donovani* is fatal unless treated.

The list of current drugs useful for the treatment of all forms of leishmaniasis has been described (Alvar et al., 2006; Croft, 2008; Olliaro et al., 2005). The classic therapy for all species of *Leishmania* is pentavalent antimony (sodium antimony gluconate; sodium stibogluconate; PENTOSTAM); resistance to this compound has led to widespread failure of this drug in India, although it remains useful in other parts of the world. As an alternative, liposomal amphotericin B is a highly effective agent for visceral leishmaniasis, and it is currently the drug of choice for antimony-resistant disease (Chappuis et al., 2007) (Chapter 57). Importantly, treatment of leishmania has undergone major changes owing to the success of the first orally active agent, miltefosine, in clinical trials (Berman, 2008; Bhattacharya et al., 2007). Miltefosine was approved in India for the treatment of visceral leishmaniasis in 2002. The drug also appears to have promise for the treatment of the cutaneous disease and for the treatment of dogs, which serve as an important animal reservoir of the disease (Berman, 2008). Paromomycin has been used with success as a parenteral agent for visceral disease (Sundar et al., 2007), and topical formulations of paromomycin have efficacy against cutaneous disease. Pentamidine may also be used for cutaneous disease (Croft, 2008).

Other Protozoal Infections. Just a few of the many less common protozoal infections of humans are highlighted here.

Babesiosis, caused by either *Babesia microcoti* or *B. divergens*, is a tick-borne zoonosis that superficially resembles malaria in that the parasites invade erythrocytes, producing a febrile illness, hemolysis, and hemoglobinuria. This infection usually is mild and self-limiting but can be severe or even fatal in asplenic or severely immunocompromised individuals. Currently recommended therapy is with a combination of clindamycin and quinine for severe disease, and the combination of azithromycin and atovaquone for mild or moderate infections.

Balantidiasis, caused by the ciliated protozoan *Balantidium coli*, is an infection of the large intestine that may be confused with amebiasis. Unlike amebiasis, however, this infection usually responds to tetracycline therapy.

Isospora belli, a coccidian parasite, causes diarrhea in AIDS patients and responds to treatment with trimethoprim-sulfamethoxazole. *Cyclospora cayentanensis*, another coccidian parasite, causes self-limited diarrhea in normal hosts and can cause prolonged diarrhea in individuals with AIDS. It is susceptible to trimethoprim-sulfamethoxazole.

Microsporidia are spore-forming unicellular eukaryotic fungal parasites that can cause a number of disease syndromes, including diarrhea in immunocompromised individuals. Infections with microsporidia of the *Encephalitozoon* genus, including *E. hellum*, *E. intestinalis*, and *E. cuniculi*, have been treated successfully with albendazole, a benzimidazole derivative and inhibitor of β -tubulin polymerization (Gross, 2003) (Chapter 51). Immunocompromised individuals with intestinal microsporidiosis due to *E. bienersi* (which does not respond as well to albendazole) have been treated successfully with the antibiotic fumagillin (Molina et al., 2002).

ANTI-PROTOZOAL DRUGS

The myriad agents used to treat nonmalarial protozoal diseases are presented alphabetically.

Amphotericin B

The pharmacology, formulation, and toxicology of amphotericin B are presented in Chapter 57. Only those features of the drug pertinent to its use in leishmaniasis are described here.

Antiprotozoal Effects. In 1997, the FDA approved liposomal amphotericin B (AMBISOME) for the treatment of visceral leishmaniasis. Amphotericin B is a highly effective antileishmanial agent that cures >90% of the cases of visceral leishmaniasis in clinical studies, and it has become the drug of choice for antimonial-resistant cases (Bern et al., 2006; Croft, 2008; Olliaro et al., 2005). It is considered a second-line drug for cutaneous or mucosal leishmaniasis, where it has been shown effective for the treatment of immunocompromised patients (Alvar et al., 2006). However, because cutaneous leishmaniasis is typically self-limiting, the drug has not been evaluated for treatment of a broader range of patient populations. The lipid preparations of the drug have reduced toxicity, but the cost of the drug and the difficulty of administration remain a problem in endemic regions.

The mechanism of action of amphotericin B against leishmania is similar to the basis for the drug's antifungal activities (Chapter 57). Amphotericin complexes with ergosterol precursors in the cell membrane, forming pores that allow ions to enter the cell. Leishmania has similar sterol composition to fungal pathogens, and the drug binds to these sterols preferentially over the host cholesterol. No significant resistance to the drug has been encountered after nearly 30 years of use as an antifungal agent.

Therapeutic Uses. Numerous dosing schedules have been reported for the treatment of visceral leishmaniasis, with most achieving high cure rates and good safety (Alvar et al., 2006; Bern et al., 2006; Olliaro et al., 2005). Typical schemes of 10-20 mg/kg total dose given in divided doses over 10-20 days by intravenous infusion have yielded >95% cure rates. In the U.S., the FDA recommends 3 mg/kg intravenously on days 1-5, 14, and 21 for a total dose of 21 mg/kg (Meyerhoff, 1999). Shorter courses of the drug have been tested with good efficacy and provide a potential alternative with lower cost,

although only a limited number of patients have been tested: Cure rates of 89-91% were observed for single doses of 3.75, 5, and 7.5 mg/kg. Recent data suggest that a single dose of 5 mg/kg followed by 7-14 days treatment with oral miltefosine was effective at curing visceral leishmaniasis, and this dosing scheme warrants additional study (Sundar et al., 2008).

Chloroquine

The pharmacology and toxicology of chloroquine are presented in Chapter 49 (anti-malarials). Chloroquine does have an FDA-approved use for *extra-intestinal amebiasis* at a dose of 1 g (600 mg base) daily for 2 days, followed by 500 mg daily for at least 2-3 weeks. Treatment is usually combined with an effective intestinal amebicide. The interested reader should consult the 11th edition of this book for further details.

Diloxanide Furoate

Diloxanide furoate (FURAMIDE, others) is the furoate ester of diloxanide, a derivative of dichloroacetamide. Diloxanide furoate is a very effective luminal agent for the treatment of *E. histolytica* infection but is no longer available in the U.S. The interested reader should consult the 10th edition of this book for further details on this agent.

Eflornithine

Eflornithine (α -D,L difluoromethylornithine, DFMO, ORNIDYL) is an irreversible catalytic (suicide) inhibitor of ornithine decarboxylase, the enzyme that catalyzes the first and rate-limiting step in the biosynthesis of polyamines (Casero and Marton, 2007). The polyamines—putrescine, spermidine, and in mammals, spermine—are required for cell division and for normal cell differentiation. In trypanosomes, spermidine additionally is required for the synthesis of trypanothione, which is a conjugate of spermidine and glutathione that replaces many of the functions of glutathione in the parasite cell (Fries and Fairlamb, 2003).

Both in animal models and *in vitro*, eflornithine arrests the growth of several types of tumor cells, providing the basis for its clinical evaluation as an antitumor agent. The discovery that eflornithine cured rodent infections with *T. brucei* first focused attention on protozoal polyamine biosynthesis as a potential target for chemotherapeutic attack (Bacchi et al., 1980). Eflornithine currently is used to treat West African (Gambian) trypanosomiasis caused by *T. brucei gambiense* (Balasegaram et al., 2006a, 2009; Chappuis,

2007, Chappuis et al., 2005; Priotto et al., 2006, 2008; Robays et al., 2008a). In contrast, the drug is largely ineffective for East African trypanosomiasis. Eflornithine's difficult treatment regimen is the primary limitation to its use in the field. However, the negotiation of the World Health Organization (WHO) of a stable supply of eflornithine through 2011 has led to the widespread availability of the drug and to its use in control and research programs run by world health agencies.

Eflornithine is both safer and more efficacious than melarsoprol for late-stage Gambiense sleeping sickness, and it is now the recommended first-line treatment for this disease when adequate care can be provided for its administration. Eflornithine is no longer available for systemic use in the U.S. but is available for treatment of Gambian trypanosomiasis by special request from the CDC.

Antitrypanosomal Effects. The effects of eflornithine have been evaluated both on drug-susceptible and drug-resistant *T. brucei* *in vitro* and in infections with these parasites in rodent models (reviewed in: Barrett et al., 2007). Eflornithine is a cytostatic agent that has multiple biochemical effects on trypanosomes, all of which are a consequence of polyamine depletion. The polyamine putrescine is depleted to undetectable levels, intracellular levels of spermidine and trypanothione are reduced by 25-50%, and methionine metabolism is altered. Depletion of the polyamines, or of trypanothione, would be expected to be lethal to the cells based on genetic studies that have disrupted the biosynthetic genes in the pathway. As a consequence, macromolecular biosynthesis is depressed, and the parasites transform from the long, slender dividing forms into the short, stumpy nonreplicating forms. These latter parasites are unable to synthesize variable cell surface glycoprotein and eventually are cleared by the immune system.

The molecular mechanism of eflornithine action clearly is inhibition of ornithine decarboxylase. Eflornithine irreversibly inhibits both mammalian and trypanosomal ornithine decarboxylases, thereby preventing the synthesis of putrescine, a precursor of polyamines needed for cell division. Eflornithine inactivates the enzyme through covalent labeling of an active-site cysteine residue, and an X-ray structure of the *T. brucei* enzyme bound to the drug has been reported (Grishin et al., 1999). A number of studies demonstrate conclusively that ornithine decarboxylase is the target of eflornithine action that leads to cell death. Mutant bloodstream trypanosomes lacking ornithine decarboxylase or wild-type trypanosomes treated with eflornithine cannot replicate, and mice inoculated with these null parasites become resistant to infection by wild-type parasites (Mutomba et al., 1999). The product of the ornithine decarboxylase reaction, putrescine, rescues the growth deficit in both the mutant parasites and eflornithine-treated cells. The null mutant parasites grown with putrescine are not affected by eflornithine, demonstrating the selectivity of the drug for the target enzyme.

The mechanisms of selective toxicity between the host and parasite, or between the different species of *T. brucei*, are less clear (Barrett et al., 2007). The parasite and human enzymes are equally susceptible to inhibition by eflornithine; however, the mammalian enzyme is turned over rapidly, whereas the parasite enzyme is stable, and this difference likely plays a role in the selective toxicity. In addition, mammalian cells may be able to replenish polyamine pools through uptake of extracellular polyamines, whereas the slender bloodstream forms of human trypanosomes divide within human blood, which contains only very low levels of these essential compounds. Further, the parasites lack efficient transport mechanisms.

T. brucei rhodesiense cells are less sensitive to eflornithine inhibition than *T. brucei gambiense* cells, and studies *in vitro* suggest that the effective doses are increased by 10-20 times in the refractory cells. The molecular basis for the higher dose requirement in *T. brucei rhodesiense* is still poorly understood; however, it has been postulated to involve differences both in enzyme stability and in the metabolism of *S*-adenosylmethionine compared with the sensitive *T. brucei gambiense* cell lines.

Absorption, Fate, and Excretion. Eflornithine is given by intravenous infusion. The drug does not bind to plasma proteins but is well distributed and penetrates into the CSF, where it is estimated that concentrations of at least 50 μM must be reached to clear parasites (Burri and Brun, 2003). Despite the ability of the drug to penetrate the blood-brain barrier, studies in mice suggest that eflornithine crosses the healthy blood-CNS interface poorly, and that it is the breakdown of this barrier caused by *T. brucei* infection that allows greater penetration to occur (Sanderson et al., 2008). In these studies, suramin enhanced eflornithine uptake into the CNS, suggesting that this combination might lead to lower dose requirements for eflornithine. Renal clearance after intravenous administration is rapid (2 mL/minute per kilogram), with >80% of the drug cleared by the kidney largely in unchanged form (Burri and Brun, 2003). There is some evidence that eflornithine displays dose-dependent pharmacokinetics at the highest doses used clinically.

Therapeutic Uses. Eflornithine is used for the treatment of late-stage West African trypanosomiasis caused by *T. brucei gambiense* (Balasegaram et al., 2006a, 2008; Chappuis, 2007; Chappuis et al., 2005; Priotto et al., 2006, 2008; Robays et al., 2008a). Most patients in the reported studies had advanced disease with CNS complications. The preferred regimen for adult patients was found to be 100 mg/kg given intravenously every 6 hours as a 2-hour infusion for 14 days. Virtually all patients improved on this regimen unless they were extremely ill, and the WHO and Médecins Sans Frontières report improved rates >90%. The probability of disease-free survival 2 years after treatment was calculated to be 0.88 in one study (Priotto et al., 2008) and the case-fatality rate of 1% for eflornithine was the lowest reported for second-stage sleeping sickness in any study (Chappuis et al., 2005). Children (<12 years of age) received higher doses of eflornithine (150 mg/kg given intravenously every 6 hours for 14 days) based on prior findings that eflornithine trough concentrations in both the CSF and blood were significantly lower among children than in adults (Milord et al., 1993). Patients who failed therapy in this study tended to have trough CSF concentrations <50 μM . Equal doses of eflornithine were less effective when given by the oral route probably because of limited bioavailability. The problem cannot be overcome simply by increasing the oral dose because of ensuing osmotic diarrhea.

Eflornithine has proven to be less successful for treating AIDS patients with West African trypanosomiasis, presumably because host defenses play a critical role in clearing drug-treated *T. brucei gambiense* from the bloodstream.

The standard course eflornithine treatment regime is very challenging to administer in rural settings in Africa. A randomized phase III trial testing nifurtimox-eflornithine combination therapy for second-stage *T. brucei gambiense* suggested that the treatment course for eflornithine could be reduced to 7 days in combination with nifurtimox. A recently concluded clinical trial confirms the efficacy of

nifurtimox used in combination with eflornithine (NECT) (Priotto, 2009). This new protocol uses a shortened course of eflornithine in combination with oral nifurtimox, with dosing as follows: 400 mg/kg per day given intravenously every 12 h by 2 h infusion for 7 days plus nifurtimox (orally at 15 mg/kg per day in 3 divided doses [every 8 h]) for 10 days. This combination is logistically easier to administer and it requires less eflornithine, which is expensive to synthesize. Importantly, compared to eflornithine alone, NECT achieves a higher cure rate (96.5% vs. 91.5%). NECT has been added to the WHO essentials medicines list and is likely to become the front line treatment for the indication. Drug combination may also reduce the potential for eflornithine resistance to develop in the field. Given the paucity of drugs available for the treatment of late stage disease, the development of eflornithine resistance would represent a very serious problem.

Toxicity and Side Effects. Eflornithine is reported to cause adverse reactions in most of the treated patients (Balasegaram et al., 2008; Burri and Brun, 2003; Chappuis, 2007; Chappuis et al., 2005; Priotto et al., 2006, 2008); however, they are generally reversible on withdrawal of the drug. Abdominal pain, both mild and moderate, and headache were the predominant complaints followed by reactions at the injection sites. Tissue infections and pneumonia were also observed. The most severe reactions reported for one study, with numbers given for events classified as major, included fever peaks (6%), seizures (4%), and diarrhea (2%) (Priotto et al., 2008). The case fatality rate for eflornithine (~1.2%) is significantly lower than for melarsoprol (4.9%), and overall eflornithine is superior to melarsoprol with respect to both safety and efficacy. Reversible hearing loss can occur after prolonged therapy with oral doses. Although this has been a problem in the use of eflornithine for cancer chemotherapy, hearing loss has not been observed during the treatment of sleeping sickness.

Therapeutic doses of eflornithine are large and require coadministration of substantial volumes of intravenous fluid. This poses significant practical limitations in remote settings and can cause fluid overload in susceptible patients. For NECT, the severe adverse events were reduced compared to eflornithine alone (14% vs. 29%), and treatment related deaths were also fewer (0.7% vs. 2%) (Priotto, 2009). Both NECT and eflornithine alone showed significantly fewer treatment-related deaths than what has been reported for melarsoprol. With eflornithine alone, most reported deaths were due to septic shock. The typical side effects of eflornithine (diarrhea, fever, infection, hypertension, and skin rash) were reduced in the NECT arm of the study, however more patients experienced tremors, nausea and vomiting.

Emetine and Dehydroemetine

The use of emetine, an alkaloid derived from *ipecac* ("Brazil root"), as a direct-acting systemic amebicide dates from the early part of the 20th century. Dehydroemetine (MEBADIN) has similar pharmacological properties but is considered to be less toxic. Although both drugs were once used widely to treat severe invasive intestinal amebiasis and extraintestinal amebiasis, they have been replaced by metronidazole, which is as effective and far safer. Thus, emetine and dehydroemetine should not be used unless metronidazole is contraindicated. In the U.S., dehydroemetine is available under an investigational new drug protocol from the CDC drug service. Details of the pharmacology and toxicology of emetine and dehydroemetine are presented in the fifth and earlier editions of this book.

Fumagillin

Fumagillin (FUMIDIL B, others) is an acyclic polyene macrolide produced by the fungus *Aspergillus fumigatus*.

Both fumagillin and its synthetic analog TNP-470 are toxic to microsporidia, and fumagillin is used widely to treat the microsporidian *Nosema apis*, a pathogen of honey bees. Fumagillin and TNP-470 also inhibit angiogenesis and suppress tumor growth, and TNP-470 is undergoing clinical trials as an anticancer agent (Chapter 61). Human methionine-aminopeptidase-2 (MetAP2) has been identified as the target for the drugs' antitumor activity, and a gene encoding MetAP2 has been identified in the genome of the microsporidian parasite *E. cuniculi*.

Fumagillin is used topically to treat keratoconjunctivitis caused by *E. hellem* at a dose of 3-10 mg/mL in a balanced salt suspension. For the treatment of intestinal microsporidiosis caused by *E. bienersi*, fumagillin was used at a dose of 20 mg orally three times daily for 2 weeks (Molina et al., 2002). Adverse effects of fumagillin may include abdominal cramps, nausea, vomiting, and diarrhea. Reversible thrombocytopenia and neutropenia also have been reported (Molina et al., 2002). Fumagillin has not been approved for the systemic treatment of microsporidia infection in the U.S.

8-Hydroxyquinolines

The halogenated 8-hydroxyquinolines iodoquinol (diiodohydroxyquin) and clioquinol (iodochlorhydroxyquin) have been used as luminal agents to eliminate intestinal colonization with *E. histolytica*. Iodoquinol (YODOXIN) is the safer of the two agents and is the only one available for use as an oral agent in the U.S. When used at appropriate doses (never to exceed 2 g/day and duration of therapy not greater than 20 days in adults), adverse effects are unusual. However, the use of these drugs, especially at doses exceeding 2 g/day, for long periods is associated with significant risk. The most important toxic reaction, which has been ascribed primarily to clioquinol, is subacute myelo-optic neuropathy. This disease is a myelitis-like illness that was first described in epidemic form (thousands of afflicted patients) in Japan; only sporadic cases have been reported elsewhere, but the actual prevalence is undoubtedly higher. Peripheral neuropathy is a less severe manifestation of neurotoxicity owing to these drugs. Administration of iodoquinol in high doses to children with chronic diarrhea has been associated with optic atrophy and permanent loss of vision.

Because of its superior adverse-event profile, paromomycin is preferred by many authorities as the luminal agent used to treat amebiasis; however, iodoquinol is a reasonable alternative. Iodoquinol is used in combination with metronidazole to treat

individuals with amebic colitis or amebic liver abscess but may be used as a single agent for asymptomatic individuals found to be infected with *E. histolytica*. For adults, the recommended dose of iodoquinol is 650 mg orally three times daily for 20 days, whereas children receive 10 mg/kg of body weight orally three times a day (not to exceed 1.95 g/day) for 20 days.

The pharmacology and toxicology of the 8-hydroxyquinolines are described in greater detail in the fifth and earlier editions of this book.

Melarsoprol

In 1949, Friedheim demonstrated that melarsoprol, the dimercaptopropanol derivative of melarsen oxide, was effective in the treatment of late-stage trypanosomiasis. It was considerably safer than other trypanocides available at the time. Despite the fact that it causes an often fatal encephalopathy in 2-10% of the patients, melarsoprol has remained the only drug for the treatment of late (CNS) stages of East African trypanosomiasis caused by *T. brucei rhodesiense* (Barrett et al., 2007; Croft, 2008; Kennedy, 2008). Although melarsoprol is also effective against late-stage West African trypanosomiasis caused by *T. brucei gambiense*, eflornithine has become the first-line treatment for this disease. The continued use of melarsoprol in the field is indicative of the paucity of alternative therapies for late-stage sleeping sickness.

MELARSOPROL

Melarsoprol (MEL B; ARSOBAL), consisting of two arsenic-containing stereoisomers in a 3:1 ratio, is insoluble in water and is supplied as a 3.6% (w/v) solution in propylene glycol for intravenous administration. It is available in the U.S. only from the CDC.

Antiprotozoal Effects. Melarsoprol has many wide-ranging nonspecific effects on both the trypanosome and host cells (Fries and Fairlamb, 2003). Melarsoprol is a prodrug and is metabolized rapidly ($t_{1/2} = 30$ minutes) to melarsen oxide, the active form of the drug. Arsenic-oxides react avidly and reversibly with vicinal sulfhydryl groups, including those of proteins, and thereby inactivate a great number and variety of enzymes. The same nonspecific mechanisms by which melarsoprol is lethal to parasites are probably responsible for its toxicity to host tissues. The basis for the trypanocidal action of melarsoprol is not understood, probably owing to its high reactivity with many biomolecules. Disruption of energy metabolism by inhibition of glycolytic enzyme was long thought to explain its trypanocidal activity. Other evidence suggests, however, that this is not a primary effect. Melarsoprol reacts with trypanothione, the spermidine-glutathione adduct that substitutes for glutathione in these parasites. Binding of melarsoprol to trypanothione results in formation

of melarsen oxide-trypanothione adduct (Mel T), a compound that is a potent competitive inhibitor of trypanothione reductase, the enzyme responsible for maintaining trypanothione in its reduced form. Both the sequestering of trypanothione and the inhibition of trypanothione reductase would be expected to have lethal consequences to the cell. However, critical evidence directly linking melarsoprol's action on the trypanothione system to parasite death is still lacking.

The number of treatment failures owing to increasing resistance of trypanosomes to melarsoprol has risen sharply in recent years. Failure rates of 20-27% in Uganda, Angola, and the Congo have been reported (Burri and Keiser, 2001; Pepin and Mpia, 2005; Robays et al., 2008b). *In vitro* analysis of field isolates indicates that resistant strains are an order of magnitude less sensitive to the drug than sensitive strains (Brun et al., 2001). However, not all treatment failures can be linked to drug resistance, suggesting that additional factors contribute to lack of efficacy (Maina et al., 2007).

Resistance to melarsoprol is likely to involve transport defects, although the situation is complicated by evidence for multiple transport mechanisms of the drug (de Koning, 2008). The best characterized transporter is an unusual adenine-adenosine transporter termed the *P2 transporter* that has activity on melarsoprol as well as pentamidine and berenil. Cross-resistance between these compounds is observed frequently. Point mutations in this transporter are found in melarsoprol-resistant field isolates. However, null mutant cell lines that lack this transporter were resistant to berenil but had only two-fold resistance to melarsoprol and pentamidine. Another transporter, HAPT1, has been identified, and the concomitant loss of both the *P2* and HAPT transporters led to high-level cross-resistance to both melarsen and pentamidine (de Koning, 2008).

Absorption, Fate, and Excretion. Melarsoprol is always administered intravenously. A small but therapeutically significant amount of the drug enters the CSF and has a lethal effect on trypanosomes infecting the CNS. The compound is excreted rapidly, with 70-80% of the arsenic appearing in the feces.

Therapeutic Uses. Melarsoprol is the only effective drug available for treatment of the late meningoencephalitic stage of East African (Rhodesian) trypanosomiasis, which is 100% fatal if untreated. The drug is also effective in the early hemolymphatic stage of these infections, but because of its toxicity, it is reserved for therapy of late-stage infections. Patients infected with *T. brucei rhodesiense* who relapse after a course of melarsoprol usually respond to a second course of the drug. In contrast, patients infected with *T. brucei gambiense* who are not cured with melarsoprol rarely benefit from repeated treatment with this drug. Such patients often respond well to eflornithine.

The original treatment schedules for melarsoprol were derived empirically >40 years ago; new clinical trials have been undertaken with dosage schemes based on a better knowledge of melarsoprol pharmacokinetics, and these have yielded new recommendations for treatment protocols (Pepin and Mpia, 2006; Schmid et al., 2005). Melarsoprol is administered by slow intravenous injection, with care to avoid leakage into the surrounding tissues because the drug is intensely irritating. For *T. brucei gambiense* a continuous 10-day course of 2.2 mg/kg per day is equivalent to the longer course treatment and is now recommended (Pepin and Mpia, 2006; Schmid et al., 2005). The 10-day therapy has not reduced the incidence of

encephalopathy (the treatment-related death rate was still 5.9% for this protocol), but it has the advantage of easier administration, and in an area where hospitalization is difficult, this is particularly important. These studies further demonstrated that historically used graded dosing schemes led to increased incidence of convulsions and reduced efficacy; thus these schedules should not be used for the treatment of *T. brucei gambiense* (Pepin and Mpia, 2006).

The 10-day therapy is currently undergoing clinical testing for *T. brucei rhodesiense*. However, until clinical data are available to support a dosing change, patients with Rhodesian sleeping sickness should instead receive one of several older schedules developed for this disease. A number of dosing schemes are in use or recommended by various agencies, including the WHO (1998) and Médecins Sans Frontières (2007). In the U.S., the CDC recommends the following treatment schedule: three series of three daily doses with a 7-day rest period between series. The first series gives 1.8, 2.7, and 3.6 mg/kg on days 1, 2, and 3, respectively. The subsequent series are 3.6 mg/kg daily. Encephalopathy develops more frequently in patients with *T. brucei rhodesiense* compared to *T. brucei gambiense*, possibly related to this graded dosing regimen. Concurrent administration of prednisolone is frequently employed throughout the treatment course; prednisolone it is not proven to reduce the frequency of reactive encephalopathy (Schmid et al., 2005) but it does help to control hypersensitivity reactions that occur most often during the second or subsequent courses of melarsoprol therapy.

Toxicity and Side Effects. Treatment with melarsoprol is associated with significant toxicity and morbidity (Balasegaram et al., 2006b; Burri and Brun, 2003; Kennedy, 2008; Schmid et al., 2005). A febrile reaction often occurs soon after drug injection, especially if parasitemia is high. The most serious complications involve the nervous system. A reactive encephalopathy occurs in ~5-10% of patients, leading to death in about half of these. The cause is unknown, but encephalopathy, when it occurs, typically develops 9-11 days after treatment starts (Schmid et al., 2005). Peripheral neuropathy, noted in ~10% of patients receiving melarsoprol, probably is due to a direct toxic effect of the drug. Hypertension and myocardial damage are not uncommon, although shock is rare. Albuminuria occurs frequently, and occasionally the appearance of numerous casts in the urine or evidence of hepatic disturbances may necessitate modification of treatment. Vomiting and abdominal colic also are common, but their incidence can be reduced by injecting melarsoprol slowly into the supine, fasting patient. The patient should remain in bed and not eat for several hours after the injection is given.

Precautions and Contraindications. Melarsoprol should be given only to patients under hospital supervision so that the dosage regimen may be modified if necessary. Initiation of therapy during a febrile episode has been associated with an increased incidence of reactive encephalopathy. Administration of melarsoprol to leprosy patients may precipitate erythema nodosum. Use of the drug is contraindicated during epidemics of influenza. Severe hemolytic reactions have been reported in patients with deficiency of glucose-6-phosphate dehydrogenase. Pregnancy is not a contraindication for treatment with melarsoprol.

Metronidazole

Isolation of the antibiotic azomycin (2-nitro-imidazole) from a streptomycete by Maeda and collaborators in

1953 and demonstration of its trichomonacidal properties by Horie in 1956 led to the chemical synthesis and biological testing of many nitroimidazoles. One compound, 1-(β -hydroxyethyl)-2-methyl-5-nitroimidazole, or metronidazole (FLAGYL, others), had especially high activity *in vitro* and *in vivo* against the anaerobic protozoa *T. vaginalis* and *E. histolytica*. In 1960, Durel and associates reported that oral doses of the drug imparted trichomonacidal activity to semen and urine and that high cure rates could be obtained in both male and female patients with trichomoniasis. Later studies revealed that metronidazole had extremely useful clinical activity against a variety of anaerobic pathogens that included both gram-negative and gram-positive bacteria and the protozoan *G. lamblia* (Freeman et al., 1997). Other clinically effective 5-nitroimidazoles closely related in structure and activity to metronidazole include tinidazole (TINDAMAX, FASIGYN, others), secnidazole (SE CZOL-DS, others), and ornidazole (TIBERAL, others). Among these, only tinidazole is available in the U.S. Benzimidazole (ROCHAGAN), another 5-nitroimidazole derivative, is unusual in that it is effective in acute Chagas' disease.

Antiparasitic and Antimicrobial Effects. Metronidazole and related nitroimidazoles are active *in vitro* against a wide variety of anaerobic protozoal parasites and anaerobic bacteria (Freeman et al., 1997). The compound is directly trichomonacidal. Sensitive isolates of *T. vaginalis* are killed by <0.05 $\mu\text{g}/\text{mL}$ of the drug under anaerobic conditions; higher concentrations are required when 1% oxygen is present or to affect isolates from patients who display poor therapeutic responses to metronidazole. The drug also has potent amebicidal activity against *E. histolytica*. Trophozoites of *G. lamblia* are affected by metronidazole at concentrations of 1-50 $\mu\text{g}/\text{mL}$ *in vitro*. *In vitro* studies on drug-sensitive and drug-resistant protozoan parasites indicate that the nitro group on C5 of metronidazole is essential for activity and that substitutions at the 2 position of the imidazole ring that enhance the resonance conjugation of the chemical structure increase antiprotozoal activity. In contrast, substitution of an acyl group at the 2 position ablates such conjugation and reduces antiprotozoal activity (Upcroft et al., 1999).

Metronidazole manifests antibacterial activity against all anaerobic cocci and both anaerobic gram-negative bacilli, including *Bacteroides* spp., and anaerobic spore-forming gram-positive bacilli. Nonsporulating gram-positive bacilli often are resistant, as are aerobic and facultatively anaerobic bacteria.

Metronidazole is clinically effective in trichomoniasis, amebiasis, and giardiasis, as well as in a variety of infections caused by obligate anaerobic bacteria, including *Bacteroides*, *Clostridium*, and

microaerophilic bacteria such as *Helicobacter* and *Campylobacter* spp. Metronidazole may facilitate extraction of adult guinea worms in dracunculiasis even though it has no direct effect on the parasite (Chapter 51).

Mechanism of Action and Resistance. Metronidazole is a prodrug; it requires reductive activation of the nitro group by susceptible organisms. Its selective toxicity toward anaerobic and microaerophilic pathogens such as the amitochondriate protozoa *T. vaginalis*, *E. histolytica*, and *G. lamblia* and various anaerobic bacteria derives from their energy metabolism, which differs from that of aerobic cells (Land and Johnson, 1997; Samuelson, 1999; Upcroft and Upcroft, 1999). These organisms, unlike their aerobic counterparts, contain electron transport components such as ferredoxins, small Fe-S proteins that have a sufficiently negative redox potential to donate electrons to metronidazole. The single electron transfer forms a highly reactive nitro radical anion that kills susceptible organisms by radical-mediated mechanisms that target DNA and possibly other vital biomolecules. Metronidazole is catalytically recycled; loss of the active metabolite's electron regenerates the parent compound. Increasing levels of O₂ inhibit metronidazole-induced cytotoxicity because O₂ competes with metronidazole for electrons generated by energy metabolism. Thus, O₂ can both decrease reductive activation of metronidazole and increase recycling of the activated drug. Anaerobic or microaerophilic organisms susceptible to metronidazole derive energy from the oxidative fermentation of ketoacids such as pyruvate. Pyruvate decarboxylation, catalyzed by pyruvate:ferredoxin oxidoreductase (PFOR), produces electrons that reduce ferredoxin, which, in turn, catalytically donates its electrons to biological electron acceptors or to metronidazole.

Clinical resistance to metronidazole is well documented for *T. vaginalis*, *G. lamblia*, and a variety of anaerobic and microaerophilic bacteria but has yet to be shown for *E. histolytica*. Resistant strains of *T. vaginalis* derived from nonresponsive patients have shown two major types of abnormalities when tested under aerobic conditions. The first correlates with impaired oxygen-scavenging capabilities, leading to higher local O₂ concentrations, decreased activation of metronidazole, and futile recycling of the activated drug. The second type is associated with lowered levels of PFOR and ferredoxin, the latter owing to reduced transcription of the ferredoxin gene. That PFOR and ferredoxin are not completely absent may explain why infections with such strains usually respond to higher doses of metronidazole or more prolonged therapy. Studies on metronidazole-resistant isolates of *G. intestinalis* indicate that similar mechanisms may be operating, with PFOR levels reduced 5-fold compared with susceptible strains (Upcroft and Upcroft, 2001). Metronidazole resistance has not been found in clinical isolates of *E. histolytica* but has been induced *in vitro* by culturing trophozoites in gradually increasing concentrations of the drug. Interestingly, although some decrease in PFOR levels was reported, metronidazole resistance was mediated primarily by increased expression of superoxide dismutase and peroxiredoxin in amebic trophozoites (Wassmann et al., 1999). Resistance of anaerobic bacteria to metronidazole is being recognized increasingly and has important clinical consequences. In the case of *Bacteroides* spp., metronidazole resistance has been linked to a family of nitroimidazole (*nim*) resistance genes, *nimA*, *-B*, *-C*, *-D*, *-E*, and *-F*, that can be encoded chromosomally or episomally (Gal and Brazier, 2004). The exact mechanisms

underlying resistance are not known, but *nim* genes appear to encode a nitroimidazole reductase capable of converting a 5-nitroimidazole to a 5-aminoimidazole, thus stopping the formation of the reactive nitroso group responsible for microbial killing. Metronidazole has been used widely for the treatment of the microaerophilic organism *Helicobacter pylori*, the major cause of ulcer disease and gastritis worldwide. However, *Helicobacter* can develop resistance to metronidazole rapidly. Multiple mechanisms probably are operating, but there are data associating loss-of-function mutations in an oxygen-independent NADPH nitroreductase (*rdxA* gene) with resistance to metronidazole (Mendz and Mégraud, 2002).

Absorption, Fate, and Excretion. The pharmacokinetic properties of metronidazole and its two major metabolites have been investigated intensively (Lamp et al., 1999). Preparations of metronidazole are available for oral, intravenous, intravaginal, and topical administration. The drug usually is absorbed completely and promptly after oral intake, reaching concentrations in plasma of 8-13 µg/mL within 0.25-4 hours after a single 500-mg dose. (Mean effective concentrations of the compound are ≤8 µg/mL for most susceptible protozoa and bacteria.) A linear relationship between dose and plasma concentration pertains for doses of 200-2000 mg. Repeated doses every 6-8 hours result in some accumulation of the drug; systemic clearance exhibits dose dependence. The t_{1/2} of metronidazole in plasma is ~8 hours; its volume of distribution approximates total body water. Less than 20% of the drug is bound to plasma proteins. With the exception of the placenta, metronidazole penetrates well into body tissues and fluids, including vaginal secretions, seminal fluid, saliva, breast milk, and CSF.

After an oral dose, >75% of labeled metronidazole is eliminated in the urine largely as metabolites; ~10% is recovered as unchanged drug. The liver is the main site of metabolism, and this accounts for >50% of the systemic clearance of metronidazole. The two principal metabolites result from oxidation of side chains, a hydroxy derivative and an acid. The hydroxy metabolite has a longer t_{1/2} (~12 hours) and has ~50% of the antitrichomonal activity of metronidazole. Formation of glucuronides also is observed. Small quantities of reduced metabolites, including ring-cleavage products, are formed by the gut flora. The urine of some patients may be reddish brown owing to the presence of unidentified pigments derived from the drug. Oxidative metabolism of metronidazole is induced by phenobarbital, prednisone, rifampin, and possibly ethanol. Cimetidine appears to inhibit hepatic metabolism of the drug.

Therapeutic Uses. The uses of metronidazole for anti-protozoal therapy have been reviewed extensively (Freeman et al., 1997; Nash, 2001; Stanley, 2003). Metronidazole cures genital infections with *T. vaginalis* in both females and males in >90% of cases. The preferred treatment regimen is 2 g metronidazole as a single oral dose for both males and females. Tinidazole, which has a longer t_{1/2} than metronidazole, is also used at a 2-g single dose and appears to provide equivalent or better responses than metronidazole. For patients who cannot tolerate a single 2-g dose of metronidazole (or 1 g twice daily in the same day), an alternative regimen is a 250-mg dose given three times daily or a 375-mg dose given twice daily for 7 days. When repeated courses or higher doses of the drug are required for uncured or recurrent infections, it is recommended that intervals of 4-6 weeks

elapse between courses. In such cases, leukocyte counts should be carried out before, during, and after each course of treatment.

Treatment failures owing to the presence of metronidazole-resistant strains of *T. vaginalis* are becoming increasingly common. Most of these cases can be treated successfully by giving a second 2-g dose to both patient and sexual partner. In addition to oral therapy, the use of a topical gel containing 0.75% metronidazole or a 500- to 1000-mg vaginal suppository will increase the local concentration of drug and may be beneficial in refractory cases. Metronidazole is an effective amebicide and is the agent of choice for the treatment of all symptomatic forms of amebiasis, including amebic colitis and amebic liver abscess. The recommended dose is 500-750 mg metronidazole taken orally three times daily for 7-10 days, or for children, 35-50 mg/kg/day given in three divided doses for 7-10 days.

Although standard recommendations are for 7-10 days' duration of therapy, amebic liver abscess has been treated successfully by short courses (2.4 g daily as a single oral dose for 2 days) of metronidazole or tinidazole (Stanley, 2003). *E. histolytica* persist in most patients who recover from acute amebiasis after metronidazole therapy, so it is recommended that all such individuals also be treated with a luminal amebicide.

Although effective for the therapy of giardiasis, metronidazole has yet to be approved for treatment of this infection in the U.S. However, tinidazole is approved for the treatment of giardiasis as a single 2-g dose and is appropriate first-line therapy. Metronidazole is a relatively inexpensive, highly versatile drug with clinical efficacy against a broad spectrum of anaerobic and microaerophilic bacteria. It is used for the treatment of serious infections owing to susceptible anaerobic bacteria, including *Bacteroides*, *Clostridium*, *Fusobacterium*, *Peptococcus*, *Peptostreptococcus*, *Eubacterium*, and *Helicobacter*. The drug is also given in combination with other antimicrobial agents to treat polymicrobial infections with aerobic and anaerobic bacteria. Metronidazole achieves clinically effective levels in bones, joints, and the CNS. Metronidazole can be given intravenously when oral administration is not possible. A loading dose of 15 mg/kg is followed 6 hours later by a maintenance dose of 7.5 mg/kg every 6 hours, usually for 7-10 days. Metronidazole is used as a component of prophylaxis for colorectal surgery and is employed as a single agent to treat bacterial vaginosis. It is used in combination with other antibiotics and a proton pump inhibitor in regimens to treat infection with *H. pylori* (Chapter 45).

Metronidazole is used as primary therapy for *Clostridium difficile* infection, the major cause of pseudomembranous colitis. Given at doses of 250-500 mg orally three times daily for 7-14 days (or even longer), metronidazole is an effective and cost-saving alternative to oral vancomycin therapy. However, a reported increase in treatment failures and higher rates of disease recurrence with metronidazole (as compared to oral vancomycin) are raising questions about the role of metronidazole as first-line therapy (McFarland, 2008). Finally, metronidazole is also used in the treatment of patients with Crohn's disease who have perianal fistulas, and it can help control colonic (but not small bowel) Crohn's disease. However, high doses (750 mg three times daily) for prolonged periods may be necessary, and neurotoxicity may be limiting (Podolsky, 2002). Metronidazole and other nitroimidazoles can sensitize hypoxic tumor cells to the effects of ionizing radiation, but these drugs are not used clinically for this purpose.

Toxicity, Contraindications, and Drug Interactions. The toxicity of metronidazole has been reviewed (Raether and Hanel, 2003). Side effects only rarely are severe enough to discontinue therapy. The most common are headache, nausea, dry mouth, and a metallic taste. Vomiting, diarrhea, and abdominal distress are experienced occasionally. Furry tongue, glossitis, and stomatitis occurring during therapy may be associated with an exacerbation of candidiasis. Dizziness, vertigo, and very rarely, encephalopathy, convulsions, incoordination, and ataxia are neurotoxic effects that warrant discontinuation of metronidazole. The drug also should be withdrawn if numbness or paresthesias of the extremities occur. Reversal of serious sensory neuropathies may be slow or incomplete. Urticaria, flushing, and pruritus are indicative of drug sensitivity that can require withdrawal of metronidazole. Metronidazole is a rare cause of Stevens-Johnson syndrome (toxic epidermal necrolysis); one report described a high rate of this syndrome among individuals receiving high doses of metronidazole and concurrent therapy with the antihelminthic mebendazole (Chen et al., 2003).

Dysuria, cystitis, and a sense of pelvic pressure have been reported. Metronidazole has a well-documented disulfiram-like effect, and some patients experience abdominal distress, vomiting, flushing, or headache if they drink alcoholic beverages during or within 3 days of therapy with this drug. Patients should be cautioned to avoid consuming alcohol during metronidazole treatment even though the risk of a severe reaction is low. By the same token, metronidazole and disulfiram or any disulfiram-like drug should not be taken together because confusional and psychotic states may occur. Although related chemicals have caused blood dyscrasias, only a temporary neutropenia, reversible after discontinuation of therapy, occurs with metronidazole.

Metronidazole should be used with caution in patients with active disease of the CNS because of its potential neurotoxicity. The drug also may precipitate CNS signs of lithium toxicity in patients receiving high doses of lithium. Plasma levels of metronidazole can be elevated by drugs such as cimetidine that inhibit hepatic microsomal metabolism. Moreover, metronidazole can prolong the prothrombin time of patients receiving therapy with coumadin anticoagulants. The dosage of metronidazole should be reduced in patients with severe hepatic disease.

Given in high doses for prolonged periods, metronidazole is carcinogenic in rodents; it also is mutagenic in bacteria (Raether and Hanel, 2003). Mutagenic activity is associated with metronidazole and several of its metabolites found in the urine of patients treated with therapeutic doses of the drug. However, there is no evidence that therapeutic doses of metronidazole pose any significant increased risk of cancer to human patients. There is conflicting evidence about the teratogenicity of metronidazole in animals. Although metronidazole has been taken during all stages of pregnancy with no apparent adverse effects, its use during the first trimester generally is not advised.

Miltefosine

Miltefosine (IMPAVIDO) is an alkylphosphocholine (APC) analog that was developed originally as an anti-cancer agent. Its antiprotozoal activity was discovered in the 1980s during the time that it was being evaluated for cancer chemotherapy. In 2002, it was

approved in India as the first orally active treatment available for visceral leishmaniasis. Miltefosine is the first orally available therapy for leishmaniasis. It is highly curative against visceral leishmaniasis in the trials conducted to date and also appears to be effective against the cutaneous forms of the disease (Berman, 2008; Bhattacharya et al., 2007). Its main drawback is its teratogenicity; consequently, it must not be used in pregnant woman.

Antiprotozoal Effects. *In vitro* analysis of a large number of alkylglycerophosphoethanolamines (AGPEs), alkylglycerophosphocholines (AGPCs), and APCs, originally developed as anticancer agents, demonstrated that a number of these compounds had potent antileishmanial activity against cultured promastigote or amastigote parasites (Croft et al., 2003). Of the APCs, miltefosine demonstrated the best activity against both stages of parasites. The potency of miltefosine varies for different *Leishmania* spp., with *L. donovani* being the most sensitive ($1.2 < ED_{50} < 5 \mu\text{M}$ against amastigotes) and *L. major* being the least sensitive ($8 < ED_{50} < 40 \mu\text{M}$ against amastigotes). Several phospholipid analogs also had good potency against cultured *T. cruzi* parasites, whereas they were relatively inactive against *T. brucei*. *In vivo*, miltefosine had the best activities of the tested APCs, and by 5 days of treatment with 20 mg/kg orally, it gave >95% suppression of *L. donovani* and *L. infantum* amastigotes in the affected organs of mice. It also had good activity when administered as a 6% ointment to skin lesions of *L. mexicana* or *L. major* on BALB/c mice.

Against visceral leishmaniasis, 95-98% cure rates were observed with a 100 mg/day oral dose for 28-42 days (Croft et al., 2003) and 95% with a 28-day regimen of 100 mg/day orally for adults and 2.5 mg/kg daily for children (Bhattacharya et al., 2007). Thus, oral miltefosine appears to be a safe and effective treatment for visceral leishmaniasis (Berman, 2008). Recent studies of oral miltefosine also have shown >90% efficacy against some species of cutaneous leishmaniasis (registered in Colombia for this use in 2005). However, significant strain variation has been observed in the clinical trials (Soto and Berman, 2006; Soto et al., 2007): For *L. panamensis* in Colombia, cure rates were from 84-91% (versus the placebo cure rate of 37%), and it was considerably less effective for *L. brasiliensis* in Guatemala.

The mechanism of action of miltefosine is not yet understood. Potential targets in mammalian cells include PKC; CTP:phosphocholine-cytidyltransferase inhibition, which disrupts phosphatidylcholine biosynthesis; and altered sphingomyelin biosynthesis, where increased levels of cellular ceramide may trigger apoptosis (Croft et al., 2003). Studies in *Leishmania* suggest that the drug may alter ether-lipid metabolism, cell signaling, or glycosylphosphatidylinositol anchor biosynthesis. A transporter for miltefosine has been cloned recently by functional rescue of a laboratory-generated resistant strain of *L. donovani*. The transporter is a P-type ATPase that belongs to the aminophospholipid translocase

subfamily, and the basis for the drug resistance appears to be point mutation in the transporter leading to decreased drug uptake. Mutations in this transporter lead to miltefosine resistance in laboratory models (Croft et al., 2006; Seifert et al., 2007).

Absorption, Fate, and Excretion. Miltefosine is well absorbed orally and distributed throughout the human body. Detailed pharmacokinetic data are lacking, with the exception that miltefosine has a long $t_{1/2}$ in humans (Berman, 2008). Plasma concentrations are proportional to the dose, and maximum serum concentrations for dosing of 50-150 mg per day were 20-70 $\mu\text{g/mL}$ with a $t_{1/2}$ of 1 week and a terminal $t_{1/2}$ of ~4 weeks. The C_{max} in children was ~30% less than in adults.

Therapeutic Uses. Oral miltefosine is registered for use in India for the treatment of visceral leishmaniasis with clinical trial study patients receiving the following oral doses (Bhattacharya, 2007): for adults >25 kg, 100 mg daily divided into two parts, and for adults <25 kg, 50 mg daily in 1 dose for 28 days; for children, 2.5 mg/kg/day in two divided doses. For cutaneous disease, the dose in clinical testing is 2.5 mg/kg per day orally (maximum, 150 mg/day) for 28 days. In the U.S., the recommended dose for both visceral and cutaneous disease is 2.5 mg/kg per day (maximum dose of 150 mg/day) for 28 days, given in two divided doses (Medical Letter, 2007). Miltefosine is also available in Afghanistan, Pakistan, and South America. Because of its teratogenic potential, miltefosine is contraindicated in pregnant women. Women should receive a negative pregnancy test prior to treatment, and birth control is required during and for at least 2 months after treatment. The compound cannot be given intravenously because it has hemolytic activity.

Toxicity and Side Effects. Vomiting and diarrhea have been reported as frequent side effects in up to 60% of the patients. Elevations in hepatic transaminases and serum creatinine also have been reported. These effects are typically mild and reversible, and they resolve quickly once the drug is withdrawn.

Nifurtimox and Benznidazole

A variety of nitrofurans and nitroimidazole analogs are effective in experimental infections with American trypanosomiasis caused by *T. cruzi* (Bern et al., 2007; Tarleton et al., 2007). Of these, nifurtimox and benznidazole are currently used clinically to treat the disease. Nifurtimox (Bayer 2502, LAMPIT), a nitrofuran analog, and benznidazole (Roche 7-1051, ROCHAGAN), a nitroimidazole analog, can be obtained in the U.S. from the CDC.

Antiprotozoal Effects and Mechanisms of Action. Nifurtimox and benznidazole are trypanocidal against both the trypomastigote and amastigote forms of *T. cruzi*. Nifurtimox also has activity against

T. brucei and can be curative against both early- and late-stage disease (see earlier discussion on nifurtimox-eflornithine combination therapy).

Both nifurtimox and benznidazole are activated by a NADH-dependent mitochondrial nitroreductase, leading to the intracellular generation of nitro radical anions that are thought to account for the trypanocidal effects. The generated nitro anion radicals form covalent attachments to macromolecules leading to cellular damage that kills the parasites. Transfer of electrons from the activated drug regenerates the native nitrofurans and forms superoxide radical anions and other reactive oxygen species such as hydrogen peroxide and hydroxyl radical. Reaction of free radicals with cellular macromolecules results in cellular damage that includes lipid peroxidation and membrane injury, enzyme inactivation, and damage to DNA. Reduced nitroreductase expression through single allele gene knockout experiments or through drug selection leads to drug resistance (Wilkinson et al., 2008).

Absorption, Fate, and Excretion. Nifurtimox is well absorbed after oral administration, with peak plasma levels observed after ~3.5 hours (Paulos et al., 1989). Despite this, only low concentrations of the drug (10–20 μM) are present in plasma, and <0.5% of the dose is excreted in urine. The elimination $t_{1/2}$ is ~3 hours. High concentrations of several unidentified metabolites are found, however, and nifurtimox clearly undergoes rapid biotransformation, probably via a presystemic first-pass effect. Whether the metabolites have any trypanocidal activity is unknown.

Therapeutic Uses. Nifurtimox and benznidazole are employed in the treatment of American trypanosomiasis (Chagas' disease) caused by *T. cruzi* (Bern et al., 2007; Tarleton et al., 2007). However, because of toxicity issues, benznidazole is the preferred treatment. Both drugs markedly reduce the parasitemia, morbidity, and mortality of acute Chagas' disease, with parasitological cures obtained in 80% of these cases. Parasitological cure is defined by a negative result in PCR and serological tests for the parasite. In the chronic form of the disease, parasitological cures are still possible in up to 50% of the patients, although the drug is less effective than in the acute stage. Treatment with nifurtimox or benznidazole has no effect on irreversible organ lesions. Although a component of tissue destruction may be autoimmune in nature, the continued presence of parasites in the infected organs of patients with chronic disease argues that Chagas' disease should be treated as a parasitic disease.

The clinical response of the acute illness to drug therapy varies with geographic region; parasite strains present in Argentina, southern Brazil, Chile, and Venezuela appear to be more susceptible than those in central Brazil. A large-scale clinical trial (BENEFIT) is currently underway to test the efficacy of benznidazole in the treatment of both acute and chronic Chagas' disease (<http://clinicaltrials.gov/show/NCT00123916>); (Marin-Neto et al., 2008); until the trial's results are available, the current recommendations are that patients <50 years of age with either acute- or recent chronic-phase disease, without advanced cardiomyopathy, should be treated (Bern et al., 2007); in patients >50 years of age, treatment is optional because of lowered drug tolerability in this group; dosing is 5 mg/kg per day for 60 days. Therapy is strongly encouraged for patients that will receive immunosuppressive therapy or who are HIV positive. For patients with late chronic-phase disease (>10 years) with advanced cardiomyopathy, parasitological cure is less likely, and the general consensus is not to treat these patients. However, the decision to treat should be made on

an individual basis. Therapy with nifurtimox or benznidazole should start promptly after exposure for persons at risk of *T. cruzi* infection from laboratory accidents or from blood transfusions.

Both drugs are given orally. The treatment schedules recommended by the CDC in the U.S. are as follows: for nifurtimox, adults (>17 years of age) with acute infection should receive 8–10 mg/kg per day in three to four divided doses for 90 days; children 1–10 years of age should receive 15–20 mg/kg per day in three to four divided doses for 90 days; for individuals 11–16 years old, the daily dose is 12.5–15 mg/kg given according to the same schedule. For benznidazole, the recommended treatment for adults (>13 years) is 5–7 mg/kg per day in two divided doses for 60 days, with children up to 12 years receiving 10 mg/kg per day (Bern et al., 2007). Gastric upset and weight loss can occur during treatment. If the latter occurs, dosage should be reduced. The ingestion of alcohol should be avoided during treatment because the incidence of side effects may increase.

Nifurtimox is used in combination with eflornithine in treating late stage *T.b. gambiense* sleeping sickness (see "Eflornithine" earlier in this chapter).

Toxicity and Side Effects. Children tolerate nifurtimox and benznidazole better than adults. Nonetheless, drug-related side effects are common. They range from hypersensitivity reactions (e.g., dermatitis, fever, icterus, pulmonary infiltrates, and anaphylaxis) to dose- and age-dependent complications primarily referable to the GI tract and both the peripheral and central nervous systems. Nausea and vomiting are common, as are myalgia and weakness. Peripheral neuropathy and GI symptoms are especially common after prolonged treatment; the latter complication may lead to weight loss and preclude further therapy. Headache, psychic disturbances, paresthesias, polyneuritis, and CNS excitability are less frequent. Leukopenia and decreased sperm counts also have been reported. Because of the seriousness of Chagas' disease and the lack of superior drugs, there are few absolute contraindications to the use of these drugs.

Nitazoxanide

Nitazoxanide (*N*-[nitrothiazolyl] salicylamide, ALINA) is an oral synthetic broad-spectrum antiparasitic agent that was synthesized originally in the 1980s based on the structure of the antihelminthic niclosamide (Chapter 51). It was found initially to have activity against tapeworms (Rossignol and Maisonneuve, 1984); subsequent *in vitro* studies suggested that it was effective against a number of intestinal helminths and protozoans. Nitazoxanide is FDA-approved for the treatment of cryptosporidiosis and giardiasis in children.

Antimicrobial Effects. Nitazoxanide and its active metabolite, tizoxanide (desacetyl-nitazoxanide), inhibit the growth of sporozoites

and oocytes of *C. parvum* and inhibit the growth of the trophozoites of *G. intestinalis*, *E. histolytica*, and *T. vaginalis* *in vitro* (Adagu et al., 2002). Activity against other protozoans, including *Blastocystis hominis*, *Isospora belli*, and *Cyclospora cayetanensis* also has been reported. Nitazoxanide also demonstrated activity against the intestinal helminths: *Hymenolepis nana*, *Trichuris trichiura*, *Ascaris lumbricoides*, *Enterobius vermicularis*, *Ancylostoma duodenale*, *Strongyloides stercoralis*, and the liver fluke *Fasciola hepatica*. Effects against some anaerobic or microaerophilic bacteria, including *Clostridium* spp. and *H. pylori*, also have been reported. Nitazoxanide reportedly displays antiviral activity and is now undergoing clinical trials for the treatment of hepatitis C (Rossignol and Keeffe, 2008).

Mechanism of Action and Resistance. Nitazoxanide interferes with the PFOR enzyme-dependent electron-transfer reaction, which is essential to anaerobic metabolism in protozoan and bacterial species. One proposed mechanism of nitazoxanide is blockade of the first step in the PFOR chain by inhibiting the binding of pyruvate to the thiamine pyrophosphate cofactor (Hoffman et al., 2007). Resistance to nitazoxanide has been induced in *Giardia* *in vitro*, but clinically resistant clinical isolates have not yet been reported.

Absorption, Fate, and Excretion. Following oral administration, nitazoxanide is hydrolyzed rapidly to its active metabolite, tizoxanide, which undergoes conjugation primarily to tizoxanide glucuronide. Bioavailability after an oral dose is excellent, and maximum plasma concentrations of the metabolites are detected within 1-4 hours following administration of the parent compound. Tizoxanide is >99.9% bound to plasma proteins. Tizoxanide is excreted in the urine, bile, and feces; tizoxanide glucuronide is excreted in the urine and bile. The pharmacokinetics of nitazoxanide in individuals with impaired hepatic or renal function have not been reported.

Therapeutic Uses. In the U.S., nitazoxanide is approved for the treatment of *G. intestinalis* infection (therapeutic efficacy of 85-90% for clinical response) and for the treatment of diarrhea caused by cryptosporidia (therapeutic efficacy, 56-88% for clinical response) in adults and children >1 year of age (Amadi et al., 2002; Rossignol et al., 2001). The efficacy of nitazoxanide in children (or adults) with cryptosporidia infection and AIDS has not been clearly established. For children ages 12-47 months, the recommended dose is 100 mg nitazoxanide every 12 hours for 3 days; for children ages 4-11 years, the dose is 200 mg nitazoxanide every 12 hours for 3 days. A 500-mg tablet, suitable for adult dosing (every 12 hours), is available.

Nitazoxanide has been used as a single agent to treat mixed infections with intestinal parasites (protozoa and helminths) in several trials. Effective parasite clearance (based on negative follow-up fecal samples) after nitazoxanide treatment was shown for *G. intestinalis*, *E. histolytica/E. dispar*, *B. hominis*, *C. parvum*, *C. cayetanensis*, *I. belli*, *H. nana*, *T. trichiura*, *A. lumbricoides*, and *E. vermicularis* (Romero-Cabello et al., 1997), although more than one course of therapy was required in some cases. Nitazoxanide may have some efficacy against *Fasciola hepatica* infections (Favennec et al., 2003) and has been used to treat infections with *G. intestinalis* that are resistant to metronidazole and albendazole (Abboud et al., 2001).

Toxicity and Side Effects. To date, adverse effects appear to be rare with nitazoxanide. Abdominal pain, diarrhea, vomiting, and headache have been reported, but rates were no different from those in patients receiving placebo. A greenish tint to the urine is seen in

most individuals taking nitazoxanide. Nitazoxanide is a pregnancy Category B agent, based on animal teratogenicity and fertility studies, but there is no clinical experience with its use in pregnant women or nursing mothers.

Paromomycin

Paromomycin (aminosidine, HUMATIN) is an aminoglycoside of the neomycin/kanamycin family (Chapter 54) that is used as an oral agent to treat *E. histolytica* infection. The drug is not absorbed from the GI tract and thus the actions of an oral dose are confined to the GI tract. Paromomycin also has been used orally to treat cryptosporidiosis and giardiasis. A topical formulation has been used to treat trichomoniasis, and parenteral administration has been used for visceral leishmaniasis.

Mechanism of Action. Paromomycin shares the same mechanism of action as neomycin and kanamycin (binding to the 30S ribosomal subunit) and has the same spectrum of antibacterial activity. Paromomycin is available only for oral use in the U.S. Following oral administration, 100% of the drug is recovered in the feces, and even in cases of compromised gut integrity, there is little evidence for clinically significant absorption of paromomycin. *Parenteral administration carries the same risks of nephrotoxicity and ototoxicity seen with other aminoglycosides.*

Antimicrobial Effects; Therapeutics Uses. Paromomycin is the drug of choice for treating intestinal colonization with *E. histolytica*. It is used in combination with metronidazole to treat amebic colitis and amebic liver abscess and can be used as a single agent for asymptomatic individuals found to have *E. histolytica* intestinal colonization. Recommended dosing for adults and children is 25-35 mg/kg per day orally in three divided doses. Adverse effects are rare with oral usage but include abdominal pain and cramping, epigastric pain, nausea and vomiting, steatorrhea, and diarrhea. Rarely, rash and headache have been reported. Paromomycin has been used to treat cryptosporidiosis in AIDS patients both as a single agent and in combination with azithromycin, but in a randomized controlled trial, paromomycin was no more effective than placebo for this indication (Hewitt et al., 2000). Paromomycin has been advocated as a treatment for giardiasis in pregnant women, especially during the first trimester, when metronidazole is contraindicated and as an alternative agent for metronidazole-resistant isolates of *G. intestinalis*. Although there is limited clinical experience, response rates of 55-90% have been reported (Gardner and Hill, 2001). Dosing in adults is 500 mg orally three times daily for 10 days,

whereas children have been treated with 25–30 mg/kg per day in three divided oral doses. Paromomycin formulated as a 6.25% cream has been used to treat vaginal trichomoniasis in patients who had failed metronidazole therapy or could not receive metronidazole. Some cures have been reported, but vulvovaginal ulcerations and pain have complicated treatment and absorption via this route (and the possibility of aminoglycoside-related toxicities) must be anticipated.

Paromomycin is also efficacious as a topical formulation containing 15% paromomycin in combination with 12% methylbenzoniium chloride for the treatment of cutaneous leishmaniasis (Alvar et al., 2006). The drug has been administered parenterally alone or in combination with antimony to treat visceral leishmaniasis. Paromomycin (intramuscular injection, 11 mg/kg per day for 21 days) produced a cure rate for visceral leishmaniasis (94.6%) that was statistically equivalent to liposomal amphotericin B (Sundar et al., 2007). However, adverse events were more common with paromomycin than with liposomal amphotericin B.

Pentamidine

Pentamidine is a positively charged aromatic diamine that was discovered in 1937 as a fortuitous consequence of the search for hypoglycemic compounds that might compromise parasite energy metabolism. Of the compounds tested, three were found to possess outstanding activity: stilbamidine, pentamidine, and propamidine. Pentamidine was the most useful clinically because of its relative stability, lower toxicity, and ease of administration. Pentamidine is a broad-spectrum agent with activity against several species of pathogenic protozoa and some fungi.

Pentamidine as the di-isethionate salt is marketed for injection (PENTAM 300, others) or for use as an aerosol (NEBUPENT). One milligram of pentamidine base is equivalent to 1.74 mg of the pentamidine isethionate. The di-isethionate salt is highly water soluble; however, solutions should be used promptly after preparation because pentamidine is unstable in solution.

Antiprotozoal and Antifungal Effects. The positively charged aromatic diamidines are toxic to a number of different protozoa yet show rather marked selectivity of action. Pentamidine is used for the treatment of early-stage *T. brucei gambiense* infection (Barrett et al., 2007; Kennedy, 2008) but is ineffective in the treatment of late-stage disease and has reduced efficacy against *T. brucei rhodesiense*. Its use is therefore limited to treatment of first-stage *T. brucei gambiense* sleeping sickness. Pentamidine is an alternative agent for the treatment of cutaneous leishmaniasis (Alvar et al., 2006; Croft, 2008). It has been used for the treatment of visceral disease but less toxic agents are preferred. Pentamidine is an alternative agent for the treatment and prophylaxis of *Pneumocystis pneumonia* caused by the ascomycetous fungus *Pneumocystis jiroveci* (formerly known as *Pneumocystis carinii*) (Thomas and Limper, 2004).

Diminazene (BERENIL) is a related diamidine that is used as an inexpensive alternative to pentamidine for the treatment of early African trypanosomiasis and has been used outside the U.S. for the treatment of early-stage *T. b. gambiense* in periods of pentamidine shortage.

Mechanism of Action and Resistance. The mechanism of action of the diamidines is unknown. The dicationic compounds appear to display multiple effects on any given parasite and act by disparate mechanisms in different parasites (Barrett et al., 2007). In *T. brucei*, for example, the diamidines are concentrated via an energy-dependent high-affinity uptake system to millimolar concentrations in cells; this selective uptake is essential to their efficacy. The best-characterized diamidine transporter is the P2 purine transporter used by the melamine-based arsenicals, which explains the cross-resistance to diamidines exhibited by certain arsenical-resistant strains of *T. brucei in vitro* (de Koning, 2008). It is increasingly clear that multiple transporters are responsible for pentamidine uptake, and this may account for the fact that little resistance to this drug is observed in field isolates despite its years of use as a prophylactic agent. Although failure to concentrate diamidines is the usual cause of pentamidine resistance *in vitro*, other mechanisms also may be involved.

The positively charged hydrophobic diamidines may exert their trypanocidal effects by reacting with a variety of negatively charged intracellular targets. Indeed, ribosomal aggregation, inhibition of DNA and protein synthesis, inhibition of several enzymes, and loss of trypanosomal kinetoplast DNA have been reported. The loss of kinetoplast DNA may be mediated through inhibition of topoisomerase II. It is doubtful that an effect on topoisomerase accounts for the drug's broad antimicrobial activity or fully explains its mechanism of action. Inhibition of *S*-adenosyl-L-methionine decarboxylase *in vitro* (but no change in polyamine levels *in vivo*) and inhibition of a plasma Ca^{2+} , Mg^{2+} -ATPase also have been reported.

Absorption, Fate, and Excretion. The pharmacokinetics and bi-disposition of pentamidine isethionate have been studied most extensively in AIDS patients with *P. jiroveci* infections (Vöhringer and Arastéh, 1993); information from patients with Gambian trypanosomiasis is more limited (Bronner et al., 1995). Pentamidine isethionate is fairly well absorbed from parenteral sites of administration. Following a single intravenous dose, the drug disappears from plasma with an apparent $t_{1/2}$ of several minutes to a few hours and maximum plasma concentrations after intramuscular injection occurring at 1 hour. The $t_{1/2}$ of elimination is very slow, lasting from weeks to months, and the drug is 70% bound to plasma proteins. This highly charged compound is poorly absorbed orally and does not cross the blood-brain barrier, explaining why it is ineffective against late-stage trypanosomiasis.

After multiple parenteral doses, the liver, kidney, adrenal, and spleen contain the highest concentrations of drug, whereas only traces are found in the brain (Donnelly et al., 1988). The lungs contain intermediate but therapeutic concentrations after five daily doses of 4 mg/kg. Inhalation of pentamidine aerosols is used for prophylaxis of *Pneumocystis pneumonia*; delivery of drug by this route results in little systemic absorption and decreased toxicity compared with intravenous administration in both adults and children (Hand et al., 1994; Leoung et al., 1990). The actual dose delivered to the

lungs depends on both the size of particles generated by the nebulizer and the patient's ventilatory patterns.

Therapeutic Uses. Pentamidine isethionate is used for the treatment of early-stage *T. brucei gambiense* and is given by intramuscular injection in single doses of 4 mg/kg per day for 7 days. Pentamidine has been used successfully in courses of 15-20 intramuscular doses of 4 mg/kg every other day to treat visceral leishmaniasis (Alvar et al., 2006). This compound provides an alternative to antimonials, lipid formulations of amphotericin B, or miltefosine but it is overall the least well tolerated of the available therapies and is not used routinely for this disease. Pentamidine isethionate given as 4-7 intramuscular doses of 4 mg/kg every other day has enjoyed some success in the treatment of cutaneous leishmaniasis (Oriental sore caused by *L. tropica*) but is not used routinely to treat this infection (Alvar et al., 2006).

Pentamidine is one of several drugs or drug combinations used to treat or prevent *Pneumocystis* infection. *Pneumocystis pneumonia* (PCP) is a major cause of mortality in individuals with HIV infection and AIDS and can occur in patients who are immunosuppressed by other mechanisms (e.g., high-dose corticosteroids or underlying malignancy). The availability of highly active antiretroviral therapy (HAART) has reduced the number of cases of PCP significantly within the U.S. and E.U. and greatly reduced the number of individuals requiring prophylaxis for PCP. Trimethoprim-sulfamethoxazole is the drug of choice for the treatment and prevention of PCP (Chapter 52). Pentamidine is reserved for two indications. Pentamidine given intravenously as a 4 mg/kg single daily dose for 21 days is used to treat severe PCP in individuals who cannot tolerate trimethoprim-sulfamethoxazole and are not candidates for alternative agents such as atovaquone or the combination of clindamycin and primaquine. Pentamidine has been recommended as a "salvage" agent for individuals with PCP who failed to respond to initial therapy (usually trimethoprim-sulfamethoxazole), but a meta-analysis suggested that pentamidine is less effective than other therapies (specifically the combination of clindamycin and primaquine or atovaquone) for this indication (Smego et al., 2001). Pentamidine administered as an aerosol preparation is used for the prevention of PCP in at-risk individuals who cannot tolerate trimethoprim-sulfamethoxazole and are not deemed candidates for either dapson (alone or in combination with pyrimethamine) or atovaquone. Candidates for PCP prophylaxis are individuals with HIV infection and a CD4 count of $<200/\text{mm}^3$ and individuals with HIV infection and persistent unexplained fever or oropharyngeal candidiasis. Secondary prophylaxis is recommended for everyone with a documented PCP episode. For prophylaxis, pentamidine isethionate is given monthly as a 300-mg dose in a 5-10% nebulized solution over 30-45 minutes. Although the monthly dosage regimen is convenient, aerosolized pentamidine has several disadvantages, including its failure to treat any extrapulmonary sites of *Pneumocystis*, the lack of efficacy against any other potential opportunistic pathogens (compared with trimethoprim-sulfamethoxazole), and a slightly increased risk for pneumothorax. Long-term aerosolized pentamidine prophylaxis (≥ 5 years) has not been associated with the development of any pulmonary disease (Obaji et al., 2003). For individuals who receive HAART and develop CD4 counts persistently above $200/\text{mm}^3$ for 3 months, primary or secondary PCP prophylaxis can be stopped.

Toxicity and Side Effects. Pentamidine is a toxic agent, and ~50% of individuals receiving the drug at recommended doses (4 mg/kg per day) show some adverse effect. Intravenous administration of pentamidine may be associated with hypotension, tachycardia, and headache. These effects are probably secondary to the ability of pentamidine to bind imidazoline receptors (Chapter 14) and can be ameliorated by slowing the rate of the intravenous infusion (Wood et al., 1998). As noted earlier, the diamidines were designed originally for use as hypoglycemics, and pentamidine retains that property. Hypoglycemia, which can be life threatening, may occur at any time during pentamidine treatment, even weeks into therapy. Careful monitoring of blood sugar is key. Paradoxically, pancreatitis, hyperglycemia, and the development of insulin-dependent diabetes have been seen in some patients. Pentamidine is nephrotoxic (~25% of treated patients show signs of renal dysfunction), and if the serum creatinine concentration rises >1.0 - 2.0 mg/dL, it may be necessary to withhold the drug temporarily or change to an alternative agent. Individuals developing pentamidine-induced renal dysfunction are at higher risk for hypoglycemia. Other adverse effects include skin rashes, thrombophlebitis, anemia, neutropenia, and elevation of hepatic enzymes. Intramuscular administration of pentamidine, while effective, is associated with the development of sterile abscesses at the injection site, which can become infected secondarily. For this reason, most authorities recommend intravenous administration. Aerosolized pentamidine is associated with few adverse events.

Quinacrine

Quinacrine is an acridine derivative used widely during World War II as an antimalarial agent. *Quinacrine hydrochloride* is very effective against *G. lamblia*, producing cure rates of at least 90%. However, quinacrine is no longer available in the U.S. For a description of the pharmacology and toxicology of quinacrine, consult the fifth and earlier editions of this book.

Sodium Stibogluconate

Antimonials were introduced in 1945 and have been used for therapy of leishmaniasis and other protozoal infections (Alvar et al., 2006; Croft, 2008; Olliaro et al., 2005). The first trivalent antimonial compound used to treat cutaneous leishmaniasis and kala azar was antimony potassium tartrate (tartar emetic), which was both toxic and difficult to administer. Tartar emetic and other trivalent arsenicals eventually were replaced by pentavalent antimonial derivatives of phenylstibonic acid. An early member of this family of compounds was sodium stibogluconate (sodium antimony gluconate, PENTOSTAM). This drug is used widely today and, together with meglumine antimonate (GLUCANTIME), a pentavalent antimonial compound preferred in French-speaking countries, has been the mainstay of the treatment of leishmaniasis. However, increasing resistance to antimonials has reduced their efficacy and they are no longer useful in India (Croft, 2008; Croft et al.,

Clinical formulations of sodium stibogluconate consist of multiple uncharacterized molecular forms, some of which have higher molecular masses than the compound shown. Typical preparations contain 30-34% pentavalent antimony by weight and *m*-chlorocresol (as a preservative). In the U.S., sodium stibogluconate can be obtained from the CDC.

Antiprotozoal Effects and Drug Resistance. The mechanism of the antileishmanial action of sodium stibogluconate remains an active area of research, and recent studies have provided interesting new insights (Croft et al., 2006). These studies support the old hypothesis that relatively nontoxic pentavalent antimonials act as prodrugs. These compounds are reduced to the more toxic Sb^{3+} species that kill amastigotes within the phagolysosomes of macrophages. This reduction preferentially occurs in the intracellular amastigote stage, and recently an enzyme, As^{5+} reductase, was characterized that is able to reduce Sb^{5+} to the active Sb^{3+} form. Furthermore, the overexpression of this enzyme in promastigotes increased their sensitivity to the drugs. Classically, it was thought that the antiparasitic effects of antimonials occurred through inhibition of glucose catabolism and fatty acid oxidation; however, recent studies suggest that the drugs operate by interfering with the trypanothione redox system. In drug-sensitive cell lines, Sb^{3+} induces a rapid efflux of trypanothione and glutathione from the cells, and also inhibits trypanothione reductase, thereby causing a significant loss of thiol reduction potential in the cells. This hypothesis is further supported by the observation that laboratory-generated resistance to antimonials leads to overexpression of glutathione and polyamine biosynthetic enzymes, resulting in increased trypanothione levels, which conjugate to the drug. Elevated levels of ABC efflux transporters (see Chapter 5) were observed, though these transporters seem to play only a minor role in drug resistance.

Absorption, Fate, and Excretion. The pentavalent antimonials attain much higher concentrations in plasma than do the trivalent compounds. Consequently, most of a single dose of sodium stibogluconate is excreted in the urine within 24 hours. Its pharmacokinetic behavior is similar whether the drug is given intravenously or intramuscularly; it is not active orally (Chulay et al., 1988). The agent is absorbed rapidly, distributed in an apparent volume of ~ 0.22 L/kg, and eliminated in two phases. The first has a $t_{1/2}$ of ~ 2 hours, and the second is much slower ($t_{1/2} = 33$ -76 hours). The prolonged terminal elimination phase may reflect conversion of the Sb^{5+} to the more toxic Sb^{3+} that is concentrated and slowly released from tissues. Indeed, $\sim 20\%$ of the plasma antimony is present in the trivalent form after pentavalent antimonial administration. Sequestration of

antimony in macrophages also may contribute to the prolonged antileishmanial effect after plasma antimony levels have dropped below the minimal inhibitory concentration observed *in vitro*.

Therapeutic Uses. The changing use of sodium stibogluconate, meglumine antimonate, and other agents for the chemotherapy of leishmaniasis has been reviewed extensively (Alvar et al., 2006; Croft, 2008; Olliaro et al., 2005). Sodium stibogluconate is given parenterally, with the dosage regimen individualized depending on the local responsiveness of a particular form of leishmaniasis to this compound. The standard course is 20 mg/kg per day for 21 days for cutaneous disease and for 28 days for visceral disease. In some regions of the world prolonged dosage schedules with maximally tolerated doses are now needed for successful therapy of visceral, mucosal, and some cutaneous forms of leishmaniasis, in part to overcome increasing clinical resistance to antimonial drugs. Even high-dose regimens may no longer produce satisfactory results. Increased resistance has greatly compromised the effectiveness of these drugs, and the drug is now obsolete in India. This is in contrast to previous cure rates of $>85\%$ for both visceral and cutaneous disease. Liposomal amphotericin B is the recommended alternative for treatment of either visceral leishmaniasis (kala azar) in India or mucosal leishmaniasis in general; the orally effective compound miltefosine is likely to see much wider use in the coming years. Intravesicular treatment has also been advocated as a safer, alternative method for treating cutaneous disease (Munir et al., 2008).

Children usually tolerate the drug well, and the dose per kilogram is the same as that given to adults. Patients who respond favorably show clinical improvement within 1-2 weeks of initiation of therapy. The drug may be given on alternate days or for longer intervals if unfavorable reactions occur in especially debilitated individuals. Patients infected with HIV present a challenge because they usually relapse after successful initial therapy with either pentavalent antimonials or amphotericin B.

Toxicity and Side Effects. The toxicity of the pentavalent antimonials is best evaluated in patients without systemic disease (i.e., visceral leishmaniasis). In general, high-dose regimens of sodium stibogluconate are fairly well tolerated; toxic reactions usually are reversible, and most subside despite continued therapy. Effects noted most commonly include pain at the injection site after intramuscular administration; chemical pancreatitis in nearly all patients; elevation of serum hepatic transaminase levels; bone marrow suppression manifested by decreased red cell, white cell, and platelet counts in the blood; muscle and joint pain; weakness and malaise; headache; nausea and abdominal pain; and skin rashes. Changes in the electrocardiogram that include T-wave flattening and inversion and prolongation of the QT interval found in patients with systemic disease are uncommon in other forms of leishmaniasis (Navin et al., 1992). Reversible polyneuropathy has been reported. Hemolytic anemia and renal damage are rare manifestations of antimonial toxicity, as are shock and sudden death.

Suramin

Based on the trypanocidal activity of the dyes *trypan red*, *trypan blue*, and *afridol violet*, research in Germany resulted in the introduction of suramin into therapy in 1920. Today, the drug is used primarily for

treatment of African trypanosomiasis; it has no clinical utility against American trypanosomiasis. Although suramin is effective in clearing adult filariae in *onchocerciasis*, ivermectin has supplanted suramin for the treatment of this condition (Chapter 51). Suramin is a potent inhibitor of retroviral reverse transcriptase *in vitro*, but it is ineffective in HIV infection. The antiproliferative activity of suramin led to its experimental use, alone and with other compounds, for the therapy of a variety of tumors, particularly in androgen-independent prostate cancer. However, only modest palliative effects were observed and treatment for this indication was complicated by high toxicity. The antiparasitic and antineoplastic properties of suramin, along with its clinical uses and limitations, have been the topic of numerous reviews (Kennedy, 2008; McGeary et al., 2008).

Suramin sodium (BAYER 205, formerly GERMANIN, others) is soluble in water, but solutions deteriorate quickly in air; only freshly prepared solutions should be used. In the U.S., suramin is available only from the CDC.

Antiparasitic Effects. Suramin is a relatively slowly acting trypanocide (>6 hours *in vitro*) with high clinical activity against both *T. b. gambiense* and *T. b. rhodesiense*. Its mechanism of action is unknown (Barrett et al., 2007). Selective toxicity is likely to result from the ability of the parasite to take up the drug by receptor-mediated endocytosis of the protein-bound drug, with low-density lipoproteins the most important interacting proteins for this event. Suramin reacts reversibly with a variety of biomolecules *in vitro*, inhibiting many trypanosomal and mammalian enzymes and receptors unrelated to its antiparasitic effects. Compartmentation protects many vital molecules, such as the glycolytic enzymes inside trypanosomal glycosomes, from suramin because this compound does not cross membrane barriers by passive diffusion. Suramin-treated trypanosomes exhibit damage to intracellular membrane structures other than lysosomes, but whether or not this relates to the drug's primary action is unknown. Inhibition of a trypanosomal cytosolic serine oligopeptidase may account for part of the activity of suramin, but the drug is also an inhibitor of dihydrofolate reductase, thymidine kinase, and several glycolytic enzymes. No clear consensus for the mechanism of action has emerged, and the lack of any significant field resistance points to multiple potential targets.

Absorption, Fate, and Excretion. The clinical pharmacology of suramin was determined during clinical trials for its application as an antitumor agent. Because it is not absorbed after oral intake, suramin is given intravenously to avoid local inflammation and necrosis

associated with subcutaneous or intramuscular injections. After its administration, the drug displays complex pharmacokinetics with marked interindividual variability. The drug is 99.7% serum protein bound and has a terminal elimination $t_{1/2}$ of 41–78 days. Suramin is not appreciably metabolized, and renal clearance accounts for elimination of ~80% of the compound from the body. This large polar anion does not enter cells readily, and tissue concentrations are uniformly lower than those in plasma. In experimental animals the kidneys contain considerably more suramin than do other organs. Such retention may account for the fairly frequent occurrence of albuminuria following injection of the drug in humans. Very little suramin penetrates the CSF, consistent with its lack of efficacy once the CNS has been invaded by trypanosomes.

Therapeutic Uses. Suramin is the first-line therapy for early-stage *T. brucei rhodesiense* infection (Barrett et al., 2007; Kennedy, 2008). Although it shows activity against *T. brucei gambiense*, it is not used for this application because other drugs are available for the treatment of this disease that are not complicated by the high activity of suramin against *Onchocerca* and *Brugia*, and possible immunological reactions resulting from killing of these parasitic worms. Because only small amounts of the drug enter the brain, suramin is used only for the treatment of early-stage African trypanosomiasis (before CNS involvement). Suramin will clear the hemolymphatic system of trypanosomes even in late-stage disease, so it is often administered before initiating melarsoprol to reduce the risk of reactive encephalopathy associated with the administration of that arsenical. Suramin is given by slow intravenous injection as a 10% aqueous solution. Treatment of active African trypanosomiasis should not be started until 24 hours after diagnostic lumbar puncture to ensure no CNS involvement, and caution is required if the patient has onchocerciasis (river blindness) because of the potential for eliciting a Mazzotti reaction (i.e., pruritic rash, fever, malaise, lymph node swelling, eosinophilia, arthralgias, tachycardia, hypotension, and possibly permanent blindness). The normal single dose for adults with *T. brucei rhodesiense* infection is 1 g. It is advisable to employ a test dose of 200 mg initially to detect sensitivity, after which the normal dose is given intravenously on days 1, 3, 7, 14, and 21, although a wide range of schedules are in use. The pediatric dose is 20 mg/kg, given according to the same schedule. Patients in poor condition should be treated with lower doses during the first week. Patients who relapse after suramin therapy should be treated with melarsoprol.

Toxicity and Side Effects. Suramin can cause a variety of untoward reactions that vary in intensity and frequency and tend to be more severe in debilitated patients. Fortunately, the most serious immediate reaction consisting of nausea, vomiting, shock, and loss of consciousness is rare (~1 in 2000 patients). Malaise, nausea, and fatigue are also common immediate reactions. Parasite destruction may cause febrile episodes and skin hypersensitivity rashes that are reduced by pretreatment with glucocorticoids; concomitant onchocerciasis optimally should be treated first with ivermectin to minimize these reactions (Chapter 51). The most common problem encountered after several doses of suramin is renal toxicity, manifested by albuminuria, and delayed neurological complications, including headache, metallic taste, paresthesias, and peripheral neuropathy. These complications usually disappear spontaneously despite continued therapy. Other, less prevalent reactions include vomiting, diarrhea,

stomatitis, chills, abdominal pain, and edema. Laboratory abnormalities noted in 12-26% of patients with AIDS include leukopenia and occasional agranulocytosis, thrombocytopenia, proteinuria, and elevations of plasma creatinine, transaminases, and bilirubin, which are reversible. Unexpected findings in patients with AIDS include adrenal insufficiency and vortex keratopathy.

Precautions and Contraindications. Patients receiving suramin should be followed closely. Therapy should not be continued in patients who show intolerance to initial doses, and the drug should be employed with great caution in individuals with renal insufficiency. Moderate albuminuria is common during control of the acute phase, but persisting, heavy albuminuria calls for caution as well as modification of the treatment schedule. If casts appear, treatment with suramin should be discontinued. The occurrence of palmar-plantar hyperesthesia may presage peripheral neuritis.

Chemotherapy of Helminth Infections

James McCarthy, Alex Loukas,
and Peter J. Hotez

Infections with helminths, or parasitic worms, affect more than two billion people worldwide. In regions of rural poverty in the tropics, where prevalence is greatest, simultaneous infection with more than one type of helminth is common. The relative incidence of common helminthic infections in humans worldwide is illustrated in Figure 51–1.

Worms pathogenic for humans are Metazoa and can be classified into roundworms (nematodes) and two types of flatworms, flukes (trematodes) and tapeworms (cestodes). These biologically diverse eukaryotes vary with respect to life cycle, bodily structure, development, physiology, localization within the host, and susceptibility to chemotherapy. Immature forms invade humans via the skin or GI tract and evolve into well-differentiated adult worms with characteristic tissue distributions. With few exceptions, such as *Strongyloides* and *Echinococcus*, these organisms cannot complete their life cycle and replicate within the human host to produce mature offspring. Therefore, the extent of exposure to these parasites dictates the number of parasites infecting the host, a characteristic recognized as infection intensity, which itself determines the morbidity caused by infection. Secondly, any reduction in the number of adult organisms by chemotherapy is sustained unless reinfection occurs. The burden of parasitic helminths within an infected population is not uniformly distributed, and it typically displays a negative binomial distribution whereby relatively few persons carry the heaviest parasite burden, resulting in increased morbidity in these individuals who also contribute disproportionately to transmission.

Anthelmintics are drugs that act either locally within the gut lumen to cause expulsion of worms from the GI tract, or systemically against helminths residing

outside the GI tract. Safe and effective broad-spectrum anthelmintics, initially developed for veterinary use, are currently available for use in humans. However, therapy for many tissue-dwelling helminths, such as filarial parasites, is not fully effective. For many reasons, including their long-lived and relatively complex life cycles, acquired resistance to anthelmintics in humans has yet to become a major clinical problem. However, with the increasing deployment of mass drug therapy, and considering the veterinary experience with resistance, the potential for drug resistance among helminths in humans requires monitoring.

Primarily as a result of stepped-up advocacy by the World Health Organization (WHO), the World Bank, the Global Network for Neglected Tropical Diseases, and smaller nongovernmental organizations such as the London-based Partnership for Child Development (PCD), there is increasing appreciation for the impact of helminth infections on the health and education of school-aged children. These organizations have promoted the periodic and frequent use of anthelmintic drugs in schools as a means to control morbidity caused by soil-transmitted helminths and schistosomes in developing countries. In addition, interest has grown in eliminating arthropod-borne helminth infections by interrupting their transmission through the widespread use of anthelmintics. Today, control programs employing anthelmintics rank among the world's largest health efforts, and hundreds of millions of people receive treatment annually (Hotez et al., 2009).

This chapter is divided into two main parts:

- clinical presentation and recommended chemotherapy for common helminth infections in humans
- pharmacological properties of specific anthelmintics

Figure 51-1. Relative incidence of helminth infections worldwide.

HELMINTH INFECTIONS AND THEIR TREATMENT

Nematodes (Roundworms)

The major nematode parasites of humans include the soil-transmitted helminths (STHs; sometimes referred to as “geohelminths”) and the filarial nematodes.

The major STH infections (ascariasis [roundworm], trichuriasis [whipworm], and hookworm infection) are among the most prevalent infections in developing countries. Because STH worm burdens are higher in school-aged children than in any other single group, the WHO and the PCD advocate school-based administration of broad-spectrum anthelmintics on a periodic and frequent basis. The agents most widely employed for reducing morbidity are the benzimidazole anthelmintics (BZ), either albendazole (ALBENZA and ZENTEL) or mebendazole (VERMOX, others) (Table 51-1, p. 1450).

Single dose therapy with a BZ reduces worm burden to a varying degree, with greatest efficacy for ascariasis, followed by whipworm and hookworm (Keiser and Utzinger, 2008) and subsequently reduces morbidity attributable to the parasite. Treatment improves host iron stores and hemoglobin levels, physical growth, cognition, educational achievement, and school absenteeism, as well as having a positive influence on the entire community by reducing transmission (Bethony et al., 2006). In 2001, the World Health Assembly adopted a resolution urging that by 2010 member states should regularly administer anthelmintics to at least 75% of all

school-age children at risk for morbidity (WHO, 2002). Concerns with this recommendation have included:

- The scope of the undertaking
- The high rate of post-treatment reinfection that occur in areas of high transmission
- Documented drug failures against hookworm with mebendazole
- The possibility that widespread treatment will lead to the emergence of BZ drug resistance
- The possibility that by focusing exclusively on school-aged children, other groups and vulnerable populations, such as preschool children and women of reproductive age, will be omitted

In addition to targeting STH infections among school-aged children, there are ongoing programs to eliminate lymphatic filariasis (LF) and onchocerciasis (river blindness) over the next 10-20 years (Molyneux and Zagaria, 2002; Molyneux et al., 2003). The term *elimination*, as opposed to *eradication*, refers to the reduction of disease incidence to zero or close to zero, with a requirement for ongoing control efforts (Hotez et al., 2004). The major goals for the LF elimination program (and to some extent, the onchocerciasis elimination programs) are to interrupt arthropod-borne transmission by administering combination therapy with either diethylcarbamazine (DEC; HETRAZAN; available from CDC in the U.S.) and albendazole (in LF-endemic regions such as India and Egypt), or ivermectin (STROMEKTOL) and albendazole (in LF regions where onchocerciasis and/or loiasis are co-endemic). For onchocerciasis, ivermectin also reduces the microfilarial load in the skin, leading to reductions in so-called troublesome itching and ultimately, in preventing river blindness. DEC and ivermectin target the microfilarial stages of the parasite, which circulate in blood and are taken up by arthropod vectors where further parasite development takes place. Both control programs rely heavily on the generosity of major drug companies that donate ivermectin and albendazole, respectively (Burnham and Mebrahtu, 2004; Molyneux et al., 2003).

Ascaris lumbricoides and Toxocara canis. *Ascaris lumbricoides*, known as the “roundworm,” parasitizes a billion or more people worldwide (de Silva et al., 2003; Hotez et al, 2009). Ascariasis may affect from 70-90% of persons in some tropical regions; it is also seen in temperate climates. People become infected by ingesting food or soil contaminated with embryonated *A. lumbricoides* eggs. The highest ascaris worm burdens occur in school-aged children in whom the parasite can cause intestinal obstruction or hepatobiliary ascariasis (Crompton, 2001).

Effective and safe anthelmintics have replaced the older ascaricides. The preferred agents are the benzimidazoles (BZ), mebendazole and albendazole, and the broad spectrum drug pyrantel pamoate. Cure with any of these drugs can be achieved in nearly 100% of cases. Mebendazole and albendazole are preferred for therapy of asymptomatic to moderate ascariasis, as well as for mass drug administration campaigns because those agents have a broad spectrum of activity against GI nematodes. Both compounds should be used with caution to treat heavy *Ascaris* infections, alone

or with hookworms. In rare instances, following chemotherapy hyperactive ascarids may migrate to unusual loci and cause serious complications such as appendicitis, occlusion of the common bile duct, and intestinal obstruction and perforation with peritonitis. For this reason, some clinicians recommend the use of pyrantel for heavy *Ascaris* infections because this agent paralyzes the worms prior to their expulsion. Surgery may be required to alleviate obstructive complications. Pyrantel is considered safe for use during pregnancy, whereas BZ should be avoided during the first trimester. Albendazole is available off-label for treatment of ascariasis in the U.S.

Toxocariasis, a zoonotic infection caused by the canine ascarid *Toxocara canis*, is a common helminthiasis in North America and Europe. Although precise information is not available, toxocariasis may have displaced pinworm as the most common helminth infection in the U.S. (Hotez and Wilkins, 2009). In the U.S., the highest rates of infection are found within African American and Hispanic American populations, with some evidence to suggest that toxocariasis is the most common neglected infection associated with poverty (Hotez, 2008; Hotez and Wilkins, 2009).

Three major syndromes are caused by *T. canis* infection: visceral larva migrans (VLM), ocular larva migrans (OLM), and covert toxocariasis (CTox). CTox may represent an under-appreciated cause of asthma and seizures (Sharghi et al., 2001). Specific treatment of VLM is reserved for patients with severe, persistent, or progressive symptoms (Bethany et al., 2006). Albendazole is the drug of choice. In contrast, anthelmintic therapy for treatment of OLM and CT is controversial. In the case of OLM, surgical management often is indicated, sometimes accompanied by systemic or topical steroids (Sabrosa and de Souza, 2001).

Hookworm

Necator americanus, *Ancylostoma duodenale*. These closely related hookworm species infect ~1 billion people in developing countries (Figure 51–1).

N. americanus is the predominant hookworm worldwide, especially in the Americas, sub-Saharan Africa, South China, and Southeast Asia, whereas *A. duodenale* is focally endemic in Egypt and in parts of northern India and China. Infection also occurs farther north in unusual but relatively warm settings such as mines and large mountain tunnels, hence the terms *miner's disease* and *tunnel disease*. Hookworm larvae live in the soils and penetrate exposed skin. After reaching the lungs, the larvae migrate to the oral cavity and are swallowed. After attaching to the small intestinal mucosa, the derived adult worms feed on host blood. There is a general relationship between the number of hookworms (hookworm burden) as determined by quantitative fecal egg counts and fecal blood loss. In individuals with low iron reserves, the correlation extends to hookworm burden and degree of iron-deficiency anemia. Unlike heavy *Ascaris* and *Trichuris* infections, which occur predominantly in children, heavy hookworm infections also occur in adults, including women of reproductive age. In some

endemic areas, the heaviest hookworm burdens occur exclusively in adult populations.

Although iron supplementation (and transfusion in severe cases) often is helpful in individuals with severe iron-deficiency anemia, the major goal of treatment is to remove blood-feeding adult hookworms from the intestines. Albendazole is the agent of first choice against both *A. duodenale* and *N. americanus*. This drug has the advantage of activity against other GI nematodes (Hotez, 2009). Mebendazole is also commonly used; however, especially when used in a single dose, albendazole is considered far superior to mebendazole at removing adult hookworms from the GI tract (Keiser and Utzinger, 2008). Oral albendazole is the drug of choice for treating *cutaneous larva migrans*, or “creeping eruption,” which is due most commonly to skin migration by larvae of the dog hookworm, *A. braziliense*. Oral ivermectin or topical *thiabendazole* also can be used.

Trichuris trichiura. *Trichuris* (whipworm) infection occurs in ~1 billion people in developing countries (Bethony et al., 2006; de Silva et al., 2003; Hotez et al., 2009). The infection is acquired by ingestion of embryonated eggs. In children, heavy *Trichuris* worm burdens can lead to colitis, *Trichuris* dysentery syndrome, and rectal prolapse (Bundy and Cooper, 1989).

Mebendazole and albendazole are the most effective agents for treatment of whipworm, either as a single agent or together with *Ascaris* and hookworm infections. Both drugs provide significant reductions in host worm burdens even when used in a single dose, such as what might be used in mass drug administration campaigns (Hotez, 2009). However, single-dose therapy with either drug is often ineffective for achieving “cure” (i.e., total worm burden removal), so that a 3-day course of therapy is typically required (Keiser and Utzinger, 2008).

Strongyloides stercoralis. *S. stercoralis*, sometimes called the threadworm or dwarf threadworm, is almost unique among helminths in being able to complete its life cycle within the human host. The organism infects 30–100 million people worldwide, most frequently in the tropics and other hot, humid locales. In the U.S., strongyloidiasis is still endemic in the Appalachian region and in parts of the American South (Hotez, 2008). It also is found in institutionalized individuals living in unsanitary conditions and in immigrants, travelers, and military personnel who lived in endemic areas.

Infective larvae in fecally contaminated soil penetrate the skin or mucous membranes, travel to the lungs, and ultimately mature into adult worms in the small intestine, where they reside. Many infected individuals are asymptomatic, but some experience skin rashes, nonspecific GI symptoms, and cough. Life-threatening disseminated disease, known as the hyperinfection syndrome, can occur in immunosuppressed persons, even decades after the initial infection when parasite replication in the small intestine is unchecked by a competent immune response. Most deaths caused by parasites in the U.S. probably are due to *Strongyloides*

hyperinfection. Ivermectin is the drug of choice for treatment of strongyloidiasis. Hyperinfection may require prolonged or repeated therapy. Although the BZ drugs show some efficacy, they are less effective than ivermectin.

Enterobius vermicularis. *Enterobius*, the pinworm, is one of the most common helminth infections in temperate climates, including the U.S. Although this parasite rarely causes serious complications, pruritus in the perianal and perineal region can be severe, and scratching may cause secondary infection. In female patients, worms may wander into the genital tract and penetrate into the peritoneal cavity. Salpingitis or even peritonitis may ensue. Because the infection easily spreads throughout members of a family, a school, or an institution, the physician must decide whether to treat all individuals in close contact with an infected person. More than one course of therapy may be required.

Pyrantel pamoate, mebendazole, and albendazole are highly effective. Single oral doses of each should be repeated after 2 weeks. When their use is combined with rigid standards of personal hygiene, a very high proportion of cures can be obtained. Treatment is simple and almost devoid of side effects.

Trichinella spiralis. *T. spiralis* is an ubiquitous zoonotic nematode parasite. Trichinosis in the U.S. and the developing world is usually caused by eating under- or uncooked venison and wild pigs. When released by acid stomach contents, encysted larvae mature into adult worms in the intestine. Adults then produce infectious larvae that invade tissues, especially skeletal muscle and heart.

Severe infection can be fatal, but more typically causes marked muscle pain and cardiac complications. Fortunately, infection is readily preventable. All pork, including pork sausages, should be thoroughly cooked before being eaten. The encysted larvae are killed by exposure to heat of 60°C for 5 minutes.

Albendazole and mebendazole are effective against the intestinal forms of *T. spiralis* that are present early in infection. The efficacy of these agents or any anthelmintic agent on larvae that have migrated to muscle is questionable. Glucocorticoids may be of considerable value in controlling the acute and dangerous manifestations of established infection, although steroids can alter the metabolism of albendazole.

Lymphatic Filariasis: Wuchereria bancrofti, Brugia malayi, and B. timori. Adult worms that cause human lymphatic filariasis (LF) dwell in the lymphatic vessels. Transmission occurs through the bite of infected mosquitoes; ~90% of cases are due to *W. bancrofti*, most of the rest are due to *B. malayi*. The major endemic regions are sub-Saharan Africa, the Indian subcontinent, Southeast Asia and the Pacific region, and in four tropical countries of the Americas (Haiti, Dominican Republic, Guyana, and Brazil).

In LF, host reaction to the adult worms initially cause lymphatic inflammation manifested by fevers, lymphangitis, and lymphadenitis. This can progress to lymphatic obstruction and is often exacerbated by secondary attacks of bacterial cellulitis, leading to lymphedema manifested by hydrocele and elephantiasis. An accentuated immune reaction to microfilariae, termed *tropical pulmonary eosinophilia*, also occurs in some persons.

The Global Program for the Elimination of LF recommends that all at-risk individuals be treated once yearly with an oral two-drug combination (Molyneux and Zagaria, 2002). Today, >500 million people are treated annually (Hotez, 2009). For most countries, the WHO recommends diethylcarbamate (DEC) for its micro- and macrofilaricidal effect in combination with albendazole to enhance macrofilaricidal activity. The exceptions are in many parts of sub-Saharan Africa and Yemen, where either loiasis or onchocerciasis are co-endemic. In these regions, ivermectin is substituted for DEC (Molyneux et al., 2003). DEC and ivermectin clear circulating microfilariae from infected subjects (Molyneux and Zagaria, 2002), thereby reducing the likelihood that mosquitoes will transmit LF to other individuals. The number of serious adverse events from LF-control chemotherapy programs has been remarkably low, 1 out of 4.5 million subjects treated (Molyneux et al., 2003).

DEC is the drug of choice for specific therapy directed against adult worms. However, the anthelmintic effect on the adult worms is variable. Although chemotherapy decreases the incidence of filarial lymphangitis, it is unclear whether it reverses lymphatic damage or other chronic manifestations of LF. In longstanding elephantiasis, surgical measures may be required to improve lymph drainage and remove redundant tissue.

Loa loa (loiasis). *L. loa* is a tissue-migrating filarial parasite found in large river regions of Central and West Africa; the parasite is transmitted by deerflies. Adult worms reside in subcutaneous tissues, and infection may be recognized when these migrating worms cause episodic and transient subcutaneous “Calabar” swellings. Adult worms may also pass across the sclera, causing “eyeworm.” Rarely, encephalopathy, cardiopathy, or nephropathy occurs in association with heavy infection, particularly following chemotherapy.

DEC currently is the best single drug for the treatment of loiasis, but it is advisable to start with a small initial dose to diminish host reactions that result from destruction of microfilariae. Glucocorticoids may be administered to ameliorate post-treatment acute reactions. In rare instances, life-threatening encephalopathy follows the treatment of loiasis, probably due to the inflammatory reaction to dead or dying microfilariae lodged in the cerebral microvasculature. Guidelines have been developed aimed at screening out populations with heavy infection so that they are not administered ivermectin, which has also been associated with fatal encephalopathy. The potential complications of unmonitored DEC treatment of loiasis are a major reason why this agent is not recommended for mass chemoprophylaxis of LF in regions of sub-Saharan Africa where *L. loa* is co-endemic.

Onchocerca volvulus (Onchocerciasis or River Blindness). Transmitted by blackflies near fast-flowing

streams and rivers, *O. volvulus* infects 17-37 million people in 22 countries in sub-Saharan Africa (Hotez et al., 2009; Molyneux et al., 2003), and <100,000 people in six Latin American countries (Mexico, Guatemala, Ecuador, Colombia, Venezuela, and Brazil). Cases also occur in Yemen. Inflammatory reactions, primarily to microfilariae rather than adult worms, affect the subcutaneous tissues, lymph nodes, and eyes. Onchocerciasis is a leading cause of infectious blindness worldwide and results from the cumulative destruction of microfilariae in the eyes, a process that evolves over decades.

Ivermectin is the drug of choice for control and treatment of onchocerciasis. DEC is no longer recommended because ivermectin produces far milder systemic reactions and few if any ocular complications. Ivermectin treatment clears microfilariae in the tissues, prevents the development of blindness, and interrupts transmission. It also results in delayed resumption of production of microfilariae in the uterus of female worms. The African Programme for Onchocerciasis Control coordinates treatment of river blindness in Central and West Africa (www.who.int/pbd/blindness/onchocerciasis). Although suramin (Chapter 50) kills adult *O. volvulus* worms, treatment with this relatively toxic agent is generally not advised.

Dracunculus medinensis. Known as the guinea, dragon, or Medina worm, this parasite causes dracunculiasis, an infection in decline with <5000 cases as of 2009, most of which occurred in rural Sudan, Ghana, and Mali. People become infected by drinking water containing copepods that carry infective larvae. After ~1 year, the adult female worms migrate and emerge through the skin, usually of the lower legs or feet. Through the advocacy and work of the Carter Center in partnership with WHO, strategies such as filtering drinking water and reducing contact of infected individuals with water have markedly reduced the transmission and prevalence of dracunculiasis in most endemic regions.

There is no effective anthelmintic for treatment of *D. medinensis* infection. Traditional treatment for this disabling condition is to draw the live adult female worm out day by day by rolling it onto a small piece of wood. This procedure risks significant secondary bacterial infection. *Metronidazole*, 250 mg given three times a day for 10 days, may provide symptomatic and functional relief by facilitating removal of the worm through indirect suppression of host inflammatory responses.

Cestodes (Flatworms)

Taenia saginata. Humans are the definitive hosts for *Taenia saginata*, known as the beef tapeworm. This most common form of tapeworm usually is detected after passage of proglottids from the intestine. It is cosmopolitan, occurring most commonly in sub-Saharan Africa and the Middle East, where undercooked or raw

beef is consumed. Preventable by cooking beef to 60°C for >5 minutes, this infection rarely produces serious clinical disease, but it must be distinguished from that produced by *Taenia solium*.

Praziquantel (BILTRICIDE) is the drug of choice for treatment of infection by *T. saginata*, although niclosamide can also be used. Both drugs are very effective, simple to administer, and comparatively free from side effects. Assessment of cure can be difficult because the worm (segments as well as scolex) usually is passed in a partially digested state. If the parasitological diagnosis is uncertain, niclosamide (not available in the U.S.) is the preferred drug because of the danger of an inadvertent secondary inflammatory response to occult cysticercosis.

Taenia solium. *Taenia solium*, or pork tapeworm, also has a cosmopolitan distribution; immigrant populations are a common source of infection in the U.S. This cestode causes two types of infection. The intestinal form with adult tapeworms is caused by eating undercooked meat containing cysticerci, or more commonly by fecal-oral transmission of infective *T. solium* eggs from another infected human host. *Cysticercosis*, the far more dangerous systemic form that usually coexists with the intestinal form, is caused by invasive larval forms of the parasite (Garcia and Del Brutto, 2000). Systemic infection results either from ingestion of fecally contaminated infectious material, or from eggs liberated from a gravid segment passing upward into the duodenum, where the outer layers are digested. In either case, larvae gain access to the circulation and tissues, exactly as in their cycle in the intermediate host, usually the pig. The seriousness of the resulting disease depends on the particular tissue involved. Invasion of the brain (neurocysticercosis) is common and dangerous. Epilepsy, meningitis, and increased intracranial pressure can develop, depending on the inflammatory reactions to the cysticerci and/or their size and location.

Niclosamide is preferred for treatment of intestinal infections with *T. solium* because it will have no effect on occult neurocysticercosis. Albendazole is the drug of choice for treating cysticercosis. The advisability of chemotherapy for neurocysticercosis is controversial (Salinas and Prasad, 2000), being appropriate only when it is directed at live cysticerci and not against dead or dying cysticerci (as evidenced by neuroimaging using contrast agents) or in settings where cerebral imaging reveals a large burden of parasites. Pretreatment with glucocorticoids is strongly advised in this situation to minimize inflammatory reactions to dying parasites (Evans et al., 1997). Anthelmintic treatment can shrink brain cysts but also can have adverse consequences leading to seizures and hydrocephalus especially if corticosteroids are not administered beforehand. Some experts advocate use of albendazole therapy for patients with multiple cysts or viable cysts (as determined by absence of ring enhancement on contrast neuroimaging studies).

Diphyllobothrium latum. *Diphyllobothrium latum*, the fish tapeworm, is found most commonly in rivers and lakes of the Northern Hemisphere. In North America, the pike is the most common second intermediate host. The eating of inadequately cooked infested fish introduces the larvae into the human intestine; the larvae can develop into adult worms up to 25 m long. Most infected individuals are asymptomatic. The most frequent manifestations include abdominal symptoms and weight loss; megaloblastic anemia develops due to a deficiency of vitamin B₁₂, which is taken up by the parasite.

Therapy with praziquantel readily eliminates the worm and ensures hematological remission.

Hymenolepis nana. *Hymenolepis nana*, the dwarf tapeworm, is the smallest and most common tapeworm parasitizing humans. Infection with this cestode is cosmopolitan, more prevalent in tropical than temperate climates, and most common among institutionalized children, including those in the southern U.S. *H. nana* is the only cestode that can develop from ovum to mature adult in humans without an intermediate host. Cysticerci develop in the villi of the intestine and then regain access to the intestinal lumen where larvae mature into adults. Treatment therefore must be adapted to this cycle of autoinfection.

Praziquantel is effective against *H. nana* infections, but higher doses than used for other tapeworm infections usually are required. In addition, therapy may have to be repeated. Treatment failure or reinfection is indicated by the appearance of eggs in the stool ~4 weeks after the last dose. Albendazole is partially efficacious against *H. nana*; in 277 cases from 11 studies, 69.5% of patients were cured by albendazole (400 mg daily for 3 days) (Horton, 2000).

Echinococcus Species. Humans serve as one of several intermediate hosts for larval forms of *Echinococcus* species that cause “cystic” (*E. granulosus*) and “alveolar” (*E. multilocularis* and *E. vogeli*) hydatid disease. Dogs and related canids are definitive hosts for these tapeworms. Parasite eggs from canine stools are a major worldwide cause of disease in associated livestock (e.g., sheep and goats). *E. granulosus* produces unilocular, slowly growing cysts, most often in liver and lung, whereas *E. multilocularis* creates multilocular invasive cysts, predominantly in the same organs. Removal of the cysts by surgery is the preferred treatment, but leakage from ruptured cysts may spread disease to other organs.

Prolonged regimens of albendazole, either alone or as an adjunct to surgery, are reportedly of some benefit. However, some patients are not cured despite multiple courses of therapy, especially

in alveolar echinococcosis where lifelong therapy with albendazole may be required. Treatment of infected dogs with praziquantel eradicates adult worms and interrupts transmission of these infections. New treatment methods, such as percutaneous puncture, aspiration, injection of scolicidal agents, and re-aspiration-based techniques, have received much attention, and they yield rates of cure and relapse equivalent to those following surgery. Benzimidazole treatment should be administered in the perioperative period (Kern, 2003).

Trematodes (Flukes)

Schistosoma haematobium, Schistosoma mansoni, Schistosoma japonicum. These are the main species of blood flukes that cause human schistosomiasis; less common species are *Schistosoma intercalatum* and *Schistosoma mekongi*. The infection affects >200 million people (Figure 51–1), and >700 million are at risk (Steinmann et al., 2006). In the Americas, schistosomiasis occurs in Brazil, Suriname, Venezuela and certain Caribbean islands (*S. mansoni*), much of Africa and the Arabian Peninsula (*S. mansoni* and *S. haematobium*), and China, the Philippines, and Indonesia (*S. japonicum*). More than 90% of the cases of schistosomiasis occur in sub-Saharan Africa, with approximately two-thirds of the cases caused by *S. haematobium* and one-third caused by *S. mansoni*. Infected freshwater snails act as intermediate hosts for transmission of the infection, which continues to spread as agriculture and water resources increase. Like most helminth infections, the clinical manifestations of schistosomiasis generally correlate with the intensity of infection, with pathology primarily involving the liver, spleen, and GI tract (for *S. mansoni* and *S. japonicum*) or the urinary and genital tracts (*S. haematobium*). Heavy infection with *S. haematobium* predisposes to squamous cell carcinoma of the bladder. Chronic infections can cause porto-systemic shunting due to hepatic granuloma formation and periportal fibrosis in the liver.

Praziquantel is the drug of choice for treatment of schistosomiasis. The drug is safe and effective when given in single or divided oral doses on the same day. These properties make praziquantel especially suitable for population-based chemotherapy. Moreover, repeated chemotherapy with praziquantel is thought to accelerate protective immune responses by increasing exposure to antigens released from dying worms that induce a T_H2 response (Mutapi et al., 1998). In sub-Saharan Africa, praziquantel is typically administered in mass drug administration campaigns for populations infected with schistosomiasis, with the use of a height pole as a guide to drug dosage. Sadly, even the modest cost of US \$0.08 per tablet is beyond the health budgets of many sub-Saharan African countries (Hotez, 2009). Although not effective clinically against *S. haematobium* and *S. japonicum*, oxamniquine is effective for treatment of *S. mansoni* infections, particularly in South America, where the sensitivity of most strains may permit single-dose therapy. However, resistance has

been reported and higher doses of the drug are required to treat African strains than to treat Brazilian strains of *S. mansoni*. Metrifonate (trichlorfon) has been used with considerable success in the treatment of *S. haematobium* infections, but the drug is not effective against *S. mansoni* and *S. japonicum*. Metrifonate is relatively inexpensive and can be combined with oxamniquine for treatment of mixed infections with *S. haematobium* and *S. mansoni*.

The artemisinin derivative artemether (Chapter 49) shows promise as an anti-schistosomal agent. Artemether targets the larval schistosomula stages of the parasite. Clinical trials confirmed that artemether (administered in an oral dose of 6 mg/kg once every 2-3 weeks) significantly reduced the incidence and intensity of schistosome infections without adverse reactions. In animals harboring juvenile and adult schistosome worms, the combination of artemether and praziquantel resulted in significant reductions of worm burden than each drug administered singly (Xiao et al., 1985). There is concern, however, that widespread use of artemether as an anthelmintic may induce drug-resistant malaria in areas where multidrug resistant plasmodia still respond to artemether therapy.

Paragonimus westermani and Other Paragonimus Species. Lung flukes, including several *Paragonimus* species, infect humans and carnivores; *P. westermani* is the most common. Found in the Far East and on the African and South American continents, these parasites have two intermediate hosts: snails and crustaceans. Humans become infected by eating raw or undercooked crabs or crayfish. Disease is caused by reactions to adult worms in the lungs or ectopic sites.

Praziquantel is effective, as is triclabendazole (EGATEN), in a dose of 10 mg/kg daily for 3 days (Gao et al., 2003). Bithionol is considered a second-line agent; it is available in the U.S. through the Centers for Disease Control and Prevention (CDC).

Clonorchis sinensis, Opisthorchis viverrini, Opisthorchis felineus. These closely related trematodes exist in the Far East (*C. sinensis*, “the Chinese liver fluke,” and *O. viverrini*) and parts of Eastern Europe (*O. felineus*). Metacercariae released from poorly cooked infected cyprinoid fish mature into adult flukes that inhabit the human biliary system. Heavy infections can cause obstructive liver disease, inflammatory gallbladder pathology associated with cholangiocarcinoma, and obstructive pancreatitis.

One-day therapy with praziquantel is highly effective against these parasites.

Fasciola hepatica. Humans are only accidentally infected with *F. hepatica*, the large liver fluke that exists worldwide and primarily affects herbivorous ruminants such as cattle and sheep. Eating contaminated freshwater plants such as watercress initiates the infection. Migratory larvae penetrate the intestine, invade the liver from the peritoneum, and eventually reside in the bil-

iary tract. The acute illness is characterized by fever, urticaria, and abdominal symptoms, whereas chronic infection resembles that caused by other hepatic flukes. Unlike other flukes, *Fasciola* spp. do not respond to praziquantel.

Triclabendazole, given as a single oral dose of 10 mg/kg, or in cases of severe infection 20 mg/kg divided into two doses, is the drug of choice for treatment of fascioliasis. In the U.S., this agent is available only from the manufacturer (Novartis). The cure rate among a cohort of Turkish patients was 78%, and the addition of another course(s) increased this to 90%. No significant side effects were reported (Saba et al., 2004). Bithionol was previously the recommended drug.

Fasciolopsis buski, Heterophyes heterophyes, Metagonimus yokogawai, Nanophyetus salmincola. Obtained by eating contaminated water chestnuts and other caltrops in Southeast Asia, *F. buski* is one of the largest parasites causing human infection. Undercooked fish transmit infection with the other, much smaller GI trematodes that are widely distributed geographically. Abdominal symptoms produced by reactions to these flukes usually are mild, but heavy infections with *F. buski* can cause intestinal obstruction and peritonitis.

Infections with all the intestinal trematodes respond well to single-day therapy with praziquantel.

ANTHELMINTIC DRUGS

Benzimidazoles (BZ)

History. The discovery by Brown and coworkers that thiabendazole possessed potent activity against GI nematodes sparked development of the benzimidazoles as broad-spectrum anthelmintic agents against parasites of importance in both veterinary and human medicine. Of the hundreds of derivatives tested, those most therapeutically useful have modifications at the 2 and/or 5 positions of the benzimidazole ring system. Three compounds, thiabendazole, mebendazole, and albendazole, have been used extensively for the treatment of human helminth infections. The chemical structures of these drugs are shown in Table 51-1.

Thiabendazole, which contains a thiazole at position 2, is active against a wide range of nematodes that infect the GI tract. However, its clinical value against these organisms has declined markedly because of thiabendazole’s toxicity (particularly unwanted central nervous system [CNS], liver, hypersensitivity, and visual side effects) relative to that of other equally effective drugs. Mebendazole, the prototype benzimidazole carbamate, was introduced for the treatment of intestinal roundworm infections as a result of research carried out >30 years ago. Albendazole is a newer benzimidazole carbamate that is used worldwide, both for treatment of intestinal nematodes and cestodes, but also because of the systemic bioavailability of its sulphoxide metabolite against tissue-dwelling nematodes and cestodes (Venkatesan, 1998). Albendazole has become the drug of choice for treating cysticercosis (Garcia and Del

Table 51-1

Structure of the Benzimidazoles

—NHCO ₂ CH ₃	CH ₃ CH ₂ CH ₂ S—	Albendazole

Brutto, 2000) and cystic hydatid disease (Horton, 1997). When used in single dose in conjunction with either ivermectin or DEC, it has shown additive effect in the control of lymphatic filariasis and related tissue filarial infections (Molyneux and Zagaria, 2002; Molyneux et al., 2003). Of note, albendazole lacks activity against the liver fluke *F. hepatica*.

Anthelmintic Action. The primary mechanism of action of BZ is thought to be inhibition of microtubule polymerization by binding to β -tubulin (Prichard, 1994). The selective toxicity of these agents against helminths results from their higher affinity for parasite β -tubulin than for the same target in higher eukaryotes. A range of other biochemical changes are found in nematodes following BZ exposure, including inhibition of mitochondrial fumarate reductase, reduced glucose transport, and uncoupling of oxidative phosphorylation,

Studies of BZ resistance by site-directed mutagenesis of the β -tubulin gene in the free-living nematode *Caenorhabditis elegans* (Driscoll et al., 1989) and of BZ resistance in the sheep nematode *Haemonchus contortus* have provided insights into the mechanisms of action of BZ drugs and of the mechanism of resistance (Prichard, 1994). In drug-resistant isolates of *H. contortus*, BZ drugs display reduced affinity binding to β -tubulin and specific mutations occur in the β -tubulin gene (Kwa et al., 1995; Roos, 1997). The major mechanism of drug resistance in nematodes involves selection of a naturally occurring “resistant” genotype entailing a Phe \rightarrow Tyr change at position 200 of β -tubulin (Sangster and Gill, 1999). Evidence for the emergence of β -tubulin gene mutations associated with resistance among human nematodes is confined to *T. trichuria* (Diawara et al., 2009) and *W. bancrofti* (Schwab et al., 2005). Drug treatment failures have been reported in hookworm infections (Flohr et al., 2007), but there is little evidence of widespread dissemination of resistant forms. However, these recent observations, and the increasing use of BZs in parasite control

programs, suggest that monitoring for BZ resistance is critically important, especially as veterinary experience indicates that drug-resistant helminths can persist even after selection pressure is withdrawn.

The BZs, exemplified by mebendazole and albendazole, are versatile anthelmintic agents, particularly against GI nematodes, where their action is not limited by a requirement for absorption. Appropriate doses of mebendazole and albendazole are highly effective in treating most of the major STH infections (ascariasis, enterobiasis, trichuriasis, and hookworm) as well as less common human nematode infections. These drugs are active against both larval and adult stages of nematodes that cause these infections, and they are ovicidal for *Ascaris* and *Trichuris*. Immobilization and death of susceptible GI parasites occur slowly, and their clearance from the GI tract may not be complete until several days after treatment.

Removal of STHs in children by a single-dose treatment with either albendazole or mebendazole improves their health, as evidenced by post-treatment catch-up growth and replenishment of iron stores (Hotez et al., 2004, 2009). In addition, BZ treatment of STH infections results in improvements in childhood intellectual and cognitive development (Drake et al., 2000). These observations have led to advocacy for the implementation of large-scale STH control programs that target school-aged children (Hotez et al., 2009; WHO, 2002).

Albendazole is superior to mebendazole in curing hookworm and trichuriasis infections in children (de Silva et al., 2003), especially when used as a single dose (Keiser and Utzinger, 2008). Moreover, albendazole is more effective than mebendazole against strongyloidiasis (Liu and Weller, 1993) and is superior to mebendazole against all tissue-dwelling helminths due to its active metabolite albendazole sulfoxide. It is therefore the drug of choice against cystic and alveolar hydatid disease caused by *Echinococcus granulosus* and *E. multilocularis* (Davis et al., 1989; Horton, 1997), and neurocysticercosis caused by larval forms of *Taenia solium* (Evans et al., 1997; Garcia and Del Brutto, 2000). The BZs probably are active against the intestinal stages of *Trichinella spiralis* in humans but probably do not affect the larval stages in tissues. Albendazole is highly effective against the migrating forms of dog and cat hookworms that cause cutaneous larval migrans, although thiabendazole can be applied topically for this purpose. Microsporidial species that cause intestinal infections in HIV-infected individuals respond partially (*Enterocytozoon bieneusi*) or completely (*Encephalitozoon intestinalis* and related *Encephalitozoon* species) to albendazole. The sulfoxide metabolite of albendazole appears to be especially effective against these parasites *in vitro* (Katiyar and Edlind, 1997). Albendazole also has efficacy against anaerobic protozoa such as *Trichomonas vaginalis* and *Giardia lamblia* (Ottesen et al., 1999). Although BZs exert antifungal activity *in vitro*, they have no clinical utility in human mycoses.

Absorption, Fate, and Excretion. Thiabendazole is soluble in water; mebendazole and albendazole are poorly soluble in aqueous solution. The low systemic bioavailability (22%) of mebendazole results from a combination of poor absorption and rapid first-pass hepatic metabolism. Co-administration of *cimetidine* will increase plasma levels of mebendazole, possibly due to

inhibition of first-pass CYP-mediated metabolism (Dayan, 2003). The small proportion of mebendazole that is absorbed is ~95% bound to plasma proteins and is extensively metabolized. Mebendazole, rather than its metabolites, appears to be the active drug form (Gottschall et al., 1990). Conjugates of mebendazole and its metabolites have been found in bile, but little unchanged mebendazole appears in the urine.

Albendazole is variably and erratically absorbed after oral administration; absorption is enhanced by the presence of fatty foods and possibly by bile salts. A fatty meal or eating enhances absorption by up to 5-fold in humans (Dayan, 2003). After a 400-mg oral dose, albendazole cannot be detected in plasma because the drug is rapidly metabolized in the liver and possibly in the intestine, to albendazole sulfoxide, which has potent anthelmintic activity (Redondo et al., 1999).

Both the (+) and (-) enantiomers of albendazole sulfoxide are formed, but the (+) enantiomer reaches much higher peak plasma concentrations in humans and is cleared much more slowly than the (-) form (Marques et al., 1999). Albendazole sulfoxide is ~70% bound to plasma proteins and has a highly variable plasma $t_{1/2}$ of 4-15 hours (Marques et al., 1999). It is well distributed into various tissues including hydatid cysts, where it reaches a concentration of ~20% that in plasma (Morris et al., 1987). The bioavailability of parent drug and activity of albendazole sulfoxide explain why albendazole is more effective than mebendazole for treatment of tissue-dwelling helminths. Oxidation of the sulfoxide derivatives to the nonchiral sulfone metabolite of albendazole, which is pharmacologically inactive, is probably rate limiting in determining the clearance and plasma $t_{1/2}$ of the bioactive (+) sulfoxide metabolite. In animal models, BZs can induce their own metabolism (Gleizes et al., 1991). Albendazole metabolites are excreted mainly in the urine.

Therapeutic Uses. The introduction of thiabendazole (MINTEZOL) was a major advance in anthelmintic chemotherapy, but its clinical use is now limited, due to the better tolerability and generally better activity of mebendazole and albendazole. Thiabendazole remains a useful drug when applied topically for treatment of cutaneous larva migrans (creeping eruption). Most patients thus treated experience marked relief of symptoms of creeping eruption, and a high percentage of cures are achieved after topical treatment with an extemporaneously compounded 15% thiabendazole in a water-soluble cream base applied to the affected area two to three times daily for 5 days (Davies et al., 1993). For treatment of strongyloidiasis, thiabendazole has been replaced by ivermectin.

Mebendazole is an effective drug for treatment of GI nematode infections. It is only administered orally, with the same dosage schedule applying to adults and to children >2 years of age. For treatment of enterobiasis, a single 100-mg tablet is taken; a second dose should be given after 2 weeks. For control of ascariasis, trichuriasis, or hookworm infections, the recommended regimen is 100 mg of mebendazole taken in the morning and evening for three consecutive days (or a single 500-mg tablet administered once). If the patient is not cured 3 weeks after treatment, a second course should be given. The

3-day mebendazole regimen is more effective than single doses of either mebendazole (500 mg) or albendazole (400 mg). A single dose of albendazole is superior to a single dose of mebendazole against hookworms and trichuriasis (Keiser and Utzinger 2008).

Like mebendazole, albendazole is a safe and highly effective therapy for infections with GI nematodes, including *A. lumbricoides*, *T. trichuria*, and hookworms. For treatment of STH infections (enterobiasis, ascariasis, trichuriasis, and hookworm), albendazole is taken as a single oral 400-mg dose by adults and children >2 years of age. In children between the ages of 12 and 24 months, the WHO recommends a reduced dose of 200 mg. Cure rates for light to moderate *Ascaris* infections typically are >97%, although heavy infections may require therapy for 2-3 days. A 400-mg dose of albendazole appears to be superior to a 500-mg dose of mebendazole for curing hookworm infections and reducing egg counts (Keiser and Utzinger, 2008). When administered at a dose of 400 mg daily for 3 days, albendazole shows some efficacy in treatment of strongyloidiasis but is less effective than ivermectin for treatment of this infection (Marti et al., 1996).

Albendazole is the drug of choice for treating cystic hydatid disease due to *Echinococcus granulosus*. Although the drug provides only a modest cure rate when used alone, it is a useful adjunctive treatment in the perioperative period to reduce the risk of disseminated infection resulting from spillage of cyst contents at the time of surgery, or with nonoperative puncture, aspiration, injection, and re-aspiration (PAIR) procedures (Horton, 1997; Schantz, 1999). A typical dosage regimen for adults is 400 mg given twice a day (for children, 15 mg/kg per day with a maximum of 800 mg) for 1-6 months. Although it is the only drug available with useful activity against alveolar echinococcosis caused by *E. multilocularis* (Venkatesan, 1998), it is parasiti-static rather than -cidal, and lifelong therapy with or without surgical intervention is usually required to control the infection.

Albendazole also is the preferred treatment of neurocysticercosis caused by larval forms of *Taenia solium* (Evans et al., 1997; Garcia and Del Brutto, 2000). The recommended dosage is 400 mg given twice a day for adults for 8-30 days, depending on the number, type, and location of the cysts. For children, the dose is 15 mg/kg per day (maximum: 800 mg) in two doses for 8-30 days. For both adults and children, the course can be repeated as necessary, as long as liver and bone marrow toxicities are monitored. Glucocorticoid therapy is usually begun before initiating albendazole therapy and continued for several days after institution of therapy to reduce the incidence of side effects resulting from inflammatory reactions to dead and dying cysticerci. Glucocorticoids increase plasma levels of albendazole sulfoxide. Prior to initiating chemotherapy of neurocysticercosis, physicians should consult with a neurologist and/or neurosurgeon regarding anticonvulsant therapy, the possible development of complications of arachnoiditis, vasculitis, or cerebral edema, and the need for surgical intervention should obstructive hydrocephalus occur.

Albendazole, 400 mg per day, also has shown efficacy for therapy of microsporidial intestinal infections in patients with AIDS. Infection with *Capillaria philippinensis* can be treated with a 10-day treatment regimen with albendazole (400 mg/day).

Albendazole has been combined with either DEC or ivermectin in programs directed toward controlling LF (Molyneux and Zagaria, 2002; Ottesen et al., 1999). The strategy is annual dosing

with combination therapy for 4–6 years to maintain the microfilariaemia at such low levels that transmission cannot occur. The period of therapy is estimated to correspond to the duration of fecundity of adult worms. Albendazole is given with DEC to control LF in most parts of the world. However, to avoid serious reactions to dying microfilariae, the albendazole/ivermectin combination is recommended in locations where filariasis co-exists with either onchocerciasis or loiasis. Recently, the benefits of adding albendazole to either DEC or ivermectin for LF control were evaluated (Addiss et al., 2004); there currently is insufficient reliable research to confirm or refute whether adding albendazole has an effect on LF.

Toxicity, Side Effects, Precautions, and Contraindications. Excluding thiabendazole, the BZs have excellent safety profiles. To date millions of children have been treated in mass deworming chemotherapy programs. Overall, the incidence of side effects, primarily mild GI symptoms, occur in only 1% of treated children (Urbani and Albonico, 2003).

The clinical utility of thiabendazole in adults is compromised by its toxicity. Side effects frequently encountered with therapeutic doses include anorexia, nausea, vomiting, and dizziness.

Less frequently, diarrhea, fatigue, drowsiness, giddiness, or headache occur. Occasional fever, rashes, erythema multiforme, hallucinations, sensory disturbances, and Stevens-Johnson syndrome have been reported. Angioedema, shock, tinnitus, convulsions, and intrahepatic cholestasis are rare complications of therapy. Some patients excrete a metabolite that imparts an odor to the urine much like that occurring after ingestion of asparagus. Crystalluria without hematuria has been reported on occasion; it promptly subsides with discontinuation of therapy. Transient leukopenia has been noted in a few patients on thiabendazole therapy. Because CNS side effects occur frequently, activities requiring mental alertness should be avoided during therapy. Thiabendazole has hepatotoxic potential and should be used with caution in patients with hepatic disease or decreased hepatic function. The effects of thiabendazole in pregnant women have not been studied adequately, so it should be used in pregnancy only when the potential benefit justifies the unknown risk.

Mebendazole does not cause significant systemic toxicity in routine clinical use, even in the presence of anemia and malnutrition. This probably reflects its low systemic bioavailability. Transient symptoms of abdominal pain, distention, and diarrhea have occurred in cases of massive infestation and expulsion of GI worms.

Rare side effects in patients treated with high doses of mebendazole include allergic reactions, alopecia, reversible neutropenia, agranulocytosis, and hypospermia. Reversible elevation of serum transaminases has been observed when the drug was given in long courses for treatment of hydatid disease. Mebendazole treatment has been associated with occipital seizures (Wilmshurst and Robb, 1998). Mebendazole is a potent embryo toxin and teratogen in laboratory animals; effects may occur in pregnant rats at single oral doses as low as 10 mg/kg. However, there is no evidence for

teratogenicity in humans, probably due to its poor systemic bioavailability. Although the general advice is that mebendazole should not be given to pregnant women or to children <2 years of age, it has been safely used after the first trimester of pregnancy for its beneficial effect on anemia due to clearance of hookworm (WHO, 2006). Because the soil-transmitted helminths are important causes of maternal and child morbidity during pregnancy, the WHO recommends its use for infected pregnant women in the second or third trimester.

Albendazole produces few side effects when used for short-term therapy of GI helminth infections, even in patients with heavy worm burdens. Transient mild GI symptoms (epigastric pain, diarrhea, nausea, and vomiting) occur in ~1% of treated individuals. Dizziness and headache occur on occasion. In school-age mass treatments, the incidence of side effects with albendazole is very low (Horton, 2000).

Even in long-term therapy of cystic hydatid disease and neurocysticercosis, albendazole is well tolerated by most patients. The most common side effect is liver dysfunction, generally manifested by an increase in serum transaminase levels; rarely jaundice may be noted, but enzyme activities return to normal after therapy is completed.

A pharmaco-epidemiological analysis concluded that long-term treatment of echinococcosis or cysticercosis with high-dose albendazole accounted for most of the adverse drug reactions attributed to anthelmintic therapy (Bagheri et al., 2004). Therefore, liver function tests should be monitored during protracted albendazole therapy, and the drug is not recommended for patients with cirrhosis (Davis et al., 1989). Especially if not pretreated with glucocorticoids, some patients with neurocysticercosis may experience serious neurological sequelae that depend on the location of inflamed cysts with dying cysticerci. Other side effects during extended therapy include GI pain, severe headaches, fever, fatigue, loss of hair, leukopenia, and thrombocytopenia. Albendazole is teratogenic and embryotoxic in animals, and it should not be given to pregnant women. The safety of albendazole in children < 2 years of age has not been established.

The BZs as a group display remarkably few clinically significant interactions with other drugs. The most versatile member of this family, albendazole, probably induces its own metabolism, and plasma levels of its sulfoxide metabolites can be increased by co-administration of glucocorticoids and possibly praziquantel. Caution is advised when using high doses of albendazole together with general inhibitors of hepatic CYPs. As indicated earlier, co-administration of cimetidine can increase the bioavailability of mebendazole.

Use in Pregnancy. Because of the ongoing and anticipated widespread use of BZs in global control programs for both STH and filarial infections, there is a high level of interest about their use in young children and in the second and third trimesters of pregnancy.

As indicated earlier, both albendazole and mebendazole are embryotoxic and teratogenic in pregnant rats, and they are not generally recommended for use in pregnancy (Bethony et al., 2006). However, in postmarketing surveys on women who inadvertently consumed mebendazole during the first trimester, the incidence of spontaneous abortion and malformations did not exceed that of the

general population; comparable studies with albendazole are not available. A review of the risk of congenital abnormalities from BZs concluded that their use during pregnancy was not associated with an increased risk of major congenital defects; nonetheless, it is recommended that treatment should be avoided during the first trimester of pregnancy (Urbani and Albonico, 2003).

Hookworm occurs in many pregnant women in developing countries, including up to one-third of pregnant women in sub-Saharan Africa (Brooker et al., 2008). Because some of these infected women may develop iron-deficiency anemia leading to adverse pregnancy outcomes, BZ treatment would be beneficial during the second and third trimesters of pregnancy (WHO, 2002, 2006). There is no evidence that maternal BZ therapy presents a risk to breast-fed infants (Urbani and Albonico, 2003).

Use in Young Children. The BZs have not been extensively studied in children <2 years of age. The WHO concluded that BZs may be used to treat children >1 year if the risks from adverse consequences caused by STHs are justified. The recommended dose is 200 mg of albendazole in children between the ages of 12 and 24 months (WHO, 2006).

Diethylcarbamazine (DEC)

Diethylcarbamazine (DEC) is a first-line agent for control and treatment of lymphatic filariasis caused by *Wuchereria bancrofti* and *Brugia malayi* and for therapy of tropical pulmonary eosinophilia, an uncommon manifestation of lymphatic filarial infection (Ottesen and Ramachandran, 1995). DEC is also the drug of choice for treatment of loiasis, caused by infection with the filarial parasite *L. loa*. However, caution must be used in treatment of high-grade *L. loa* infection because the rapid killing of large numbers of microfilariae can cause life-threatening post-treatment complications. Annual single-dose combination chemotherapy with both DEC and albendazole show considerable promise for the control of lymphatic filariasis in geographic regions where onchocerciasis and loiasis are not endemic (Molyneux and Zagaria, 2002; Molyneux et al., 2003).

Chemistry. Diethylcarbamazine (HETRAZAN) is formulated as the water-soluble citrate salt containing 51% by weight of the active base. Because the compound is tasteless, odorless, and stable to heat, it also can be taken in the form of fortified table salt containing 0.2-0.4% by weight of the base. The drug is available outside the U.S.; in the U.S., it is supplied by the CDC.

Anthelmintic Action. The mechanism of action of DEC against susceptible filarial species is not well understood, but the drug appears to exert a direct effect on *W. bancrofti* microfilariae by causing organelle damage

and apoptosis (Peixoto et al., 2004). The mechanism of filaricidal action of DEC against adult worms is unknown. Some studies suggest that DEC compromises intracellular processing and transport of certain macromolecules to the plasma membrane (Spiro et al., 1986). The drug also may affect specific immune and inflammatory responses of the host by undefined mechanisms (Martin et al., 1997).

Microfilarial forms of susceptible filarial species are most affected by DEC. These developmental forms of *W. bancrofti*, *B. malayi*, and *L. loa* rapidly disappear from human blood after consumption of the drug. Microfilariae of *O. volvulus* rapidly disappear from skin after DEC administration, but the drug does not kill microfilariae in nodules that contain the adult (female) worms. The drug has some activity against the adult lifecycle stages of *W. bancrofti*, *B. malayi*, and *L. Loa* but negligible activity against adult *O. volvulus*.

Absorption, Fate, and Excretion. DEC is absorbed rapidly from the GI tract. Peak plasma levels occur within 1-2 hours after a single oral dose, and the plasma $t_{1/2}$ varies from 2-10 hours, depending on the urinary pH. DEC is excreted by both urinary and extra-urinary routes; >50% of an oral dose appears in acidic urine as the unchanged drug, but this value is decreased when the urine is alkaline. Indeed, alkalinizing the urine can elevate plasma levels, prolong the plasma $t_{1/2}$, and increase both the therapeutic effect and toxicity of DEC (Awadzi et al., 1986). Therefore, dosage reduction may be required for people with renal dysfunction or sustained alkaline urine. Metabolism is rapid and extensive; a major metabolite, DEC-*N*-oxide, is active.

Therapeutic Uses. Dosages of DEC citrate used to prevent or treat filarial infections have evolved empirically and vary according to local experience. Recommended regimens differ according to whether the drug is used for population-based chemotherapy, treatment of confirmed filarial infection, or prophylaxis against infection.

***W. bancrofti*, *B. malayi*, and *B. timori*.** The standard regimen for the treatment of LF traditionally has been a 12-day, 72-mg/kg (6 mg/kg per day) course of DEC. In the U.S., it is common practice to administer small test doses of 50-100 mg (1-2 mg/kg for children) over a 3-day period prior to beginning the 12-day regimen. However, a single dose of 6 mg/kg had comparable microfilaricidal and microfilaricidal efficacy to the standard regimen (Addiss and Dreyer, 2000). Single-dose therapy may be repeated every 6-12 months, as necessary.

Although DEC does not usually reverse existing lymphatic damage, early treatment of asymptomatic individuals may prevent new lymphatic damage. In men, the effect of the drug can be monitored by scrotal ultrasound ~2-4 weeks following treatment. Repeat treatment sometimes is recommended if microfilariae remain in the circulation or if motile adult worms remain visible on the ultrasound

(Addiss and Dreyer, 2000). Expanded use of ultrasound also has facilitated the identification of infected individuals who are microfilaria negative on blood examination. These individuals also benefit from DEC treatment. During acute episodes of lymphangitis, treatment with DEC is not recommended until acute symptoms subside (Addiss and Dreyer, 2000).

For mass treatment with the objective of reducing microfilaremia to levels whereby transmission is interrupted, effective strategies have included the introduction of DEC into table salt (0.2-0.4% by weight of the base) (Gelband, 1994). DEC, given annually as a single oral dose of 6 mg/kg, is most effective in reducing microfilaremia when co-administered with either albendazole (400 mg) or ivermectin (0.2-0.4 mg/kg) (Ottesen et al., 1999). Although the adverse reactions to microfilarial destruction are greater after the oral therapy with DEC tablets than when the mass drug administration is administered by medicated table salt, therapy is usually well tolerated.

***O. volvulus* and *L. loa*.** DEC is contraindicated for the treatment of onchocerciasis because it causes severe reactions related to microfilarial destruction, including worsening ocular lesions. Thus use of DEC for control is considered contraindicated in areas where onchocerciasis is endemic (Molyneux et al., 2003). Such reactions are far less severe in response to ivermectin, the preferred drug for this infection. Despite its drawbacks, DEC remains the best available drug for therapy of loiasis. Treatment is initiated with test doses of 50 mg (1 mg/kg in children) daily for 2-3 days, escalating to maximally tolerated daily doses of 9 mg/kg in three doses for a total of 2-3 weeks.

In patients with high-grade microfilaremia, low test doses are used, often accompanied by pretreatment with glucocorticoids or antihistamines, to minimize reactions to dying microfilariae. Such reactions may manifest as severe allergic reactions, and occasionally meningoencephalitis and coma likely caused by CNS effects of dying microfilariae. Repeated courses of DEC treatment, separated by 3-4 weeks, may be required to cure loiasis. Although ivermectin is not a good alternative to DEC for treatment of loiasis, albendazole may be useful in patients who either fail therapy with DEC or who cannot tolerate the drug (Klion et al., 1999).

DEC is clinically effective against microfilariae and adult worms of *Dipetalonema streptocerca*, but filariasis due to *Mansonella perstans*, *M. ozzardi*, or *Dirofilaria immitis* responds minimally to this agent. DEC is no longer recommended as a first-line drug for the treatment of toxocarasis.

Toxicity and Side Effects. Below a daily dose of 8-10 mg/kg, direct toxic reactions to DEC are rarely severe and usually disappear within a few days despite continuation of therapy. These reactions include anorexia, nausea, headache, and, at high doses, vomiting. Major adverse effects result directly or indirectly from the host response to destruction of parasites, primarily microfilariae.

Delayed reactions to dying adult worms may result in lymphangitis, swelling, and lymphoid abscesses in bancroftian and brugian filariasis, and small skin wheals in loiasis. Reactions typically are most severe in patients heavily infected with *O. volvulus*, less serious in *B. malayi* or *L. loa* infections, and mild in bancroftian filariasis. As noted, the drug occasionally causes severe side effects in heavy *L. loa* infections, including retinal hemorrhages and severe

encephalopathy. In patients with onchocerciasis, the *Mazzotti reaction* typically occurs within a few hours after the first dose, and it manifests as intense itching, a papular rash, enlargement and tenderness of the lymph nodes, and sometimes fever, tachycardia, arthralgia, and headache. This reaction persists for 3-7 days and then subsides. Ocular complications include limbitis, punctate keratitis, uveitis, and atrophy of the retinal pigment epithelium (Dominguez-Vazquez et al., 1983). DEC appears to be safe for use during pregnancy

Precautions and Contraindications. Population-based therapy with DEC should be avoided where onchocerciasis or loiasis is endemic, although the drug can be used to protect foreign travelers from these infections. Pretreatment with glucocorticoids and antihistamines often is undertaken to minimize indirect reactions to DEC that result from release of antigen by dying microfilariae. Dosage reduction may be appropriate for patients with impaired renal function or persistent alkaline urine.

Doxycycline

The discovery that filarial parasites, including *W. bancrofti* and *O. volvulus*, harbor bacterial symbionts of the genus *Wolbachia* led to studies that have established the efficacy of courses of doxycycline of duration ≥ 6 weeks in bancroftian filariasis and onchocerciasis (Taylor and Hoerauf, 2001). A 6-week regimen of doxycycline (100 mg daily), by killing the *Wolbachia*, leads to sterility of adult female *Onchocerca* worms (Hoerauf et al., 2000). Studies using shorter treatment courses and alternative antibiotics including rifampicin are in progress. The pharmacology of doxycycline is discussed in Chapter 55.

Ivermectin

History. In the mid-1970s, surveys of natural products revealed that a fermentation broth of the soil actinomycete *Streptomyces avermitilis* ameliorated infection with *Nematospiroides dubius* in mice. Isolation of the anthelmintic components from cultures of this organism led to discovery of the avermectins, a novel class of 16-membered macrocyclic lactones (Campbell, 1989). Ivermectin (MECTIZAN; STROMEKTOL; 22,23-dihydroavermectin B_{1a}) is a semi-synthetic analog of avermectin B_{1a} (abamectin), an insecticide developed for crop management. Ivermectin now is used extensively to control and treat a broad spectrum of infections caused by parasitic nematodes (roundworms) and arthropods (insects, ticks, and mites) that plague livestock and domestic animals (Campbell, 1993).

Chemistry. Ivermectin exists as an odorless off-white powder with high lipid solubility but poor solubility in water. It is a mixture of at least 80% 22,23-dihydroavermectin B_{1a} and no more than 20% 22,23-dihydroavermectin B_{1b}. B_{1a} and B_{1b} have nearly identical antiparasitic activities. The hydrogenation of avermectin B₁ at the C22-23 linkage confers increased activity against *Haemonchus contortus*, an important veterinary parasite, and against the cattle parasite *Onchocerca cervicalis*.

Antiparasitic Activity and Resistance. Ivermectin immobilizes affected organisms by inducing a tonic paralysis of the musculature. Studies of *Caenorhabditis elegans* indicate that avermectins induce paralysis by activating a family of ligand-gated Cl⁻ channels, particularly glutamate-gated Cl⁻ channels that are found only in invertebrates. There is close correlation among activation and potentiation by avermectins and milbemycin D of glutamate-sensitive Cl⁻ current, nematocidal activity, and membrane binding affinity (Arena et al., 1995; Cully et al., 1996). Moreover, glutamate-gated Cl⁻ channels are expressed in the pharyngeal muscle cells of these worms, consistent with the marked and potent inhibitory effect of avermectins on the feeding behavior of the organisms (Sangster and Gill, 1999). Therefore, ivermectin probably binds to glutamate-activated Cl⁻ channels found in nematode nerve or muscle cells, and causes hyperpolarization by increasing intracellular chloride concentration. This results in paralysis of the parasite. Resistance or relative unresponsiveness to avermectin action has been observed in different nematodes, especially those species parasitizing livestock.

Several different avermectin-“resistant” developmental and physiological phenotypes have been described, but definitive relationships among these phenotypes and native avermectin receptor subtypes, locations, numbers, and binding affinities require clarification (Hejmadi et al., 2000; Sangster and Gill, 1999). Alterations in genes encoding ATP-dependent P-glycoprotein transporters that bind avermectins and in those encoding putative components of the glutamate-gated Cl⁻ channel have been associated with the development of resistance in *Haemonchus contortus* (Xu et al., 1998). A significant increase in low-affinity glutamate binding has been detected in ivermectin-resistant nematodes, but how this relates to drug resistance is unclear (Hejmadi et al., 2000).

Glutamate-gated Cl⁻ channels probably are one of several sites of ivermectin action among invertebrates (Zufall et al., 1989). Avermectins also bind with high affinity to γ -aminobutyric acid (GABA)-gated and other ligand-gated Cl⁻ channels in nematodes such as *Ascaris* and in insects, but the physiological consequences are less well defined. Lack of high-affinity avermectin receptors in cestodes and trematodes may explain why these helminths are not sensitive to ivermectin (Shoop et al., 1995). Avermectins also interact with GABA receptors in mammalian brain, but their affinity for invertebrate receptors is ~100-fold higher (Schaeffer and Haines, 1989).

In humans infected with *O. volvulus*, ivermectin causes a rapid, marked decrease in microfilarial counts in the skin and ocular tissues that lasts for 6-12 months (Newland et al., 1988). The drug has little discernible effect on adult parasites, even at doses as high as 800 μ g/kg (Molyneux et al., 2003) but affects developing larvae and blocks egress of microfilariae from the uterus of adult female worms (Court et al., 1985). By reducing microfilariae in the skin, ivermectin decreases transmission to the *Simulium* black fly vector (Cupp et al., 1989). Regular treatment with ivermectin also has been conjectured to act prophylactically against the development of *Onchocerca* infection (Molyneux et al., 2003).

Ivermectin also is effective against microfilaria but not against adult worms of *W. bancrofti*, *B. malayi*, *L. loa*, and *M. ozzardi*. The drug exhibits excellent efficacy in humans against *Ascaris lumbricoides*, *Strongyloides stercoralis*, and cutaneous larva migrans. Other GI nematodes are either variably affected (*Trichuris trichura* and *Enterobius vermicularis*), or unresponsive (*Necator americanus* and *Ancylostoma duodenale*).

Absorption, Fate, and Excretion. In humans, peak levels of ivermectin in plasma are achieved within 4-5 hours after oral administration. The long terminal t_{1/2} (~57 hours in adults) primarily reflects a low systemic clearance (~1-2 L/hour) and a large apparent volume of distribution. Ivermectin is ~93% bound to plasma proteins. The drug is extensively converted by hepatic CYP3A4 to at least 10 metabolites, mostly hydroxylated and demethylated derivatives (Zeng et al., 1998). Virtually no ivermectin appears in human urine in either unchanged or conjugated form (Krishna and Klotz, 1993). Studies in transgenic mice lacking a P-glycoprotein efflux pump showed neurotoxicity, indicating that this drug transporter, located in the endothelium of brain microvasculature, reduces ivermectin penetration to the CNS (Schinkel et al., 1994). This, and the relatively lower affinity of ivermectin for mammalian CNS receptors, may explain the paucity of CNS side effects and the relative safety of this drug in humans.

Therapeutic Uses

Onchocerciasis. Ivermectin administered as a single oral dose (150 to 200 μ g/kg) given every 6-12 months is the drug of choice for treatment of onchocerciasis, in adults and children \geq 5 years of age (Goa et al., 1991). Ivermectin given in mass drug administration programs has become a critical component of onchocerciasis control programs in the Americas and in sub-Saharan Africa. Equally important, such therapy results in reversal of inflammatory changes in ocular tissues and arrests the development of further ocular pathology due to microfilariae. Marked reduction of microfilariae in the skin results in major relief of the intense pruritus that is a feature of onchocerciasis. Clearance of microfilariae from skin and ocular tissues occurs within a few days and lasts for 6-12 months; the dose then should be repeated. The drug is not curative, however, because ivermectin has little effect on adult *O. volvulus*. Ivermectin has been used since 1987 as the mainstay for onchocerciasis control programs in all of Africa and in the Middle East and Latin America, where the disease is endemic. Nearly 20 million people have received at least one dose of the drug, and many have received six to nine doses (Dull and Meredith, 1998). The Onchocerciasis Elimination Programme in the Americas (OEPA) has effectively reduced transmission in the endemic nations of the Americas, Brazil, Colombia, Ecuador, Guatemala, Mexico, and Venezuela through biannual treatment with

ivermectin (Molyneux et al., 2003), and there is interest in extending biannual ivermectin coverage to the endemic regions of sub-Saharan Africa. Annual doses of the drug are quite safe and substantially reduce transmission of this infection (Boatin et al., 1998; Brown, 1998). How long such therapy should continue is unknown.

Resistance to ivermectin and the related agent moxidectin have been reported in a variety of parasites of veterinary importance, as have poor parasitological responses to ivermectin in the onchocerciasis control program (Osei-Atweneboana et al., 2007). Recent laboratory work with *C. elegans* has shown that exposure to increasing doses of ivermectin resulted in the development of a stable multidrug resistance phenotype with cross-resistance to the related drug moxidectin and to other anthelmintics, levamisole and pyrantel, but not albendazole (James and Davey, 2009). The potential for the development of similar resistance in human parasites exists, particularly in the setting of mass treatment campaigns.

Lymphatic Filariasis. Initial studies indicated that single annual doses of ivermectin (400 µg/kg) was both effective and safe for mass chemotherapy of infections with *W. bancrofti* and *B. malayi* (Ottesen and Ramachandran, 1995). Ivermectin is as effective as DEC for controlling lymphatic filariasis, and unlike DEC, it can be used in regions where onchocerciasis, loiasis, or both are endemic. Although ivermectin as a single agent can reduce *W. bancrofti* microfilaremia, the duration of treatment required to eliminate LF at 65% coverage of the affected population presumably would be >6 years (Molyneux et al., 2003). More recent evidence indicates that a single annual dose of ivermectin (200 µg/kg) and a single annual dose of albendazole (400 mg) are even more effective in controlling lymphatic filariasis than either drug alone (www.filarisis.org). The duration of treatment is at least 5 years, based on the estimated fecundity of the adult worms. This dual-drug regimen also reduces infections with intestinal nematodes. Facilitated by corporate donation of ivermectin and albendazole, the drug combination now serves as the treatment standard for mass chemotherapy and control of lymphatic filariasis (Ottesen et al., 1999).

Strongyloidiasis. Ivermectin administered as a single dose of 150 to 200 µg/kg is the drug of choice for treatment of human strongyloidiasis (Marti et al., 1996). It is at least as active as the older drug of choice, thiabendazole, and significantly better tolerated. It is generally recommended that a second dose be administered a week following the first dose. It is more efficacious than a 3-day course of albendazole (Marti et al., 1996). In the life-threatening Strongyloides hyperinfection syndrome where GI absorption of oral dose may be poor, parenteral veterinary ivermectin has been administered “off-label” to human subjects by the subcutaneous route (Chiodini et al., 2000).

Infections with Other Intestinal Nematodes. Ivermectin also is variably effective against other intestinal nematodes. It is more effective in ascariasis and enterobiasis than in trichuriasis or hookworm infection (Keiser and Utzinger, 2008). In the latter two infections, although it is not curative, it significantly reduces the intensity of infection.

Other Indications. Although ivermectin has activity against microfilaria (but not adult worms) of *L. loa* and *M. ozzardi*, it is not used clinically to treat infections with these parasites. Taken as a single 200-µg/kg oral dose, ivermectin is a first-line drug for treatment of cutaneous larva migrans caused by dog or cat hookworms. Ivermectin, administered orally in a dose of 200 µg/kg, is an effective treatment of scabies. In uncomplicated scabies, two doses should be administered, 1-2 weeks apart. It should be used in severe

(crusted) scabies in repeated doses, with one recommended regimen entailing 7 doses of 200 µg/kg given with food, on days 1, 2, 8, 9, 15, 22, and 29 (Roberts et al., 2005). The drug appears to be effective against human head lice as well.

Toxicity, Side Effects, and Precautions. Ivermectin is well tolerated by uninfected humans.

In filarial infection, ivermectin therapy frequently causes a Mazzotti-like reaction to dying microfilariae. The intensity and nature of these reactions relate to the microfilarial burden. After treatment of *O. volvulus* infections, these side effects usually are limited to mild itching and swollen, tender lymph nodes, which occur in 5-35% of people, last just a few days, and are relieved by aspirin and antihistamines (Goa et al., 1991). Rarely, more severe reactions occur that include high fever, tachycardia, hypotension, prostration, dizziness, headache, myalgia, arthralgia, diarrhea, and facial and peripheral edema; these may respond to glucocorticoid therapy. Ivermectin induces milder side effects than does DEC, and unlike the latter, it seldom exacerbates ocular lesions in onchocerciasis. The drug can cause rare but serious side effects including marked disability and encephalopathies in patients with heavy *L. loa* microfilaria (Gardon et al., 1997). *Loa* encephalopathy is associated with ivermectin treatment of individuals with *Loa* microfilaremia levels ≥30,000 microfilariae per milliliter of blood (Molyneux et al., 2003). There is little evidence that ivermectin is teratogenic or carcinogenic.

Possible adverse interactions of ivermectin with other drugs that are extensively metabolized by hepatic CYP3A4 have yet to be evaluated. Because of its effects on GABA receptors in the CNS, ivermectin is contraindicated in conditions associated with an impaired blood-brain barrier (e.g., African trypanosomiasis and meningitis). Ivermectin is not approved for use in children <5 years of age or in pregnant women. Lactating women taking the drug secrete low levels in their milk; the consequences for nursing infants are unknown. Currently, the WHO recommends against ivermectin treatments in mass drug administration campaigns for pregnant women, lactating women in the first week after birth, children <90 cm in height (~15 kg in body weight), and the severely ill (WHO, 2006).

Praziquantel

Praziquantel (BILTRICIDE, DISTOCIDE) is a pyrazinoisoquinoline derivative developed after this class of compounds was discovered to have anthelmintic activity in 1972. The (–) isomer is responsible for most of the drug’s anthelmintic activity.

The drug shows useful activity against most cestodes and trematodes that infect humans, whereas nematodes generally are unaffected (Andrews, 1985; Symposium, 1981). The drug is best studied and most commonly used for treatment of schistosomiasis, caused by *S. mansoni*, *S. haematobium*, and *S. japonicum*.

PRAZIQUANTEL

Anthelmintic Action. After rapid and reversible uptake, praziquantel has two major effects on adult schistosomes. At the lowest effective concentrations, it causes increased muscular activity, followed by contraction and spastic paralysis. Affected worms detach from blood vessel walls and migrate from the mesenteric veins to the liver. At slightly higher concentrations, praziquantel causes tegumental damage and exposes a number of tegumental antigens (Redman et al., 1996). The clinical efficacy of this drug correlates better with tegumental action (Xiao et al., 1985). The drug is ineffective against juvenile schistosomes and therefore is relatively ineffective in early infection. An intact immune response is believed to be important for the clinical efficacy of the drug.

The primary site of action of praziquantel is uncertain (Aragon et al., 2009). The drug may act through generation of reactive oxygen species. It also promotes an influx of Ca^{2+} , and possibly interacts with the variant Ca^{2+} channel $\text{Ca-v}\alpha\beta$ (Jeziorski and Greenberg, 2006), which is found in schistosomes and other praziquantel-sensitive parasites. However, Ca^{2+} influx does not correlate with sensitivity to the drug in all settings (Pica-Mattoccia et al., 2008). Praziquantel inhibits adenosine flux (Angelucci et al., 2007), but definitive evidence that this action contributes to the anthelmintic effect is lacking.

Absorption, Fate, and Excretion. Praziquantel is readily absorbed after oral administration, the drug reaching maximal levels in human plasma in 1-2 hours. The pharmacokinetics of praziquantel are dose related. Extensive first-pass metabolism to many inactive hydroxylated and conjugated products limits the bioavailability of this drug and results in plasma concentrations of metabolites at least 100-fold higher than that of praziquantel. The drug is ~80% bound to plasma proteins. Its plasma $t_{1/2}$ is 0.8-3 hours, depending on the dose, compared with 4-6 hours for its metabolites; this may be prolonged in patients with severe liver disease, including those with hepatosplenic schistosomiasis. About 70% of an oral dose of praziquantel is recovered as metabolites in the urine within 24 hours; most of the remainder is metabolized in the liver and eliminated in the bile.

Therapeutic Uses. Praziquantel is approved in the U.S. for therapy of schistosomiasis and liver fluke infections. However, the drug has activity against many other trematodes and cestodes. Praziquantel should be stored at temperatures $<30^{\circ}\text{C}$ and swallowed with water without chewing because of its bitter taste.

Praziquantel is the drug of choice for treating schistosomiasis caused by all *Schistosoma* species that infect humans. Although dosage regimens vary, a single oral dose of 40 mg/kg or three doses of 20 mg/kg each, given 4-6 hours apart, generally produce cure rates of 70-95% and consistently high reductions ($>85\%$) in egg counts. Tablets of 600 mg currently are available from generic manufacturers; on average, treatment of a school-aged child in Africa requires 2.5 tablets (WHO, 2002).

The absence of weighing scales in Africa and elsewhere in developing countries led to the development dosing in proportion to height (WHO 2006; www.who.int/wormcontrol).

Strains of *S. mansoni* and *S. japonicum* resistant to praziquantel have been selected in laboratory studies (Fallon et al., 1996). Moreover, decreased clinical efficacy of praziquantel against infections with *S. mansoni* has been reported in two human populations (Ismail et al., 1999). However, praziquantel-tolerant or -resistant schistosome strains are not currently of clinical importance (Fallon et al., 1996).

Three doses of 25 mg/kg taken 4-8 hours apart on the same day result in high rates of cure for infections with either the liver flukes *Clonorchis sinensis* and *Opisthorchis viverrini*, or the intestinal flukes *Fasciolopsis buski*, *Heterophyes heterophyes*, and *Metagonimus yokogawai*. The same three-dose regimen, used over 2 days, is highly effective against infections with the lung fluke, *Paragonimus westermani*. Of note, the liver fluke *Fasciola hepatica* is resistant to praziquantel and should be treated with the BZ drug triclabendazole.

Low doses of praziquantel can be used successfully to treat intestinal infections with adult cestodes, for example, a single oral dose of 25 mg/kg for *Hymenolepis nana* and 10 to 20 mg/kg for *Diphyllobothrium latum*, *Taenia saginata*, or *T. solium*. Retreatment after 7-10 days is advisable for individuals heavily infected with *H. nana*. Although albendazole is preferred for therapy of human cysticercosis, praziquantel represents an alternative agent, but its use for this indication is hampered by the important pharmacokinetic interaction with dexamethasone and other corticosteroids that should be co-administered in this condition (Evans et al., 1997). Neither the "cystic" nor "alveolar" hydatid disease caused by larval stages of *Echinococcus* tapeworms responds to praziquantel, but the drug may have a role in the uncommon setting of perioperative cyst spillage (Horton, 1997; Schantz, 1999).

Toxicity, Precautions, and Interactions. Abdominal discomfort, particularly pain and nausea, diarrhea, headache, dizziness, and drowsiness may occur shortly after taking praziquantel; these direct effects are transient and dose related. Indirect effects such as fever, pruritus, urticaria, rashes, arthralgia, and myalgia are noted occasionally. Such side effects and increases in eosinophilia often relate to parasite burden and are therefore believed to be a consequence of parasite killing and antigen release. In neurocysticercosis, inflammatory reactions to praziquantel may produce meningismus, seizures, mental changes, and cerebrospinal fluid pleocytosis. These effects usually are delayed in onset, last 2-3 days, and respond to appropriate symptomatic therapy such as analgesics and anticonvulsants.

Praziquantel is considered safe in children >4 years of age (or >94 cm in height), who probably tolerate the drug better than adults. Low levels of the drug appear in the breast milk, but there is no evidence that this compound is mutagenic or carcinogenic. High doses of praziquantel increase abortion rates in rats, but a retrospective study showed that treatment of pregnant women in Sudan resulted in no significant differences between treated and untreated women in the rates of abortion or preterm deliveries. Moreover, no congenital abnormalities were noted by clinical examination in any of the infants born to either group (Adam et al., 2004).

The bioavailability of praziquantel is reduced by inducers of hepatic CYPs such as carbamazepine and phenobarbital; predictably, co-administration of the CYP inhibitor, cimetidine, has the opposite effect (Dachman et al., 1994). Dexamethasone reduces the

bioavailability of praziquantel. Under certain conditions, praziquantel may increase the bioavailability of albendazole (Homeida et al., 1994).

Praziquantel is contraindicated in ocular cysticercosis because the host response can irreversibly damage the eye. Shortly after taking the drug, driving, operating machinery, and other tasks requiring mental alertness should be avoided. Severe hepatic disease can prolong the $t_{1/2}$ of praziquantel, requiring dosage adjustment in such patients (Mandour et al., 1990).

Metrifonate

Metrifonate (trichlorfon; BILARCIL) is an organophosphorus compound used first as an insecticide and later as an anthelmintic, especially for treatment of *Schistosoma haematobium*.

Metrifonate is a prodrug; at physiological pH, it is converted nonenzymatically to *dichlorvos* (2,2-dichlorovinyl dimethyl phosphate, DDVP), a potent cholinesterase inhibitor (Chapter 10). However, inhibition of cholinesterase alone is unlikely to explain the antischistosomal properties of metrifonate (Bloom, 1981). *In vitro*, dichlorvos is about equally potent as an inhibitor of both *S. mansoni* and *S. haematobium* acetylcholinesterases, yet metrifonate is effective clinically only against infections with *S. haematobium*. The molecular basis for this species-selective effect is not understood. Trichlorfon is the formulation of metrifonate approved for veterinary purposes in the U.S. More complete information on the pharmacology and therapeutic uses of metrifonate can be found in the tenth edition of this book.

Oxamniquine

Oxamniquine is a 2-aminomethyltetrahydroquinoline derivative that is used as a second-line drug after praziquantel for the treatment of *Schistosoma mansoni* infection. *S. haematobium* and *S. japonicum* are refractory to this drug. Although it has largely been replaced by praziquantel and is not commercially available in the U.S., it continues to be used in *S. mansoni* control programs, especially in South America. More details on the pharmacology and therapeutic uses of oxamniquine can be found in the ninth edition of this book.

Niclosamide

Niclosamide, a halogenated salicylanilide derivative, was introduced in the 1960s for human use as a taeniocide. This compound was considered as a second-choice drug to praziquantel for treating human intestinal infections with *Taenia saginata*, *Diphyllobothrium latum*, *Hymenolepis nana*, and most other cestodes because it was cheap, effective, and readily available in many parts of the world. However, therapy with niclosamide poses a risk to people infected with *T. solium* because ova released from drug-damaged gravid worms develop into larvae that can cause cysticercosis, a dangerous infection that responds poorly to chemotherapy. Niclosamide is no longer approved for use

in the U.S. More complete information on the pharmacology and therapeutic uses of niclosamide can be found in the ninth edition of this book.

Piperazine

Piperazine, a cyclic secondary amine, has been superseded as a first-line anthelmintic by the better tolerated and more easily administered benzimidazole anthelmintics (BZs). Piperazine is highly effective against *Ascaris lumbricoides* and *Enterobius vermicularis*. The predominant effect of piperazine on *Ascaris* is a flaccid paralysis that results in expulsion of the worm by peristalsis. Affected worms recover if incubated in drug-free medium. Piperazine acts as a GABA-receptor agonist. By increasing chloride ion conductance of *Ascaris* muscle membrane, the drug produces hyperpolarization and reduced excitability that leads to muscle relaxation and flaccid paralysis (Martin, 1985). Piperazine and dipiperazine are licensed as veterinary medications in the U.S. More complete information on the pharmacology and therapeutic uses of piperazine may be found in the tenth edition of this book.

Pyrantel Pamoate

Pyrantel pamoate first was introduced into veterinary practice as a broad-spectrum anthelmintic directed against pinworm, roundworm, and hookworm infections. Its effectiveness and lack of toxicity led to its trial against related intestinal helminths in humans. *Oxantel pamoate*, an *m*-oxyphenol analog of pyrantel, is effective for single-dose treatment of trichuriasis.

Anthelmintic Action. Pyrantel and its analogs are depolarizing neuromuscular blocking agents. They open nonselective cation channels and induce persistent activation of nicotinic acetylcholine receptors and spastic paralysis of the worm (Robertson et al., 1994).

Pyrantel also inhibits cholinesterases. It causes a slowly developing contracture of isolated preparations of *Ascaris* at 1% of the concentration of acetylcholine required to produce the same effect. Pyrantel exposure leads to depolarization and increased spike-discharge frequency, accompanied by increases in tension, in isolated helminth muscle preparations. Pyrantel is effective against hookworm, pinworm, and roundworm but is ineffective against *Trichuris trichiura*, which responds paradoxically to the analog oxantel.

Absorption, Fate, and Excretion. Pyrantel pamoate is poorly absorbed from the GI tract, a property that confines its action to intraluminal GI nematodes. Less than 15% is excreted in the urine as parent drug and metabolites. The major proportion of an administered dose is recovered in the feces.

Therapeutic Uses. Pyrantel pamoate is an alternative to mebendazole or albendazole in the treatment of ascariasis and enterobiasis. High cure rates have been achieved after a single oral dose of 11 mg/kg, to a maximum of 1 g. Pyrantel also is effective against hookworm infections caused by *Ancylostoma duodenale* and *Necator americanus*, although repeated doses are needed to cure heavy infections by *N. americanus*. The drug should be used in combination with oxtel for mixed infections with *T. trichiura*. In the case of pinworm, it is wise to repeat the treatment after an interval of 2 weeks. In the U.S., pyrantel is sold as an over-the-counter pinworm treatment (PIN-x, others).

Precautions. When given parenterally to experimental animals, pyrantel can produce complete neuromuscular blockade; only very large oral doses produce toxic effects. Transient and mild GI symptoms occasionally are observed in humans, as are headache, dizziness, rash, and fever. Pyrantel pamoate has not been studied in pregnant women. Thus its use in pregnant patients and children <2 years of age is not recommended. Because pyrantel pamoate and piperazine are mutually antagonistic with respect to their neuromuscular effects on parasites, they should not be used together.

52 chapter

Sulfonamides, Trimethoprim-Sulfamethoxazole, Quinolones, and Agents for Urinary Tract Infections

William A. Petri, Jr.

SULFONAMIDES

The sulfonamide drugs were the first effective chemotherapeutic agents to be employed systemically for the prevention and cure of bacterial infections in humans. The considerable medical and public health importance of their discovery and their subsequent widespread use was quickly reflected in the sharp decline in morbidity and mortality figures for treatable infectious diseases. The advent of penicillin and subsequently of other antibiotics has diminished the usefulness of the sulfonamides, and they presently occupy a relatively small place in the therapeutic armamentarium of the physician. However, the introduction in the mid-1970s of the combination of trimethoprim and sulfamethoxazole has increased the use of sulfonamides for the prophylaxis and treatment of specific microbial infections.

History. Investigations in 1932 at the I. G. Farbenindustrie resulted in the patenting of PRONTOSIL and several other azo dyes containing a sulfonamide group. Prompted by the knowledge that synthetic azo dyes had been studied for their action against streptococci, Domagk tested the new compounds and observed that mice with streptococcal and other infections could be protected by PRONTOSIL. In 1933, Foerster reported giving PRONTOSIL to a 10-month-old infant with staphylococcal septicemia and achieving a dramatic cure. Favorable clinical results with PRONTOSIL and its active metabolite, sulfanilamide, in puerperal sepsis and meningococcal infections awakened the medical profession to the new field of antibacterial chemotherapy, and experimental and clinical articles soon appeared in profusion. The development of the carbonic anhydrase inhibitor-type diuretics and the sulfonyleurea hypoglycemic agents followed from observations made with the sulfonamide antibiotics. For discovering the chemotherapeutic value of PRONTOSIL, Domagk was awarded the Nobel Prize in Medicine for 1938 (Lesch, 2007).

Chemistry. The term *sulfonamide* is employed herein as a generic name for derivatives of *para*-aminobenzenesulfonamide (sulfanilamide); the structural formulas of selected members of this class are shown in Figure 52–1. Most of them are relatively insoluble in water, but their sodium salts are readily soluble. The minimal structural prerequisites for antibacterial action are all embodied in sulfanilamide itself. The SO_2NH_2 group is not essential as such, but the important feature is that the sulfur is linked directly to the benzene ring. The *para*- NH_2 group (the N of which has been designated as N4) is essential and can be replaced only by moieties that can be converted *in vivo* to a free amino group. Substitutions made in the amide NH_2 group (position N1) have variable effects on antibacterial activity of the molecule. However, substitution of heterocyclic aromatic nuclei at N1 yields highly potent compounds.

Effects on Microbes

Sulfonamides have a wide range of antimicrobial activity against both gram-positive and gram-negative bacteria. However, resistant strains have become common, and the usefulness of these agents has diminished correspondingly. In general, the sulfonamides exert only a bacteriostatic effect, and cellular and humoral defense mechanisms of the host are essential for final eradication of the infection.

Antibacterial Spectrum. Resistance to sulfonamides is increasingly a problem. Microorganisms that may be susceptible *in vitro* to sulfonamides include *Streptococcus pyogenes*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Haemophilus ducreyi*, *Nocardia*, *Actinomyces*, *Calymmatobacterium granulomatis*, and *Chlamydia trachomatis*. Minimal inhibitory concentrations (MICs) range from 0.1 $\mu\text{g}/\text{mL}$ for *C. trachomatis* to 4–64 $\mu\text{g}/\text{mL}$ for *Escherichia coli*. Peak plasma drug concentrations achievable *in vivo* are ~100–200 $\mu\text{g}/\text{mL}$.

Figure 52–1. Structural formulas of selected sulfonamides and *para*-aminobenzoic acid. The N of the *para*-NH₂ group is designated as N4; that of the amide NH₂, as N1.

Although sulfonamides were used successfully for the management of meningococcal infections for many years, most isolates of *Neisseria meningitidis* of serogroups B and C in the U.S. and group A isolates from other countries are now resistant. A similar situation prevails with respect to *Shigella*. Strains of *E. coli* isolated from patients with urinary tract infections (community acquired) often are resistant to sulfonamides, which are no longer the therapy of choice for such infections.

Mechanism of Action. Sulfonamides are competitive inhibitors of dihydropteroate synthase, the bacterial enzyme responsible for the incorporation of PABA into dihydropteroic acid, the immediate precursor of folic acid (Figure 52–2). Thus, these structural analogs of *para*-aminobenzoic acid (PABA) prevent normal bacterial use of PABA for the synthesis of folic acid (pteroylglutamic acid). Sensitive microorganisms are those that must synthesize their own folic acid; bacteria that can use preformed folate are not affected. Bacteriostasis induced by sulfonamides is counteracted by PABA competitively. Mammalian cells require preformed folic acid, cannot synthesize it, and are insensitive to drugs acting by this mechanism. Thus, mammalian cells are comparable to sulfonamide-insensitive bacteria that use preformed folate.

Synergists of Sulfonamides. One of the most active agents that exerts a synergistic effect when used with a sulfonamide is trimethoprim (Bushby and Hitchings,

1968). This compound is a potent and selective competitive inhibitor of microbial dihydrofolate reductase, the enzyme that reduces dihydrofolate to tetrahydrofolate. It is this reduced form of folic acid that is required for one-carbon transfer reactions. The simultaneous administration of a sulfonamide and trimethoprim thus introduces sequential blocks in the pathway by which microorganisms synthesize tetrahydrofolate from precursor molecules (Figure 52–2). The expectation that

Figure 52–2. Steps in folate metabolism blocked by sulfonamides and trimethoprim.

such a combination would yield synergistic antimicrobial effects has been realized both *in vitro* and *in vivo*.

Acquired Bacterial Resistance to Sulfonamides.

Bacterial resistance to sulfonamides presumably originates by random mutation and selection or by transfer of resistance by plasmids (Chapter 48). Such resistance, once it is maximally developed, usually is persistent and irreversible, particularly when produced *in vivo*. Acquired resistance to sulfonamide usually does not involve cross-resistance to antimicrobial agents of other classes. The *in vivo* acquisition of resistance has little or no effect on either virulence or antigenic characteristics of microorganisms.

Resistance to sulfonamide probably is the consequence of an altered enzymatic constitution of the bacterial cell; the alteration may be characterized by (1) a lower affinity of dihydropteroate synthase for sulfonamides, (2) decreased bacterial permeability or active efflux of the drug, (3) an alternative metabolic pathway for synthesis of an essential metabolite, or (4) an increased production of an essential metabolite or drug antagonist. For example, some resistant staphylococci may synthesize 70 times as much PABA as do the susceptible parent strains. Nevertheless, an increased production of PABA is not a constant finding in sulfonamide-resistant bacteria, and resistant mutants may possess enzymes for folate biosynthesis that are less readily inhibited by sulfonamides. Plasmid-mediated resistance is due to plasmid-encoded drug-resistant dihydropteroate synthetase.

Absorption, Fate, and Excretion

Except for sulfonamides especially designed for their local effects in the bowel (Chapter 47), this class of drugs is absorbed rapidly from the GI tract. Approximately 70-100% of an oral dose is absorbed, and sulfonamide can be found in the urine within 30 minutes of ingestion. Peak plasma levels are achieved in 2-6 hours, depending on the drug. The small intestine is the major site of absorption, but some of the drug is absorbed from the stomach. Absorption from other sites, such as the vagina, respiratory tract, or abraded skin, is variable and unreliable, but a sufficient amount may enter the body to cause toxic reactions in susceptible persons or to produce sensitization.

All sulfonamides are bound in varying degree to plasma proteins, particularly to albumin. The extent to which this occurs is determined by the hydrophobicity of a particular drug and its pK_a ; at physiological pH, drugs with a high pK_a exhibit a low degree of protein binding, and *vice versa*.

Sulfonamides are distributed throughout all tissues of the body. The diffusible fraction of sulfadiazine is distributed uniformly throughout the total-body water, whereas sulfisoxazole is confined largely to the extracellular space. The sulfonamides readily enter

pleural, peritoneal, synovial, ocular, and similar body fluids and may reach concentrations therein that are 50-80% of the simultaneously determined concentration in blood. Because the protein content of such fluids usually is low, the drug is present in the unbound active form.

After systemic administration of adequate doses, sulfadiazine and sulfisoxazole attain concentrations in cerebrospinal fluid that may be effective in meningeal infections. At steady state, the concentration ranges between 10% and 80% of that in the blood. However, because of the emergence of sulfonamide-resistant microorganisms, these drugs are used rarely for the treatment of meningitis.

Sulfonamides pass readily through the placenta and reach the fetal circulation. The concentrations attained in the fetal tissues are sufficient to cause both antibacterial and toxic effects.

The sulfonamides undergo metabolic alterations *in vivo*, especially in the liver. The major metabolic derivative is the N4-acetylated sulfonamide. Acetylation, which occurs to a different extent with each agent, is disadvantageous because the resulting products have no antibacterial activity and yet retain the toxic potential of the parent substance.

Sulfonamides are eliminated from the body partly as the unchanged drug and partly as metabolic products. The largest fraction is excreted in the urine, and the $t_{1/2}$ of sulfonamides in the body thus depends on renal function. In acid urine, the older sulfonamides are insoluble and may precipitate, forming crystalline deposits that can cause urinary obstruction. Small amounts are eliminated in the feces, bile, milk, and other secretions.

Pharmacological Properties of Individual Sulfonamides

The sulfonamides may be classified on the basis of the rapidity with which they are absorbed and excreted (Table 52-1):

- agents that are absorbed and excreted rapidly, such as sulfisoxazole and sulfadiazine
- agents that are absorbed very poorly when administered orally and hence are active in the bowel lumen, such as sulfasalazine
- agents that are used mainly topically, such as sulfacetamide, mafenide, and silver sulfadiazine
- long-acting sulfonamides, such as sulfadoxine, that are absorbed rapidly but excreted slowly

Rapidly Absorbed and Eliminated Sulfonamides

Sulfisoxazole. Sulfisoxazole is a rapidly absorbed and excreted sulfonamide with excellent antibacterial activity. Because its high solubility eliminates much of the renal toxicity inherent in the use of older sulfonamides, it has essentially replaced the less soluble agents.

Sulfisoxazole is bound extensively to plasma proteins. Following an oral dose of 2-4 g, peak concentrations in plasma of 110-250 $\mu\text{g/mL}$ are found in 2-4 hours. From 28-35% of sulfisoxazole in the blood and ~30% in the urine is in the acetylated form. The kidney excretes ~95% of a single dose in 24 hours. Concentrations of the drug in urine thus greatly exceed those in blood and may be bactericidal. The concentration in cerebrospinal fluid averages about a third of that in the blood.

Table 52-1

Classes of Sulfonamides

CLASS	SULFONAMIDE	SERUM $t_{1/2}$ (hours)
Absorbed and excreted rapidly	Sulfisoxazole	5-6
	Sulfamethoxazole	11
	Sulfadiazine	10
Poorly absorbed—active in bowel lumen	Sulfasalazine	—
Topically used	Sulfacetamide	—
	Silver sulfadiazine	—
Long-acting	Sulfadoxine	100-230

Sulfisoxazole acetyl is tasteless and hence preferred for oral use in children. Sulfisoxazole acetyl is marketed in combination with erythromycin ethylsuccinate for use in children with otitis media.

Fewer than 0.1% of patients receiving sulfisoxazole suffer serious toxic reactions. The untoward effects produced by this agent are similar to those which follow the administration of other sulfonamides, as discussed later. Because of its relatively high solubility in the urine as compared with sulfadiazine, sulfisoxazole only infrequently produces hematuria or crystalluria (0.2-0.3%). Despite this, patients taking this drug should ingest an adequate quantity of water. Sulfisoxazole and all sulfonamides that are absorbed must be used with caution in patients with impaired renal function. Like all sulfonamides, sulfisoxazole may produce hypersensitivity reactions, some of which are potentially lethal. Sulfisoxazole currently is preferred over other sulfonamides by most clinicians when a rapidly absorbed and rapidly excreted sulfonamide is indicated.

Sulfamethoxazole. Sulfamethoxazole is a close congener of sulfisoxazole, but its rates of enteric absorption and urinary excretion are slower. It is administered orally and employed for both systemic and urinary tract infections. Precautions must be observed to avoid sulfamethoxazole crystalluria because of the high percentage of the acetylated, relatively insoluble form of the drug in the urine. The clinical uses of sulfamethoxazole are the same as those for sulfisoxazole. In the U.S., it is marketed only in fixed-dose combinations with trimethoprim.

Sulfadiazine. Sulfadiazine given orally is absorbed rapidly from the GI tract, and peak blood concentrations are reached within 3-6 hours after a single dose. Following an oral dose of 3 g, peak concentrations in plasma are 50 $\mu\text{g/mL}$. About 55% of the drug is bound to plasma protein at a concentration of 100 $\mu\text{g/mL}$ when plasma protein levels are normal. Therapeutic concentrations are attained in cerebrospinal fluid within 4 hours of a single oral dose of 60 mg/kg.

Sulfadiazine is excreted quite readily by the kidney in both the free and acetylated forms, rapidly at first and then more slowly over a period of 2-3 days. It can be detected in the urine within 30 minutes of oral ingestion. About 15-40% of the excreted sulfadiazine is in acetylated form. This form of the drug is excreted more

readily than the free fraction, and the administration of alkali accelerates the renal clearance of both forms by further diminishing their tubular reabsorption.

In adults and children who are being treated with sulfadiazine, every precaution must be taken to ensure fluid intake adequate to produce a urine output of at least 1200 mL in adults and a corresponding quantity in children. If this cannot be accomplished, sodium bicarbonate may be given to reduce the risk of crystalluria.

Poorly Absorbed Sulfonamides

Sulfasalazine. Sulfasalazine (AZULFIDINE, others) is very poorly absorbed from the GI tract. It is used in the therapy of ulcerative colitis and regional enteritis (Chapter 47). Intestinal bacteria break sulfasalazine down to sulfapyridine, an active sulfonamide that is absorbed and eventually excreted in the urine, and 5-aminosalicylate (5-ASA, mesalamine; Figures 47-2 through 47-4), which reaches high levels in the feces. Whereas sulfapyridine is responsible for most of the toxicity 5-ASA is the effective agent in inflammatory bowel disease. Toxic reactions include Heinz-body anemia, acute hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency, and agranulocytosis. Nausea, fever, arthralgias, and rashes occur in up to 20% of patients treated with the drug; desensitization has been an effective treatment. Sulfasalazine can cause a reversible infertility in males owing to changes in sperm number and morphology.

Sulfonamides for Topical Use

Sulfacetamide. Sulfacetamide is the N1-acetyl-substituted derivative of sulfanilamide. Its aqueous solubility (1:140) is ~90 times that of sulfadiazine. Solutions of the sodium salt of the drug are employed extensively in the management of ophthalmic infections. Although topical sulfonamide for most purposes is discouraged because of lack of efficacy and a high risk of sensitization, sulfacetamide has certain advantages. Very high aqueous concentrations are not irritating to the eye and are effective against susceptible microorganisms. A 30% solution of the sodium salt has a pH of 7.4, whereas the solutions of sodium salts of other sulfonamides are highly alkaline. The drug penetrates into ocular fluids and tissues in high concentration. Sensitivity reactions to sulfacetamide are rare, but the drug should not be used in patients with known hypersensitivity to sulfonamides. See Chapters 64 and 65 for ocular and dermatological uses.

Silver Sulfadiazine. Silver sulfadiazine (SILVADENE, others) inhibits the growth *in vitro* of nearly all pathogenic bacteria and fungi, including some species resistant to sulfonamides. The compound is used topically to reduce microbial colonization and the incidence of infections from burns. It should not be used to treat an established deep infection. Silver is released slowly from the preparation in concentrations that are selectively toxic to the microorganisms. However, bacteria may develop resistance to silver sulfadiazine. Although little silver is absorbed, the plasma concentration of sulfadiazine may approach therapeutic levels if a large surface area is involved. Adverse reactions—burning, rash, and itching—are infrequent. Silver sulfadiazine is considered by most authorities to be an agent of choice for the prevention of burn infections.

Mafenide. This sulfonamide (α -amino-*p*-toluene-sulfonamide) is marketed as mafenide acetate (SULFAMYLON). When applied topically, it effectively prevents colonization of burns by a large variety of gram-negative and gram-positive bacteria. It should not be used in

treatment of an established deep infection. Superinfection with *Candida* occasionally may be a problem. The cream is applied once or twice daily to a thickness of 1-2 mm over the burned skin. Cleansing of the wound and removal of debris should be carried out before each application of the drug. Therapy is continued until skin grafting is possible. Mafenide is rapidly absorbed systemically and converted to *para*-carboxybenzenesulfonamide. Studies of absorption from the burn surface indicate that peak plasma concentrations are reached in 2-4 hours. Adverse effects include intense pain at sites of application, allergic reactions, and loss of fluid by evaporation from the burn surface because occlusive dressings are not used. The drug and its primary metabolite inhibit carbonic anhydrase, and the urine becomes alkaline. Metabolic acidosis with compensatory tachypnea and hyperventilation may ensue; these effects limit the usefulness of mafenide.

Long-Acting Sulfonamides

Sulfadoxine. This agent, N1-[5,6-dimethoxy-4-pyrimidinyl] sulfanilamide, has a particularly long plasma $t_{1/2}$ (7-9 days). It is used in combination with pyrimethamine (500 mg sulfadoxine plus 25 mg pyrimethamine as FANSIDAR) for the prophylaxis and treatment of malaria caused by mefloquine-resistant strains of *Plasmodium falciparum* (Chapter 49). However, because of severe and sometimes fatal reactions, including the Stevens-Johnson syndrome, and the emergence of resistant strains, the drug has limited usefulness for the treatment of malaria.

Sulfonamide Therapy

The number of conditions for which the sulfonamides are therapeutically useful and constitute drugs of first choice has been reduced sharply by the development of more effective antimicrobial agents and by the gradual increase in the resistance of a number of bacterial species to this class of drugs. However, the combination of sulfamethoxazole and trimethoprim is widely employed.

Urinary Tract Infections. Because a significant percentage of urinary tract infections in many parts of the world are caused by sulfonamide-resistant microorganisms, sulfonamides are no longer a therapy of first choice. Trimethoprim-sulfamethoxazole, a quinolone, trimethoprim, fosfomycin, or ampicillin are the preferred agents. However, sulfisoxazole may be used effectively in areas where the prevalence of resistance is not high or when the organism is known to be sensitive. The usual dosage is 2-4 g initially followed by 1-2 g, orally four times a day for 5-10 days. Patients with acute pyelonephritis with high fever and other severe constitutional manifestations are at risk of bacteremia and shock and should not be treated with a sulfonamide.

Nocardiosis. Sulfonamides are of value in the treatment of infections due to *Nocardia* spp. A number of instances of complete recovery from the disease after adequate treatment with a sulfonamide have been recorded. Sulfisoxazole or sulfadiazine may be given in dosages of 6-8 g daily. Concentrations of sulfonamide in plasma should be 80-160 $\mu\text{g}/\text{mL}$. This schedule is continued for several months after all manifestations have been controlled. The

administration of sulfonamide together with a second antibiotic has been recommended, especially for advanced cases, and ampicillin, erythromycin, and streptomycin have been suggested for this purpose. The clinical response and the results of sensitivity testing may be helpful in choosing a companion drug. Notably, there are no clinical data to show that combination therapy is better than therapy with a sulfonamide alone. Trimethoprim-sulfamethoxazole also has been effective, and some authorities consider it to be the drug of choice.

Toxoplasmosis. The combination of pyrimethamine and sulfadiazine is the treatment of choice for toxoplasmosis (Montoya et al., 2005) (Chapter 50). Pyrimethamine is given as a loading dose of 75 mg followed by 25 mg orally per day, with sulfadiazine 1 g orally every 6 hours, plus folinic acid (leucovorin) 10 mg orally each day for at least 3-6 weeks. Patients should receive at least 2 L of fluid intake daily to prevent crystalluria during therapy.

Use of Sulfonamides for Prophylaxis. The sulfonamides are as efficacious as oral penicillin in preventing streptococcal infections and recurrences of rheumatic fever among susceptible subjects. Despite the efficacy of sulfonamides for long-term prophylaxis of rheumatic fever, their toxicity and the possibility of infection by drug-resistant streptococci make sulfonamides less desirable than penicillin for this purpose. They should be used, however, without hesitation in patients who are hypersensitive to penicillin. If untoward responses occur, they usually do so during the first 8 weeks of therapy; serious reactions after this time are rare. White blood cell counts should be carried out once weekly during the first 8 weeks.

Untoward Reactions to Sulfonamides

The untoward effects that follow the administration of sulfonamides are numerous and varied; the overall incidence of reactions is ~5%.

Disturbances of the Urinary Tract. Although the risk of crystalluria was relatively high with the older, less soluble sulfonamides, the incidence of this problem is very low with more soluble agents such as sulfisoxazole. Crystalluria has occurred in dehydrated patients with acquired immune deficiency syndrome (AIDS) who were receiving sulfadiazine for *Toxoplasma* encephalitis. Fluid intake should be sufficient to ensure a daily urine volume of at least 1200 mL (in adults). Alkalinization of the urine may be desirable if urine volume or pH is unusually low because the solubility of sulfisoxazole increases greatly with slight elevations of pH.

Disorders of the Hematopoietic System.

Acute Hemolytic Anemia. The mechanism of the acute hemolytic anemia produced by sulfonamides is not always readily apparent. In some cases, it may be a sensitization phenomenon; in other instances, the hemolysis is related to an erythrocytic deficiency of glucose-6-phosphate dehydrogenase activity. Hemolytic anemia is rare after treatment with sulfadiazine (0.05%); its exact incidence following therapy with sulfisoxazole is unknown.

Agranulocytosis. Agranulocytosis occurs in ~0.1% of patients who receive sulfadiazine; it also can follow the use of other sulfonamides. Although return of granulocytes to normal levels may be delayed for weeks or months after sulfonamide is withdrawn, most patients recover spontaneously with supportive care.

Aplastic Anemia. Complete suppression of bone marrow activity with profound anemia, granulocytopenia, and thrombocytopenia is an extremely rare occurrence with sulfonamide therapy. It probably results from a direct myelotoxic effect and may be fatal. However, reversible suppression of the bone marrow is quite common in patients with limited bone marrow reserve (e.g., patients with AIDS or those receiving myelosuppressive chemotherapy).

Hypersensitivity Reactions. The incidence of other hypersensitivity reactions to sulfonamides is quite variable. Among the skin and mucous membrane manifestations attributed to sensitization to sulfonamide are morbilliform, scarlatiniform, urticarial, erysipeloid, pemphigoid, purpuric, and petechial rashes, as well as erythema nodosum, erythema multiforme of the Stevens-Johnson type, Behçet's syndrome, exfoliative dermatitis, and photosensitivity. These hypersensitivity reactions occur most often after the first week of therapy but may appear earlier in previously sensitized individuals. Fever, malaise, and pruritus frequently are present simultaneously. The incidence of untoward dermal effects is ~2% with sulfisoxazole, although patients with AIDS manifest a higher frequency of rashes with sulfonamide treatment than do other individuals. A syndrome similar to serum sickness may appear after several days of sulfonamide therapy. Drug fever is a common untoward manifestation of sulfonamide treatment; the incidence approximates 3% with sulfisoxazole.

Focal or diffuse necrosis of the liver owing to direct drug toxicity or sensitization occurs in <0.1% of patients. Headache, nausea, vomiting, fever, hepatomegaly, jaundice, and laboratory evidence of hepatocellular dysfunction usually appear 3-5 days after sulfonamide administration is started, and the syndrome may progress to acute yellow atrophy and death.

Miscellaneous Reactions. Anorexia, nausea, and vomiting occur in 1-2% of persons receiving sulfonamides, and these manifestations probably are central in origin. The administration of sulfonamides to newborn infants, especially if premature, may lead to the displacement of bilirubin from plasma albumin. In newborn infants, free bilirubin can become deposited in the basal ganglia and subthalamic nuclei of the brain, causing an encephalopathy called *kernicterus*. Sulfonamides should not be given to pregnant women near term because these drugs pass through the placenta and are secreted in milk.

Drug Interactions. The most important interactions of the sulfonamides involve those with the oral anticoagulants, the sulfonylurea hypoglycemic agents, and the hydantoin anticonvulsants. In each case, sulfonamides can potentiate the effects of the other drug by mechanisms that appear to involve primarily inhibition of metabolism and, possibly, displacement from albumin. Dosage adjustment may be necessary when a sulfonamide is given concurrently.

TRIMETHOPRIM-SULFAMETHOXAZOLE

The introduction of trimethoprim in combination with sulfamethoxazole constitutes an important advance in the development of clinically effective antimicrobial agents and represents the practical application of a theoretical consideration; that is, if two drugs act on sequential steps in the pathway of an obligate enzymatic

reaction in bacteria (Figure 52-2), the result of their combination will be synergistic (Hitchings, 1961). In much of the world the combination of trimethoprim with sulfamethoxazole is known as cotrimoxazole. In addition to its combination with sulfamethoxazole (BACTRIM, SEPTRA, others), trimethoprim also is available as a single-entity preparation.

Chemistry. Sulfamethoxazole was discussed earlier in this chapter, and its structural formula is shown in Figure 52-1. Trimethoprim, a diaminopyrimidine, inhibits bacterial dihydrofolate reductase. The drug's properties are reviewed in Chapter 49.

Antibacterial Spectrum. The antibacterial spectrum of trimethoprim is similar to that of sulfamethoxazole, although the former drug usually is 20-100 times more potent than the latter. Most gram-negative and gram-positive microorganisms are sensitive to trimethoprim, but resistance can develop when the drug is used alone. *Pseudomonas aeruginosa*, *Bacteroides fragilis*, and enterococci usually are resistant. There is significant variation in the susceptibility of Enterobacteriaceae to trimethoprim in different geographic locations because of the spread of resistance mediated by plasmids and transposons (see Chapter 48).

Efficacy of Trimethoprim-Sulfamethoxazole in Combination. *Chlamydia diphtheriae* and *N. meningitidis* are susceptible to trimethoprim-sulfamethoxazole. Although most *S. pneumoniae* are susceptible, there has been a disturbing increase in resistance. From 50-95% of strains of *Staphylococcus aureus*, *Staphylococcus epidermidis*, *S. pyogenes*, the *viridans* group of streptococci, *E. coli*, *Proteus mirabilis*, *Proteus morgani*, *Proteus rettgeri*, *Enterobacter* spp., *Salmonella*, *Shigella*, *Pseudomonas pseudomallei*, *Serratia*, and *Alcaligenes* spp. are inhibited. Also sensitive are *Klebsiella* spp., *Brucella abortus*, *Pasteurella haemolytica*, *Yersinia pseudotuberculosis*, *Yersinia enterocolitica*, and *Nocardia asteroides*.

Mechanism of Action. The antimicrobial activity of the combination of trimethoprim and sulfamethoxazole results from its actions on two steps of the enzymatic pathway for the synthesis of tetrahydrofolic acid. Sulfonamide inhibits the incorporation of PABA into folic acid, and trimethoprim prevents the reduction of dihydrofolate to tetrahydrofolate (Figure 52-2). Tetrahydrofolate is essential for one-carbon transfer reactions (e.g., the synthesis of thymidylate from deoxyuridylate). Selective toxicity for microorganisms is achieved in two ways. Mammalian cells use preformed folates from the diet and do not synthesize the compound. Furthermore, trimethoprim is a highly selective inhibitor of dihydrofolate reductase of lower organisms: ~100,000 times more drug is required to inhibit human reductase than the bacterial enzyme. This relative selectivity is vital because this enzymatic function is essential to all species.

The synergistic interaction between sulfonamide and trimethoprim is predictable from their respective mechanisms. There is an optimal ratio of the concentrations of the two agents for synergism that equals the ratio of the minimal inhibitory concentrations of the drugs acting independently. Although this ratio varies for different bacteria, the most effective ratio for the greatest number of microorganisms is 20 parts sulfamethoxazole to 1 part trimethoprim. The combination is thus formulated to achieve a sulfamethoxazole concentration *in vivo* that is 20 times greater than that of trimethoprim. The pharmacokinetic properties of the sulfonamide chosen to be in combination with trimethoprim are critical because relative constancy of the concentrations of the two compounds in the body is desired.

Bacterial Resistance. Bacterial resistance to trimethoprim-sulfamethoxazole is a rapidly increasing problem, although resistance is lower than it is to either of the agents alone. Resistance often is due to the acquisition of a plasmid that codes for an altered dihydrofolate reductase. Resistance to trimethoprim-sulfamethoxazole is reportedly formed in almost 30% of urinary isolates of *E. coli* (Olson, et al., 2009).

Absorption, Distribution, and Excretion. The pharmacokinetic profiles of sulfamethoxazole and trimethoprim are closely but not perfectly matched to achieve a constant ratio of 20:1 in their concentrations in blood and tissues. The ratio in blood is often >20:1, and that in tissues is frequently less. After a single oral dose of the combined preparation, trimethoprim is absorbed more rapidly than sulfamethoxazole. The concurrent administration of the drugs appears to slow the absorption of sulfamethoxazole. Peak blood concentrations of trimethoprim usually occur by 2 hours in most patients, whereas peak concentrations of sulfamethoxazole occur by 4 hours after a single oral dose. The half-lives of trimethoprim and sulfamethoxazole are ~11 and 10 hours, respectively.

When 800 mg sulfamethoxazole is given with 160 mg trimethoprim (the conventional 5:1 ratio) twice daily, the peak concentrations of the drugs in plasma are ~40 and 2 µg/mL, the optimal ratio. Peak concentrations are similar (46 and 3.4 µg/mL) after intravenous infusion of 800 mg sulfamethoxazole and 160 mg trimethoprim over a period of 1 hour.

Trimethoprim is distributed and concentrated rapidly in tissues, and ~40% is bound to plasma protein in the presence of sulfamethoxazole. The volume of distribution of trimethoprim is almost nine times that of sulfamethoxazole. The drug readily enters cerebrospinal fluid and sputum. High concentrations of each component of the mixture also are found in bile. About 65% of sulfamethoxazole is bound to plasma protein.

About 60% of administered trimethoprim and from 25% to 50% of administered sulfamethoxazole are excreted in the urine in 24 hours. Two-thirds of the sulfonamide is unconjugated. Metabolites of trimethoprim also are excreted. The rates of excretion and the concentrations of both compounds in the urine are reduced significantly in patients with uremia.

Therapeutic Uses.

Urinary Tract Infections. Treatment of uncomplicated lower urinary tract infection (UTI) with trimethoprim-sulfamethoxazole often is highly effective for sensitive bacteria. The preparation has been shown to produce a better therapeutic effect than does either of its components given separately when the infecting microorganisms are of the family

Enterobacteriaceae. Single-dose therapy (320 mg trimethoprim plus 1600 mg sulfamethoxazole in adults) has been effective in some cases for the treatment of acute uncomplicated UTI, but a minimum of 3 days of therapy is more likely to be effective (Fihn, 2003; Zinner and Mayer, 2005).

The combination appears to have special efficacy in chronic and recurrent infections of the urinary tract. Small doses (200 mg sulfamethoxazole plus 40 mg trimethoprim per day and postcoitally or 2-4 times these amounts once or twice per week) effectively reduce the number of recurrent urinary tract infections in women. This effect may be related to the presence of therapeutic concentrations of trimethoprim in vaginal secretions. Enterobacteriaceae surrounding the urethral orifice may be eliminated or markedly reduced in number, thus diminishing the chance of an ascending reinfection. Trimethoprim also is found in therapeutic concentrations in prostatic secretions, and trimethoprim-sulfamethoxazole is often effective for the treatment of bacterial prostatitis.

Bacterial Respiratory Tract Infections. Trimethoprim-sulfamethoxazole is effective for acute exacerbations of chronic bronchitis. Administration of 800-1200 mg sulfamethoxazole plus 160-240 mg trimethoprim twice a day appears to be effective in decreasing fever, purulence and volume of sputum, and sputum bacterial count. Trimethoprim-sulfamethoxazole should *not* be used to treat streptococcal pharyngitis because it does not eradicate the microorganism. It is effective for acute otitis media in children and acute maxillary sinusitis in adults caused by susceptible strains of *H. influenzae* and *S. pneumoniae*.

GI Infections. The combination is an alternative to a fluoroquinolone for treatment of shigellosis because many strains of the causative agent now are resistant to ampicillin; however, resistance to trimethoprim-sulfamethoxazole is increasingly common. It also is a second-line drug (ceftriaxone or a fluoroquinolone is the preferred treatment) for typhoid fever, but resistance is an increasing problem. In adults, trimethoprim-sulfamethoxazole appears to be effective when the dose is 800 mg sulfamethoxazole plus 160 mg trimethoprim every 12 hours for 15 days. The same regimen has been used for 5 days for Travelers' diarrhea.

Trimethoprim-sulfamethoxazole appears to be effective in the management of carriers of sensitive strains of *Salmonella typhi* and other *Salmonella* spp. One proposed schedule is the administration of 800 mg sulfamethoxazole plus 160 mg trimethoprim twice a day for 3 months; however, failures have occurred. The presence of chronic disease of the gallbladder may be associated with a high incidence of failure to clear the carrier state. Acute diarrhea owing to sensitive strains of enteropathogenic *E. coli* can be treated or prevented with either trimethoprim or trimethoprim plus sulfamethoxazole (Hill et al., 2006). However, antibiotic treatment (either trimethoprim-sulfamethoxazole or cephalosporin) of diarrheal illness owing to enterohemorrhagic *E. coli* O157:H7 may increase the risk of hemolytic-uremic syndrome, perhaps by increasing the release of Shiga toxin by the bacteria (Wong et al., 2000).

Infection by *Pneumocystis jiroveci*. High-dose therapy (trimethoprim 15-20 mg/kg per day plus sulfamethoxazole 75-100 mg/kg per day in three or four divided doses) is effective for this severe infection in patients with AIDS (Thomas and Limper, 2004). This combination compares favorably with pentamidine for treatment of this disease. Adjunctive corticosteroids should be given at the onset of

anti-*Pneumocystis* therapy in patients with a $PO_2 < 70$ mm Hg or an alveolar-arterial gradient > 35 mm Hg (Centers for Disease Control and Prevention, 2009). However, the incidence of side effects is high for both regimens. Prophylaxis with 800 mg sulfamethoxazole and 160 mg trimethoprim once daily or three times a week is effective in preventing pneumonia caused by this organism in patients with AIDS (Centers for Disease Control and Prevention, 2009). Adverse reactions are less frequent with the lower prophylactic doses of trimethoprim-sulfamethoxazole. The most common problems are rash, fever, leukopenia, and hepatitis.

Prophylaxis in Neutropenic Patients. Several studies have demonstrated the effectiveness of low-dose therapy (150 mg/m² of body surface area of trimethoprim and 750 mg/m² of body surface area of sulfamethoxazole) for the prophylaxis of infection by *P. jiroveci*. In addition, significant protection against sepsis caused by gram-negative bacteria was noted when 800 mg sulfamethoxazole and 160 mg trimethoprim were given twice daily to severely neutropenic patients. The emergence of resistant bacteria may limit the usefulness of trimethoprim-sulfamethoxazole for prophylaxis (Hughes et al., 2002).

Miscellaneous Infections. *Nocardia* infections have been treated successfully with the combination, but failures also have been reported. Although a combination of doxycycline and streptomycin or gentamicin now is considered to be the treatment of choice for brucellosis, trimethoprim-sulfamethoxazole may be an effective substitute for the doxycycline combination. Trimethoprim-sulfamethoxazole also has been used successfully in the treatment of Whipple's disease, infection by *Stenotrophomonas maltophilia*, and infection by the intestinal parasites *Cyclospora* and *Isospora*. Wegener's granulomatosis may respond, depending on the stage of the disease.

Untoward Effects. There is no evidence that trimethoprim-sulfamethoxazole, when given in the recommended doses, induces folate deficiency in normal persons. However, the margin between toxicity for bacteria and that for humans may be relatively narrow when the cells of the patient are deficient in folate. In such cases, trimethoprim-sulfamethoxazole may cause or precipitate megaloblastosis, leukopenia, or thrombocytopenia. In routine use, the combination appears to exert little toxicity. About 75% of the untoward effects involve the skin. However, trimethoprim-sulfamethoxazole has been reported to cause up to three times as many dermatological reactions as does sulfisoxazole alone (5.9% versus 1.7%).

Exfoliative dermatitis, Stevens-Johnson syndrome, and toxic epidermal necrolysis (Lyell's syndrome) are rare, occurring primarily in older individuals. Nausea and vomiting constitute the bulk of GI reactions; diarrhea is rare. Glossitis and stomatitis are relatively common. Mild and transient jaundice has been noted and appears to have the histological features of allergic cholestatic hepatitis. Central nervous system reactions consist of headache, depression, and hallucinations, manifestations known to be produced by sulfonamides. Hematological reactions, in addition to those just mentioned, are various anemias (including aplastic, hemolytic, and macrocytic), coagulation disorders, granulocytopenia, agranulocytosis, purpura,

Henoch-Schönlein purpura, and sulfhemoglobinemia. Permanent impairment of renal function may follow the use of trimethoprim-sulfamethoxazole in patients with renal disease, and a reversible decrease in creatinine clearance has been noted in patients with normal renal function.

Patients with AIDS frequently have hypersensitivity reactions to trimethoprim-sulfamethoxazole (rash, neutropenia, Stevens-Johnson syndrome, Sweet's syndrome, and pulmonary infiltrates). It may be possible to continue therapy in such patients following rapid oral desensitization (Gluckstein and Ruskin, 1995).

THE QUINOLONES

The first quinolone, *nalidixic acid*, was isolated as a by-product of the synthesis of *chloroquine* and made available for the treatment of urinary tract infections. The introduction of fluorinated 4-quinolones, such as ciprofloxacin (CIPRO, others), and moxifloxacin (AVELOX), represents a particularly important therapeutic advance: These agents have broad antimicrobial activity and are effective after oral administration for the treatment of a wide variety of infectious diseases (Table 52–2) (Hooper, 2005a). Rare and potentially fatal side effects, however, have resulted in the withdrawal from the U.S. market of lomefloxacin, sparfloxacin (phototoxicity, QTc prolongation), gatifloxacin (hypoglycemia), temafloxacin (immune hemolytic anemia), trovafloxacin (hepatotoxicity), grepafloxacin (cardiotoxicity), and clinafloxacin (phototoxicity). In all these cases, the side effects were detected by postmarketing surveillance (Sheehan and Chew, 2003).

Chemistry. The compounds that are currently available for clinical use in the U.S. are quinolones containing a carboxylic acid moiety at position 3 of the primary ring structure. Many of the newer fluoroquinolones also contain a fluorine substituent at position 6 and a piperazine moiety at position 7 (Table 52–2).

Mechanism of Action. The quinolone antibiotics target bacterial DNA gyrase and topoisomerase IV (Hooper, 2005a). For many gram-positive bacteria (such as *S. aureus*), topoisomerase IV is the primary activity inhibited by the quinolones. In contrast, DNA gyrase is the primary quinolone target in many gram-negative microbes (such as *E. coli*) (Alovero et al., 2000; Hooper, 2005a). Individual strands of double-helical DNA must be separated to permit DNA replication or transcription. However, anything that separates the strands results in “overwinding” or excessive positive supercoiling of the DNA in front of the point of separation. To combat this mechanical obstacle, the bacterial enzyme DNA gyrase is responsible for the continuous introduction of negative supercoils into

Table 52-2

Structural Formulas of Selected Quinolones and Fluoroquinolones

Gemifloxacin		-F		-N-

DNA via an ATP-dependent reaction requiring that both strands of the DNA be cut to permit passage of a segment of DNA through the break; the break then is resealed.

The DNA gyrase of *E. coli* is composed of two 105,000 Da A subunits and two 95,000 Da B subunits encoded by the *gyrA* and *gyrB* genes, respectively. The A subunits, which carry out the strand-cutting function of the gyrase, are the site of action of the quinolones (Figure 52–3). The drugs inhibit gyrase-mediated DNA supercoiling at concentrations that correlate well with those required to inhibit bacterial growth (0.1–10 µg/mL). Mutations of the gene that encodes the A subunit polypeptide can confer resistance to these drugs (Hooper, 2005a).

Topoisomerase IV is also composed of four subunits encoded by the *parC* and *parE* genes in *E. coli* (Hooper, 2005a). Topoisomerase IV separates interlinked (catenated) daughter DNA molecules that are the product of DNA replication. Eukaryotic cells do not contain DNA gyrase, but they do contain a conceptually and mechanistically similar type II DNA topoisomerase that removes positive supercoils from DNA to prevent its tangling during replication. This enzyme is the target for some antineoplastic agents (Chapters 60 and 61). Quinolones inhibit eukaryotic type II topoisomerase only concentrations (100–1000 µg/mL) much higher than those that inhibit bacterial DNA gyrase (Mitscher and Ma, 2003).

Antibacterial Spectrum. The fluoroquinolones are potent bactericidal agents against *E. coli* and various species of *Salmonella*, *Shigella*, *Enterobacter*, *Campylobacter*, and *Neisseria* (Hooper, 2005a). MICs of the fluoroquinolones for 90% of these strains (MIC₉₀) usually are <0.2 µg/mL. Ciprofloxacin is more active than norfloxacin (NOROXIN) against *P. aeruginosa*; values of MIC₉₀ range from 0.5–6 µg/mL. Fluoroquinolones also have good activity against staphylococci, but not against methicillin-resistant strains (MIC₉₀ = 0.1–2 µg/mL).

Activity against streptococci is limited to a subset of the quinolones, including levofloxacin (LEVAQUIN), gatifloxacin, and moxifloxacin (AVELOX) (Hooper, 2005a). Several intracellular bacteria are inhibited by fluoroquinolones at concentrations that can be achieved in plasma; these include species of *Chlamydia*, *Mycoplasma*, *Legionella*, *Brucella*, and *Mycobacterium* (including *Mycobacterium tuberculosis*) (American Thoracic Society, 2003). Ciprofloxacin (CIPRO, others), ofloxacin (FLOXIN), and pefloxacin have MIC₉₀ values from 0.5–3 µg/mL for *M. fortuitum*, *M. kansasii*, and *M. tuberculosis*; ofloxacin and pefloxacin (not available in U.S.) are active in animal

models of leprosy (Hooper, 2005a). However, clinical experience with these pathogens remains limited.

Several fluoroquinolones, including garenoxacin (not available in U.S.) and gemifloxacin, have activity against anaerobic bacteria (Medical Letter, 2000, 2004).

Resistance to quinolones may develop during therapy via mutations in the bacterial chromosomal genes encoding DNA gyrase or topoisomerase IV or by active transport of the drug out of the bacteria (Oethinger et al., 2000). No quinolone-modifying or -inactivating activities have been identified in bacteria (Gold and Moellering, 1996). Resistance has increased after the introduction of fluoroquinolones, especially in *Pseudomonas* and staphylococci. Increasing fluoroquinolone resistance also is being observed in *C. jejuni*, *Salmonella*, *N. gonorrhoeae*, and *S. pneumoniae*.

As mentioned in Chapter 48, the pharmacokinetic and pharmacodynamic parameters of antimicrobial agents are important in preventing the selection and spread of resistant strains and have led to description of the mutation-prevention concentration, which is the lowest concentration of antimicrobial that prevents selection of resistant bacteria from high bacterial inocula. β-Lactams are time-dependent agents without significant post-antibiotic effects, resulting in bacterial eradication when unbound serum concentrations exceed MICs of these agents against infecting pathogens for >40–50% of the dosing interval. By contrast, fluoroquinolones are concentration- and time-dependent agents, resulting in bacterial eradication when unbound serum area under the curve-to-MIC ratios exceed 25–30. An extended release formulation of ciprofloxacin (PROQUIN XR) exemplifies this principle.

Absorption, Fate, and Excretion. The quinolones are well absorbed after oral administration and are distributed widely in body tissues. Peak serum levels of the fluoroquinolones are obtained within 1–3 hours of an oral dose of 400 mg, with peak levels ranging from 1.1 µg/mL for sparfloxacin to 6.4 µg/mL for levofloxacin. Relatively low serum levels are reached with norfloxacin and limit its usefulness to the treatment of urinary tract infections. Food does not impair oral absorption but may delay the time to peak serum concentrations. Oral doses in adults are 200–400 mg every 12 hours for ofloxacin, 400 mg every 12 hours for norfloxacin and pefloxacin, and 250 to 750 mg every 12 hours for ciprofloxacin. Bioavailability of the fluoroquinolones is >50% for all agents and >95% for several. The serum t_{1/2} is 3–5 hours for norfloxacin and ciprofloxacin. The volume of distribution of quinolones is high, with concentrations of quinolones in urine, kidney, lung and prostate tissue, stool, bile, and macrophages and neutrophils higher than serum levels. Quinolone

Figure 52–3. Model of the formation of negative DNA supercoils by DNA gyrase. The enzyme binds to two segments of DNA (1), creating a node of positive (+) superhelix. The enzyme then introduces a double-strand break in the DNA and passes the front segment through the break (2). The break is then resealed (3), creating a negative (–) supercoil. Quinolones inhibit the nicking and closing activity of the gyrase and, at higher concentrations, block the decatenating activity of topoisomerase IV. From Cozzarelli NR. DNA gyrase and the supercoiling of DNA. *Science*, 1980, 207:953–960. Reprinted with permission from AAAS.

concentrations in cerebrospinal fluid, bone, and prostatic fluid are lower than in serum. Pefloxacin and ofloxacin levels in ascites fluid are close to serum levels, and ciprofloxacin, ofloxacin, and pefloxacin have been detected in human breast milk.

Most quinolones are cleared predominantly by the kidney, and dosages must be adjusted for renal failure. Exceptions are pefloxacin and moxifloxacin, which are metabolized predominantly by the liver and should not be used in patients with hepatic failure. None of the agents is removed efficiently by peritoneal dialysis or hemodialysis.

Therapeutic Uses

Urinary Tract Infections. Nalidixic acid is useful only for UTI caused by susceptible microorganisms. The fluoroquinolones are significantly more potent and have a much broader spectrum of antimicrobial activity. Norfloxacin is approved for use in the U.S. only for urinary tract infections. Comparative clinical trials indicate that the fluoroquinolones are more efficacious than trimethoprim-sulfamethoxazole for the treatment of UTI (Hooper, 2005b). Ciprofloxacin XR is FDA-approved only for UTI.

Prostatitis. Norfloxacin, ciprofloxacin, and ofloxacin all have been effective in uncontrolled trials for the treatment of prostatitis caused by sensitive bacteria. Fluoroquinolones administered for 4-6 weeks appear to be effective in patients not responding to trimethoprim-sulfamethoxazole.

Sexually Transmitted Diseases. The quinolones are contraindicated in pregnancy. Fluoroquinolones lack activity for *Treponema pallidum* but have activity *in vitro* against *C. trachomatis* and *H. ducreyi*. For chlamydial urethritis/cervicitis, a 7-day course of ofloxacin is an alternative to a 7-day treatment with doxycycline or a single dose of azithromycin; other available quinolones have not been reliably effective. A single oral dose of a fluoroquinolone such as ofloxacin or ciprofloxacin had been effective treatment for sensitive strains of *N. gonorrhoeae*, but increasing resistance to fluoroquinolones has led to ceftriaxone being the first-line agent for this infection (Newman et al., 2004). Chancroid (infection by *H. ducreyi*) can be treated with 3 days of ciprofloxacin.

GI and Abdominal Infections. For traveler's diarrhea (frequently caused by enterotoxigenic *E. coli*), the quinolones are equal to trimethoprim-sulfamethoxazole in effectiveness, reducing the duration of loose stools by 1-3 days (Hill et al., 2006). Norfloxacin, ciprofloxacin, and ofloxacin given for 5 days all have been effective in the treatment of patients with shigellosis, with even shorter courses effective in many cases. Ciprofloxacin and ofloxacin treatment cures most patients with enteric fever caused by *S. typhi*, as well as bacteremic nontyphoidal infections in AIDS patients, and it clears chronic fecal carriage. Shigellosis is treated effectively with either ciprofloxacin or azithromycin. The *in vitro* ability of the quinolones to induce the Shiga toxin *stx2* gene (the cause of the hemolytic-uremic syndrome) in *E. coli* suggests that the quinolones should not be used for Shiga toxin-producing *E. coli* (Miedouge et al., 2000). Ciprofloxacin and ofloxacin have been less effective in treating episodes of peritonitis occurring in patients on chronic ambulatory peritoneal dialysis likely owing to the higher MICs for these drugs for the coagulase-negative staphylococci that are a common cause of peritonitis in this setting.

Respiratory Tract Infections. The major limitation to the use of quinolones for the treatment of community-acquired pneumonia and

bronchitis had been the poor *in vitro* activity of ciprofloxacin, ofloxacin, and norfloxacin against *S. pneumoniae* and anaerobic bacteria. However, newer fluoroquinolones, including gatifloxacin (available only for ophthalmic use in U.S.) and moxifloxacin, have excellent activity against *S. pneumoniae*. The fluoroquinolones have *in vitro* activity against the rest of the commonly recognized respiratory pathogens, including *H. influenzae*, *Moraxella catarrhalis*, *S. aureus*, *M. pneumoniae*, *Chlamydia pneumoniae*, and *Legionella pneumophila*. Either a fluoroquinolone (ciprofloxacin or levofloxacin) or azithromycin is the antibiotic of choice for *L. pneumophila* (Edelstein & Cianciotto, 2005). Fluoroquinolones have been very effective at eradicating both *H. influenzae* and *M. catarrhalis* from sputum. Mild to moderate respiratory exacerbations owing to *P. aeruginosa* in patients with cystic fibrosis have responded to oral fluoroquinolone therapy. Emerging clinical data are demonstrating a clear role for the newer fluoroquinolones as single agents for treatment of community-acquired pneumonia (Hooper, 2005b). However, on the horizon is a decreasing susceptibility of *S. pneumoniae* to fluoroquinolones (Chen et al., 1999; Wortmann and Bennett, 1999).

Bone, Joint, and Soft Tissue Infections. The treatment of chronic osteomyelitis requires prolonged (weeks to months) antimicrobial therapy with agents active against *S. aureus* and gram-negative rods. The fluoroquinolones, by virtue of their oral administration and appropriate antibacterial spectrum for these infections, may be used appropriately in some cases; recommended doses are 500 mg every 12 hours or, if severe, 750 mg twice daily. Bone and joint infections may require treatment for 4-6 weeks or more. Dosage should be reduced for patients with severely impaired renal function. Clinical cures have been as high as 75% in chronic osteomyelitis in which gram-negative rods predominated (Hooper, 2005b). Failures have been associated with the development of resistance in *S. aureus*, *P. aeruginosa*, and *Serratia marcescens*. In diabetic foot infections, which are commonly caused by a mixture of bacteria including gram-negative rods, anaerobes, streptococci, and staphylococci, the fluoroquinolones in combination with an agent with antianaerobic activity are a reasonable choice.

Other Infections. Ciprofloxacin received wide usage for the prophylaxis of anthrax and has been shown to be effective for the treatment of tularemia (Chocarro et al., 2000; Swartz, 2001). The quinolones may be used as part of multiple-drug regimens for the treatment of multidrug-resistant tuberculosis and for the treatment of atypical mycobacterial infections as well as *Mycobacterium avium* complex infections in AIDS (Chapter 56). Quinolones, when used as prophylaxis in neutropenic patients, have decreased the incidence of gram-negative rod bacteremias (Hughes et al., 2002).

Adverse Effects. Quinolones and fluoroquinolones generally are well tolerated (Mandell, 2003). The most common adverse reactions involve the GI tract, with 3-17% of patients reporting mostly mild nausea, vomiting, and/or abdominal discomfort. Ciprofloxacin is the most common cause of *C. difficile* colitis. Gatifloxacin is associated with both hypo- and hyperglycemia in older adults (Park-Wyllie et al., 2006). CNS side effects, predominantly mild headache and dizziness, have been seen in 0.9-11% of patients. Rarely, hallucinations, delirium, and seizures have occurred, predominantly in patients who

were also receiving theophylline or a nonsteroidal anti-inflammatory drug. Ciprofloxacin and pefloxacin inhibit the metabolism of theophylline, and toxicity from elevated concentrations of the methylxanthine may occur (Schwartz et al., 1988). Nonsteroidal anti-inflammatory drugs may augment displacement of γ -aminobutyric acid (GABA) from its receptors by the quinolones (Halliwell et al., 1993). Rashes, including photosensitivity reactions, also can occur. Achilles tendon rupture or tendinitis is a recognized adverse effect, especially in those >60 years old, patients taking corticosteroids, and in solid organ transplant recipients (Mandell, 2003). All these agents can produce arthropathy in several species of immature animals. Traditionally, the use of quinolones in children has been contraindicated for this reason. However, children with cystic fibrosis given ciprofloxacin, norfloxacin, and nalidixic acid have had few, and reversible, joint symptoms (Burkhardt et al., 1997; Sabharwal & Marchant, 2006). Therefore, in some cases the benefits may outweigh the risks of quinolone therapy in children. Ciprofloxacin should not be given to pregnant women.

Leukopenia, eosinophilia, and mild elevations in serum transaminases occur rarely. QT_c interval (QT interval corrected for heart rate) prolongation has been observed with sparfloxacin and to a lesser extent with gatifloxacin and moxifloxacin. Quinolones probably should be used only with caution in patients on class III (amiodarone) and class IA (quinidine, procainamide) antiarrhythmics (Chapter 29).

ANTISEPTIC AND ANALGESIC AGENTS FOR URINARY TRACT INFECTIONS

Urinary tract antiseptics are concentrated in the renal tubules where they inhibit the growth of many species of bacteria. These agents cannot be used to treat systemic infections because effective concentrations are not achieved in plasma with safe doses; however, they can be administered orally to treat infections of the urinary tract. Furthermore, effective antibacterial concentrations reach the renal pelvis and the bladder. Treatment with such drugs can be thought of as local therapy: Only in the kidney and bladder, with the rare exceptions mentioned below, are adequate therapeutic levels achieved (Hooper, 2005b).

Methenamine. Methenamine is a urinary tract antiseptic and pro-drug that owes its activity to its capacity to generate formaldehyde.

METHENAMINE

Chemistry. Methenamine is hexamethylenetetramine (hexamethylenamine). The compound decomposes in water to generate formaldehyde, according to the following reaction:

At pH 7.4, almost no decomposition occurs; the yield of formaldehyde is 6% of the theoretical amount at pH 6 and 20% at pH 5. Thus, acidification of the urine promotes formaldehyde formation and the formaldehyde-dependent antibacterial action. The decomposition reaction is fairly slow, and 3 hours are required to reach 90% completion.

Antimicrobial Activity. Nearly all bacteria are sensitive to free formaldehyde at concentrations of ~ 20 $\mu\text{g}/\text{mL}$. Urea-splitting microorganisms (e.g., *Proteus* spp.) tend to raise the pH of the urine and thus inhibit the release of formaldehyde. Microorganisms do not develop resistance to formaldehyde.

Pharmacology and Toxicology. Methenamine is absorbed orally, but 10-30% decomposes in the gastric juice unless the drug is protected by an enteric coating. Because of the ammonia produced, methenamine is contraindicated in hepatic insufficiency. Excretion in the urine is nearly quantitative. When the urine pH is 6 and the daily urine volume is 1000-1500 mL, a daily dose of 2 g will yield a urine concentration of 18-60 $\mu\text{g}/\text{mL}$ of formaldehyde; this is more than the MIC for most urinary tract pathogens. Various poorly metabolized acids can be used to acidify the urine. Low pH alone is bacteriostatic, so acidification serves a double function. The acids commonly used are mandelic acid and hippuric acid (UREX, HIPREX).

GI distress frequently is caused by doses >500 mg four times a day, even with enteric-coated tablets. Painful and frequent micturition, albuminuria, hematuria, and rashes may result from doses of 4 to 8 g/day given for longer than 3-4 weeks. Once the urine is sterile, a high dose should be reduced. Because systemic methenamine has low toxicity at the typically used doses, renal insufficiency does not constitute a contraindication to the use of methenamine alone, but the acids given concurrently may be detrimental; methenamine mandelate is contraindicated in renal insufficiency. Crystalluria from the mandelate moiety can occur. Methenamine combines with sulfamethizole and perhaps other sulfonamides in the urine, which results in mutual antagonism; therefore, these drugs should not be used in combination.

Therapeutic Uses and Status. Methenamine is not a primary drug for the treatment of acute urinary tract infections, but it is of value for chronic suppressive treatment (Fihn, 2003). The agent is most useful when the causative organism is *E. coli*, but it usually can suppress the common gram-negative offenders and often *S. aureus* and *S. epidermidis* as well. *Enterobacter aerogenes* and *Proteus vulgaris* are usually resistant. Urea-splitting bacteria (mostly *Proteus*) make it difficult to control the urine pH. The physician should strive to keep the pH <5.5.

Nitrofurantoin. Nitrofurantoin (FURADANTIN, MACROBID, others) is a synthetic nitrofuran that is used for the prevention and treatment of infections of the urinary tract.

NITROFURANTOIN

Antimicrobial Activity. Enzymes capable of reducing nitrofurantoin appear to be crucial for its activation. Highly reactive intermediates are formed, and these seem to be responsible for the observed capacity of the drug to damage DNA. Bacteria reduce nitrofurantoin more rapidly than do mammalian cells, and this is thought to account for the selective antimicrobial activity of the compound. Bacteria that are susceptible to the drug rarely become resistant during therapy. Nitrofurantoin is active against many strains of *E. coli* and enterococci. However, most species of *Proteus* and *Pseudomonas* and many species of *Enterobacter* and *Klebsiella* are resistant. Nitrofurantoin is bacteriostatic for most susceptible microorganisms at concentrations of $\leq 32 \mu\text{g/mL}$ or less and is bactericidal at concentrations of $\geq 100 \mu\text{g/mL}$. The antibacterial activity is higher in an acidic urine.

Pharmacology and Toxicity. Nitrofurantoin is absorbed rapidly and completely from the GI tract. The macrocrystalline form of the drug is absorbed and excreted more slowly. Antibacterial concentrations are not achieved in plasma following ingestion of recommended doses because the drug is eliminated rapidly. The plasma $t_{1/2}$ is 0.3-1 hour; $\sim 40\%$ is excreted unchanged into the urine. The average dose of nitrofurantoin yields a concentration in urine of $\sim 200 \mu\text{g/mL}$. This concentration is soluble at $\text{pH} > 5$, but the urine should not be alkalinized because this reduces antimicrobial activity. The rate of excretion is linearly related to the creatinine clearance, so in patients with impaired glomerular function, the efficacy of the drug may be decreased and the systemic toxicity increased. Nitrofurantoin colors the urine brown.

The most common untoward effects are nausea, vomiting, and diarrhea; the macrocrystalline preparation is better tolerated than traditional formulations. Various hypersensitivity reactions occur occasionally. These include chills, fever, leukopenia, granulocytopenia, hemolytic anemia (associated with G6PD deficiency), cholestatic jaundice, and hepatocellular damage. Chronic active hepatitis is an uncommon but serious side effect. Acute pneumonitis with fever, chills, cough, dyspnea, chest pain, pulmonary infiltration, and eosinophilia may occur within hours to days of the initiation of therapy; these symptoms usually resolve quickly after discontinuation of the drug. More insidious subacute reactions also may be noted, and interstitial pulmonary fibrosis can occur in patients taking the drug chronically. This appears to be due to generation of oxygen radicals as a result of redox cycling of the drug in the lung. Elderly patients are especially susceptible to the pulmonary toxicity of nitrofurantoin. Megaloblastic anemia is rare. Various neurological disorders are observed occasionally. Headache, vertigo, drowsiness, muscular aches, and nystagmus are readily reversible, but severe polyneuropathies with demyelination and degeneration of both sensory and motor nerves have been reported; signs of denervation and muscle atrophy result. Neuropathies are most likely to occur in patients with impaired renal function and in persons on long-continued treatment.

The oral dosage of nitrofurantoin for adults is 50-100 mg four times a day with meals and at bedtime, less for the macrocrystalline formulation (100 mg every 12 hours for 7 days). Alternatively, the daily dosage is better expressed as 5-7 mg/kg in four divided doses (not to exceed 400 mg). A single 50-100-mg dose at bedtime may be sufficient to prevent recurrences. The daily dose for children is 5 to 7 mg/kg but may be as low as 1 mg/kg for long-term therapy. A course of therapy should not exceed 14 days, and repeated courses

should be separated by rest periods. Pregnant women, individuals with impaired renal function (creatinine clearance $< 40 \text{ mL/minute}$), and children < 1 month of age should not receive nitrofurantoin.

Nitrofurantoin is approved only for the treatment of urinary tract infections caused by microorganisms known to be susceptible to the drug. Currently, bacterial resistance to nitrofurantoin is more frequent than resistance to fluoroquinolones or trimethoprim-sulfamethoxazole, making nitrofurantoin a second-line agent for treatment of urinary tract infections (Fihn, 2003). Nitrofurantoin is not recommended for treatment of pyelonephritis or prostatitis.

Phenazopyridine. Phenazopyridine hydrochloride (PYRIDIUM, others) is *not* a urinary antiseptic. However, it does have an analgesic action on the urinary tract and alleviates symptoms of dysuria, frequency, burning, and urgency.

The usual dose is 200 mg three times daily. The compound is an azo dye, which colors urine orange or red; the patient should be so informed. GI upset is seen in up to 10% of patients and can be reduced by administering the drug with food; overdosage may result in methemoglobinemia. Phenazopyridine has been marketed since 1925 and has had dual prescription/over-the-counter (OTC) marketing status since 1951. As part of their ongoing review of OTC drug products, the Food and Drug Administration (FDA) is currently in the process of evaluating products containing $< 200 \text{ mg}$ phenazopyridine to determine whether these products generally are recognized as safe and effective as urinary analgesics. The outcome of this evaluation will determine the continued availability of OTC phenazopyridine products in the U.S. Products containing 200 mg phenazopyridine are sold by prescription, but their long-term availability in the marketplace also may be affected by the FDA's final OTC ruling. Phenazopyridine is no longer available in Canada.

53 chapter

Penicillins, Cephalosporins, and Other β -Lactam Antibiotics

William A. Petri, Jr.

The β -lactam antibiotics are useful and frequently prescribed antimicrobial agents that share a common structure and mechanism of action: inhibition of synthesis of the bacterial peptidoglycan cell wall. The group includes penicillins, cephalosporins, and carbapenems.

The penicillins consist of penicillins G and V, which are highly active against susceptible gram-positive cocci; penicillinase-resistant penicillins such as nafcillin, which are active against penicillinase-producing *Staphylococcus aureus*; ampicillin and other agents with an improved gram-negative spectrum, especially when combined with a β -lactamase inhibitor; and extended-spectrum penicillins with activity against *Pseudomonas aeruginosa*, such as piperacillin.

The β -lactams also include the cephalosporin antibiotics, which are classified by generation: First-generation agents have excellent gram-positive and modest gram-negative activity; second-generation agents have somewhat better activity against gram-negative organisms and include some agents with antianaerobe activity; third-generation agents have activity against gram-positive organisms and much more activity against the Enterobacteriaceae, with a subset active against *P. aeruginosa*; and fourth-generation agents encompass the antimicrobial spectrum of all the third-generation agents and have increased stability to hydrolysis by inducible chromosomal β -lactamases.

Carbapenems, including imipenem, doripenem, ertapenem and meropenem, have the broadest antimicrobial spectrum of any antibiotic, whereas the monobactam aztreonam has a gram-negative spectrum resembling that of the aminoglycosides.

β -Lactamase inhibitors such as clavulanate are used to extend the spectrum of penicillins against β -lactamase-producing organisms. Bacterial resistance against the β -lactam antibiotics continues to increase at a dramatic rate. Mechanisms of resistance include not

only production of β -lactamases that in some cases destroy all β -lactam antibiotics, but also alterations in or acquisition of novel penicillin-binding proteins PBPs and decreased entry and/or active efflux of the antibiotic. It is not an exaggeration to state that we are re-entering the pre-antibiotic era, with many nosocomially acquired gram-negative bacterial infections resistant to all available antibiotics.

THE PENICILLINS

Despite the existence of microbial resistance, the penicillins constitute one of the most important groups of antibiotics. Many of these have unique advantages such that members of this group of antibiotics are currently the drugs of choice for a large number of infectious diseases.

History. The history of the brilliant research that led to the discovery and development of penicillin is well chronicled. In 1928, while studying *Staphylococcus* variants in the laboratory at St. Mary's Hospital in London, Alexander Fleming observed that a mold contaminating one of his cultures caused the bacteria in its vicinity to undergo lysis. Broth in which the fungus was grown was markedly inhibitory for many microorganisms. Because the mold belonged to the genus *Penicillium*, Fleming named the antibacterial substance *penicillin*.

A decade later, penicillin was developed as a systemic therapeutic agent by the concerted research of a group of investigators at Oxford University headed by Florey, Chain, and Abraham. By May 1940, a crude preparation was found to produce dramatic therapeutic effects when administered parenterally to mice with streptococcal infections. Sufficient penicillin was accumulated by 1941 to conduct therapeutic trials in several patients desperately ill with staphylococcal and streptococcal infections refractory to all other therapy. At this stage, the crude, amorphous penicillin was only ~10% pure, and it required nearly 100 L of the broth in which the mold had been grown to obtain enough of the antibiotic to treat one patient for 24 hours. Bedpans actually were used by the Oxford group for growing cultures of *Penicillium notatum*. Case 1 in the 1941 report from Oxford

was that of a policeman who was suffering from a severe mixed staphylococcal and streptococcal infection. He was treated with penicillin, some of which had been recovered from the urine of other patients who had been given the drug. It is said that an Oxford professor referred to penicillin as a remarkable substance grown in bed-pans and purified by passage through the Oxford Police Force.

A vast research program soon was initiated in the U.S. During 1942, 122 million units of penicillin were made available, and the first clinical trials were conducted at Yale University and the Mayo Clinic, with dramatic results. By the spring of 1943, 200 patients had been treated with the drug. The results were so impressive that the surgeon general of the U.S. Army authorized a trial of the antibiotic in a military hospital. Soon thereafter, penicillin was adopted throughout the medical services of the U.S. Armed Forces.

The deep-fermentation procedure for the biosynthesis of penicillin marked a crucial advance in the large-scale production of the antibiotic. From a total production of a few hundred million units a month in the early days, the quantity manufactured rose to over 200 trillion units (nearly 150 tons) by 1950. The first marketable penicillin cost several dollars per 100,000 units; today, the same dose costs only a few cents.

Chemistry. The basic structure of the penicillins, as shown in Figure 53-1, consists of a thiazolidine ring (A) connected to a β -lactam ring (B) to which is attached a side chain (R). The penicillin nucleus itself is the chief structural requirement for biological activity; metabolic transformation or chemical alteration of this portion of the molecule causes loss of all significant antibacterial activity. The side chain (Table 53-1) determines many of the antibacterial and pharmacological characteristics of a particular type of penicillin. Several natural penicillins can be produced depending on the chemical composition of the fermentation medium used to culture *Penicillium*. Penicillin G (benzylpenicillin) has the greatest antimicrobial activity of these and is the only natural penicillin used clinically. For penicillin G, the side chain (R in Figure 53-1) is a phenyl-methyl substituent (Table 53-1).

Semisynthetic Penicillins. The discovery that 6-aminopenicillanic acid could be obtained from cultures of *P. chrysogenum* that were depleted

of side-chain precursors led to the development of the semisynthetic penicillins. Side chains can be added that alter the susceptibility of the resulting compounds to inactivating enzymes (β -lactamases) and that change the antibacterial activity and the pharmacological properties of the drug. 6-Aminopenicillanic acid is now produced in large quantities with the aid of an amidase from *P. chrysogenum* (Figure 53-1). This enzyme splits the peptide linkage by which the side chain of penicillin is joined to 6-aminopenicillanic acid. Table 53-1 shows the variety of side chains that have been added to 6-aminopenicillanic acid to produce the medicinal penicillins in current use; the table also summarizes their major therapeutic properties (e.g., absorption following oral administration, resistance to penicillinase, and antimicrobial spectrum).

Unitage of Penicillin. The international unit of penicillin is the specific penicillin activity contained in 0.6 μ g of the crystalline sodium salt of penicillin G. One milligram of pure penicillin G sodium thus equals 1667 units; 1.0 mg of pure penicillin G potassium represents 1595 units. The dosage and the antibacterial potency of the semisynthetic penicillins are expressed in terms of weight.

Mechanism of Action of the Penicillins and Cephalosporins. The β -lactam antibiotics can kill susceptible bacteria. Although knowledge of the mechanism of this action is incomplete, numerous researchers have supplied information that allows understanding of the basic phenomenon (Bayles, 2000; Ghuysen, 1991).

The cell walls of bacteria are essential for their normal growth and development. Peptidoglycan is a heteropolymeric component of the cell wall that provides rigid mechanical stability by virtue of its highly cross-linked latticework structure (Figure 53-2). In gram-positive microorganisms, the cell wall is 50-100 molecules thick, but it is only 1 or 2 molecules thick in gram-negative bacteria (Figure 53-3A). The peptidoglycan is composed of glycan chains, which are linear strands of two alternating amino sugars (*N*-acetylglucosamine and *N*-acetylmuramic acid) that are cross-linked by peptide chains.

The biosynthesis of the peptidoglycan involves ~30 bacterial enzymes and may be considered in three stages. The first stage, precursor formation, takes place in the cytoplasm. The product, uridine

Figure 53-1. Structure of penicillins and products of their enzymatic hydrolysis.

Figure 53–2. Action of β -lactam antibiotics in *Staphylococcus aureus*. The bacterial cell wall consists of glycopeptide polymers (a NAM-NAG amino-hexose backbone) linked via bridges between amino acid side chains. In *S. aureus*, the bridge is (Gly)₅-D-Ala between lysines. The cross-linking is catalyzed by a transpeptidase, the enzyme that penicillins and cephalosporins inhibit. NAM, N-acetyl-muramic acid; NAG, N-acetyl-glucosamine.

diphosphate (UDP)-acetylmuramyl-pentapeptide, accumulates in cells when subsequent synthetic stages are inhibited. The last reaction in the synthesis of this compound is the addition of a dipeptide, D-alanyl-D-alanine. Synthesis of the dipeptide involves prior racemization of L-alanine and condensation catalyzed by D-alanyl-D-alanine synthase. D-Cycloserine is a structural analog of D-alanine and acts as a competitive inhibitor of both the racemase and the synthase (Chapter 56).

During reactions of the second stage, UDP-acetylmuramyl-pentapeptide and UDP-acetylglucosamine are linked (with the release of the uridine nucleotides) to form a long polymer. The third and final stage involves completion of the cross-link. This is accomplished by peptidoglycan glycosyltransferases outside the cell membrane of gram-positive and within the periplasmic space of gram-negative bacteria (Figure 53–3B). The terminal glycine residue of the pentaglycine bridge is linked to the fourth residue of the pentapeptide (D-alanine), releasing the fifth residue (also D-alanine) (Figure 53–2). It is this last step in peptidoglycan synthesis that is inhibited by the β -lactam antibiotics and glycopeptide antibiotics such as vancomycin (by a different mechanism than the β -lactams; Chapter 54). Stereo models reveal that the conformation of penicillin is very similar to that of D-alanyl-D-alanine. The transpeptidase probably is acylated by penicillin; i.e., penicilloyl enzyme apparently is formed, with cleavage of the —CO—N— bond of the β -lactam ring. Although the transpeptidase activity has been targeted with the β -lactams and vancomycin, the glycosyltransferase is a relatively unexplored target for antibiotics (Lovering et al., 2007).

Although inhibition of the transpeptidase just described is demonstrably important, there are additional, related targets for the actions of penicillins and cephalosporins; these are collectively termed *penicillin-binding proteins* (PBPs). All bacteria have several such entities; e.g., *S. aureus* has four PBPs, whereas *Escherichia coli* has at least seven. The PBPs vary in their affinities for different β -lactam antibiotics, although the interactions eventually become covalent. The higher molecular weight PBPs of *E. coli* (PBPs 1a and 1b) include the transpeptidases responsible for synthesis of the peptidoglycan. Other PBPs in *E. coli* include those that are necessary for maintenance of the rod-like shape of the bacterium and for septum formation at division. Inhibition of the transpeptidases causes spheroplast formation and rapid lysis. However, inhibition of the activities of other PBPs may cause delayed lysis (PBP 2) or the production of long filamentous forms of the bacterium (PBP 3). The lethality of penicillin for bacteria appears to involve both lytic and nonlytic mechanisms. Penicillin's disruption of the balance between PBP-mediated peptidoglycan assembly and murein hydrolase activity results in autolysis. Non-lytic killing by penicillin may involve holin-like proteins in the bacterial membrane that collapse the membrane potential (Bayles, 2000).

Mechanisms of Bacterial Resistance to Penicillins and Cephalosporins.

Although all bacteria with cell walls contain PBPs, β -lactam antibiotics cannot kill or even inhibit all bacteria because bacteria can be resistant to these agents by myriad mechanisms. The microorganism may be intrinsically resistant because of structural differences in the PBPs that are the targets of these drugs. Furthermore, a sensitive strain may acquire resistance of this type by the development of high-molecular-weight PBPs that have decreased affinity for the antibiotic. Because the β -lactam antibiotics inhibit many different PBPs in a single bacterium, the affinity for β -lactam antibiotics of several PBPs must decrease for the organism to be resistant. Altered PBPs with decreased affinity for β -lactam antibiotics are acquired by homologous recombination between PBP genes of different bacterial species. Four of the five high-molecular-weight PBPs of the most highly penicillin-resistant *Streptococcus pneumoniae* isolates have decreased affinity for β -lactam antibiotics as a result of interspecies homologous recombination events (Figure 53–4). In contrast, isolates with high-level resistance to third-generation cephalosporins contain alterations of only two of the five high-molecular-weight PBPs because the other PBPs have inherently low affinity for the third-generation cephalosporins. Penicillin resistance in *Streptococcus sanguis* and other *viridans* streptococci apparently emerged as a result of replacement of its PBPs with resistant PBPs from *S. pneumoniae* (Carratalá et al., 1995; Spratt, 1994). Methicillin-resistant *S. aureus* are resistant via acquisition of an additional high-molecular-weight PBP (via a transposon from an unknown organism) with a very low affinity for all β -lactam antibiotics. The gene (*MecA*) encoding this new PBP also is present in and responsible for methicillin resistance in the coagulase-negative staphylococci (Moran et al., 2006).

Other instances of bacterial resistance to the β -lactam antibiotics are caused by the inability of the agent to penetrate to its site of action (Jacoby and Munoz-Price, 2005) (Figure 53–5). In gram-positive bacteria, the peptidoglycan polymer is very near the cell surface (Figure 53–3). Some gram-positive bacteria have polysaccharide capsules that are external to the cell wall, but these structures are not a barrier to the diffusion of the β -lactams; the small

Figure 53–3. A. Comparison of the structure and composition of gram-positive and gram-negative cell walls. (Fig. 4-11, pg 83 from *Microbiology: An Introduction*, 3rd ed. By Gerard J. Tortora, Berdell R. Funke, and Christine L. Case. Copyright © 1989, 1986, 1982 by the Benjamin/Cummings Company, Inc. Reprinted by permission of Pearson Education, Inc.) B. Schematic of Penicillin Binding Protein 2 (PBP2) from *S. aureus*. PBP2 has two enzymatic activities that are crucial to synthesis of the peptidoglycan layers of bacterial cell walls: a transpeptidase that crosslinks amino acid side chains, and a glucosyltransferase that links subunits of the glycopeptide polymer (see Figure 53–2). The transpeptidase and glucosyltransferase domains are separated by a linker region. The glucosyltransferase is thought to be partially embedded in the membrane.

β -lactam antibiotic molecules can penetrate easily to the outer layer of the cytoplasmic membrane and the PBPs, where the final stages of the synthesis of the peptidoglycan take place. The situation is different with gram-negative bacteria. Their surface structure is more complex, and their inner membrane, which is analogous to the cytoplasmic membrane of gram-positive bacteria, is covered by the outer membrane, lipopolysaccharide, and capsule (Figure 53–3). The outer membrane functions as an impenetrable barrier for some antibiotics (Nakae, 1986). Some small hydrophilic antibiotics, however, diffuse through aqueous channels in the outer membrane that are formed by proteins called *porins*. Broader-spectrum penicillins, such as ampicillin

and amoxicillin, and most of the cephalosporins diffuse through the pores in the *E. coli* outer membrane significantly more rapidly than can penicillin G. The number and size of pores in the outer membrane vary among different gram-negative bacteria. An extreme example is *P. aeruginosa*, which is intrinsically resistant to a wide variety of antibiotics because it lacks the classical high-permeability porins (Nikaido, 1994). Active efflux pumps serve as another mechanism of resistance, removing the antibiotic from its site of action before it can act (Nikaido, 1998) (Figure 53–5). This is an important mechanism of β -lactam resistance in *P. aeruginosa*, *E. coli*, and *Neisseria gonorrhoeae*.

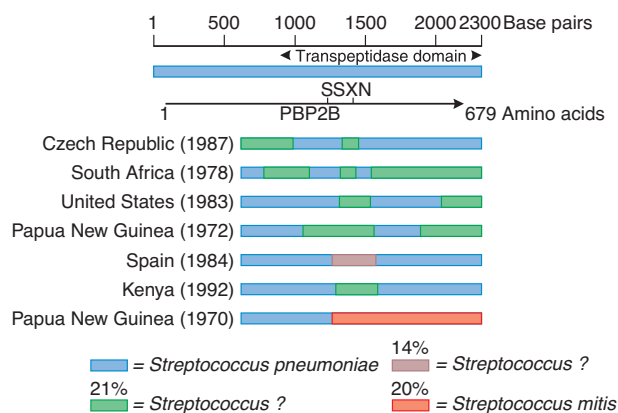

Figure 53-4. Mosaic penicillin-binding protein (PBP) 2B genes in penicillin-resistant pneumococci. The divergent regions in the PBP2B genes of seven resistant pneumococci from different countries are shown. These regions have been introduced from at least three sources, one of which appears to be *Streptococcus mitis*. The approximate percent sequence divergence of the divergent regions from the PBP2B genes of susceptible pneumococci is shown. (From Spratt BG. Resistance to antibiotics mediated by target alterations. *Science*, 1994, 264:388–393. Reprinted with permission from AAAS.)

Bacteria also can destroy β -lactam antibiotics enzymatically. β -Lactamases are capable of inactivating certain of these antibiotics and may be present in large quantities (Figures 53-1 and 53-3). Different microorganisms elaborate a number of distinct β -lactamases, although most bacteria produce only one form of the enzyme. The substrate specificities of some of these enzymes are relatively narrow, and these often are described as either penicillinases or cephalosporinases. Other “extended-spectrum” enzymes are less discriminant and

can hydrolyze a variety of β -lactam antibiotics. β -Lactamases are grouped into four classes: A through D. Class A β -lactamases include the extended-spectrum β -lactamases (ESBLs) that degrade penicillins, some cephalosporins, and, in some instances, carbapenems. Perhaps most worrisome of the class A enzymes is the *KPC carbapenemase* that is rapidly emerging in the Enterobacteriaceae. This enzyme confers resistance to carbapenems, penicillins, and all of the extended-spectrum cephalosporins (Jones et al., 2008). Some class A and D enzymes are inhibited by the commercially available β -lactamase inhibitors, such as clavulanate and *tazobactam*. Class B β -lactamases are Zn^{2+} -dependent enzymes that destroy all β -lactams except aztreonam, whereas class C β -lactamases are active against cephalosporins. Class D includes cloxacillin-degrading enzymes (Bush, 2001; Jacoby and Munoz-Price, 2005; Walsh, 2008).

In general, gram-positive bacteria produce and secrete a large amount of β -lactamase (Figure 53-3A). Most of these enzymes are penicillinases. The information for staphylococcal penicillinase is encoded in a plasmid, and this may be transferred by bacteriophage to other bacteria. The enzyme is inducible by substrates, and 1% of the dry weight of the bacterium can be penicillinase. In gram-negative bacteria, β -lactamases are found in relatively small amounts but are located in the periplasmic space between the inner and outer cell membranes (Figure 53-3A). Because the enzymes of cell wall synthesis are on the outer surface of the inner membrane, these β -lactamases are strategically located for maximal protection of the microbe. β -Lactamases of gram-negative bacteria are encoded either in chromosomes or in plasmids, and they may be constitutive or inducible. The plasmids can be transferred between bacteria by conjugation. These enzymes can hydrolyze penicillins, cephalosporins, or both (Bush, 2001; Jacoby and Munoz-Price, 2005; Walsh, 2008). However, there is an inconsistent correlation between the susceptibility of an antibiotic to inactivation by β -lactamase and the ability of that antibiotic to kill the microorganism.

Other Factors That Influence the Activity of β -Lactam Antibiotics.

Microorganisms adhering to implanted prosthetic devices (e.g., catheters, artificial joints, prosthetic heart valves, etc.) produce biofilms. Bacteria in biofilms produce extracellular polysaccharides and, in part owing to decreased growth rates, are much less sensitive to antibiotic therapy (Donlan, 2001). The density of the bacterial population and the age of an infection influence the activity of β -lactam antibiotics. The drugs may be several thousand times more potent when tested against small bacterial inocula than when tested against a dense culture. Many factors are involved. Among these are the greater number of relatively resistant microorganisms in a large population, the amount of β -lactamase produced, and the phase of growth of the culture. The clinical significance of this effect of inoculum size is uncertain. The intensity and duration of penicillin therapy needed to abort or cure experimental infections in animals increase with the duration of the infection. The primary reason is that the bacteria are no longer multiplying as rapidly as they do in a fresh infection. These antibiotics are most active against bacteria in the logarithmic phase of growth and have little effect on microorganisms in the stationary phase, when there is no need to synthesize components of the cell wall.

The presence of proteins or other constituents of pus, low pH, or low O_2 tension does not appreciably decrease the ability of β -lactam antibiotics to kill bacteria. However, bacteria that survive inside viable cells of the host generally are protected from the action of the β -lactam antibiotics.

Figure 53-5. Antibiotic efflux pumps of gram-negative bacteria. Multidrug efflux pumps traverse both the inner and outer membranes of gram-negative bacteria. The pumps are composed of a minimum of three proteins and are energized by the proton motive force. Increased expression of these pumps is an important cause of antibiotic resistance. Antibiotic resistance caused by gram-negative multidrug efflux pumps. *Clin Infect Dis*, 1998, 27(suppl 1):S32–S41. © 1998 by the Infectious Diseases Society of America. All rights reserved.)

Classification of the Penicillins and Summary of Their Pharmacological Properties

It is useful to classify the penicillins according to their spectra of antimicrobial activity (Table 53–1) (Chambers, 2005).

- *Penicillin G* and its close congener *penicillin V* are highly active against sensitive strains of gram-positive cocci, but they are readily hydrolyzed by penicillinase. Thus they are ineffective against most strains of *S. aureus*.
- The penicillinase-resistant penicillins (methicillin, discontinued in U.S.), nafcillin, oxacillin, cloxacillin (not currently marketed in the United States), and dicloxacillin have less potent antimicrobial activity against microorganisms that are sensitive to penicillin G, but they are the agents of first choice for treatment of penicillinase-producing *S. aureus* and *S. epidermidis* that are not methicillin resistant.
- Ampicillin, amoxicillin, and others make up a group of penicillins whose antimicrobial activity is extended to include such gram-negative microorganisms as *Haemophilus influenzae*, *E. coli*, and *Proteus mirabilis*. Frequently these drugs are administered with a β -lactamase inhibitor such as clavulanate or sulbactam to prevent hydrolysis by class A β -lactamases.
- The antimicrobial activity of carbenicillin (discontinued in the U.S.), its indanyl ester (carbenicillin indanyl), and ticarcillin (marketed only in combination with clavulanate in the U.S.) is extended to include *Pseudomonas*, *Enterobacter*, and *Proteus* spp. These agents are inferior to ampicillin against gram-positive cocci and *Listeria monocytogenes* and are less active than piperacillin against *Pseudomonas*.
- Mezlocillin, azlocillin (both discontinued in the U.S.), and piperacillin have excellent antimicrobial activity against many isolates of *Pseudomonas*, *Klebsiella*, and certain other gram-negative microorganisms. However, the emergence of broad-spectrum beta-lactamases is threatening the utility of these agents (Jacoby and Munoz-Price, 2005; Walsh, 2008). Piperacillin retains the activity of ampicillin against gram-positive cocci and *L. monocytogenes*.

Although the pharmacological properties of the individual drugs are discussed in detail later in this chapter, certain generalizations are useful. Following absorption of orally administered penicillins, these

agents are distributed widely throughout the body. Therapeutic concentrations of penicillins are achieved readily in tissues and in secretions such as joint fluid, pleural fluid, pericardial fluid, and bile. Penicillins do not penetrate living phagocytic cells to a significant extent, and only low concentrations of these drugs are found in prostatic secretions, brain tissue, and intraocular fluid. Concentrations of penicillins in cerebrospinal fluid (CSF) are variable but are <1% of those in plasma when the meninges are normal. When there is inflammation, concentrations in CSF may increase to as much as 5% of the plasma value. Penicillins are eliminated rapidly, particularly by glomerular filtration and renal tubular secretion, such that their half-lives in the body are short, typically 30-90 minutes. As a consequence, concentrations of these drugs in urine are high.

Penicillin G and Penicillin V

Antimicrobial Activity. The antimicrobial spectra of penicillin G (benzylpenicillin) and penicillin V (the phenoxymethyl derivative) are very similar for aerobic gram-positive microorganisms. However, penicillin G is 5-10 times more active than penicillin V against *Neisseria* spp. that are sensitive to penicillins and against certain anaerobes.

Penicillin G has activity against a variety of species of gram-positive and gram-negative cocci, although many bacteria previously sensitive to the agent are now resistant. Most streptococci (but not enterococci) are very susceptible to the drug; concentrations of <0.01 $\mu\text{g/mL}$ usually are effective. However, penicillin-resistant *viridans* streptococci (Carratalá et al., 1995) and *S. pneumoniae* are becoming more common. Penicillin-resistant pneumococci are especially common in pediatric populations, such as children attending day-care centers. Many penicillin-resistant pneumococci also are resistant to third-generation cephalosporins.

Whereas most strains of *S. aureus* were highly sensitive to penicillin G when this agent was first employed therapeutically, >90% of strains of staphylococci isolated from individuals inside or outside of hospitals are now resistant to penicillin G (and nearly half are methicillin-resistant). Most strains of *S. epidermidis* also are resistant to penicillin. Unfortunately, penicillinase-producing strains of gonococci that are highly resistant to penicillin G have become widespread. With rare exceptions, meningococci are quite sensitive to penicillin G.

Although the vast majority of strains of *Corynebacterium diphtheriae* are sensitive to penicillin G, some are highly resistant. The presence of chromosomally encoded β -lactamase in *Bacillus anthracis* is the reason that penicillin was not used for prophylaxis of anthrax exposure, although most isolates are susceptible. Most anaerobic

microorganisms, including *Clostridium* spp., are highly sensitive. *Bacteroides fragilis* is an exception, displaying resistance to penicillins and cephalosporins by virtue of expressing a broad-spectrum cephalosporinase. Some strains of *Prevotella melaninogenica* also have acquired this trait. *Actinomyces israelii*, *Streptobacillus moniliformis*, *Pasteurella multocida*, and *L. monocytogenes* are inhibited by penicillin G. Most species of *Leptospira* are moderately susceptible to the drug. One of the most exquisitely sensitive microorganisms is *Treponema pallidum*. *Borrelia burgdorferi*, the organism responsible for Lyme disease, also is susceptible. None of the penicillins is effective against amebae, plasmodia, rickettsiae, fungi, or viruses.

Absorption

Oral Administration of Penicillin G. About one-third of an orally administered dose of penicillin G is absorbed from the intestinal tract under favorable conditions. Gastric juice at pH 2 rapidly destroys the antibiotic. The decrease in gastric acid production with aging accounts for better absorption of penicillin G from the gastrointestinal (GI) tract of older individuals. Absorption is rapid, and maximal concentrations in blood are attained in 30-60 minutes. The peak value is ~0.5 unit/mL (0.3 $\mu\text{g/mL}$) after an oral dose of 400,000 units (~250 mg) in an adult. Ingestion of food may interfere with enteric absorption of all penicillins, perhaps by adsorption of the antibiotic onto food particles. Thus, oral penicillin G should be administered at least 30 minutes before a meal or 2 hours after. Despite the convenience of oral administration of penicillin G, this route should be used only in infections in which clinical experience has proven its efficacy.

Oral Administration of Penicillin V. The virtue of penicillin V in comparison with penicillin G is that it is more stable in an acidic medium and therefore is better absorbed from the GI tract. On an equivalent oral-dose basis, penicillin V (K^+ salt) yields plasma concentrations two to five times greater than those provided by penicillin G. The peak concentration in the blood of an adult after an oral dose of 500 mg is nearly 3 $\mu\text{g/mL}$. Once absorbed, penicillin V is distributed in the body and excreted by the kidney in a manner similar to that of penicillin G.

Parenteral Administration of Penicillin G. After intramuscular injection, peak concentrations in plasma are reached within 15-30 minutes. This value declines rapidly because the $t_{1/2}$ of penicillin G is 30 minutes.

Many means for prolonging the sojourn of the antibiotic in the body and thereby reducing the frequency of injections have been explored. *Probenecid* blocks renal tubular secretion of penicillin, but it is used rarely for this purpose. More commonly, repository preparations of penicillin G are employed. The compound currently favored is penicillin G benzathine (BICILLIN L-A, PERMAPEN), which releases penicillin G slowly from the area in which it is injected and produces relatively low but persistent concentrations of antibiotic in the blood. Penicillin G benzathine suspension is the aqueous suspension of the salt obtained by the combination of 1 mol of an ammonium base and 2 mol of penicillin G to yield *N,N'*-dibenzylethylenediamine dipenicillin G. The salt itself is only 0.02% soluble in water. The long persistence of penicillin in the blood after a suitable intramuscular dose reduces cost, need for repeated injections, and local trauma. The local anesthetic effect of penicillin G benzathine is comparable with that of penicillin G procaine.

Penicillin G benzathine is absorbed very slowly from intramuscular depots and produces the longest duration of detectable

antibiotic of all the available repository penicillins. For example, in adults, a dose of 1.2 million units given intramuscularly produces a concentration in plasma of 0.09 $\mu\text{g/mL}$ on the first, 0.02 $\mu\text{g/mL}$ on the fourteenth, and 0.002 $\mu\text{g/mL}$ on the thirty-second day after injection. The average duration of demonstrable antimicrobial activity in the plasma is ~26 days. It is administered once monthly for rheumatic fever prophylaxis and can be given in a single injection to treat streptococcal pharyngitis.

Distribution. Penicillin G is distributed widely throughout the body, but the concentrations in various fluids and tissues differ widely. Its apparent volume of distribution is ~0.35 L/kg. Approximately 60% of the penicillin G in plasma is reversibly bound to albumin. Significant amounts appear in liver, bile, kidney, semen, joint fluid, lymph, and intestine.

Although probenecid markedly decreases the tubular secretion of the penicillins, this is not the only factor responsible for the elevated plasma concentrations of the antibiotic that follow its administration. Probenecid also produces a significant decrease in the apparent volume of distribution of the penicillins.

Penetration into Cerebrospinal Fluid. Penicillin does not readily enter the CSF when the meninges are normal. However, when the meninges are acutely inflamed, penicillin penetrates into the CSF more easily. Although the concentrations attained vary and are unpredictable, they are usually in the range of 5% of the value in plasma and are therapeutically effective against susceptible microorganisms.

Penicillin and other organic acids are secreted rapidly from the CSF into the bloodstream by an active transport process. Probenecid competitively inhibits this transport and thus elevates the concentration of penicillin in CSF. In uremia, other organic acids accumulate in the CSF and compete with penicillin for secretion; the drug occasionally reaches toxic concentrations in the brain and can produce convulsions.

Excretion. Under normal conditions, penicillin G is eliminated rapidly from the body mainly by the kidney but in small part in the bile and by other routes. Approximately 60-90% of an intramuscular dose of penicillin G in aqueous solution is eliminated in the urine, largely within the first hour after injection. The remainder is metabolized to penicilloic acid. The $t_{1/2}$ for elimination of penicillin G is ~30 minutes in normal adults. Approximately 10% of the drug is eliminated by glomerular filtration and 90% by tubular secretion. Renal clearance approximates the total renal plasma flow. The maximal tubular secretory capacity for penicillin in the normal adult male is ~3 million units (1.8 g) per hour.

Clearance values are considerably lower in neonates and infants because of incomplete development of renal function; as a result, after doses proportionate to surface area, the persistence of penicillin in the blood is several times as long in premature infants as in children and adults. The $t_{1/2}$ of the antibiotic in children <1 week of age is 3 hours; by 14 days of age it is 1.4 hours. After renal function is fully established in young children, the rate of renal excretion of penicillin G is considerably more rapid than in adults.

Anuria increases the $t_{1/2}$ of penicillin G from a normal value of 0.5 hour to ~10 hours. When renal function is impaired, 7-10% of the antibiotic may be inactivated each hour by the liver. Patients with renal shutdown who require high-dose therapy with penicillin can be treated adequately with 3 million units of aqueous penicillin G followed by

1.5 million units every 8-12 hours. The dose of the drug must be readjusted during dialysis and the period of progressive recovery of renal function. If, in addition to renal failure, hepatic insufficiency also is present, the $t_{1/2}$ will be prolonged even further.

Therapeutic Uses

Pneumococcal Infections. Penicillin G remains the agent of choice for the management of infections caused by sensitive strains of *S. pneumoniae*. However, strains of pneumococci resistant to usual doses of penicillin G are being isolated more frequently in several countries, including the U.S. (Fiore et al., 2000).

Pneumococcal Pneumonia. Until it is highly likely or established that the infecting isolate of pneumococcus is penicillin-sensitive, pneumococcal pneumonia should be treated with a third-generation cephalosporin or with 20-24 million units of penicillin G daily by constant intravenous infusion. If the organism is sensitive to penicillin, then the dose can be reduced (Medical Letter, 2007). For parenteral therapy of sensitive isolates of pneumococci, penicillin G is favored. Although oral treatment with 500 mg penicillin V given every 6 hours for treatment of pneumonia owing to penicillin-sensitive isolates has been used with success in this disease, it cannot be recommended for routine initial use because of the existence of resistance. Therapy should be continued for 7-10 days, including 3-5 days after the patient's temperature has returned to normal.

Pneumococcal Meningitis. Until it is established that the infecting pneumococcus is sensitive to penicillin, pneumococcal meningitis should be treated with a combination of vancomycin and a third-generation cephalosporin (Catalan et al., 1994; John, 1994). Dexamethasone given at the same time as antibiotics was associated with an improved outcome (de Gans and van de Beek, 2002). Prior to the appearance of penicillin resistance, penicillin treatment reduced the death rate in this disease from nearly 100% to ~25%. The recommended therapy is 20-24 million units of penicillin G daily by constant intravenous infusion or divided into boluses given every 2-3 hours. The usual duration of therapy is 14 days.

Streptococcal Infections. Streptococcal Pharyngitis (Including Scarlet Fever). This is the most common disease produced by *S. pyogenes* (group A β -hemolytic streptococcus). Penicillin-resistant isolates have yet to be observed for *S. pyogenes*. The preferred oral therapy is with penicillin V, 500 mg every 6 hours for 10 days. Penicillin therapy of streptococcal pharyngitis reduces the risk of subsequent acute rheumatic fever; however, current evidence suggests that the incidence of glomerulonephritis that follows streptococcal infections is not reduced to a significant degree by treatment with penicillin.

Streptococcal Toxic Shock and Necrotizing Fasciitis. These are life-threatening infections associated with toxin production and are treated optimally with penicillin plus clindamycin (to decrease toxin synthesis) (Bisno and Stevens, 1996; Brown, 2004).

Streptococcal Pneumonia, Arthritis, Meningitis, and Endocarditis. Although uncommon, these conditions should be treated with penicillin G when they are caused by *S. pyogenes*; daily doses of 12-20 million units are administered intravenously for 2-4 weeks. Such treatment of endocarditis should be continued for a full 4 weeks.

Infections Caused by Other Streptococci. The *viridans* group of streptococci are the most common cause of infectious endocarditis. These are nongroupable α -hemolytic microorganisms that are

increasingly resistant to penicillin G (minimum inhibitory concentration [MIC] >0.1 μ g/mL). Because enterococci also may be α -hemolytic, and certain other α -hemolytic strains may be relatively resistant to penicillin, it is important to determine quantitative microbial sensitivities to penicillin G in patients with endocarditis. Patients with penicillin-sensitive *VIRIDANS* group streptococcal endocarditis can be treated successfully with daily doses of 12-20 million units of intravenous penicillin G for 2 weeks in combination with gentamicin 1 mg/kg every 8 hours. Some physicians prefer a 4-week course of treatment with penicillin G alone.

Enterococcal endocarditis is one of the few diseases treated optimally with two antibiotics. The recommended therapy for penicillin- and aminoglycoside-sensitive enterococcal endocarditis is 20 million units of penicillin G or 12 g ampicillin daily administered intravenously in combination with a low dose of gentamicin. Therapy usually should be continued for 6 weeks, but selected patients with a short duration of illness (<3 months) have been treated successfully in 4 weeks (Wilson et al., 1984).

Infections with Anaerobes. Many anaerobic infections are caused by mixtures of microorganisms. Most are sensitive to penicillin G. An exception is the *B. fragilis* group, in which up to 75% of strains may be resistant to high concentrations of this antibiotic. Pulmonary and periodontal infections (with the exception of β -lactamase-producing *Prevotella melaninogenica*) usually respond well to penicillin G, although a multicenter study indicated that clindamycin is more effective than penicillin for therapy of lung abscess (Levison et al., 1983). Mild-to-moderate infections at these sites may be treated with oral medication (either penicillin G or penicillin V 400,000 units [250 mg] four times daily). More severe infections should be treated with 12-20 million units of penicillin G intravenously. Brain abscesses also frequently contain several species of anaerobes, and most authorities prefer to treat such disease with high doses of penicillin G (20 million units per day) plus metronidazole or chloramphenicol. Some physicians add a third-generation cephalosporin for activity against aerobic gram-negative bacilli.

Staphylococcal Infections. The vast majority of staphylococcal infections are caused by microorganisms that produce penicillinase (Swartz, 2004). Hospital-acquired methicillin-resistant staphylococci are resistant to penicillin G, all the penicillinase-resistant penicillins, and the cephalosporins. Isolates occasionally may appear to be sensitive to various cephalosporins *in vitro*, but resistant populations arise during therapy and lead to failure. Vancomycin, linezolid, quinupristin-dalfopristin, and daptomycin are active for infections caused by these bacteria, although reduced susceptibility to vancomycin has been observed. Community-acquired methicillin-resistant *S. aureus* (MRSA) in many cases retains susceptibility to trimethoprim-sulfamethoxazole, doxycycline, and clindamycin (Medical Letter, 2007).

Meningococcal Infections. Penicillin G remains the drug of choice for meningococcal disease. Patients should be treated with high doses of penicillin given intravenously, as described for pneumococcal meningitis. Penicillin-resistant strains of *N. meningitidis* have been reported in Britain and Spain but are infrequent at present. The occurrence of penicillin-resistant strains should be considered in patients who are slow to respond to treatment. Penicillin G does not eliminate the meningococcal carrier state, and its administration thus is ineffective as a prophylactic measure.

Gonococcal Infections. Gonococci gradually have become more resistant to penicillin G, and penicillins are no longer the therapy of choice, unless it is known that gonococcal strains in a particular geographic area are susceptible. Uncomplicated gonococcal urethritis is the most common infection, and a single intramuscular injection of 250 mg ceftriaxone is the recommended treatment (Handsfield and Sparling, 2005).

Gonococcal arthritis, disseminated gonococcal infections with skin lesions, and gonococcemia should be treated with ceftriaxone 1 g daily given either intramuscularly or intravenously for 7-10 days. Ophthalmia neonatorum also should be treated with ceftriaxone for 7-10 days (25-50 mg/kg per day intramuscularly or intravenously).

Syphilis. Therapy of syphilis with penicillin G is highly effective. Primary, secondary, and latent syphilis of <1-year duration may be treated with penicillin G procaine (2.4 million units per day intramuscularly) plus probenecid (1.0 g/day orally) for 10 days or with 1-3 weekly intramuscular doses of 2.4 million units of penicillin G benzathine (three doses in patients with HIV infection). Patients with late latent syphilis, neurosyphilis, or cardiovascular syphilis may be treated with a variety of regimens. Because the latter two conditions are potentially lethal and their progression can be halted (but not reversed), intensive therapy with 20 million units of penicillin G daily for 10 days is recommended. There are no proven alternatives for treating syphilis in pregnant women, so penicillin-allergic individuals must be acutely desensitized to prevent anaphylaxis (Centers for Disease Control and Prevention, 2006).

Infants with congenital syphilis discovered at birth or during the postnatal period should be treated for at least 10 days with 50,000 units/kg daily of aqueous penicillin G in two divided doses or 50,000 units/kg of procaine penicillin G in a single daily dose (Tramont, 2005).

Most patients (70-90%) with secondary syphilis develop the Jarisch-Herxheimer reaction. This also may be seen in patients with other forms of syphilis. Several hours after the first injection of penicillin, chills, fever, headache, myalgias, and arthralgias may develop. The syphilitic cutaneous lesions may become more prominent, edematous, and brilliant in color. Manifestations usually persist for a few hours, and the rash begins to fade within 48 hours. It does not recur with the second or subsequent injections of penicillin. This reaction is thought to be due to release of spirochetal antigens with subsequent host reactions to the products. Aspirin gives symptomatic relief, and therapy with penicillin should not be discontinued.

Actinomycosis. Penicillin G is the agent of choice for the treatment of all forms of actinomycosis. The dose should be 10-20 million units of penicillin G intravenously per day for 6 weeks. Some physicians continue therapy for 2-3 months with oral penicillin V (500 mg four times daily). Surgical drainage or excision of the lesion may be necessary before cure is accomplished.

Diphtheria. There is no evidence that penicillin or any other antibiotic alters the incidence of complications or the outcome of diphtheria; specific antitoxin is the only effective treatment. However, penicillin G eliminates the carrier state. The parenteral administration of 2-3 million units per day in divided doses for 10-12 days eliminates the diphtheria bacilli from the pharynx and other sites in practically 100% of patients. A single daily injection of penicillin G procaine for the same period produces comparable results.

Anthrax. Strains of *Bacillus anthracis* resistant to penicillin have been recovered from human infections. When penicillin G is used, the dose should be 12-20 million units per day.

Clostridial Infections. Penicillin G is the agent of choice for gas gangrene; the dose is in the range of 12-20 million units per day given parenterally as an adjunct to the antitoxin. Adequate debridement of the infected areas is essential. Antimicrobial drugs probably have no effect on the ultimate outcome of tetanus. Débridement and administration of human tetanus immune globulin may be indicated. Penicillin is administered, however, to eradicate the vegetative forms of the bacteria that may persist.

Fusospirochetal Infections. Gingivostomatitis, produced by the synergistic action of *Leptotrichia buccalis* and spirochetes that are present in the mouth, is readily treatable with penicillin. For simple "trench mouth," 500 mg penicillin V given every 6 hours for several days is usually sufficient to clear the disease.

Rat-Bite Fever. The two microorganisms responsible for this infection, *Spirillum minor* in the Far East and *Streptobacillus moniliformis* in America and Europe, are sensitive to penicillin G, the therapeutic agent of choice. Because most cases due to *Streptobacillus* are complicated by bacteremia and, in many instances, by metastatic infections, especially of the synovia and endocardium, the dose should be large; a daily dose of 12-15 million units given parenterally for 3-4 weeks has been recommended.

Listeria Infections. Ampicillin (with gentamicin for immunosuppressed patients with meningitis) and penicillin G are the drugs of choice in the management of infections owing to *L. monocytogenes*. The recommended dose of ampicillin is 1-2 g intravenously every 4 hours. The recommended dose of penicillin G is 15-20 million units parenterally per day for at least 2 weeks. When endocarditis is the problem, the dose is the same, but the duration of treatment should be no less than 4 weeks.

Lyme Disease. Although a tetracycline is the usual drug of choice for early disease, amoxicillin is effective; the dose is 500 mg three times daily for 21 days. Severe disease is treated with a third-generation cephalosporin or up to 20 million units of intravenous penicillin G daily for 10-14 days.

Erysipeloid. The causative agent of this disease, *Erysipelothrix rhusiopathiae*, is sensitive to penicillin. The uncomplicated infection responds well to a single injection of 1.2 million units of penicillin G benzathine. When endocarditis is present, penicillin G, 12-20 million units per day, has been found to be effective; therapy should be continued for 4-6 weeks.

Pasteurella multocida. *Pasteurella multocida* is the cause of wound infections after a cat or dog bite. It is uniformly susceptible to penicillin G and ampicillin and resistant to penicillinase-resistant penicillins and first-generation cephalosporins (Goldstein et al., 1988). When the infection causes meningitis, a third-generation cephalosporin is preferred because the MICs are slightly lower than for penicillin.

Prophylactic Uses of the Penicillins. The demonstrated effectiveness of penicillin in eradicating microorganisms was followed quickly and quite naturally by attempts to prove that it also was effective in preventing infection in susceptible hosts. As a result, the antibiotic has been administered in almost every situation in which a risk of bacterial invasion has been present. As prophylaxis has been investigated

under controlled conditions, it has become clear that penicillin is highly effective in some situations, useless and potentially dangerous in others, and of questionable value in still others (Chapter 48).

Streptococcal Infections. The administration of penicillin to individuals exposed to *S. pyogenes* affords protection from infection. The oral ingestion of 200,000 units of penicillin G or penicillin V twice a day or a single injection of 1.2 million units of penicillin G benzathine is effective. Indications for this type of prophylaxis include outbreaks of streptococcal disease in closed populations, such as boarding schools or military bases. Patients with extensive deep burns are at high risk of severe wound infections with *S. pyogenes*; “low-dose” prophylaxis for several days appears to be effective in reducing the incidence of this complication.

Recurrences of Rheumatic Fever. The oral administration of 200,000 units of penicillin G or penicillin V every 12 hours produces a striking decrease in the incidence of recurrences of rheumatic fever in susceptible individuals. Because of the difficulties of compliance, parenteral administration is preferable, especially in children. The intramuscular injection of 1.2 million units of penicillin G benzathine once a month yields excellent results. In cases of hypersensitivity to penicillin, sulfisoxazole or sulfadiazine, 1 g twice a day for adults, also is effective; for children weighing <27 kg, the dose is halved. Prophylaxis must be continued throughout the year. The duration of such treatment is an unsettled question. It has been suggested that prophylaxis should be continued for life because instances of acute rheumatic fever have been observed in the fifth and sixth decades. However, the necessity for such prolonged prophylaxis has not been established and may be unnecessary for young adults judged to be at low risk for recurrence (Berrios et al., 1993).

Syphilis. Prophylaxis for a contact with syphilis consists of a course of therapy as described for primary syphilis. A serological test for syphilis should be performed at monthly intervals for at least 4 months thereafter.

Surgical Procedures in Patients with Valvular Heart Disease. About 25% of cases of subacute bacterial endocarditis follow dental extractions. This observation, together with the fact that up to 80% of persons who have teeth removed experience a transient bacteremia, emphasizes the potential importance of chemoprophylaxis for those who have congenital or acquired valvular heart disease of any type and need to undergo dental procedures. Since transient bacterial invasion of the bloodstream occurs occasionally after surgical procedures (e.g., tonsillectomy and genitourinary and GI procedures) and during childbirth, these, too, are indications for prophylaxis in patients with valvular heart disease. Whether the incidence of bacterial endocarditis actually is altered by this type of chemoprophylaxis remains to be determined.

Detailed recommendations for adults and children with valvular heart disease have been formulated (Wilson et al., 2007).

The Penicillinase-Resistant Penicillins

The penicillins described in this section are resistant to hydrolysis by staphylococcal penicillinase. Their appropriate use should be restricted to the treatment of infections that are known or suspected to be caused by staphylococci that elaborate the enzyme, which now includes the vast majority of strains of this bacterium

that are encountered clinically. These drugs are much less active than penicillin G against other penicillin-sensitive microorganisms, including non-penicillinase-producing staphylococci.

The role of the penicillinase-resistant penicillins as the agents of choice for most staphylococcal disease is changing with the increasing incidence of isolates of so-called *methicillin-resistant microorganisms*. As commonly used, this term denotes resistance of these bacteria to all the penicillinase-resistant penicillins and cephalosporins. Hospital-acquired strains usually are resistant to the aminoglycosides, tetracyclines, erythromycin, and clindamycin as well. Vancomycin is considered the drug of choice for such infections, although intermediate-level resistance is emerging (Centers for Disease Control and Prevention, 2004). Some physicians use a combination of vancomycin and rifampin, especially for life-threatening infections and those involving foreign bodies. Community-acquired methicillin-resistant strains are less likely to be resistant to other classes of antibiotics with the exception of macrolides (Okuma et al., 2002). MRSA contains an additional high-molecular-weight PBP with a very low affinity for β -lactam antibiotics (Spratt, 1994). From 40-60% of strains of *S. epidermidis* also are resistant to the penicillinase-resistant penicillins by the same mechanism. As with MRSA, these strains may appear to be susceptible to cephalosporins on disk-sensitivity testing, but there usually is a significant population of microbes that is resistant to cephalosporins and emerges during such therapy. Vancomycin also is the drug of choice for serious infection caused by methicillin-resistant *S. epidermidis*; rifampin is given concurrently when a foreign body is involved.

The Isoxazolyl Penicillins: Oxacillin, Cloxacillin, and Dicloxacillin. These three congeneric semisynthetic penicillins are similar pharmacologically and thus conveniently are considered together. Their structural formulas are shown in Table 53-1. All are relatively stable in an acidic medium and absorbed adequately after oral administration. All are markedly resistant to cleavage by penicillinase. These drugs are not substitutes for penicillin G in the treatment of diseases amenable to it, and they are not active against enterococci or *Listeria*. Furthermore, because of variability in intestinal absorption, oral administration is not a substitute for the parenteral route in the treatment of serious staphylococcal infections that require a penicillin unaffected by penicillinase.

Pharmacological Properties. The isoxazolyl penicillins are potent inhibitors of the growth of most penicillinase-producing staphylococci.

This is their valid clinical use. Dicloxacillin is the most active, and many strains of *S. aureus* are inhibited by concentrations of 0.05–0.8 $\mu\text{g}/\text{mL}$. Comparable values for cloxacillin (not currently marketed in the U.S.) and oxacillin are 0.1–3 and 0.4–6 $\mu\text{g}/\text{mL}$, respectively. These differences may have little practical significance, however, because dosages are adjusted accordingly. These agents are, in general, less effective against microorganisms susceptible to penicillin G, and they are not useful against gram-negative bacteria.

These agents are absorbed rapidly but incompletely (30–80%) from the GI tract. Absorption of the drugs is more efficient when they are taken on an empty stomach; preferably they are administered 1 hour before or 2 hours after meals to ensure better absorption. Peak concentrations in plasma are attained by 1 hour and ~5–10 $\mu\text{g}/\text{mL}$ after the ingestion of 1 g oxacillin. Slightly higher concentrations are achieved after the administration of 1 g cloxacillin, whereas the same oral dose of dicloxacillin yields peak plasma concentrations of 15 $\mu\text{g}/\text{mL}$. There is little evidence that these differences are of clinical significance. All these congeners are bound to plasma albumin to a great extent (~90–95%); none is removed from the circulation to a significant degree by hemodialysis.

The isoxazolyl penicillins are excreted rapidly by the kidney. Normally, ~50% of a dose of these drugs is excreted in the urine in the first 6 hours after oral administration. There also is significant hepatic elimination of these agents in the bile. The half-lives for all are between 30 and 60 minutes. Intervals between doses of oxacillin, cloxacillin, and dicloxacillin do not have to be altered for patients with renal failure. The differences just noted in plasma concentrations produced by the isoxazolyl penicillins are related mainly to differences in rate of urinary excretion and degree of resistance to degradation in the liver.

Nafcillin. This semisynthetic penicillin is highly resistant to penicillinase and has proven effective against infections caused by penicillinase-producing strains of *S. aureus*. Its structural formula is shown in Table 53–1.

Pharmacological Properties. Nafcillin is slightly more active than oxacillin against penicillin G-resistant *S. aureus* (most strains are inhibited by 0.06–2 $\mu\text{g}/\text{mL}$). Although it is the most active of the penicillinase-resistant penicillins against other microorganisms, it is not as potent as penicillin G. The peak plasma concentration is ~8 $\mu\text{g}/\text{mL}$ 60 minutes after a 1-g intramuscular dose. Nafcillin is ~90% bound to plasma protein. Peak concentrations of nafcillin in bile are well above those found in plasma. Concentrations of the drug in CSF appear to be adequate for therapy of staphylococcal meningitis.

The Aminopenicillins: Ampicillin, Amoxicillin, and Their Congeners

These agents have similar antibacterial activity and a spectrum that is broader than the antibiotics already discussed. They all are destroyed by β -lactamase (from both gram-positive and gram-negative bacteria).

Antimicrobial Activity. Ampicillin and the related aminopenicillins are bactericidal for both gram-positive and gram-negative bacteria. The meningococci and *L. monocytogenes* are sensitive to this class of drugs.

Many pneumococcal isolates have varying levels of resistance to ampicillin. Penicillin-resistant strains should be considered ampicillin/amoxicillin-resistant. *H. influenzae* and the *viridans* group of streptococci exhibit varying degrees of resistance. Enterococci are about twice as sensitive to ampicillin on a weight basis as they are to penicillin G (MIC for ampicillin averages 1.5 $\mu\text{g}/\text{mL}$). Although most strains of *N. gonorrhoeae*, *E. coli*, *P. mirabilis*, *Salmonella*, and *Shigella* were highly susceptible when ampicillin was first used in the early 1960s, an increasing percentage of these species now is resistant. From 30% to 50% of *E. coli*, a significant number of *P. mirabilis*, and practically all species of *Enterobacter* presently are insensitive. Resistant strains of *Salmonella* (plasmid mediated) have been recovered with increasing frequency in various parts of the world. Most strains of *Shigella* now are resistant. Most strains of *Pseudomonas*, *Klebsiella*, *Serratia*, *Acinetobacter*, and indole-positive *Proteus* also are resistant to this group of penicillins; these antibiotics are less active against *B. fragilis* than penicillin G. However, concurrent administration of a β -lactamase inhibitor such as clavulanate or *sulbactam* markedly expands the spectrum of activity of these drugs.

Ampicillin. This drug is the prototype of the group. Its structural formula is shown in Table 53–1.

Pharmacological Properties. Ampicillin (PRINCIPEN, others) is stable in acid and is well absorbed after oral administration. An oral dose of 0.5 g produces peak concentrations in plasma of ~3 $\mu\text{g}/\text{mL}$ at 2 hours. Intake of food prior to ingestion of ampicillin diminishes absorption. Intramuscular injection of 0.5 or 1 g sodium ampicillin yields peak plasma concentrations of ~7 or 10 $\mu\text{g}/\text{mL}$, respectively, at 1 hour; these decline exponentially, with a $t_{1/2}$ of ~80 minutes. Severe renal impairment markedly prolongs the persistence of ampicillin in the plasma. Peritoneal dialysis is ineffective in removing the drug from the blood, but hemodialysis removes ~40% of the body store in ~7 hours. Adjustment of the dose of ampicillin is required in the presence of renal dysfunction. Ampicillin appears in the bile, undergoes enterohepatic circulation, and is excreted in appreciable quantities in the feces.

Amoxicillin. This drug, a penicillinase-susceptible semi-synthetic penicillin, is a close chemical and pharmacological relative of ampicillin (Table 53–1). The drug is stable in acid and designed for oral use. It is absorbed more rapidly and completely from the GI tract than ampicillin, which is the major difference between the two. The antimicrobial spectrum of amoxicillin is essentially identical to that of ampicillin, with the important exception that amoxicillin appears to be less effective than ampicillin for shigellosis.

Peak plasma concentrations of amoxicillin (AMOXIL, others) are 2–2.5 times greater for amoxicillin than for ampicillin after oral

Table 53-1

Chemical Structures and Major Properties of Various Penicillins

Penicillins are substituted 6-aminopenicillanic acids

R	NONPROPRIETARY NAME	MAJOR PROPERTIES		
		Absorption after Oral Administration	Resistance to Penicillinase	Useful Antimicrobial Spectrum
	Penicillin G	Variable (poor)	No	<i>Streptococcus</i> species, ^a Enterococci, ^a <i>Listeria</i> , <i>Neisseria meningitidis</i> , many anaerobes (not <i>Bacteroides fragilis</i>), ^b spirochetes, <i>Actinomyces</i> , <i>Erysipelothrix</i> spp., <i>Pasteurella multocida</i> ^b
	Penicillin V	Good	No	
	Methicillin	Poor (not given orally)	Yes	
	Oxacillin (R ₁ = R ₂ = H) Cloxacillin (R ₁ = Cl; R ₂ = H) Dicloxacillin (R ₁ = R ₂ = Cl)	Good	Yes	Indicated only for non-methicillin-resistant strains of <i>Staphylococcus aureus</i> and <i>Staphylococcus epidermidis</i> . Compared to other penicillins, these penicillinase-resistant penicillins lack activity against <i>Listeria monocytogenes</i> and <i>Enterococcus</i> spp.
	Nafcillin	Variable	Yes	
	Ampicillin ^c (R ₁ = H)	Good	No	
	Amoxicillin (R ₁ = OH)	Excellent		Extends spectrum of penicillin to include sensitive strains of Enterobacteriaceae, ^b <i>Escherichia coli</i> , <i>Proteus mirabilis</i> , <i>Salmonella</i> , <i>Shigella</i> , <i>Haemophilus influenzae</i> , ^b and <i>Helicobacter pylori</i> . Superior to penicillin for treatment of <i>Listeria monocytogenes</i> and sensitive enterococci. Amoxicillin most active of all oral β -lactams against penicillin-resistant <i>Streptococcus pneumoniae</i>

Table 53-1

Chemical Structures and Major Properties of Various Penicillins (Continued)

R	NONPROPRIETARY NAME	MAJOR PROPERTIES		
		Absorption after Oral Administration	Resistance to Penicillinase	Useful Antimicrobial Spectrum
	Carbenicillin (R ₁ = H)	Poor (not given orally)	No	
	Carbenicillin indanyl (R ₁ = 5-indanol)	Good		
	Ticarcillin	Poor (not given orally)	No	
	Mezlocillin	Poor (not given orally)	No	
	Piperacillin	Poor (not given orally)	No	Extends spectrum of ampicillin to include <i>Pseudomonas aeruginosa</i> , ^d Enterobacteriaceae, ^b Bacteroides species ^b

^aMany strains are resistant due to altered penicillin-binding proteins. ^bMany strains are resistant due to production of β -lactamases. ^cThere are other congeners of ampicillin; see the text. ^dSome strains are resistant due to decreased entry or active efflux.

administration of the same dose; they are reached at 2 hours and average $\sim 4 \mu\text{g/mL}$ when 250 mg is administered. Food does not interfere with absorption. Perhaps because of more complete absorption of this congener, the incidence of diarrhea with amoxicillin is less than that following administration of ampicillin. The incidence of other adverse effects appears to be similar. Although the $t_{1/2}$ of amoxicillin is similar to that for ampicillin, effective concentrations of orally administered amoxicillin are detectable in the plasma for twice as long as with ampicillin, again because of the more complete absorption. About 20% of amoxicillin is protein bound in plasma, a value similar to that for ampicillin. Most of a dose of the antibiotic is excreted in an active form in the urine. Probenecid delays excretion of the drug.

Therapeutic Indications for the Aminopenicillins

Upper Respiratory Infections. Ampicillin and amoxicillin are active against *S. pyogenes* and many strains of *S. pneumoniae* and *H. influenzae*, which are major upper respiratory bacterial pathogens.

The drugs constitute effective therapy for sinusitis, otitis media, acute exacerbations of chronic bronchitis, and epiglottitis caused by sensitive strains of these organisms. Amoxicillin is the most active of all the oral β -lactam antibiotics against both penicillin-sensitive and penicillin-resistant *S. pneumoniae*. Based on the increasing prevalence of pneumococcal resistance to penicillin, an increase in dose of oral amoxicillin (from 40–45 up to 80–90 mg/kg per day) for empirical treatment of acute otitis media in children is recommended (Dowell et al., 1999). Ampicillin-resistant *H. influenzae* may be a problem in many areas. The addition of a β -lactamase inhibitor (amoxicillin-clavulanate or ampicillin-sulbactam) extends the spectrum to β -lactamase-producing *H. influenzae* and Enterobacteriaceae. Bacterial pharyngitis should be treated with penicillin G or penicillin V because *S. pyogenes* is the major pathogen.

Urinary Tract Infections. Most uncomplicated urinary tract infections are caused by Enterobacteriaceae, and *E. coli* is the most common species; ampicillin often is an effective agent, although resistance is

increasingly common. Enterococcal urinary tract infections are treated effectively with ampicillin alone.

Meningitis. Acute bacterial meningitis in children is most frequently due to *S. pneumoniae* or *N. meningitidis*. Because 20–30% of strains of *S. pneumoniae* now may be resistant to this antibiotic, ampicillin is not indicated for single-agent treatment of meningitis. Ampicillin has excellent activity against *L. monocytogenes*, a cause of meningitis in immunocompromised persons. Thus, the combination of ampicillin and vancomycin plus a third-generation cephalosporin is a rational regimen for empirical treatment of suspected bacterial meningitis.

Salmonella Infections. Disease associated with bacteremia, disease with metastatic foci, and the enteric fever syndrome (including typhoid fever) respond favorably to antibiotics. A fluoroquinolone or ceftriaxone is considered by some to be the drug of choice, but the administration of trimethoprim-sulfamethoxazole or high doses of ampicillin (12 g/day for adults) also is effective. In some geographic areas, resistance to ampicillin is common. The typhoid carrier state has been eliminated successfully in patients without gallbladder disease with ampicillin, trimethoprim-sulfamethoxazole, or ciprofloxacin.

Anti-Pseudomonal Penicillins: The Carboxypenicillins and the Ureidopenicillins

The carboxypenicillins, carbenicillin (discontinued in the U.S.) and ticarcillin (marketed in combination with clavulanate in the U.S.) and their close relatives, are active against some isolates of *P. aeruginosa* and certain indole-positive *Proteus* spp. that are resistant to ampicillin and its congeners. They are ineffective against most strains of *S. aureus*, *Enterococcus faecalis*, *Klebsiella*, and *L. monocytogenes*. *B. fragilis* is susceptible to high concentrations of these drugs, but penicillin G is actually more active on the basis of weight. The ureidopenicillins, mezlocillin (discontinued in the U.S.) and piperacillin, have superior activity against *P. aeruginosa* compared with carbenicillin and ticarcillin. In addition, mezlocillin and piperacillin are useful for treatment of infections with *Klebsiella*. The carboxypenicillins and the ureidopenicillins are sensitive to destruction by β -lactamases.

Carbenicillin. This drug is a penicillinase-susceptible derivative of 6-aminopenicillanic acid. Its structural formula is shown in Table 53–1. Carbenicillin was the first penicillin with activity against *P. aeruginosa* and some *Proteus* strains that are resistant to ampicillin. Because carbenicillin is supplied as a disodium salt, it contains ~5 mEq Na⁺ per gram of drug, and this results in the administration of >100 mEq Na⁺ to patients treated for *P. aeruginosa* infections. In the U.S., carbenicillin has been superseded by piperacillin.

Preparations of carbenicillin may cause adverse effects in addition to those that follow the use of other penicillins. Congestive heart failure may result from the administration of excessive Na⁺. Hypokalemia may occur because of obligatory excretion of cation with the large amount of nonreabsorbable anion (carbenicillin) presented to the distal renal tubule. The drug interferes with platelet function, and bleeding may occur because of abnormal aggregation of platelets.

Carbenicillin Indanyl Sodium. This congener is the indanyl ester of carbenicillin; it is acid stable and is suitable for oral administration. After absorption, the ester is converted rapidly to carbenicillin by hydrolysis of the ester linkage. The antimicrobial spectrum of the drug is therefore that of carbenicillin. Although the concentration of carbenicillin reached in the serum is not high enough to treat a systemic *Pseudomonas* infection, the active moiety is excreted rapidly in the urine, where it achieves effective concentrations. Thus, the only use of this drug is for the management of urinary tract infections caused by *Proteus* spp. other than *P. mirabilis* and by *P. aeruginosa*.

Piperacillin. Piperacillin extends the spectrum of ampicillin to include most strains of *P. aeruginosa*, Enterobacteriaceae (non- β -lactamase-producing), many *Bacteroides* spp., and *E. faecalis*. In combination with a β -lactamase inhibitor (piperacillin-tazobactam, ZOSYN) it has the broadest antibacterial spectrum of the penicillins. Pharmacokinetic properties are reminiscent of the other ureidopenicillins. High biliary concentrations are achieved.

Therapeutic Indications. Piperacillin and related agents are important agents for the treatment of patients with serious infections caused by gram-negative bacteria. Such patients frequently have impaired immunological defenses, and their infections often are acquired in the hospital. Therefore, these penicillins find their greatest use in treating bacteremias, pneumonias, infections following burns, and urinary tract infections owing to microorganisms resistant to penicillin G and ampicillin; the bacteria especially responsible include *P. aeruginosa*, indole-positive strains of *Proteus*, and *Enterobacter* spp. Because *Pseudomonas* infections are common in neutropenic patients, therapy for severe bacterial infections in such individuals should include a β -lactam antibiotic such as piperacillin with good activity against these microorganisms.

Ticarcillin. This semisynthetic penicillin (Table 53–1) is very similar to carbenicillin, but it is two to four times more active against *P. aeruginosa*. Ticarcillin is inferior to piperacillin for the treatment of serious infections caused by *Pseudomonas*. Ticarcillin is only marketed in combination with clavulanate (TIMENTIN) in the U.S.

Mezlocillin. This ureidopenicillin is more active against *Klebsiella* than is carbenicillin; its activity against *Pseudomonas in vitro* is similar to that of ticarcillin. It is more active than ticarcillin against *E. faecalis*. *Mezlocillin sodium* has been discontinued in the U.S.

Untoward Reactions to Penicillins

Hypersensitivity Reactions. Hypersensitivity reactions are by far the most common adverse effects noted with the penicillins, and these agents probably are the most common cause of drug allergy. Allergic reactions complicate 0.7-4% of all treatment courses. There is no convincing evidence that any single penicillin differs from the group in its potential for causing true allergic reactions. In approximate order of decreasing frequency, manifestations of allergy to penicillins include maculopapular rash, urticarial rash, fever, bronchospasm, vasculitis, serum sickness, exfoliative dermatitis, Stevens-Johnson syndrome, and anaphylaxis (Weiss and Adkinson, 2005). The reported overall incidence of such reactions to the penicillins is 0.7-10%. Hypersensitivity to penicillins generally extends to the other β -lactams (e.g., cephalosporins, some carbapenems).

Hypersensitivity reactions may occur with any dosage form of penicillin; allergy to one penicillin exposes the patient to a greater risk of reaction if another is given. But the occurrence of an untoward effect does not necessarily imply repetition on subsequent exposures. Hypersensitivity reactions may appear in the absence of a previous known exposure to the drug. This may be caused by unrecognized prior exposure to penicillin in the environment (e.g., in foods of animal origin or from the fungus-producing penicillin). Although elimination of the antibiotic usually results in rapid clearing of the allergic manifestations, they may persist for 1-2 weeks or longer after therapy has been stopped. In some cases, the reaction is mild and disappears even when the penicillin is continued; in others, immediate cessation of penicillin treatment is required. In a few instances, it is necessary to interdict the future use of penicillin because of the risk of death, and the patient should be so warned. It must be stressed that fatal episodes of anaphylaxis have followed the ingestion of very small doses of this antibiotic or skin testing with minute quantities of the drug.

Penicillins and their breakdown products act as haptens after covalent reaction with proteins. The most abundant breakdown product is the penicilloyl moiety (major determinant moiety [MDM]), which is formed when the β -lactam ring is opened. A large percentage of immunoglobulin (Ig)E-mediated reactions are to the MDM, but at least 25% of reactions are to other breakdown products, and the severities of the reactions to the various components are comparable. These products are formed *in vivo* and can be found in solutions of penicillin prepared for administration. The terms *major* and *minor determinants* refer to the frequency with which antibodies to these haptens appear to be formed. They do not describe the severity of the reaction that may result. In fact, anaphylactic reactions to penicillin usually are mediated by IgE antibodies against the minor determinants.

Antipenicillin antibodies are detectable in virtually all patients who have received the drug and in many who have never knowingly been exposed to it. Recent treatment with the antibiotic induces an increase in major-determinant-specific antibodies that are skin sensitizing. The incidence of positive skin reactors is three to four times higher in atopic than in nonatopic individuals. Clinical

and immunological studies suggest that immediate allergic reactions are mediated by skin-sensitizing or IgE antibodies, usually of minor-determinant specificities. Accelerated and late urticarial reactions usually are mediated by major-determinant-specific skin-sensitizing antibodies. The recurrent-arthralgia syndrome appears to be related to the presence of skin-sensitizing antibodies of minor-determinant specificities. Some maculopapular and erythematous reactions may be due to toxic antigen-antibody complexes of major-determinant-specific IgM antibodies. Accelerated and late urticarial reactions to penicillin may terminate spontaneously because of the development of blocking antibodies.

Skin rashes of all types may be caused by allergy to penicillin. Scarlatiniform, morbilliform, urticarial, vesicular, and bullous eruptions may develop. Purpuric lesions are uncommon and usually are the result of a vasculitis; thrombocytopenic purpura may occur very rarely. Henoch-Schönlein purpura with renal involvement has been a rare complication. Contact dermatitis is observed occasionally in pharmacists, nurses, and physicians who prepare penicillin solutions. Fixed-drug reactions also have occurred. More severe reactions involving the skin are exfoliative dermatitis and exudative erythema multiforme of either the erythematopapular or vesiculobullous type; these lesions may be very severe and atypical in distribution and constitute the characteristic Stevens-Johnson syndrome. The incidence of skin rashes appears to be highest following the use of ampicillin, at ~9%; rashes follow the administration of ampicillin in nearly all patients with infectious mononucleosis. When allopurinol and ampicillin are administered concurrently, the incidence of rash also increases. Ampicillin-induced skin eruptions in such patients may represent a "toxic" rather than a truly allergic reaction. Positive skin reactions to the major and minor determinants of penicillin sensitization may be absent. The rash may clear even while administration of the drug is continued.

The most serious hypersensitivity reactions produced by the penicillins are angioedema and anaphylaxis. Angioedema, with marked swelling of the lips, tongue, face, and periorbital tissues, frequently accompanied by asthmatic breathing and "giant hives," has been observed after topical, oral, or systemic administration of penicillins of various types.

Acute anaphylactic or anaphylactoid reactions induced by various preparations of penicillin constitute the most important immediate danger connected with their use. Among all drugs, the penicillins are most often responsible for this type of untoward effect. Anaphylactoid reactions may occur at any age. Their incidence is thought to be 0.004-0.04% in persons treated with penicillins (Kucers and Bennett, 1987). About 0.001% of patients treated with these agents die from anaphylaxis. It has been estimated that at least 300 deaths per year are due to this complication of therapy. About 70% have had penicillin previously, and one-third of these reacted to it on a prior occasion. Anaphylaxis most often has followed the injection of penicillin, although it also has been observed after oral ingestion of the drug and even has resulted from the intradermal instillation of a very small quantity for the purpose of testing for the presence of hypersensitivity. The clinical pictures that develop vary in severity. The most dramatic is sudden, severe hypotension and rapid death. In other instances, bronchoconstriction with severe asthma; abdominal pain, nausea, and vomiting; extreme weakness and a fall in blood pressure; or diarrhea and purpuric skin eruptions have characterized the anaphylactic episodes.

Serum sickness varies from mild fever, rash, and leukopenia to severe arthralgia or arthritis, purpura, lymphadenopathy, splenomegaly, mental changes, electrocardiographic abnormalities suggestive of myocarditis, generalized edema, albuminuria, and hematuria. It is mediated by IgG antibodies. This reaction is rare, but when it occurs, it appears after penicillin treatment has been continued for 1 week or more; it may be delayed, however, until 1 or 2 weeks after the drug has been stopped. Serum sickness caused by penicillin may persist for a week or longer.

Vasculitis of the skin or other organs may be related to penicillin hypersensitivity. The Coombs reaction frequently becomes positive during prolonged therapy with a penicillin or cephalosporin, but hemolytic anemia is rare. Reversible neutropenia may occur. It is not known if this is truly a hypersensitivity reaction; it has been noted with all the penicillins and has been seen in up to 30% of patients treated with 8-12 g nafcillin for >21 days. The bone marrow shows an arrest of maturation.

Fever may be the only evidence of a hypersensitivity reaction to the penicillins. It may reach high levels and be maintained, remittent, or intermittent; chills occur occasionally. The febrile reaction usually disappears within 24-36 hours after administration of the drug is stopped but may persist for days.

Eosinophilia is an occasional accompaniment of other allergic reactions to penicillin. At times, it may be the sole abnormality, and eosinophils may reach levels of ≥ 10 -20% of the total number of circulating white blood cells.

Penicillins rarely cause interstitial nephritis; methicillin has been implicated most frequently. Hematuria, albuminuria, pyuria, renal cell and other casts in the urine, elevation of serum creatinine, and even oliguria have been noted. Biopsy shows a mononuclear infiltrate with eosinophilia and tubular damage. IgG is present in the interstitium. This reaction usually is reversible.

Management of the Patient Potentially Allergic to Penicillin. Evaluation of the patient's history is the most practical way to avoid the use of penicillin in patients who are at the greatest risk of adverse reaction. Most patients who give a history of allergy to penicillin should be treated with a different type of antibiotic. Unfortunately, there is no totally reliable means to confirm a history of penicillin allergy (Romano et al., 2003). Skin testing for IgE-mediated immediate-type responses is compromised by the lack of a commercially available minor-determinant mixture. A National Institute of Allergy and Infectious Diseases (NIAID) multicenter study used major and minor determinants for skin testing. Of 726 patients with a history of penicillin allergy, 566 had negative skin tests. Of those, only 7 of 566 (1.2%) had possibly IgE-mediated immediate or accelerated penicillin allergy when given penicillin (Sogn et al., 1992). Radioallergosorbent tests (RASTs) for IgE antipenicilloyl determinants suffer from the same limitations as skin tests (Weiss and Adkinson, 2005).

Occasionally, *desensitization* is recommended for penicillin-allergic patients who must receive the drug. This procedure consists of administering gradually increasing doses of penicillin in the hope of avoiding a severe reaction and should be performed only in an intensive care setting. This may result in a subclinical anaphylactic discharge and the binding of all IgE before full doses are administered. Penicillin may be given in doses of 1, 5, 10, 100, and 1000 units intradermally in the lower arm, with 60-minute intervals between doses. If this is well tolerated, then 10,000 and 50,000 units may be given subcutaneously. Desensitization also may be accomplished

by the oral administration of penicillin. When full doses are reached, penicillin should not be discontinued and then restarted because immediate reactions may recur (see Weiss and Adkinson, 2005, for details). The patient should be observed constantly during the desensitizing procedure, an intravenous line must be in place, and epinephrine and equipment and expertise for artificial ventilation must be on hand. It must be emphasized that this procedure may be dangerous, and its efficacy is unproven.

Patients with life-threatening infections (e.g., endocarditis or meningitis) may be continued on penicillin despite the development of a maculopapular rash, although alternative antimicrobial agents should be used whenever possible. The rash often resolves as therapy is continued, perhaps owing to the development of blocking antibodies of the IgG class. The rash may be treated with antihistamines or glucocorticoids, although there is no evidence that this therapy is efficacious. Rarely, exfoliative dermatitis with or without vasculitis develops in these patients if therapy with penicillin is continued.

Other Adverse Reactions. The penicillins have minimal direct toxicity. Apparent toxic effects that have been reported include bone marrow depression, granulocytopenia, and hepatitis. The last-named effect is rare but is seen most commonly following the administration of oxacillin and nafcillin. The administration of penicillin G, carbenicillin, piperacillin, or ticarcillin has been associated with a potentially significant defect of hemostasis that appears to be due to an impairment of platelet aggregation; this may be caused by interference with the binding of aggregating agents to platelet receptors (Fass et al., 1987).

Most common among the irritative responses to penicillin are pain and sterile inflammatory reactions at the sites of intramuscular injections—reactions that are related to concentration. Serum transaminases and lactic dehydrogenase may be elevated as a result of local damage to muscle. In some individuals who receive penicillin intravenously, phlebitis or thrombophlebitis develops. Many persons who take various penicillin preparations by mouth experience nausea, with or without vomiting, and some have mild to severe diarrhea. These manifestations often are related to the dose of the drug.

When penicillin is injected accidentally into the sciatic nerve, severe pain occurs and dysfunction in the area of distribution of this nerve develops and persists for weeks. Intrathecal injection of penicillin G may produce arachnoiditis or severe and fatal encephalopathy. Because of this, intrathecal or intraventricular administration of penicillins should be avoided. The parenteral administration of large doses of penicillin G (>20 million units per day, or less with renal insufficiency) may produce lethargy, confusion, twitching, multifocal myoclonus, or localized or generalized epileptiform seizures. These are most apt to occur in the presence of renal insufficiency, localized lesions of the central nervous system (CNS), or hyponatremia. When the concentration of penicillin G in CSF exceeds 10 $\mu\text{g/mL}$, significant dysfunction of the CNS is frequent. The rapid intravenous administration of 20 million units of penicillin G potassium, which contains 34 mEq of K^+ , may lead to severe or even fatal hyperkalemia in persons with renal dysfunction.

Injection of penicillin G procaine may result in an immediate reaction, characterized by dizziness, tinnitus, headache, hallucinations, and sometimes seizures. This is due to the rapid liberation of

toxic concentrations of procaine. It has been reported to occur in 1 of 200 patients receiving 4.8 million units of penicillin G procaine to treat venereal disease.

Reactions Unrelated to Hypersensitivity or Toxicity. Regardless of the route by which the drug is administered, but most strikingly when it is given by mouth, penicillin changes the composition of the microflora in the GI tract by eliminating sensitive microorganisms. This phenomenon is usually of no clinical significance, and normal microflora are typically reestablished shortly after therapy is stopped. In some persons, however, superinfection results from pathological changes to the flora. Pseudomembranous colitis, related to overgrowth and production of a toxin by *Clostridium difficile*, has followed oral and, less commonly, parenteral administration of penicillins.

THE CEPHALOSPORINS

Cephalosporium acremonium, the first source of the cephalosporins, was isolated in 1948 by Brotzu from the sea near a sewer outlet off the Sardinian coast. Crude filtrates from cultures of this fungus were found to inhibit the *in vitro* growth of *S. aureus* and to cure staphylococcal infections and typhoid fever in humans. Culture fluids in which the Sardinian fungus was cultivated were found to contain three distinct antibiotics, which were named *cephalosporin P*, *N*, and *C*. With isolation of the active nucleus of cephalosporin *C*, 7-aminocephalosporanic acid, and with the addition of side chains, it became possible to produce semisynthetic compounds with antibacterial activity very much greater than that of the parent substance.

Chemistry. Cephalosporin *C* contains a side chain derived from D- α -aminoadipic acid, which is condensed with a dihydrothiazine β -lactam ring system (7-aminocephalosporanic acid). Compounds containing 7-aminocephalosporanic acid are relatively stable in dilute acid and highly resistant to penicillinase regardless of the nature of their side chains and their affinity for the enzyme.

Cephalosporin *C* can be hydrolyzed by acid to 7-aminocephalosporanic acid. This compound subsequently has been modified by the addition of different side chains to create a whole family of cephalosporin antibiotics. It appears that modifications at position 7 of the β -lactam ring are associated with alteration in antibacterial activity and that substitutions at position 3 of the dihydrothiazine ring are associated with changes in the metabolism and pharmacokinetic properties of the drugs.

The cephamycins are similar to the cephalosporins but have a methoxy group at position 7 of the β -lactam ring of the 7-aminocephalosporanic acid nucleus. The structural formulas of representative cephalosporins and cephamycins are shown in Table 53–2, along with dosages schedules and half-lives.

Mechanism of Action. Cephalosporins and cephamycins inhibit bacterial cell wall synthesis in a manner similar to that of penicillin.

Classification. The large number of cephalosporins makes a system of classification most desirable. Although cephalosporins may be

classified by their chemical structure, clinical pharmacology, resistance to β -lactamase, or antimicrobial spectrum, the well-accepted system of classification by “generations” is very useful, although admittedly somewhat arbitrary (Table 53–3). It is important to remember that none of the cephalosporins has activity against MRSA, listeria, or enterococci.

Classification by generations is based on general features of antimicrobial activity (Andes and Craig, 2005). The *first-generation* cephalosporins, epitomized by cephalothin (discontinued in the U.S.) and cefazolin, have good activity against gram-positive bacteria and relatively modest activity against gram-negative microorganisms. Most gram-positive cocci (with the exception of enterococci, methicillin-resistant *S. aureus*, and *S. epidermidis*) are susceptible. Most oral cavity anaerobes are sensitive, but the *B. fragilis* group is resistant. Activity against *Moraxella catarrhalis*, *E. coli*, *K. pneumoniae*, and *P. mirabilis* is good. The *second-generation* cephalosporins have somewhat increased activity against gram-negative microorganisms but are much less active than the third-generation agents. A subset of second-generation agents (cefoxitin, cefotetan, and cefmetazole, which have been discontinued in the U.S.) also is active against the *B. fragilis* group. *Third-generation* cephalosporins generally are less active than first-generation agents against gram-positive cocci; these agents are much more active against the Enterobacteriaceae, although resistance is dramatically increasing due to β -lactamase-producing strains. A subset of third-generation agents (ceftazidime and cefoperazone, which are discontinued in the U.S.) also is active against *P. aeruginosa* but less active than other third-generation agents against gram-positive cocci. *Fourth-generation* cephalosporins, such as cefepime, have an extended spectrum of activity compared with the third generation and have increased stability from hydrolysis by plasmid and chromosomally mediated β -lactamases (but not the KPC class A β -lactamases). Fourth-generation agents are useful in the empirical treatment of serious infections in hospitalized patients when gram-positive microorganisms, Enterobacteriaceae, and *Pseudomonas* all are potential etiologies. It is important to remember that none of the cephalosporins has reliable activity against the following bacteria: penicillin-resistant *S. pneumoniae*, MRSA, methicillin-resistant *S. epidermidis* and other coagulase-negative staphylococci, *Enterococcus*, *L. monocytogenes*, *Legionella pneumophila*, *L. micdadei*, *C. difficile*, *Xanthomonas maltophilia*, *Campylobacter jejuni*, KPC-producing Enterobacteriaceae, and *Acinetobacter* spp.

Mechanisms of Bacterial Resistance to the Cephalosporins.

Resistance to the cephalosporins may be related to the inability of the antibiotic to reach its sites of action or to alterations in the penicillin-binding proteins (PBPs) that are targets of the cephalosporins such that the antibiotics bind to bacterial enzymes (β -lactamases) that can hydrolyze the β -lactam ring and inactivate the cephalosporin. Alterations in two PBPs (1A and 2X) that decrease their affinity for cephalosporins render pneumococci resistant to third-generation cephalosporins because the other three high-molecular-weight PBPs have inherently low affinity (Spratt, 1994).

The most prevalent mechanism of resistance to cephalosporins is destruction of the cephalosporins by hydrolysis of the β -lactam ring.

<i>Fourth generation</i> Cefepime (MAXIPIME)			I: 2 g every 8 hours $t_{1/2} = 2$ hours

^aT, tablet; C, capsule; O, oral suspension; I, injection ^bCefoxitin, a cephemycin, has a $-\text{OCH}_3$ group at position 7 of cephem nucleus. ^cCefuroxime axetil is the acetyloxyethyl ester of cefuroxime. ^dCefpodoxime proxetil has a $-\text{COOCH}(\text{CH}_3)\text{OCOCH}(\text{CH}_3)_2$ group at position 4 of cephem nucleus.

Table 53–3

Cephalosporin Generations

EXAMPLES	USEFUL SPECTRUM ^a
First Generation	
Cefazolin (ANCEF, ZOLICEF, others)	Streptococci ^b ; <i>Staphylococcus aureus</i> . ^c
Cephalexin monohydrate (KEFTAB)	
Cefadroxil (DURACEF)	
Cephadrine (VELOSEF)	
Second Generation	
Cefuroxime (ZINACEF)	<i>Escherichia coli</i> , <i>Klebsiella</i> , <i>Proteus</i> , <i>Haemophilus influenzae</i> , <i>Moraxella catarrhalis</i> . Not as active against gram-positive organisms as first-generation agents.
Cefuroxime axetil (CEFTIN)	
Cefprozil (CEFZIL)	Inferior activity against <i>S. aureus</i> compared to cefuroxime but with added activity against <i>Bacteroides fragilis</i> and other <i>Bacteroides</i> spp.
Cefmetazole (ZEFAZONE)	
Loracarbef (LORABID)	
Third Generation	
Cefotaxime (CLAFORAN)	Enterobacteriaceae ^d ; <i>Pseudomonas aeruginosa</i> ^e ; <i>Serratia</i> ; <i>Neisseria</i> <i>gonorrhoeae</i> ; activity for <i>S. aureus</i> , <i>Streptococcus pneumoniae</i> , and <i>Streptococcus pyogenes</i> ^f comparable to first-generation agents. Activity against <i>Bacteroides</i> spp. inferior to that of cefoxitin and cefotetan.
Ceftriaxone (ROCEPHIN)	
Cefdinir (OMNICEF)	
Cefditoren pivoxil (SPECTRACEF)	
Ceftibuten (CEDAX)	
Cefpodoxime proxetil (VANTIN)	
Ceftizoxime (CEFIZOX)	
Cefoperazone (CEFOBID)	
Ceftazidime (FORTAZ, others)	
Cefepime (MAXIPINE)	
	Active against <i>Pseudomonas</i>
Fourth Generation	
Cefepime (MAXIPINE)	Comparable to third generation but more resistant to some β -lactamases.

^aAll cephalosporins lack activity against enterococci, *Listeria monocytogenes*, *Legionella* spp., methicillin-resistant *S. aureus*, *Xanthomonas maltophilia*, and *Acinetobacter* species. ^bExcept for penicillin-resistant strains. ^cExcept for methicillin-resistant strains. ^dResistance to cephalosporins may be induced rapidly during therapy by de-repression of bacterial chromosomal β -lactamases, which destroy the cephalosporins. ^eCeftazidime only. ^fCeftazidime lacks significant gram-positive activity. Cefotaxime is most active in class against *S. aureus* and *S. pyogenes*.

Many gram-positive microorganisms release relatively large amounts of β -lactamase into the surrounding medium. Although gram-negative bacteria seem to produce less β -lactamase, the location of their enzyme in the periplasmic space may make it more effective in destroying cephalosporins because they diffuse to their targets on the inner membrane, as is the case for the penicillins. The cephalosporins have variable susceptibility to β -lactamase. For example, of the first-generation agents, cefazolin is more susceptible to hydrolysis by β -lactamase from *S. aureus* than is cephalothin (no longer marketed). Cefoxitin, cefuroxime, and the third-generation cephalosporins are more resistant to hydrolysis by the β -lactamases produced by gram-negative bacteria than first-generation cephalosporins. Third-generation cephalosporins are susceptible to hydrolysis by inducible, chromosomally encoded (type I) β -lactamases. Induction of type I β -lactamases by treatment of infections owing to aerobic gram-negative bacilli (especially *Enterobacter* spp., *Citrobacter freundii*, *Morganella*, *Serratia*, *Providencia*, and *P. aeruginosa*) with second- or third-generation cephalosporins and/or imipenem may result in resistance to all third-generation cephalosporins. The fourth-generation cephalosporins, such as cefepime, are poor inducers of type I β -lactamases and are less

susceptible to hydrolysis by type I β -lactamases than are the third-generation agents. They are, however, susceptible to degradation by KPC and metallo- β -lactamases (Jacoby and Munoz-Price, 2005; Jones et al., 2008; Walsh, 2008).

General Features of the Cephalosporins. Cephalexin, cephadrine, cefaclor, cefadroxil, loracarbef, cefprozil, cefpodoxime proxetil, ceftibuten, and cefuroxime axetil are absorbed readily after oral administration. Cefdinir and cefditoren are also effective orally. The other cephalosporins can be administered intramuscularly or intravenously. Cephadrine and loracarbef have been discontinued in the U.S.

Cephalosporins are excreted primarily by the kidney; thus the dosage should be altered in patients with renal insufficiency. Probenecid slows the tubular secretion of most cephalosporins. Exceptions are cefpiramide and cefoperazone, which are excreted predominantly in

the bile (neither is available in the U.S.). Cefotaxime is deacetylated *in vivo*. The metabolite has less antimicrobial activity than the parent compound and is excreted by the kidneys. None of the other cephalosporins appears to undergo appreciable metabolism.

Several cephalosporins penetrate into the CSF in sufficient concentration to be useful for the treatment of meningitis. These include cefotaxime, ceftriaxone, and cefepime (see “Therapeutic Uses” section). Cephalosporins also cross the placenta, and they are found in high concentrations in synovial and pericardial fluids. Penetration into the aqueous humor of the eye is relatively good after systemic administration of third-generation agents, but penetration into the vitreous humor is poor. Some evidence indicates that concentrations sufficient for therapy of ocular infections owing to gram-positive and certain gram-negative microorganisms can be achieved after systemic administration. Concentrations in bile usually are high, with those achieved after administration of cefoperazone and cefpiramide the highest.

Specific Agents

First-Generation Cephalosporins. Cefazolin has an antibacterial spectrum that is typical of other first-generation cephalosporins except that it also has activity against some *Enterobacter* spp. Cefazolin is relatively well tolerated after either intramuscular or intravenous administration, and concentrations of the drug in plasma after a 1-g intramuscular injection reach 64 $\mu\text{g/mL}$. Cefazolin is excreted by glomerular filtration and is bound to plasma proteins to a great extent (~85%). Cefazolin usually is preferred among the first-generation cephalosporins because it can be administered less frequently owing to its longer $t_{1/2}$.

Cephalexin is available for oral administration, and it has the same antibacterial spectrum as the other first-generation cephalosporins. However, it is somewhat less active against penicillinase-producing staphylococci. Oral therapy with cephalexin results in peak concentrations in plasma of 16 $\mu\text{g/mL}$ after a dose of 0.5 g; this is adequate for the inhibition of many gram-positive and gram-negative pathogens. The drug is not metabolized, and 70–100% is excreted in the urine.

Cephadrine is similar in structure to cephalexin, and its activity *in vitro* is almost identical. Cephadrine is not metabolized and, after rapid absorption from the GI tract, is excreted unchanged in the urine. Cephadrine can be administered orally, intramuscularly, or intravenously. When administered orally, it is difficult to distinguish cephadrine from cephalexin; some authorities believe these two drugs can be used interchangeably. Because cephadrine is so well absorbed, the concentrations in plasma are nearly equivalent after oral or intramuscular administration.

Cefadroxil is the *para*-hydroxy analog of cephalexin. Concentrations of cefadroxil in plasma and urine are at somewhat

higher levels than are those of cephalexin. The drug may be administered orally once or twice a day for the treatment of urinary tract infections. Its activity *in vitro* is similar to that of cephalexin.

Second-Generation Cephalosporins. Second-generation cephalosporins have a broader spectrum than do the first-generation agents and are active against sensitive strains of *Enterobacter* spp., indole-positive *Proteus* spp., and *Klebsiella* spp.

Cefoxitin is a cephamycin produced by *Streptomyces lactam durans*. It is resistant to some β -lactamases produced by gram-negative rods. This antibiotic is less active than the first-generation cephalosporins against gram-positive bacteria. Cefoxitin is more active than other first- or second-generation agents (except cefotetan) against anaerobes, especially *B. fragilis*. After an intramuscular dose of 1 g, concentrations in plasma are ~22 $\mu\text{g/mL}$. The $t_{1/2}$ is ~40 minutes. Cefoxitin’s special role seems to be for treatment of certain anaerobic and mixed aerobic-anaerobic infections, such as pelvic inflammatory disease and lung abscess.

Cefaclor is used orally. The concentration in plasma after oral administration is ~50% of that achieved after an equivalent oral dose of cephalexin. However, cefaclor is more active against *H. influenzae* and *Moraxella catarrhalis*, although some β -lactamase-producing strains of these organisms may be resistant.

Loracarbef is an orally administered carbacephem, similar in activity to cefaclor, that is more stable against some β -lactamases. The serum $t_{1/2}$ is 1.1 hours.

Cefuroxime is similar to loracarbef with broader gram-negative activity against some *Citrobacter* and *Enterobacter* spp. Unlike cefoxitin, cefmetazole (discontinued in the U.S.), and cefotetan, cefuroxime lacks activity against *B. fragilis*. The $t_{1/2}$ is 1.7 hours, and the drug can be given every 8 hours. Concentrations in CSF are ~10% of those in plasma, and the drug is effective (but inferior to ceftriaxone) for treatment of meningitis owing to *H. influenzae* (including strains resistant to ampicillin), *N. meningitidis*, and *S. pneumoniae* (Schaad et al., 1990).

Cefuroxime axetil is the 1-acetyloxyethyl ester of cefuroxime. Between 30% and 50% of an oral dose is absorbed, and the drug then is hydrolyzed to cefuroxime; resulting concentrations in plasma are variable.

Cefprozil is an orally administered agent that is more active than first-generation cephalosporins against penicillin-sensitive streptococci, *E. coli*, *P. mirabilis*, *Klebsiella* spp., and *Citrobacter* spp. It has a serum $t_{1/2}$ of ~1.3 hours.

Third-Generation Cephalosporins. Cefotaxime is highly resistant to many (but not the extended-spectrum product) of the bacterial β -lactamases and has good activity against many gram-positive and gram-negative aerobic bacteria. However, activity against *B. fragilis* is poor compared with agents such as clindamycin and metronidazole. Cefotaxime has a $t_{1/2}$ in plasma of ~1 hour and should be administered every 4–8 hours for serious infections. The drug is metabolized *in vivo* to desacetylcefotaxime, which is less active against most

microorganisms than is the parent compound. However, the metabolite acts synergistically with the parent compound against certain microbes. Cefotaxime has been used effectively for meningitis caused by *H. influenzae*, penicillin-sensitive *S. pneumoniae*, and *N. meningitidis*.

Ceftizoxime has a spectrum of activity *in vitro* that is very similar to that of cefotaxime, except that it is less active against *S. pneumoniae* and more active against *B. fragilis* (Haas et al., 1995). The $t_{1/2}$ is somewhat longer, 1.8 hours, and the drug thus can be administered every 8-12 hours for serious infections. Ceftizoxime is not metabolized, and 90% is recovered in urine.

Ceftriaxone has activity *in vitro* very similar to that of ceftizoxime and cefotaxime. A $t_{1/2}$ of ~8 hours is the outstanding feature. Administration of the drug once or twice daily has been effective for patients with meningitis, whereas dosage once a day has been effective for other infections. About half the drug can be recovered from the urine; the remainder appears to be eliminated by biliary secretion. A single dose of ceftriaxone (125-250 mg) is effective in the treatment of urethral, cervical, rectal, or pharyngeal gonorrhea, including disease caused by penicillinase-producing microorganisms.

Cefpodoxime proxetil is an orally administered third-generation agent that is very similar in activity to the fourth-generation agent cefepime except that it is not more active against *Enterobacter* or *Pseudomonas* spp. It has a serum $t_{1/2}$ of 2.2 hours.

Cefditoren pivoxil is a prodrug that is hydrolyzed by esterases during absorption to the active drug, cefditoren. Cefditoren has a $t_{1/2}$ of ~1.6 hours and is eliminated unchanged in the urine. The drug is active against methicillin-susceptible strains of *S. aureus*, penicillin-susceptible strains of *S. pneumoniae*, *S. pyogenes*, *H. influenzae*, *H. parainfluenzae*, and *Moraxella catarrhalis*. Cefditoren pivoxil is only indicated for the treatment of mild-to-moderate pharyngitis, tonsillitis, uncomplicated skin and skin structure infections, and acute exacerbations of chronic bronchitis.

Cefixime is an oral third-generation cephalosporin with clinical efficacy against urinary tract infections caused by *E. coli* and *P. mirabilis*, otitis media caused by *H. influenzae* and *S. pyogenes*, pharyngitis due to *S. pyogenes*, and uncomplicated gonorrhea. It is available as an oral suspension (SUPREX, others). Cefixime has a plasma $t_{1/2}$ of 3-4 hours and is both excreted in the urine and eliminated in the bile. The standard dose for adults is 400 mg/day for 5-7 days, and for a longer interval in patients with *S. pyogenes*. Doses must be reduced in patients with renal impairment (300 mg/day for creatinine clearance between 20 and 60 mL/minute, and 200 mg day for <20 mL/minute). Pediatric dosing varies with patient weight.

Ceftibuten is an orally effective cephalosporin with a $t_{1/2}$ of 2.4 hours. It is less active against gram-positive and gram-negative organisms than cefixime, with activity limited to *S. pneumoniae* and *S. pyogenes*, *H. influenzae*, and *M. catarrhalis*. Ceftibuten is only indicated for acute bacterial exacerbations of chronic bronchitis, acute bacterial otitis media, pharyngitis, and tonsillitis. It lacks useful activity against *S. aureus*.

Cefdinir is effective orally, with a $t_{1/2}$ of ~1.7 hours; it is eliminated primarily unchanged in the urine. Cefdinir has greater activ-

ity than the second-generation agents for facultative gram-negative bacteria but lacks anaerobic activity. It is also inactive against *Pseudomonas* and *Enterobacter* spp.

Third-Generation Cephalosporins with Good Activity Against *Pseudomonas*

Ceftazidime is one-quarter to one-half as active by weight against gram-positive microorganisms as is cefotaxime. Its activity against the Enterobacteriaceae is very similar, but its major distinguishing feature is excellent activity against *Pseudomonas* and other gram-negative bacteria. Ceftazidime has poor activity against *B. fragilis*. Its $t_{1/2}$ in plasma is ~1.5 hours, and the drug is not metabolized. Ceftazidime is more active *in vitro* against *Pseudomonas* than piperacillin is (Edmond et al., 1999).

Fourth-Generation Cephalosporins. Cefepime and cefpirome are fourth-generation cephalosporins. Only cefepime is available for use in the U.S. Cefepime is stable to hydrolysis by many of the previously identified plasmid-encoded β -lactamases (called TEM-1, TEM-2, and SHV-1). It is a poor inducer of, and is relatively resistant to, the type I chromosomally encoded and some extended-spectrum β -lactamases. Thus, it is active against many Enterobacteriaceae that are resistant to other cephalosporins via induction of type I β -lactamases but remains susceptible to many bacteria expressing extended-spectrum plasmid-mediated β -lactamases (such as KPC, TEM-3, and TEM-10).

Against the fastidious gram-negative bacteria (*H. influenzae*, *N. gonorrhoeae*, and *N. meningitidis*), cefepime has comparable or greater *in vitro* activity than cefotaxime. For *P. aeruginosa*, cefepime has comparable activity to ceftazidime, although it is less active than ceftazidime for other *Pseudomonas* spp. and *X. maltophilia*. Cefepime has higher activity than ceftazidime and comparable activity to cefotaxime for streptococci and methicillin-sensitive *S. aureus*. It is not active against methicillin-resistant *S. aureus*, penicillin-resistant pneumococci, enterococci, *B. fragilis*, *L. monocytogenes*, *Mycobacterium avium* complex, or *M. tuberculosis*. Cefepime is excreted almost 100% renally, and doses should be adjusted for renal failure. Cefepime has excellent penetration into the CSF in animal models of meningitis. When given at the recommended dosage for adults of 2 g intravenously every 12 hours, peak serum concentrations in humans range from 126 to 193 $\mu\text{g/mL}$. The serum $t_{1/2}$ is 2 hours.

Adverse Reactions. Hypersensitivity reactions to the cephalosporins are the most common side effects, and there is no evidence that any single cephalosporin is more or less likely to cause such sensitization. The reactions appear to be identical to those caused by the penicillins, perhaps related to the shared β -lactam structure of both groups of antibiotics. Immediate reactions such as anaphylaxis, bronchospasm, and urticaria are observed. More commonly, maculopapular rash develops, usually after several days of therapy; this may or may not be accompanied by fever and eosinophilia.

Because of the similar structures of the penicillins and cephalosporins, patients who are allergic to one class of agents may

manifest cross-reactivity to a member of the other class. Immunological studies have demonstrated cross-reactivity in as many as 20% of patients who are allergic to penicillin, but clinical studies indicate a much lower frequency (~1%) of such reactions. There are no skin tests that can reliably predict whether a patient will manifest an allergic reaction to the cephalosporins.

Patients with a history of a mild or a temporally distant reaction to penicillin appear to be at low risk of rash or other allergic reaction following the administration of a cephalosporin. However, patients who have had a recent severe, immediate reaction to a penicillin should be given a cephalosporin with great caution, if at all. A positive Coombs reaction appears frequently in patients who receive large doses of a cephalosporin. Hemolysis usually is not associated with this phenomenon, although it has been reported and has been associated with fatalities. Cephalosporins have produced rare instances of bone marrow depression, characterized by granulocytopenia.

The cephalosporins have been implicated as potentially nephrotoxic agents, although they are not nearly as toxic to the kidney as the aminoglycosides or the polymyxins. Renal tubular necrosis has followed the administration of cephaloridine in doses >4 g/day; this agent is no longer available in the U.S. Other cephalosporins are much less toxic and, when used by themselves in recommended doses, rarely produce significant renal toxicity. High doses of cephalothin (no longer available in the U.S.) have produced acute tubular necrosis in certain instances, and usual doses (8-12 g/day) have caused nephrotoxicity in patients with pre-existing renal disease. There is good evidence that the concurrent administration of cephalothin and gentamicin or tobramycin act synergistically to cause nephrotoxicity, especially in patients >60 years of age. Diarrhea can result from the administration of cephalosporins and may be more frequent with cefoperazone, perhaps because of its greater biliary excretion. Intolerance to alcohol (a disulfiram-like reaction) has been noted with cephalosporins that contain the methylthiotetrazole (MTT) group, including cefotetan, cefamandole, moxalactam, and cefoperazone (the latter three are no longer available in the U.S.). Serious bleeding related either to hypoprothrombinemia owing to the MTT group, thrombocytopenia, and/or platelet dysfunction has been reported with several β -lactam antibiotics.

Therapeutic Uses. The cephalosporins are used widely and are therapeutically important antibiotics. Clinical studies have shown cephalosporins to be effective as both therapeutic and prophylactic agents. Unfortunately, a wide array of bacteria is resistant to their activity.

The first-generation cephalosporins are excellent agents for skin and soft tissue infections owing to *S. pyogenes* and methicillin-susceptible *S. aureus*. A single dose of cefazolin just before surgery is the preferred prophylaxis for procedures in which skin flora are the likely pathogens (Medical Letter, 2006). For colorectal surgery, where prophylaxis for intestinal anaerobes is desired, the second-generation agent cefoxitin is preferred.

The second-generation cephalosporins generally have been displaced by third-generation agents. They have inferior activity against penicillin-resistant *S. pneumoniae* compared with either the

third-generation agents or ampicillin and therefore should not be used for empirical treatment of meningitis or pneumonia. The oral second-generation cephalosporins can be used to treat respiratory tract infections, although they are suboptimal (compared with oral amoxicillin) for treatment of penicillin-resistant *S. pneumoniae* pneumonia and otitis media. In situations where facultative gram-negative bacteria and anaerobes are involved, such as intra-abdominal infections, pelvic inflammatory disease, and diabetic foot infection, cefoxitin and cefotetan both are effective.

The third-generation cephalosporins, with or without aminoglycosides, have been considered to be the drugs of choice for serious infections caused by *Klebsiella*, *Enterobacter*, *Proteus*, *Providencia*, *Serratia*, and *Haemophilus* spp. Ceftriaxone is the therapy of choice for all forms of gonorrhea and for severe forms of Lyme disease. The third-generation cephalosporins cefotaxime or ceftriaxone are used for the initial treatment of meningitis in nonimmunocompromised adults and children >3 months of age (in combination with vancomycin and ampicillin pending identification of the causative agent) because of their antimicrobial activity, good penetration into CSF, and record of clinical success. They are the drugs of choice for the treatment of meningitis caused by *H. influenzae*, sensitive *S. pneumoniae*, *N. meningitidis*, and gram-negative enteric bacteria. Cefotaxime has failed in the treatment of meningitis owing to resistant *S. pneumoniae*; thus vancomycin should be added (Quagliarello and Scheld, 1997). Ceftazidime plus an aminoglycoside is the treatment of choice for *Pseudomonas* meningitis. Third-generation cephalosporins, however, lack activity against *L. monocytogenes* and penicillin-resistant pneumococci, which may cause meningitis. The antimicrobial spectra of cefotaxime and ceftriaxone are excellent for the treatment of community-acquired pneumonia, i.e., pneumonia caused by some pneumococci (achievable serum concentrations exceed MICs for many or most penicillin-resistant isolates), *H. influenzae*, or *S. aureus*.

The fourth-generation cephalosporins are indicated for the empirical treatment of nosocomial infections where antibiotic resistance owing to extended-spectrum β -lactamases or chromosomally induced β -lactamases are anticipated. For example, cefepime has superior activity against nosocomial isolates of *Enterobacter*, *Citrobacter*, and *Serratia* spp. compared with ceftazidime and piperacillin. However KPC- or metallo- β -lactamase expressing strains are resistant to cefepime.

OTHER β -LACTAM ANTIBIOTICS

Important therapeutic agents with a β -lactam structure that are neither penicillins nor cephalosporins have been developed.

Carbapenems

Carbapenems are β -lactams that contain a fused β -lactam ring and a five-member ring system that differs from the penicillins because it is unsaturated and contains a carbon atom instead of the sulfur atom. This class of antibiotics has a broader spectrum of activity than most other β -lactam antibiotics.

Imipenem. Imipenem is marketed in combination with cilastatin, a drug that inhibits the degradation of imipenem by a renal tubular dipeptidase.

Imipenem is derived from a compound produced by *Streptomyces cattleya*. The compound thienamycin is unstable, but imipenem, the *N*-formimidoyl derivative, is stable.

Antimicrobial Activity. Imipenem, like other β -lactam antibiotics, binds to penicillin-binding proteins, disrupts bacterial cell wall synthesis, and causes death of susceptible microorganisms. It is very resistant to hydrolysis by most β -lactamases.

The activity of imipenem is excellent *in vitro* for a wide variety of aerobic and anaerobic microorganisms. Streptococci (including penicillin-resistant *S. pneumoniae*), enterococci (excluding *E. faecium* and non- β -lactamase-producing penicillin-resistant strains), staphylococci (including penicillinase-producing strains), and *Listeria* all are susceptible. Although some strains of methicillin-resistant staphylococci are susceptible, many strains are not. Activity was excellent against the Enterobacteriaceae until the emergence of KPC carbapenemase-producing strains (Jones et al., 2008; Walsh, 2008). Most strains of *Pseudomonas* and *Acinetobacter* are inhibited. *S. maltophilia* is resistant. Anaerobes, including *B. fragilis*, are highly susceptible.

Pharmacokinetics and Adverse Reactions. Imipenem is not absorbed orally. The drug is hydrolyzed rapidly by a dipeptidase found in the brush border of the proximal renal tubule. Because concentrations of active drug in urine were low, cilastatin, an inhibitor of the dehydropeptidase, was synthesized. A preparation has been developed that contains equal amounts of imipenem and cilastatin (PRIMAXIN).

After the intravenous administration of 500 mg imipenem and cilastatin, peak concentrations in plasma average 33 $\mu\text{g/mL}$. Both imipenem and cilastatin have a $t_{1/2}$ of ~ 1 hour. When administered concurrently with cilastatin, $\sim 70\%$ of administered imipenem is recovered in the urine as the active drug. Dosage should be modified for patients with renal insufficiency.

Nausea and vomiting are the most common adverse reactions (1–20%). Seizures also have been noted in up to 1.5% of patients, especially when high doses are given to patients with CNS lesions and to those with renal insufficiency. Patients who are allergic to other β -lactam antibiotics may have hypersensitivity reactions when given imipenem.

Therapeutic Uses. Imipenem–cilastatin is effective for a wide variety of infections, including urinary tract and lower respiratory infections; intra-abdominal and gynecological infections; and skin, soft tissue, bone, and joint infections. The drug combination appears to be especially useful for the treatment of infections caused by cephalosporin-resistant nosocomial bacteria, such as *Citrobacter freundii* and *Enterobacter* spp. (with the exception of the increasingly

common KPC-producing strains). It would be prudent to use imipenem for empirical treatment of serious infections in hospitalized patients who have recently received other β -lactam antibiotics because of the increased risk of infection with cephalosporin- and/or penicillin-resistant bacteria. Imipenem should not be used as monotherapy for infections owing to *P. aeruginosa* because of the risk of resistance developing during therapy.

Meropenem. Meropenem (MERREM IV) is a dimethylcarbamoyl pyrrolidyl derivative of thienamycin. It does not require co-administration with cilastatin because it is not sensitive to renal dipeptidase. Its toxicity is similar to that of imipenem except that it may be less likely to cause seizures (0.5% for meropenem; 1.5% for imipenem). Its *in vitro* activity is similar to that of imipenem, with activity against some imipenem-resistant *P. aeruginosa* but less activity against gram-positive cocci. Clinical experience with meropenem demonstrates therapeutic equivalence with imipenem.

Doripenem. Doripenem (DORIBAX) has a spectrum of activity that is similar to that of imipenem and meropenem, with greater activity against some resistant isolates of *Pseudomonas* (Medical Letter, 2008).

Ertapenem. Ertapenem (INVANZ) differs from imipenem and meropenem by having a longer $t_{1/2}$ that allows once-daily dosing and by having inferior activity against *P. aeruginosa* and *Acinetobacter* spp. Its spectrum of activity against gram-positive organisms, Enterobacteriaceae, and anaerobes makes it attractive for use in intra-abdominal and pelvic infections (Solomkin et al., 2003).

Aztreonam. Aztreonam (AZACTAM) is a monocyclic β -lactam compound (a monobactam) isolated from *Chromobacterium violaceum* (Sykes et al., 1981).

Aztreonam interacts with penicillin-binding proteins of susceptible microorganisms and induces the formation of long filamentous bacterial structures. The compound is resistant to many of the β -lactamases that are elaborated by most gram-negative bacteria, including the metallo- β -lactamases but not the KPC β -lactamases (Jones et al., 2008; Walsh, 2008).

The antimicrobial activity of aztreonam differs from those of other β -lactam antibiotics and more closely resembles that of an aminoglycoside. Aztreonam has activity only against gram-negative bacteria; it has no activity against gram-positive bacteria and anaerobic organisms. However, activity against Enterobacteriaceae is excellent, as is that against *P. aeruginosa*. It is also highly active *in vitro* against *H. influenzae* and gonococci.

Aztreonam is administered either intramuscularly or intravenously. Peak concentrations of aztreonam in plasma average nearly 50 $\mu\text{g/mL}$ after a 1-g intramuscular dose. The $t_{1/2}$ for elimination is 1.7 hours, and most of the drug is recovered unaltered in the urine. The $t_{1/2}$ is prolonged to ~ 6 hours in anephric patients.

Aztreonam generally is well tolerated. Interestingly, patients who are allergic to penicillins or cephalosporins appear not to react to aztreonam, with the exception of ceftazidime.

The usual dose of aztreonam for severe infections is 2 g every 6-8 hours. This should be reduced in patients with renal insufficiency. Aztreonam has been used successfully for the therapy of a variety of infections. One of its notable features is little allergic cross-reactivity with β -lactam antibiotics, with the possible exception of ceftazidime (Perez Pimiento et al., 1998), with which it has considerable structural similarity. Aztreonam is therefore quite useful for treating gram-negative infections that normally would be treated with a β -lactam antibiotic were it not for the history of a prior allergic reaction.

β -LACTAMASE INHIBITORS

Certain molecules can inactivate β -lactamases, thereby preventing the destruction of β -lactam antibiotics that are substrates for these enzymes. β -Lactamase inhibitors are most active against plasmid-encoded β -lactamases (including the enzymes that hydrolyze ceftazidime and cefotaxime), but they are inactive at clinically achievable concentrations against the type I chromosomal β -lactamases induced in gram-negative bacilli (such as *Enterobacter*, *Acinetobacter*, and *Citrobacter*) by treatment with second- and third-generation cephalosporins.

Clavulanic acid is produced by *Streptomyces clavuligerus*; its structural formula is:

It has poor intrinsic antimicrobial activity, but it is a “suicide” inhibitor that irreversibly binds β -lactamases produced by a wide range of gram-positive and gram-negative microorganisms. Clavulanic acid is well absorbed by mouth and also can be given parenterally. It has been combined with amoxicillin as an oral preparation (AUGMENTIN, others) and with ticarcillin as a parenteral preparation (TIMENTIN).

Amoxicillin plus clavulanate is effective *in vitro* and *in vivo* for β -lactamase-producing strains of staphylococci, *H. influenzae*, gonococci, and *E. coli*. Amoxicillin-clavulanate plus ciprofloxacin has been shown to be an effective oral treatment for low-risk febrile patients with neutropenia from cancer chemotherapy (Freifeld et al., 1999; Kern et al., 1999). It also is effective in the treatment of acute otitis media in children, sinusitis, animal or human bite wounds, cellulitis, and diabetic foot infections. The addition of clavulanate to ticarcillin (timentin) extends its spectrum such that it resembles

imipenem to include aerobic gram-negative bacilli, *S. aureus*, and *Bacteroides* spp. There is no increased activity against *Pseudomonas* spp. The dosage should be adjusted for patients with renal insufficiency. The combination is especially useful for mixed nosocomial infections and is used often with an aminoglycoside.

Sulbactam is another β -lactamase inhibitor similar in structure to clavulanic acid. It may be given orally or parenterally along with a β -lactam antibiotic. It is available for intravenous or intramuscular use combined with ampicillin (UNASYN, others). Dosage must be adjusted for patients with impaired renal function. The combination has good activity against gram-positive cocci, including β -lactamase-producing strains of *S. aureus*, gram-negative aerobes (but not resistant strains of *E. coli* or *Pseudomonas*), and anaerobes; it also has been used effectively for the treatment of mixed intra-abdominal and pelvic infections.

Tazobactam is a penicillanic acid sulfone β -lactamase inhibitor. In comparison with the other available inhibitors, it has poor activity against the inducible chromosomal β -lactamases of Enterobacteriaceae but has good activity against many of the plasmid β -lactamases, including some of the extended-spectrum class. It has been combined with piperacillin as a parenteral preparation (ZOSYN).

The combination of piperacillin and tazobactam does not increase the activity of piperacillin against *P. aeruginosa* because resistance is due to either chromosomal β -lactamases or decreased permeability of piperacillin into the periplasmic space. Because the currently recommended dose (3 g piperacillin per 375 mg tazobactam every 4-8 hours) is less than the recommended dose of piperacillin when used alone for serious infections (3-4 g every 4-6 hours), concern has been raised that piperacillin-tazobactam may prove ineffective in the treatment of some *P. aeruginosa* infections that would have responded to piperacillin. The combination of piperacillin plus tazobactam should be equivalent in antimicrobial spectrum to ticarcillin plus clavulanate.

Aminoglycosides

Conan MacDougall
and Henry F. Chambers

The aminoglycoside group includes gentamicin, tobramycin, amikacin, netilmicin (not available in the U.S.), kanamycin, streptomycin, paromomycin, and neomycin. These drugs are used primarily to treat infections caused by aerobic gram-negative bacteria; streptomycin is an important agent for the treatment of tuberculosis, and paromomycin is used orally for intestinal amebiasis and in the management of hepatic coma. In contrast to most inhibitors of microbial protein synthesis, which are bacteriostatic, the aminoglycosides are bactericidal inhibitors of protein synthesis. Mutations affecting proteins in the bacterial ribosome, the target for these drugs, can confer marked resistance to their action. However, most commonly resistance is due to acquisition of plasmids or transposon-encoding genes for aminoglycoside-metabolizing enzymes or from impaired transport of drug into the cell. Thus, there can be cross-resistance between members of the class.

These agents contain amino sugars linked to an aminocyclitol ring by glycosidic bonds (Figure 54–1). They are polycations, and their polarity is responsible in part for pharmacokinetic properties shared by all members of the group. For example, none is absorbed adequately after oral administration, inadequate concentrations are found in cerebrospinal fluid (CSF), and all are excreted relatively rapidly by the normal kidney. Although aminoglycosides are widely used and important agents, serious toxicity limits their utility. All members of the group share the same spectrum of toxicity, most notably nephrotoxicity and ototoxicity, which can involve the auditory and vestibular functions of the eighth cranial nerve.

History and Source. Aminoglycosides are natural products or semisynthetic derivatives of compounds produced by a variety of soil actinomycetes. Streptomycin was first isolated from a strain of *Streptomyces griseus*. Gentamicin and netilmicin are derived from species of the actinomycete *Micromonospora*. The difference in spelling (*-micin*) compared with the other aminoglycoside antibiotics (*-mycin*) reflects this difference in origin. Tobramycin is one of several

components of an aminoglycoside complex (nebramycin) that is produced by *S. tenebrarius*. It is most similar in antimicrobial activity and toxicity to gentamicin. In contrast to the other aminoglycosides, amikacin, a derivative of kanamycin, and netilmicin, a derivative of sisomicin, are semisynthetic products. Other aminoglycoside antibiotics have been developed (e.g., arbekacin, isepamicin, and sisomicin), but they have not been introduced into clinical practice in the U.S. because numerous potent, less toxic alternatives (e.g., broad-spectrum β -lactam antibiotics and quinolones) are available.

Chemistry. The aminoglycosides consist of two or more amino sugars joined in glycosidic linkage to a hexose nucleus, which usually is in a central position (Figure 54–1). This hexose, or aminocyclitol, is either streptidine (found in streptomycin) or 2-deoxystreptamine (found in all other available aminoglycosides). These compounds thus are aminoglycosidic aminocyclitols, although the simpler term *aminoglycoside* is used commonly. A related compound, *spectinomycin*, is an aminocyclitol that does not contain amino sugars (Chapter 55).

The aminoglycoside families are distinguished by the amino sugars attached to the aminocyclitol. In the neomycin family, which includes neomycin B and paromomycin, three amino sugars are attached to the central 2-deoxystreptamine. The kanamycin and gentamicin families have only two such amino sugars.

In the kanamycin family, which includes kanamycins A and B, amikacin, and tobramycin, two amino sugars are linked to a centrally located 2-deoxystreptamine moiety; one of these is a 3-aminoheptose (Figure 54–1).

Amikacin is a semisynthetic derivative prepared from kanamycin A by acylation of the 1-amino group of the 2-deoxystreptamine moiety with 2-hydroxy-4-aminobutyric acid.

The gentamicin family, which includes gentamicins C₁, C_{1a}, and C₂, sisomicin, and netilmicin (the 1-N-ethyl derivative of sisomicin), contains a different 3-amino sugar (garosamine). Variations in methylation of the other amino sugar result in the different components of gentamicin (Figure 54–1). These modifications appear to have little effect on biological activity.

Streptomycin differs from the other aminoglycoside antibiotics in that it contains streptidine rather than 2-deoxystreptamine, and the aminocyclitol is not in a central position, as shown here.

Figure 54-1. Sites of activity of various plasmid-mediated enzymes capable of inactivating aminoglycosides. The red X indicates regions of the molecules that are protected from the designated enzyme. In gentamicin C₁, R₁=R₂=CH₃; in gentamicin C₂, R₁=CH₃, R₂=H; in gentamicin C_{1a}, R₁=R₂=H. (Reproduced with permission from Moellering RC Jr. Microbiological considerations in the use of tobramycin and related aminoglycosidic aminocyclitol antibiotics. *MJA* 1977;25:4-8. Copyright 1977. The Medical Journal of Australia.)

Mechanism of Action. The aminoglycoside antibiotics are rapidly bactericidal. Bacterial killing is concentration dependent: The higher the concentration, the greater is the rate at which bacteria are killed. A post-antibiotic effect, that is, residual bactericidal activity persisting after the serum concentration has fallen below the minimum inhibitory concentration (MIC), also is characteristic of aminoglycoside antibiotics; the duration of this effect also is concentration dependent. These properties probably account for the efficacy of high-dose, extended-interval dosing regimens of aminoglycosides.

Aminoglycosides diffuse through aqueous channels formed by porin proteins in the outer membrane of gram-negative bacteria to enter the periplasmic space. Transport of aminoglycosides across the cytoplasmic (inner) membrane depends on electron transport, in part because of a requirement for a membrane electrical potential (interior negative) to drive permeation of these antibiotics. This phase of transport has been termed *energy-dependent phase I* (EDP₁). It is rate limiting and can be blocked or inhibited by divalent cations (e.g., Ca²⁺ and Mg²⁺), hyperosmolarity, a

reduction in pH, and anaerobic conditions. The last two conditions impair the ability of the bacteria to maintain the membrane potential, which is the driving force for transport. Thus, the antimicrobial activity of aminoglycosides is reduced markedly in the anaerobic environment of an abscess, in hyperosmolar acidic urine, and in other conditions that limit EDP₁ (Mingeot-Leclercq et al., 1999).

Once inside the cell, aminoglycosides bind to polysomes and interfere with protein synthesis by causing misreading and premature termination of mRNA translation (Figure 54–2).

The primary intracellular site of action of the aminoglycosides is the 30S ribosomal subunit, which consists of 21 proteins and a single 16S molecule of RNA. At least three of these ribosomal proteins, and perhaps the 16S ribosomal RNA as well, contribute to the streptomycin-binding site, and alterations of these molecules markedly affect the binding and subsequent action of streptomycin. For example, a single amino acid substitution of asparagine for lysine at position 42 of the S₁₂ ribosomal protein prevents binding of the drug; the resulting mutant is totally resistant to streptomycin. Substitution of glutamine for lysine creates a mutant that actually requires streptomycin for survival. The other aminoglycosides also bind to the 30S ribosomal subunit; however, they also appear to bind to several sites on the 50S ribosomal subunit (Davis, 1988).

Aminoglycosides disrupt the normal cycle of ribosomal function by interfering, at least in part, with the initiation of protein synthesis, leading to the accumulation of abnormal initiation complexes, or *streptomycin monosomes*, shown schematically in Figure 54–2B (Luzzatto et al., 1969). Aminoglycosides also cause misreading of the mRNA template and incorporation of incorrect amino acids into the growing polypeptide chains. Aminoglycosides vary in their

Figure 54–2. Effects of aminoglycosides on protein synthesis. **A.** Aminoglycoside (represented by red circles) binds to the 30S ribosomal subunit and interferes with initiation of protein synthesis by fixing the 30S–50S ribosomal complex at the start codon (AUG) of mRNA. As 30S–50S complexes downstream complete translation of mRNA and detach, the abnormal initiation complexes, so-called streptomycin monosomes, accumulate, blocking further translation of the message. Aminoglycoside binding to the 30S subunit also causes misreading of mRNA, leading to **B**, premature termination of translation with detachment of the ribosomal complex and incompletely synthesized protein or **C**, incorporation of incorrect amino acids (indicated by the red X), resulting in the production of abnormal or nonfunctional proteins.

capacity to cause misreading, presumably owing to differences in their affinities for specific ribosomal proteins. Although there appears to be a strong correlation between bactericidal activity and the ability to induce misreading (Hummel and Böck, 1989), it is not clear whether misreading is the primary mechanism of aminoglycoside-induced cell death.

The resulting aberrant proteins may be inserted into the cell membrane, leading to altered permeability and further stimulation of aminoglycoside transport (Busse et al., 1992). This phase of aminoglycoside transport, termed *energy-dependent phase II* (EDP_2), is poorly understood; however, EDP_2 may link to disruption of the structure of the cytoplasmic membrane, perhaps by the aberrant proteins. This concept is consistent with the observed progression of the leakage of small ions, followed by larger molecules and, eventually, by proteins from the bacterial cell prior to aminoglycoside-induced death. This progressive disruption of the cell envelope, as well as other vital cell processes, may help to explain the lethal action of aminoglycosides (Bryan, 1989).

Microbial Resistance to the Aminoglycosides. Bacteria may be resistant to aminoglycosides because of failure of the antibiotic to penetrate intracellularly, inactivation of the drug by microbial enzymes, or low affinity of the drug for the bacterial ribosome. Intrinsic resistance to aminoglycosides may be caused by failure of the drug to penetrate the cytoplasmic (inner) membrane. Penetration of drug across the outer membrane of gram-negative microorganisms into the periplasmic space can be slow, but resistance on this basis is unimportant clinically. Transport of aminoglycosides across the cytoplasmic membrane is an oxygen-dependent active process. Strictly anaerobic bacteria thus are resistant to these drugs because they lack the necessary transport system.

Similarly, facultative bacteria are resistant when they are grown under anaerobic conditions.

Clinically, drug inactivation is the most common mechanism for acquired microbial resistance to aminoglycosides. The genes encoding aminoglycoside-modifying enzymes are acquired primarily by conjugation and transfer of resistance plasmids (Davies, 1994) (Chapter 48). These enzymes phosphorylate, adenylate, or acetylate specific hydroxyl or amino groups (Figure 54–1). Amikacin is a suitable substrate for only a few of these inactivating enzymes (Figure 54–1); thus, strains that are resistant to multiple other aminoglycosides tend to be susceptible to amikacin. The metabolites of the aminoglycosides may compete with the unaltered drug for transport across the inner membrane, but they are incapable of binding effectively to ribosomes and interfering with protein synthesis. A significant percentage of clinical isolates of *Enterococcus faecalis* and *E. faecium* are highly resistant to all aminoglycosides. Infections caused by aminoglycoside-resistant strains of enterococci can be especially difficult to treat because of the loss of the synergistic bactericidal activity between a penicillin or vancomycin and an aminoglycoside (Spera and Farber, 1992; Vemuri and Zervos, 1993). Resistance to gentamicin indicates cross-resistance to tobramycin, amikacin, kanamycin, and netilmicin because the inactivating enzyme is bifunctional and can modify all these aminoglycosides. Owing to differences in the chemical structures of streptomycin and other aminoglycosides, this enzyme does not modify streptomycin, which is inactivated by another enzyme;

consequently, gentamicin-resistant strains of enterococci may be susceptible to streptomycin.

Resistance owing to mutations that alter ribosomal structure and reduce aminoglycoside binding is relatively uncommon. Missense mutations in *Escherichia coli* that substitute a single amino acid in a crucial ribosomal protein may prevent binding of streptomycin. Although highly resistant to streptomycin, these strains are not widespread in nature. Similarly, only 5% of strains of *Pseudomonas aeruginosa* exhibit such ribosomal resistance to streptomycin. Resistance in ~50% of streptomycin-resistant strains of enterococci is attributable to ribosomal mutations (Eliopoulos et al., 1984). Because ribosomal resistance usually is specific for streptomycin, these strains of enterococci remain sensitive to a combination of penicillin and gentamicin *in vitro*.

Antibacterial Spectrum of the Aminoglycosides. The antibacterial activity of gentamicin, tobramycin, kanamycin, netilmicin, and amikacin is directed primarily against aerobic gram-negative bacilli. Kanamycin, like streptomycin, has a more limited spectrum compared with other aminoglycosides; in particular, it should not be used to treat infections caused by *Serratia* or *P. aeruginosa*. The aerobic gram-negative bacilli vary in their susceptibility to the aminoglycosides (Table 54–1). Tobramycin and gentamicin exhibit similar activity against most gram-negative bacilli, although tobramycin usually is more active against *P. aeruginosa* and some *Proteus* spp., whereas gentamicin is usually more active against *Serratia*. Many gram-negative bacilli that are resistant to gentamicin because of plasmid-mediated inactivating enzymes also are resistant to tobramycin.

Amikacin and, in some instances, netilmicin retain their activity against gentamicin-resistant strains because they are a poor substrate for many of the aminoglycoside-inactivating enzymes.

Aminoglycosides have little activity against anaerobic microorganisms or facultative bacteria under anaerobic conditions. Their action against most gram-positive bacteria is limited, and they should not be used as single agents to treat infections caused by gram-positive bacteria. In combination with a cell wall-active agent, such as a penicillin or vancomycin, an aminoglycoside produces a synergistic bactericidal effect *in vitro*. Clinically, the superiority of aminoglycoside combination regimens over β -lactams alone is not proven except in relatively few infections (discussed later).

Absorption, Distribution, Dosing, and Elimination of the Aminoglycosides

Absorption. The aminoglycosides are highly polar cations and therefore are very poorly absorbed from the GI tract. Less than 1% of a dose is absorbed after either oral or rectal administration. The drugs are not inactivated in the intestine and are eliminated quantitatively in the feces. Long-term oral or rectal administration of aminoglycosides may result in accumulation to toxic concentrations in patients with renal impairment. Absorption of gentamicin from the GI tract may be increased by GI disease (e.g., ulcers or inflammatory bowel disease). Instillation of these drugs into body cavities with serosal surfaces also may result in rapid absorption and unexpected toxicity (i.e., neuromuscular blockade). Similarly, intoxication may occur when aminoglycosides are applied topically for long periods to large

wounds, burns, or cutaneous ulcers, particularly if there is renal insufficiency.

All the aminoglycosides are absorbed rapidly from intramuscular sites of injection. Peak concentrations in plasma occur after 30-90 minutes and are similar to those observed 30 minutes after completion of an intravenous infusion of an equal dose over a 30-minute period. These concentrations typically range from 4-12 $\mu\text{g/mL}$ following a 1.5-2 mg/kg dose of gentamicin, tobramycin, or netilmicin and from 20 to 35 $\mu\text{g/mL}$ following a 7.5 mg/kg dose of amikacin or kanamycin. In critically ill patients, especially those in shock, absorption of drug may be reduced from intramuscular sites because of poor perfusion.

There is increasing use of aminoglycosides administered via inhalation, primarily for the management of patients with cystic fibrosis who have chronic *Pseudomonas aeruginosa* pulmonary infections. Amikacin and tobramycin solutions for injection have been used, as well as a commercial formulation of tobramycin designed for inhalation (TOBI, others). Studies of this formulation indicate that high sputum concentrations are obtained (mean of 1200 $\mu\text{g/g}$), but serum concentrations remain low (mean peak concentration of 0.95 $\mu\text{g/mL}$) (Geller et al., 2002).

Distribution. Because of their polar nature, the aminoglycosides do not penetrate into most cells, the CNS, or the eye. Except for streptomycin, there is negligible binding of aminoglycosides to plasma albumin. The apparent volume of distribution of these drugs is 25% of lean body weight and approximates the volume of extracellular fluid. The aminoglycosides distribute poorly into adipose tissue, which must be considered when using weight-based dosing regimens in obese patients. Approaches using ideal or adjusted body weight are recommended in conjunction with drug-level monitoring to avoid excessive serum concentrations.

Concentrations of aminoglycosides in secretions and tissues are low. High concentrations are found only in the renal cortex and the endolymph and perilymph of the inner ear; the high concentration in these sites likely contribute to the nephrotoxicity and ototoxicity caused by these drugs. As a result of active hepatic secretion, concentrations in bile approach 30% of those found in plasma, but this represents a very minor excretory route for the aminoglycosides. Penetration into respiratory secretions is poor (Panidis et al., 2005). Diffusion into pleural and synovial fluid is relatively slow, but concentrations that approximate those in the plasma may be achieved after repeated administration. Inflammation increases the penetration of aminoglycosides into peritoneal and pericardial cavities.

Concentrations of aminoglycosides achieved in CSF with parenteral administration usually are subtherapeutic. In patients, concentrations in CSF in the absence of inflammation are <10% of those in plasma; this value may approach 25% when there is meningitis (Kearney and Aweeka, 1999). Given the limit on dosage escalation due to the toxicity of aminoglycosides, treatment of meningitis with intravenous administration is generally suboptimal. Intrathecal or intraventricular administration of aminoglycosides has been used to achieve therapeutic levels, but the availability of third- and fourth-generation cephalosporins has made this unnecessary in most cases. Penetration of aminoglycosides into ocular fluids is so poor that effective therapy of bacterial endophthalmitis requires periocular and intraocular injections of the drugs.

Administration of aminoglycosides to women late in pregnancy may result in accumulation of drug in fetal plasma and amniotic fluid. Streptomycin and tobramycin can cause hearing loss in children born to women who receive the drug during pregnancy. Insufficient data are available regarding the other aminoglycosides; it is therefore recommended that they be used with caution during pregnancy and only for strong clinical indications in the absence of suitable alternatives.

Elimination. The aminoglycosides are excreted almost entirely by glomerular filtration, and urine concentrations of 50-200 $\mu\text{g/mL}$ are achieved. A large fraction of a parenterally administered dose is excreted unchanged during the first 24 hours, with most of this appearing in the first 12 hours. The half-lives of the aminoglycosides in plasma are similar, 2-3 hours in patients with normal renal function. Renal clearance of aminoglycosides is approximately two-thirds of the simultaneous creatinine clearance; this observation suggests some tubular reabsorption of these drugs.

After a single dose of an aminoglycoside, disappearance from the plasma exceeds renal excretion by 10-20%; however, after 1-2 days of therapy, nearly 100% of subsequent doses eventually is recovered in the urine. This lag period probably represents saturation of binding sites in tissues. The rate of elimination of drug from these sites is considerably longer than from plasma; the $t_{1/2}$ for tissue-bound aminoglycoside has been estimated to range from 30 to 700 hours. For this reason, small amounts of aminoglycosides can be detected in the urine for 10-20 days after drug administration is discontinued. Aminoglycoside bound to renal tissue exhibits antibacterial activity and protects experimental animals against bacterial infections of the kidney even when the drug no longer can be detected in serum (Bergeron et al., 1982).

The concentration of aminoglycoside in plasma produced by the initial dose depends only on the volume of distribution of the drug. Because the elimination of aminoglycosides depends almost entirely on the kidney, a linear relationship exists between the concentration of creatinine in plasma and the $t_{1/2}$ of all aminoglycosides in patients with moderately compromised renal function. In anephric patients, the $t_{1/2}$ varies from 20-40 times that is determined in normal individuals. *Because the incidence of nephrotoxicity and ototoxicity is likely related to the overall drug exposure to aminoglycosides, it is critical to reduce the maintenance dosage of these drugs in patients with impaired renal function.*

Aminoglycosides can be removed from the body by either hemodialysis or peritoneal dialysis. Approximately 50% of the administered dose is removed in 12 hours by hemodialysis, which has been used for the treatment of overdose. As a general rule, a dose equal to half the loading dose administered after each hemodialysis should maintain the plasma concentration in the desired range; however, a number of variables make this a rough approximation at best. Continuous arteriovenous hemofiltration (CAVH) and continuous venovenous hemofiltration (CVVH) will result in aminoglycoside clearances approximately equivalent to 15 and 15-30 mL/min of creatinine clearance, respectively, depending on the flow rate. The amount of aminoglycoside removed can be replaced by administering ~15-30% of the maximum daily dose (Table 54-2) each day. Frequent monitoring of plasma drug concentrations is again crucial.

Peritoneal dialysis is less effective than hemodialysis in removing aminoglycosides. Clearance rates are ~5-10 mL/min for the various drugs but are highly variable. If a patient who requires

Table 54-2

Algorithm for Dose Reduction of Aminoglycosides Based on Calculated Creatinine Clearance

CREATININE CLEARANCE (mL/min)	% OF MAXIMUM DAILY DOSE*	FREQUENCY OF DOSING
100	100	Every 24 hours
75	75	
50	50	
25	25	
20	80	Every 48 hours
10	60	
<10	40	

*The maximum adult daily dose for amikacin, kanamycin, and streptomycin is 15 mg/kg; for gentamicin and tobramycin, 5.5 mg/kg; and for netilmicin, 6.5 mg/kg.

dialysis has bacterial peritonitis, a therapeutic concentration of the aminoglycoside probably will not be achieved in the peritoneal fluid because the ratio of the concentration in plasma to that in peritoneal fluid may be 10:1 (Smithivas et al., 1971). Thus, it is recommended that antibiotic be added to the dialysate to achieve concentrations equal to those desired in plasma.

Aminoglycosides can be inactivated by various penicillins *in vitro* and thus should not be admixed in solution. Some reports indicate that this inactivation may occur *in vivo* in patients with end-stage renal failure (Blair et al., 1982), thus making monitoring of aminoglycoside plasma concentrations even more necessary in such patients. Amikacin appears to be the aminoglycoside least affected by this interaction, and penicillins with more nonrenal elimination (such as piperacillin) may be less prone to cause this interaction.

Although excretion of aminoglycosides is similar in adults and children >6 months of age, half-lives of the drugs may be prolonged significantly in the newborn: 8-11 hours in the first week of life in newborns weighing <2 kg and ~5 hours in those weighing >2 kg (Yow, 1977). Thus, it is critically important to monitor plasma concentrations of aminoglycosides during treatment of neonates (Philips et al., 1982). For unknown reasons, aminoglycoside clearances are increased and half-lives are reduced in patients with cystic fibrosis compared to subjects without cystic fibrosis, after controlling for age and weight (Mann et al., 1985). Larger doses of aminoglycosides may likewise be required in burn patients because of more rapid drug clearance, possibly because of drug loss through burn tissue.

Dosing. Recommended doses of individual aminoglycosides in the treatment of specific infections are given in later sections of this chapter. Historically, aminoglycosides have been administered as two or three equally divided doses, based on the short $t_{1/2}$ of the drugs. However, studies of the pharmacokinetic/pharmacodynamic properties of aminoglycosides demonstrate that administering higher doses at extended intervals (typically once daily in patients with normal renal function) is likely to be at least equally efficacious and potentially less toxic than administration of divided doses.

Figure 54-3. Plasma concentrations ($\mu\text{g}/\text{mL}$) after administration of 5.1 mg/kg of gentamicin intravenously to a hypothetical patient either as a single dose (every 24h) or as three divided doses (every 8h). The threshold for toxicity has been chosen to correspond to a plasma concentration of 2 $\mu\text{g}/\text{mL}$, the maximum recommended. The high-dose, extended-interval (once-daily) regimen produces a 3-fold higher plasma concentration, which enhances efficacy that otherwise might be compromised due to prolonged sub-MIC concentrations later in the dosing interval compared with the every-8-hours regimen. The once-daily regimen provides a 12-hour period during which plasma concentrations are below the threshold for toxicity, thereby minimizing the toxicity that otherwise might result from the high plasma concentrations early on. The every-8-hours regimen, in contrast, provides only a brief period during which plasma concentrations are below the threshold for toxicity.

A comparison of this high-dose, extended-interval dosing method to traditional divided-dose methods is illustrated in Figure 54-3. Because of the post-antibiotic effect of aminoglycosides, good therapeutic response can be attained even when concentrations of aminoglycosides fall below inhibitory concentrations for a substantial fraction of the dosing interval. High-dose, extended-interval dosing schemes for aminoglycosides may also reduce the characteristic ototoxicity and nephrotoxicity of these drugs. This diminished toxicity is probably due to a threshold effect from accumulation of drug in the inner ear or in the kidney. More drug accumulates with higher plasma concentrations, particularly at trough, and with prolonged periods of exposure. Net elimination of aminoglycoside from these organs occurs more slowly when plasma concentrations are relatively high. High-dose, extended-interval regimens, despite the higher peak concentration, provide a longer period when concentrations fall below the threshold for toxicity than does a multiple-dose regimen (12 hours versus <3 hours total in the example shown in Figure 54-3), potentially accounting for the lower toxicity of this approach.

Numerous studies and meta-analyses demonstrate that administration of the total dose once daily is associated with less nephrotoxicity and is just as effective as multiple-dose regimens (Bailey et al., 1997; Buijk et al., 2002). Extended-interval dosing also costs less and is administered more easily. For these reasons, high-dose, extended-interval administration of aminoglycosides is the preferred means of administering aminoglycosides for most indications and patient populations. Although the use of extended-interval dosing has been controversial in pregnancy, neonatal, and pediatric infections

(Knoderer et al., 2003; Rastogi et al., 2002), data from meta-analyses now support this mode of administration in appropriately selected patients from these populations (Contopoulos-Ioannidis et al., 2004; Nestaas et al., 2005; Ward and Theiler, 2008). One key exception to the use of extended-interval dosing is for aminoglycoside use as combination therapy with a cell wall-active agent in the treatment of gram-positive infections, such as endocarditis. In these infections, administration of multiple daily doses (with a lower total daily dose) is preferred because data documenting equivalent safety and efficacy of extended-interval dosing are inadequate. Although schemes exist for adjusting dosages of aminoglycosides dosed by extended-interval methods in patients with significant renal dysfunction (i.e., creatinine clearance <25 mL/minute), some clinicians prefer to use the traditional multiple-dose regimen in such patients.

Nomograms may be helpful in selecting initial doses, but variability in aminoglycoside clearance among patients is too great for these to be relied on for more than a few days (Bartal et al., 2003). If it is anticipated that the patient will be treated with an aminoglycoside for >3-4 days, then plasma concentrations should be monitored to avoid drug accumulation. Whether extended-interval or multiple-daily dosing is chosen, the dose must be adjusted for patients with creatinine clearances of <80-100 mL/minute (Table 54-2), and plasma concentrations must be monitored. Determination of the concentration of drug in plasma is an essential guide to the proper administration of aminoglycosides. In patients with life-threatening systemic infections, aminoglycoside concentrations should be determined several times per week (more frequently if renal function is changing) and should be determined within 24-48 hours of a change in dosage. The size of the individual dose, the interval between doses, or both can be altered based on the results of monitoring of drug levels in plasma. Methods for calculation of dosage are described in Appendix II. There are obvious difficulties in using any of these approaches for ill patients with rapidly changing renal function. In addition, even when known factors are taken into consideration, concentrations of aminoglycosides achieved in plasma after a given dose vary widely among patients. If the extracellular volume is expanded, the volume of distribution is increased, and concentrations will be reduced.

For twice- or thrice-daily dosing regimens, both peak and trough plasma concentrations are determined. The trough sample is obtained just before a dose, and the peak sample is obtained 60 minutes after intramuscular injection or 30 minutes after an intravenous infusion given over 30 minutes. The peak concentration documents that the dose produces therapeutic concentrations, generally accepted to be 4-10 $\mu\text{g/mL}$ for gentamicin, netilmicin, and tobramycin and 15-30 $\mu\text{g/mL}$ for amikacin and streptomycin. The trough concentration is used to avoid toxicity by monitoring for accumulation of drug. Trough concentrations should be <1-2 $\mu\text{g/mL}$ for gentamicin, netilmicin, and tobramycin and <10 $\mu\text{g/mL}$ for amikacin and streptomycin.

Monitoring of aminoglycoside plasma concentrations also is important when using an extended-interval dosing regimen, although peak concentrations are not determined routinely (these will be three to four times higher than the peak achieved with a multiple-daily-dosing regimen). Several approaches may be used to determine that drug is being cleared and not accumulating.

The most accurate method for monitoring plasma levels for dose adjustment is to measure the concentration in two plasma samples drawn several hours apart (e.g., at 2 and 12 hours after a dose).

The clearance then can be calculated and the dose adjusted to achieve the desired target range.

Another approach relies on nomograms to target a range of concentrations in a sample obtained earlier in the dosing interval. For example, if the plasma concentration from a sample obtained 8 hours after a dose of gentamicin is between 1.5 and 6 $\mu\text{g/mL}$, then the concentration at 18 hours will be <1 $\mu\text{g/mL}$ (Chambers et al., 1998). Target ranges of 1-1.5 $\mu\text{g/mL}$ for gentamicin at 18 hours for patients with creatinine clearances >50 mL/min and 1-2.5 $\mu\text{g/mL}$ for those with clearances <50 mL/min also have been used. This method also tends to be inaccurate, particularly when conditions that alter aminoglycoside clearance are present (Bartal et al., 2003; Toschlog et al., 2003).

The simplest method is to obtain a trough sample 24 hours after dosing and adjust the dose to achieve the recommended plasma concentration, (e.g., <1-2 $\mu\text{g/mL}$ in the case of gentamicin or tobramycin). This approach probably is the least desirable. An undetectable trough concentration could reflect grossly inadequate dosing in patients who clear the drug rapidly with prolonged periods (perhaps well over half the dosing interval) during which concentrations are subtherapeutic. In contrast, a 24-hour trough concentration target of 1-2 $\mu\text{g/mL}$ actually would increase aminoglycoside exposure compared with a multiple-daily-dosing regimen (Barclay et al., 1999), which defeats the goal of providing a washout with concentrations of 0-1 $\mu\text{g/mL}$ between 18 and 24 hours after a dose.

Untoward Effects

All aminoglycosides have the potential to produce reversible and irreversible vestibular, cochlear, and renal toxicity. These side effects complicate the use of these compounds and make their proper administration difficult.

Ototoxicity. Vestibular and auditory dysfunction can follow the administration of any of the aminoglycosides, and ototoxicity may become a dose-limiting adverse effect. Aminoglycoside induced ototoxicity results in irreversible, bilateral high-frequency hearing loss and temporary vestibular hypofunction. Degeneration of hair cells and neurons in the cochlea correlates with the loss of hearing. With increasing dosage and prolonged exposure, damage progresses from the base of the cochlea, where high-frequency sounds are processed, to the apex, which is necessary for the perception of low frequencies. Although these histological changes correlate with the ability of the cochlea to generate an action potential in response to sound, the biochemical mechanism for ototoxicity is poorly understood. Early changes induced by aminoglycosides in experimental ototoxicity are reversible by Ca^{2+} . Once sensory cells are lost, however, regeneration does not occur; retrograde degeneration of the auditory nerve follows, resulting in irreversible hearing loss.

Aminoglycosides may interfere with the active transport system essential for the maintenance of the

ionic balance of the endolymph (Neu and Bendush, 1976). Ototoxicity is largely irreversible and results from progressive destruction of vestibular or cochlear sensory cells, which are highly sensitive to damage by aminoglycosides. The degree of permanent dysfunction correlates with the number of destroyed or altered sensory hair cells and is related to sustained exposure to the drug. An iron-aminoglycoside complex is postulated to potentiate reactive oxygen species–induced cellular degeneration in the cochlea (Guthrie, 2008).

Accumulation within the perilymph and endolymph occurs predominantly when aminoglycoside concentrations in plasma are high. Diffusion back into the bloodstream is slow; the half-lives of the aminoglycosides are five to six times longer in the otic fluids than in plasma. Back diffusion is concentration dependent and facilitated at the trough concentration of drug in plasma. Thus, it is generally thought that ototoxicity is more likely to occur in patients with persistently elevated concentrations of drug in plasma. However, studies have not consistently shown an association between ototoxicity and putative risk factors such as aminoglycoside serum levels, total dose and duration of aminoglycoside exposure, and renal dysfunction (including aminoglycoside-induced nephrotoxicity) (de Jager and van Altena, 2002; Peloquin et al., 2004). Drugs such as ethacrynic acid and furosemide potentiate the ototoxic effects of the aminoglycosides in animals, but data from humans implicating furosemide are less convincing (Moore et al., 1984). Hearing loss following exposure to these agents also is more likely to develop in patients with pre-existing auditory impairment.

The description of families where several members experienced profound deafness from as little as a single dose of aminoglycoside led to the investigation of a potential genetic predisposition for this toxicity. Subsequent studies have identified several predisposing mutations in mitochondrial ribosomal RNA genes (Fischel-Ghodsian, 2005). The contribution of genetic susceptibility to the overall incidence of aminoglycoside-induced ototoxicity is unclear, but surveys of subjects of European origin put the prevalence of one of these mutations at 1 in 500 (Vandebona et al., 2009).

Although all aminoglycosides can affect cochlear and vestibular function, there is some preferential toxicity. Streptomycin and gentamicin produce predominantly vestibular effects, whereas amikacin, kanamycin, and neomycin primarily affect auditory function; tobramycin affects both equally. The incidence of ototoxicity is difficult to determine. Audiometric data suggest that the incidence may be as high as 25% (de Jager and van Altena, 2002); however, these data need to be interpreted in the context of the limitations of audiometric testing in acutely ill patients and day-to-day variability of audiometric testing (Brummett and Morrison, 1990). The relative incidence appears to be equal for tobramycin, gentamicin, and amikacin. Initial studies suggested that netilmicin is less ototoxic than other aminoglycosides (Lerner et al., 1983); however, the incidence of ototoxicity from netilmicin is not negligible—such complications developed in 10% of patients in one clinical trial of netilmicin. The incidence of vestibular toxicity is particularly high in patients receiving streptomycin; nearly 20% of individuals who received 500 mg twice daily for 4 weeks for enterococcal endocarditis developed clinically detectable irreversible vestibular damage (Wilson et al., 1984).

In addition, up to 75% of patients who received 2 g streptomycin for >60 days showed evidence of nystagmus or postural imbalance.

Because the initial symptoms may be reversible, patients receiving high doses and/or prolonged courses of aminoglycosides should be monitored carefully for ototoxicity; however, deafness may occur several weeks after therapy is discontinued. Screening patients for a family history of aminoglycoside-induced deafness seems reasonable, but the cost effectiveness of genetic screening for mutations predisposing to aminoglycoside ototoxicity is not yet clear.

Clinical Symptoms of Cochlear Toxicity. A high-pitched tinnitus often is the first symptom of toxicity. If the drug is not discontinued, auditory impairment may develop after a few days. The tinnitus may persist for several days to 2 weeks after therapy is stopped. Because perception of sound in the high-frequency range (outside the conversational range) is lost first, the affected individual is not always aware of the difficulty, and it will not be detected except by careful audiometric examination. If the hearing loss progresses, the lower sound ranges are affected, and conversation becomes difficult.

Clinical Symptoms of Vestibular Toxicity. Moderately intense headache lasting 1–2 days may precede the onset of labyrinthine dysfunction. This is followed immediately by an acute stage in which nausea, vomiting, and difficulty with equilibrium develop and persist for 1–2 weeks. Prominent symptoms include vertigo in the upright position, inability to perceive termination of movement (“mental past-pointing”), and difficulty in sitting or standing without visual cues. Drifting of the eyes at the end of a movement so that both focusing and reading are difficult, a positive Romberg test, and rarely, pendular trunk movement and spontaneous nystagmus, are prominent signs. The acute stage ends suddenly and is followed by the appearance of manifestations of chronic labyrinthitis, in which, although symptomless while in bed, the patient has difficulty when attempting to walk or make sudden movements; ataxia is the most prominent feature. The chronic phase persists for ~2 months; it is gradually superseded by a compensatory stage in which symptoms are latent and appear only when the eyes are closed. Adaptation to the impairment of labyrinthine function is accomplished by the use of visual cues and deep proprioceptive sensation for determining movement and position. It is more adequate in the young than in the old but may not be sufficient to permit the high degree of coordination required in many special trades. Recovery from this phase may require 12–18 months, and most patients have some permanent residual damage. Although there is no specific treatment for the vestibular deficiency, early discontinuation of the drug may permit recovery before irreversible damage of the hair cells.

Nephrotoxicity. Approximately 8–26% of patients who receive an aminoglycoside for several days develop mild renal impairment that is almost always reversible. The toxicity results from accumulation and retention of aminoglycoside in the proximal tubular cells (Lietman and Smith, 1983). The initial manifestation of damage at this site is excretion of enzymes of the renal tubular brush border (Banday et al., 2008). After several days, there is a defect in renal concentrating ability, mild proteinuria, and the appearance of hyaline and granular casts. The glomerular filtration rate is reduced after several additional days (Schentag et al., 1979). The non-oliguric phase of renal insufficiency is thought to be due to the effects of aminoglycosides on the distal portion of the nephron with a reduced sensitivity

of the collecting-duct epithelium to endogenous antidiuretic hormone (Appel, 1982). Although severe acute tubular necrosis may occur rarely, the most common significant finding is a mild rise in plasma creatinine (5–20 $\mu\text{g}/\text{mL}$; 40–175 μM). Hypokalemia, hypocalcemia, and hypophosphatemia are seen very infrequently. The impairment in renal function is almost always reversible because the proximal tubular cells have the capacity to regenerate.

The biochemical events leading to tubular cell damage and glomerular dysfunction are poorly understood but may involve perturbations of the structure of cellular membranes. Aminoglycosides inhibit various phospholipases, sphingomyelinases, and ATPases, and they alter the function of mitochondria and ribosomes (Humes et al., 1984; Queener et al., 1983). Because of the ability of cationic aminoglycosides to interact with anionic phospholipids, these drugs may impair the synthesis of membrane-derived autacoids and intracellular second messengers such as prostaglandins, inositol phosphates, and diacylglycerol.

Several variables appear to influence nephrotoxicity from aminoglycosides. Toxicity correlates with the total amount of drug administered. Consequently, toxicity is more likely to be encountered with longer courses of therapy. Continuous infusion is more nephrotoxic in animals than intermittent dosing (Powell et al., 1983). High-dose, extended-interval dosing approaches lead to less nephrotoxicity at the same level of total drug exposure (as measured by area under the curve) than divided-dose approaches (Figure 54-3). Advanced age, liver disease, diabetes mellitus, and septic shock have been suggested as risk factors for the development of nephrotoxicity from aminoglycosides, but data are not convincing. Note, however, that renal function in the elderly patient is overestimated by measurement of creatinine concentration in plasma, and overdosing will occur if this value is used as the only guide in this patient population (Baciewicz et al., 2003).

The nephrotoxic potential varies among individual aminoglycosides. The relative toxicity correlates with the concentration of drug found in the renal cortex in experimental animals. Neomycin, which concentrates to the greatest degree, is highly nephrotoxic in human beings and should not be administered systemically. Streptomycin does not concentrate in the renal cortex and is the least nephrotoxic. Most of the controversy has concerned the relative toxicities of gentamicin and tobramycin. If differences between the renal toxicity of these two aminoglycosides do exist in human beings, they appear to be slight. Comparative studies with amikacin, sisomicin, and netilmicin are not conclusive. Other drugs, such as amphotericin B, vancomycin, angiotensin-converting enzyme inhibitors, cisplatin, and cyclosporine, may potentiate aminoglycoside-induced nephrotoxicity (Wood et al., 1986). Clinical studies have not proven conclusively that furosemide potentiates aminoglycoside nephrotoxicity (Smith and Lietman, 1983), but volume depletion and wasting of K^+ that accompany the use of furosemide may predispose to aminoglycoside toxicity.

Neuromuscular Blockade. An unusual toxic reaction of acute neuromuscular blockade and apnea has been attributed to the aminoglycosides. The order of decreasing potency for blockade is neomycin, kanamycin, amikacin, gentamicin, and tobramycin. In humans, neuromuscular blockade generally has occurred after intrapleural or intraperitoneal instillation of large doses of an aminoglycoside; however, the reaction can follow intravenous, intramuscular, and even

oral administration of these agents. Most episodes have occurred in association with anesthesia or the administration of other neuromuscular blocking agents. Patients with myasthenia gravis are particularly susceptible to neuromuscular blockade by aminoglycosides (Chapter 11).

Aminoglycosides may inhibit prejunctional release of acetylcholine while also reducing postsynaptic sensitivity to the transmitter, but Ca^{2+} can overcome this effect, and the intravenous administration of a calcium salt is the preferred treatment for this toxicity (Sarkar et al., 1992). Inhibitors of acetylcholinesterase (e.g., edrophonium and neostigmine) also have been used with varying degrees of success.

Other Untoward Effects. In general, the aminoglycosides have little allergenic potential; anaphylaxis and rash are unusual. Rare hypersensitivity reactions—including skin rashes, eosinophilia, fever, blood dyscrasias, angioedema, exfoliative dermatitis, stomatitis, and anaphylactic shock—have been reported as cross-hypersensitivity among drugs in this class. Parenterally administered aminoglycosides are not associated with pseudomembranous colitis, probably because they do not disrupt the normal anaerobic flora. Other reactions that have been attributed to individual drugs are discussed next.

Therapeutic Uses of Gentamicin and Other Aminoglycosides

Gentamicin is an important agent for the treatment of many serious gram-negative bacillary infections. It is the aminoglycoside of first choice because of its lower cost and reliable activity against all but the most resistant gram-negative aerobes. Gentamicin preparations are available for parenteral, ophthalmic, and topical administration.

Gentamicin, tobramycin, amikacin, and netilmicin can be used interchangeably for the treatment of most of the following infections and therefore are discussed together. For most indications, gentamicin is the preferred agent because of long experience with its use and its lower cost. Many different types of infections can be treated successfully with these aminoglycosides; however, owing to their toxicities, prolonged use should be restricted to the therapy of life-threatening infections and those for which a less toxic agent is contraindicated or less effective.

Aminoglycosides frequently are used in combination with a cell wall–active agent (β -lactam or glycopeptide) for the therapy of serious proven or suspected bacterial infections. Three rationales exist for this approach:

- To expand the empiric spectrum of activity of the antimicrobial regimen to ensure the presence of at least one drug active against a suspected pathogen.

- To provide synergistic bacterial killing.
- To prevent the emergence of resistance to the individual agents.

The first rationale is the most common justification for the use of combination therapy in infections such as healthcare-associated pneumonia or sepsis, where multidrug-resistant gram-negative organisms such as *P. aeruginosa*, *Enterobacter*, *Klebsiella*, and *Serratia* may be causative and the consequences of failing to provide initially active therapy are dire (Dupont et al., 2001). This approach leverages the high levels of coverage that aminoglycosides continue to provide against this organism. The use of aminoglycosides to achieve synergistic bacterial killing and improve microbiological eradication and clinical response is most well established for the treatment of endocarditis due to gram-positive organisms, most importantly *Enterococcus*. Clinical data do not support the use of combination therapy for synergistic killing of gram-negative organisms, with the possible exceptions of serious *P. aeruginosa* infections (Paul et al., 2003, 2004; Safdar et al., 2004). With the exception of mycobacterial infections, the use of aminoglycosides to prevent the emergence of resistance is not supported by clinical data, despite establishment as an *in vitro* phenomenon (Bliziotis et al., 2005).

Gentamicin

The typical recommended intramuscular or intravenous dose of gentamicin sulfate when used for the treatment of known or suspected gram-negative organisms as a single agent or in combination therapy for adults with normal renal function is 5-7 mg/kg daily given over 30-60 minutes. For patients with renal dysfunction, the interval may be extended. For patients who are not candidates for extended-interval dosing, a typical dosing regimen for gram-negative coverage is a loading dose of 2 mg/kg and then 3-5 mg/kg per day, one-third given every 8 hours when administered as a multiple-daily-dosing regimen. Dosages at the upper end of this range may be required to achieve therapeutic levels for trauma or burn patients, those with septic shock, patients with cystic fibrosis, and others in whom drug clearance is more rapid or volume of distribution is larger than normal. Several dosage schedules have been suggested for newborns and infants: 3 mg/kg once daily for preterm newborns <35 weeks of gestation (Hansen et al., 2003; Rastogi et al., 2002); 4 mg/kg once daily for newborns >35 weeks of gestation; 5 mg/kg daily in two divided doses for neonates with severe infections; and 2-2.5 mg/kg every 8 hours for children up to 2 years of age. Peak plasma concentrations range from 4-10 mg/mL (dosing: 1.7 mg/kg every 8 hours) and 16-24 mg/mL (dosing: 5.1 mg/kg once daily). It should be emphasized that the recommended doses of gentamicin do not always yield desired concentrations. Periodic determinations of the plasma concentration of aminoglycosides are recommended strongly, especially in seriously ill patients, to confirm that drug

concentrations are in the desired range (see earlier sections on dosing for more details).

Urinary Tract Infections. Aminoglycosides usually are not indicated for the treatment of uncomplicated urinary tract infections, although a single intramuscular dose of gentamicin (5 mg/kg) has been effective in uncomplicated infections of the lower urinary tract. However, as strains of *E. coli* have acquired resistance to β -lactams, trimethoprim-sulfamethoxazole, and fluoroquinolones, use of aminoglycosides may increase. In the seriously ill patient with pyelonephritis, an aminoglycoside alone or in combination with a β -lactam antibiotic offers broad and effective initial coverage. Once the microorganism is isolated and its sensitivities to antibiotics are determined, the aminoglycoside should be discontinued if the infecting microorganism is sensitive to less toxic antibiotics.

Pneumonia. The organisms that cause community-acquired pneumonia are susceptible to broad-spectrum β -lactam antibiotics, macrolides, or a fluoroquinolone, and usually it is not necessary to add an aminoglycoside. Therapy with an aminoglycoside alone is likely to be ineffective; therapeutic concentrations are difficult to achieve owing to relatively poor penetration of drug into inflamed tissues and the associated conditions of low O_2 tension and low pH—both of which interfere with aminoglycoside antibacterial activity. Aminoglycosides are ineffective for the treatment of pneumonia due to anaerobes or *S. pneumoniae*, which are common causes of community-acquired pneumonia. They should not be considered as effective single-drug therapy for any aerobic gram-positive cocci (including *S. aureus* or streptococci), the microorganisms commonly responsible for suppurative pneumonia or lung abscess. An aminoglycoside in combination with a β -lactam antibiotic is recommended as standard therapy for hospital-acquired pneumonia in which a multiple-drug-resistant gram-negative aerobe is a likely causative agent (American Thoracic Society, 2005). Once it is established that the β -lactam is active against the causative agent, there is generally no benefit from continuing the aminoglycoside. Patients presenting with pulmonary exacerbations of cystic fibrosis often receive aminoglycosides as a component of therapy. Due to the altered pharmacokinetics of aminoglycosides in cystic fibrosis patients, higher daily doses (up to 10 mg/kg/day) may be necessary.

Meningitis. Availability of third-generation cephalosporins, especially cefotaxime and ceftriaxone, has reduced the need for treatment with aminoglycosides in most cases of meningitis, except for infections caused by gram-negative organisms resistant to β -lactam antibiotics (e.g., species of *Pseudomonas* and *Acinetobacter*). If therapy with an aminoglycoside is necessary, in adults, 5 mg of a preservative-free formulation of gentamicin (or equivalent dose of another aminoglycoside) is administered directly intrathecally or intraventricularly once daily (Barnes et al., 2003).

Peritonitis Associated with Peritoneal Dialysis. Patients who develop peritonitis as a result of peritoneal dialysis may be treated with aminoglycoside diluted into the dialysis fluid to a concentration of 4-8 mg/L for gentamicin, netilmicin, or tobramycin or 6-12 mg/L for amikacin. Intravenous or intramuscular administration of drug is unnecessary because serum and peritoneal fluid will equilibrate rapidly.

Bacterial Endocarditis. “Synergistic” or low-dose gentamicin (3 mg/kg per day in three divided doses) in combination with a penicillin or

vancomycin has been recommended in certain circumstances for treatment of infections due to gram-positive organisms, primarily bacterial endocarditis. Penicillin and gentamicin in combination are effective as a short-course (i.e., 2-week) regimen for uncomplicated native-valve streptococcal endocarditis. In cases of enterococcal endocarditis, concomitant administration of penicillin and gentamicin for 4-6 weeks has been recommended because of an unacceptably high relapse rate with penicillin alone. A large case series from Sweden, however, found that cure rates were not substantially affected by shortening the duration of aminoglycoside therapy to a median of 15 days (Olaison and Schadewitz, 2002). A 2-week regimen of gentamicin or tobramycin in combination with nafcillin is effective for the treatment of selected cases of staphylococcal tricuspid native-valve endocarditis in intravenous drug users (Chambers et al., 1988), although the need to include the aminoglycoside is not established (Le and Bayer, 2003). For patients with native mitral or aortic valve staphylococcal endocarditis, the risks of aminoglycoside administration likely outweigh the benefits (Cosgrove et al., 2009). Administration of an aminoglycoside in combination with a cell wall-active agent and rifampin is recommended for treatment of staphylococcal prosthetic valve endocarditis, but clinical studies supporting this practice are limited.

Sepsis. Inclusion of an aminoglycoside in an empirical regimen is commonly recommended for the febrile patient with granulocytopenia and for sepsis when *P. aeruginosa* is a potential pathogen. Most studies that demonstrate a benefit for combination aminoglycoside therapy in these infections compared weak β -lactams (e.g., carbenicillin, no longer marketed in the U.S.) alone versus these agents plus an aminoglycoside (Paul et al., 2003, 2004). More recent studies using potent broad-spectrum β -lactams (e.g., carbapenems and anti-pseudomonal cephalosporins) have demonstrated no benefit from adding an aminoglycoside to the regimen. If there is concern that an infection may be caused by a multiple-drug-resistant organism that may be susceptible only to an aminoglycoside, then adding this antibiotic to the regimen is reasonable. Evidence that aminoglycosides are beneficial for other gram-negative infections is weak if the isolate is susceptible to other antibiotics. *To avoid toxicity, aminoglycosides should be used briefly and sparingly as long as other alternatives are available.*

Topical Applications. Gentamicin is absorbed slowly when it is applied topically in an ointment and somewhat more rapidly when it is applied as a cream. When the antibiotic is applied to large areas of denuded body surface, as may be the case in burned patients, plasma concentrations can reach 4 $\mu\text{g}/\text{mL}$, and 2-5% of the drug used may appear in the urine.

Untoward Effects. Like other aminoglycosides, the most important and serious side effects of the use of gentamicin are nephrotoxicity and irreversible ototoxicity. Intrathecal or intraventricular administration is used rarely because it may cause local inflammation and can result in radiculitis and other complications.

Tobramycin

The antimicrobial activity, pharmacokinetic properties, and toxicity profile of tobramycin are very similar to

those of gentamicin. Tobramycin may be given either intramuscularly, intravenously, or by inhalation. Tobramycin (TOBREX, others) also is available in ophthalmic ointments and solutions.

Therapeutic Uses. Indications for the use of tobramycin are the same as those for gentamicin. The superior activity of tobramycin against *P. aeruginosa* makes it the preferred aminoglycoside for treatment of serious infections known or suspected to be caused by this organism; the drug has been usefully administered by inhalation to combat *P. aeruginosa* infections (LoBue, 2005). Tobramycin usually is used with an anti-pseudomonal β -lactam antibiotic. In contrast to gentamicin, tobramycin shows poor activity in combination with penicillin against many strains of enterococci. Most strains of *E. faecium* are highly resistant. Tobramycin is ineffective against mycobacteria. Dosages and serum concentrations are identical with those for gentamicin.

Untoward Effects. Tobramycin, like other aminoglycosides, causes nephrotoxicity and ototoxicity. Studies in experimental animals suggest that tobramycin may be less toxic to hair cells in the cochlear and vestibular end organs and cause less renal tubular damage than gentamicin. However, clinical data are less convincing.

Amikacin

The spectrum of antimicrobial activity of amikacin is the broadest of the group. Because of its resistance to many of the aminoglycoside-inactivating enzymes, it has a special role in hospitals where gentamicin- and tobramycin-resistant microorganisms are prevalent.

Therapeutic Uses. Amikacin is the preferred agent for the initial treatment of serious nosocomial gram-negative bacillary infections in hospitals where resistance to gentamicin and tobramycin has become a significant problem. Amikacin is active against the vast majority of aerobic gram-negative bacilli in the community and the hospital. This includes most strains of *Serratia*, *Proteus*, and *P. aeruginosa*. It is active against nearly all strains of *Klebsiella*, *Enterobacter*, and *E. coli* that are resistant to gentamicin and tobramycin. Most resistance to amikacin is found among strains of *Acinetobacter*, *Providencia*, and *Flavobacter* and strains of *Pseudomonas* other than *P. aeruginosa*; these all are unusual pathogens. Like tobramycin, amikacin is less active than gentamicin against enterococci and should not be used for this organism. Amikacin is not active against the majority of gram-positive anaerobic bacteria. It is active against *M. tuberculosis* (99% of strains inhibited by 4 $\mu\text{g}/\text{mL}$), including streptomycin-resistant strains and atypical mycobacteria. It has been used in the treatment of disseminated atypical mycobacterial infections in patients with acquired immunodeficiency syndrome (AIDS).

The recommended dose of amikacin is 15 mg/kg per day as a single daily dose or divided into two or three equal portions, which must be reduced for patients with renal failure. The drug is absorbed rapidly after intramuscular injection, and peak concentrations in plasma approximate 20 $\mu\text{g}/\text{mL}$ after injection of 7.5 mg/kg. An intravenous infusion of the same dose over a 30-minute period produces a peak concentration in plasma of nearly 40 $\mu\text{g}/\text{mL}$ at the end of

the infusion, which falls to ~ 20 $\mu\text{g/mL}$ 30 minutes later. The concentration 12 hours after a 7.5 mg/kg dose typically is 5–10 $\mu\text{g/mL}$. A 15 mg/kg once-daily dose produces peak concentrations 50–60 $\mu\text{g/mL}$ and a trough of <1 $\mu\text{g/mL}$. For treatment of mycobacterial infections, thrice-weekly dosing schedules of amikacin are often used, with doses up to 25 mg/kg.

Untoward Effects. As with the other aminoglycosides, amikacin causes ototoxicity, hearing loss, and nephrotoxicity.

Netilmicin

Netilmicin is the latest of the aminoglycosides to be marketed. It is similar to gentamicin and tobramycin in its pharmacokinetic properties and dosage. Its antibacterial activity is broad against aerobic gram-negative bacilli. Like amikacin, it is not metabolized by most of the aminoglycoside-inactivating enzymes, and it therefore may be active against certain bacteria that are resistant to gentamicin.

Therapeutic Uses. Netilmicin is useful for the treatment of serious infections owing to susceptible Enterobacteriaceae and other aerobic gram-negative bacilli. It is effective against certain gentamicin-resistant pathogens, with the exception of enterococci (Panwalker et al., 1978).

The recommended dose of netilmicin for complicated urinary tract infections in adults is 1.5–2 mg/kg every 12 hours. For other serious systemic infections, a total daily dose of 4–7 mg/kg is administered as a single dose or two to three divided doses. Children should receive 3–7 mg/kg per day in two to three divided doses; neonates receive 3.5–5 mg/kg per day as a single daily dose (Gosden et al., 2001). The distribution and elimination of netilmicin, gentamicin, and tobramycin are very similar. The $t_{1/2}$ for elimination is usually 2–2.5 hours in adults and increases with renal insufficiency.

Untoward Effects. As with other aminoglycosides, netilmicin also may produce ototoxicity and nephrotoxicity. Animal models suggest that netilmicin may be less toxic than other aminoglycosides, but this remains to be proven in humans (Tange et al., 1995).

Streptomycin

Streptomycin is used for the treatment of certain unusual infections generally in combination with other antimicrobial agents. Because it generally is less active than other members of the class against aerobic gram-negative rods, it is rarely used.

Therapeutic Uses. Bacterial Endocarditis. Streptomycin and penicillin in combination are synergistically bactericidal *in vitro* and in animal models of infection against strains of enterococci, group D streptococci, and the various oral streptococci of the *viridans* group. The combination of penicillin G, which by itself is only bacteriostatic against enterococci, and streptomycin is effective as bactericidal therapy for enterococcal endocarditis. Gentamicin is generally preferred for its lesser toxicity; also, gentamicin should be used when the strain of enterococcus is resistant to streptomycin (MIC >2 mg/mL). Streptomycin should be used instead of gentamicin when the strain

is resistant to the latter and susceptibility has been demonstrated to streptomycin, which may occur because the enzymes that inactivate these two aminoglycosides are different.

Streptomycin may be administered by deep intramuscular injection or intravenously. Intramuscular injection may be painful, with a hot tender mass developing at the site of injection. The dose of streptomycin is 15 mg/kg per day for patients with creatinine clearances >80 mL/minute. It typically is administered as a 1000-mg single daily dose for tuberculosis or 500 mg twice daily, resulting in peak serum concentrations of ~ 50 –60 and 15–30 $\mu\text{g/mL}$ and trough concentrations of <1 and 5–10 $\mu\text{g/mL}$, respectively. The total daily dose should be reduced in direct proportion to the reduction in creatinine clearance for creatinine clearances >30 mL/minute (Table 54–2).

Tularemia. Streptomycin (or gentamicin) is the drug of choice for the treatment of tularemia. Most cases respond to the administration of 1–2 g (15–25 mg/kg) streptomycin per day (in divided doses) for 10–14 days. Fluoroquinolones and tetracyclines also are effective, although the failure rate may be higher with tetracyclines.

Plague. Streptomycin is effective agent for the treatment of all forms of plague. The recommended dose is 2 g/day in two divided doses for 10 days. Gentamicin is probably as efficacious (Boulanger et al., 2004).

Tuberculosis. Streptomycin is a second-line agent for the treatment of active tuberculosis, and streptomycin always should be used in combination with at least one or two other drugs to which the causative strain is susceptible. The dose for patients with normal renal function is 15 mg/kg per day as a single intramuscular injection for 2–3 months and then two or three times a week thereafter.

Untoward Effects. Streptomycin has been replaced by gentamicin for most indications because the toxicity of gentamicin is primarily renal and reversible, whereas that of streptomycin is vestibular and irreversible. The administration of streptomycin may produce dysfunction of the optic nerve, including scotomas, presenting as enlargement of the blind spot. Among the less common toxic reactions to streptomycin is peripheral neuritis. This may be due either to accidental injection of a nerve during the course of parenteral therapy or to toxicity involving nerves remote from the site of antibiotic administration.

Kanamycin

The use of kanamycin has declined markedly because its spectrum of activity is limited compared with other aminoglycosides, and it is among the most toxic aminoglycosides. Kanamycin sulfate is available for injection and oral use. The parenteral dose for adults is 15 mg/kg per day (2–4 equally divided and spaced doses), with a maximum of 1.5 g/day. Children may be given up to 15 mg/kg per day.

Therapeutic Uses. Kanamycin is all but obsolete, and there are few indications for its use. Kanamycin has been employed to treat tuberculosis in combination with other effective drugs. It has no therapeutic advantage over streptomycin or amikacin and probably is more toxic; either should be used instead, depending on susceptibility of the isolate.

Prophylactic Uses. Kanamycin can be administered orally as adjunctive therapy in cases of hepatic encephalopathy. The dose is 4–6 g/day for 36–72 hours; quantities as large as 12 g/day (in divided doses) have been given.

Untoward Effects. Kanamycin is ototoxic and nephrotoxic. Like neomycin, its oral administration can cause malabsorption and superinfection. The untoward effects of the oral administration of aminoglycosides are considered in the section on neomycin.

Neomycin

Neomycin is a broad-spectrum antibiotic. Susceptible microorganisms usually are inhibited by concentrations of ≤ 10 $\mu\text{g/mL}$. Gram-negative species that are highly sensitive are *E. coli*, *Enterobacter aerogenes*, *Klebsiella pneumoniae*, and *Proteus vulgaris*. Gram-positive microorganisms that are inhibited include *S. aureus* and *E. faecalis*. *M. tuberculosis* also is sensitive to neomycin. Strains of *P. aeruginosa* are resistant to neomycin. Neomycin sulfate is available for topical and oral administration. Neomycin currently is available in many brands of creams, ointments, and other products alone and in combination with polymyxin, bacitracin, other antibiotics, and a variety of corticosteroids. There is no evidence that these topical preparations shorten the time required for healing of wounds or that those containing a steroid are more effective.

Therapeutic Uses. Neomycin has been used widely for topical application in a variety of infections of the skin and mucous membranes caused by microorganisms susceptible to the drug. These include infections associated with burns, wounds, ulcers, and infected dermatoses. However, such treatment does not eradicate bacteria from the lesions.

The oral administration of neomycin (usually in combination with erythromycin base) has been employed primarily for “preparation” of the bowel for surgery. For therapy of hepatic encephalopathy, an oral daily dose of 4–12 g (in divided doses) is given, provided that renal function is normal. Because renal insufficiency is a complication of hepatic failure and neomycin is nephrotoxic, it is used rarely for this indication.

Neomycin and polymyxin B have been used for irrigation of the bladder. For this purpose, 1 mL of a preparation (NEOSPORIN G.U. IRRIGANT) containing 40 mg neomycin and 200,000 units polymyxin B per milliliter is diluted in 1 L of 0.9% sodium chloride solution and is used for continuous irrigation of the urinary bladder through appropriate catheter systems. The goal is to prevent bacteriuria and bacteremia associated with indwelling catheters. The bladder is irrigated at the rate of 1 L every 24 hours.

Absorption and Excretion. Neomycin is poorly absorbed from the GI tract and is excreted by the kidney, as are the other aminoglycosides. An oral dose of 3 g produces a peak plasma concentration of 1–4 $\mu\text{g/mL}$; a total daily intake of 10 g for 3 days yields a blood concentration below that associated with systemic toxicity if renal function is normal. Patients with renal insufficiency may accumulate the drug. About 97% of an oral dose of neomycin is not absorbed and is eliminated unchanged in the feces.

Untoward Effects. Hypersensitivity reactions, primarily skin rashes, occur in 6–8% of patients when neomycin is applied topically. Individuals sensitive to this agent may develop cross-reactions when exposed to other aminoglycosides. The most important toxic effects of neomycin are renal damage and nerve deafness; as a consequence, the drug is no longer available for parenteral administration. Toxicity has been reported in patients with normal renal function after topical application or irrigation of wounds with 0.5% neomycin solution. Neuromuscular blockade with respiratory paralysis also has occurred after irrigation of wounds or serosal cavities. Individuals treated with 4–6 g/day of the drug by mouth sometimes develop a sprue-like syndrome with diarrhea, steatorrhea, and azotorrhea. Overgrowth of yeasts in the intestine also may occur; this is not associated with diarrhea or other symptoms in most cases.

CLINICAL SUMMARY

The role of aminoglycosides in the treatment of bacterial infections has diminished steadily as alternative drugs have become available. The aminoglycosides are narrow-spectrum agents, with their activity limited mainly to gram-negative aerobes. Compared with other antibacterials, aminoglycosides are among the most toxic, particularly if used for prolonged periods of time; serum concentrations must be monitored to avoid drug accumulation. These agents are first-line therapy for only a limited number of very specific, often historically prominent infections, such as plague, tularemia, and tuberculosis. Gentamicin or amikacin may have a role as a backup agent in the treatment of nosocomial infections caused by multidrug-resistant gram-negative pathogens such as *Pseudomonas* or *Acinetobacter*. Gentamicin also may be useful for the treatment of serious urinary tract infections caused by enteric organisms that have acquired resistance to sulfa drugs, penicillins, cephalosporins, and fluoroquinolones. Although gentamicin has been recommended for use in combination with vancomycin or a β -lactam to enhance bactericidal effect (i.e., synergism), the clinical benefit of such combinations is unproven for most infections. Because more effective and less toxic alternatives usually are available, aminoglycosides should be used sparingly and reserved for specific indications. If an aminoglycoside must be used, the duration of therapy should be kept to a minimum to avoid toxicity, and serum concentrations should be monitored.

55 chapter

Protein Synthesis Inhibitors and Miscellaneous Antibacterial Agents

Conan MacDougall and Henry F. Chambers

The antimicrobial agents discussed in this chapter may be assigned to three groups:

- Bacteriostatic, protein-synthesis inhibitors that target the ribosome, such as tetracyclines and glycylicyclines, chloramphenicol, macrolides and ketolides, lincosamides (clindamycin), streptogramins (quinupristin/dalfopristin), oxazolidinones (linezolid), and aminocyclitols (spectinomycin).
- Agents acting on the cell wall or cell membrane such as polymyxins, glycopeptides (vancomycin and teicoplanin), and lipopeptides (daptomycin).
- Miscellaneous compounds acting by diverse mechanisms with limited indications: bacitracin and mupirocin.

TETRACYCLINES AND GLYCYLCYCLINES

Sources and Chemistry. The tetracyclines are close congeners of polycyclic naphthacene-carboxamide. Structural formulas of the tetracyclines are shown in Table 55–1.

Chlortetracycline, the prototype of this class, was introduced in 1948 but is no longer marketed in the U.S. Oxytetracycline is a natural product elaborated by *Streptomyces rimosus*. Tetracycline is a semisynthetic derivative of chlortetracycline. Demeclocycline is the product of a mutant strain of *S. aureofaciens*, and methacycline (not available in the U.S.), doxycycline, and minocycline all are semisynthetic derivatives.

Because of their activity against *Rickettsia*, aerobic and anaerobic gram-positive and gram-negative bacteria, and *Chlamydia*, tetracyclines became known as “broad-spectrum” antibiotics. The spread of antimicrobial resistance has eroded the activity of tetracyclines against many gram-positive and gram-negative organisms. A new group of tetracycline derivatives, the glycylicyclines, have regained much of this activity. The glycylicyclines are synthetic analogs of the

tetracyclines; the glycylicline currently approved is tigecycline, the 9-*tert*-butyl-glycylamido derivative of minocycline.

Antimicrobial Activity. Tetracyclines are bacteriostatic antibiotics with activity against a wide range of aerobic and anaerobic gram-positive and gram-negative bacteria.

They also are effective against some microorganisms, such as *Rickettsia*, *Coxiella burnetii*, *Mycoplasma pneumoniae*, *Chlamydia* spp., *Legionella* spp., *Ureaplasma*, some atypical mycobacteria, and *Plasmodium* spp., that are resistant to cell-wall-active antimicrobial agents. The tetracyclines are active against many spirochetes, including *Borrelia recurrentis*, *Borrelia burgdorferi* (Lyme disease), *Treponema pallidum* (syphilis), and *Treponema pertenuis*. Tetracyclines are active against *Chlamydia* and *Mycoplasma*. Some nontuberculosis strains of mycobacteria (e.g., *M. marinum*) also are susceptible. They are not active against fungi. Demeclocycline, tetracycline, minocycline, and doxycycline are available in the U.S. for systemic use. Other derivatives are available in other countries. The more lipophilic drugs, minocycline and doxycycline, usually are the most active by weight, followed by tetracycline. Resistance of a bacterial strain to any one member of the class may or may not result in cross-resistance to other tetracyclines. Tigecycline is generally, although not universally, active against organisms that are susceptible to tetracyclines as well as those with acquired resistance to tetracyclines (Gales et al., 2008).

Bacterial strains with tetracycline minimum inhibitory concentrations (MICs) ≤ 4 $\mu\text{g}/\text{mL}$ are considered susceptible except for *Haemophilus influenzae* and *Streptococcus pneumoniae*, whose susceptibility breakpoints (defined as the upper limit of the concentration at which bacteria are still considered susceptible to a given drug) are ≤ 2 $\mu\text{g}/\text{mL}$, and *Neisseria gonorrhoeae*, with a breakpoint of ≤ 0.25 $\mu\text{g}/\text{mL}$. The MIC breakpoint for susceptible anaerobic bacteria is 8 $\mu\text{g}/\text{mL}$. Tetracyclines intrinsically are more active against gram-positive than gram-negative microorganisms, but acquired resistance is common. Recent data from the U.S. on the activity of tetracycline and other agents discussed in this chapter against selected gram-positive aerobes are displayed in Table 55–2. However, prevalence of resistant strains varies in different regions. For example, ~10% of *S. pneumoniae* isolates in the U.S. are resistant

Table 55–1

Structural Formulas of the Tetracyclines

CONGENER	SUBSTITUENT(S)	POSITION(S)
Chlortetracycline	–Cl	7
Oxytetracycline	–OH, –H	5
Demeclocycline	–OH, –H; –Cl	6; 7
Methacycline	–OH, –H; CH ₂	5; 6
Doxycycline	–OH, –H; –CH ₃ , –H	5; 6
Minocycline	–H, –H; –N(CH ₃) ₂	6; 7

to tetracycline versus 40% in the Asia-Pacific region (Hoban et al., 2001). *Bacillus anthracis* and *Listeria monocytogenes* are susceptible. Of note, the tetracyclines, doxycycline and minocycline in particular, have generally retained excellent levels of activity against staphylococci, including methicillin-resistant *Staphylococcus aureus* (MRSA). Doxycycline and minocycline can be active against some tetracycline-resistant isolates.

H. influenzae is generally susceptible, but many Enterobacteriaceae have acquired resistance. Although all strains of *Pseudomonas aeruginosa* are resistant, 90% of strains of *Burkholderia pseudomallei* (the cause of melioidosis) are sensitive. Most strains of *Brucella* also are susceptible. Tetracyclines remain useful for infections caused by *Haemophilus ducreyi* (chancroid), *Vibrio cholerae* and *V. vulnificus*, and inhibit the growth of *Legionella pneumophila*, *Campylobacter jejuni*, *Helicobacter pylori*, *Yersinia pestis*, *Yersinia enterocolitica*, *Francisella tularensis*, and *Pasteurella multocida*. Strains of *Neisseria gonorrhoeae* no longer are predictably susceptible to tetracycline, which is not recommended for treatment of gonococcal infections. The tetracyclines are active against many anaerobic and facultative microorganisms. A variable number of anaerobes (e.g.,

Table 55–2

Activity of Selected Antimicrobials Against Key Gram-positive Pathogens

CONCENTRATION OF ANTIMICROBIAL AGENT REQUIRED TO INHIBIT GROWTH OF 90% OF ISOLATES, µg/mL
(% SUSCEPTIBLE AT CLINICALLY ACHIEVABLE CONCENTRATIONS OF DRUG)

	<i>Streptococcus Pyogenes</i>	<i>Streptococcus Pneumoniae</i>		<i>Staphylococcus Aureus</i>		<i>Enterococcus Faecalis</i>	<i>Enterococcus Faecium</i>
		PCN-S	PCN-R	MSSA	MRSA		
Tetracycline	4 (89.7)	≤2 (94.6)	>8 (36.7)	≤2 (95.7)	≤2 (93.4)	>8 (24.6)	>8 (58.7)
Tigecycline	≤0.03 (100)	≤0.03 (NR)	≤0.03 (NR)	0.25 (100)	0.25 (99.9)	0.25 (99.9)	0.12 (NR)

Vancomycin	0.25 (100)	≤1 (100)	≤1 (100)	1 (99.9)	1 (99.9)	2 (94.5)	>16 (26.6)
Daptomycin	0.06 (100)	0.12 (NA)	0.12 (NA)	0.25 (100)	0.5 (100)	2 (100)	4 (100)

Entries are drug concentrations, in µg/mL, required to inhibit growth of 90% of isolates of that organism. In parentheses below each drug concentration is the percentage of isolates inhibited at clinically useful drug concentrations. PCN-S = penicillin-susceptible; PCN-R = penicillin-resistant; MSSA = methicillin-susceptible *Staphylococcus aureus*; MRSA = methicillin-resistant *Staphylococcus aureus*; NR = not reported; NA = not applicable.

Sources: Gales et al., 2008; Critchley et al., 2003.

Bacteroides spp., *Propionibacterium*, *Peptococcus*) are sensitive to doxycycline, but other antibiotics (e.g., chloramphenicol, clindamycin, metronidazole, and certain β -lactam antibiotics) have better activity. Tetracycline is active against *Actinomyces* and is a drug of choice for treating actinomycosis.

Currently established breakpoints for tigecycline susceptibility vary by organism: for *S. aureus* ≤ 0.5 $\mu\text{g/mL}$; for *Streptococcus*, *Haemophilus*, and *Enterococcus* species, ≤ 0.25 $\mu\text{g/mL}$; for *S. pneumoniae*, ≤ 0.06 $\mu\text{g/mL}$; for Enterobacteriaceae ≤ 2 $\mu\text{g/mL}$; and for anaerobic organisms ≤ 4 $\mu\text{g/mL}$. In general, tigecycline is equally or more active *in vitro* against bacteria than the tetracyclines (Table 55–1), including activity against tetracycline-resistant organisms, especially gram-negative organisms. There are a few exceptions where other tetracyclines may be more active against certain organisms, such as *Stenotrophomonas* and *Ureaplasma*. There is currently a lack of clinical experience with tigecycline for infections caused by organisms such as *Burkholderia*, *Brucella*, *Yersinia*, *Francisella*, and *Pasteurella*. Notable holes in the spectrum of activity of tigecycline (as with the tetracyclines) include *Pseudomonas*, *Proteus*, and *Providencia* spp.

Mechanism of Action. Tetracyclines and glycylyclines inhibit bacterial protein synthesis by binding to the 30S bacterial ribosome and preventing access of aminoacyl tRNA to the acceptor (A) site on the mRNA-ribosome complex (Figure 55–1). These drugs enter gram-negative bacteria by passive diffusion through the hydrophilic channels formed by the porin proteins of the outer cell membrane and by active transport via an energy-dependent system that pumps all tetracyclines

Figure 55–1. Inhibition of bacterial protein synthesis by tetracyclines. Messenger RNA (mRNA) attaches to the 30S subunit of bacterial ribosomal RNA. The P (peptidyl) site of the 50S ribosomal RNA subunit contains the nascent polypeptide chain; normally, the aminoacyl tRNA charged with the next amino acid (aa) to be added to the chain moves into the A (acceptor) site, with complementary base pairing between the anticodon sequence of tRNA and the codon sequence of mRNA. *Tetracyclines* inhibit bacterial protein synthesis by binding to the 30S subunit and blocking tRNA binding to the A site.

across the cytoplasmic membrane. Entry of these drugs into gram-positive bacteria requires metabolic energy, but the process is not as well understood.

Resistance to Tetracyclines and Glycylyclines. Resistance is primarily plasmid mediated and often inducible. The three main resistance mechanisms are (1) decreased accumulation of tetracycline as a result of either decreased antibiotic influx or acquisition of an energy-dependent efflux pathway; (2) production of a ribosomal protection protein that displaces tetracycline from its target, a “protection” that also may occur by mutation; and (3) enzymatic inactivation of tetracyclines. Cross-resistance, or lack thereof, among tetracyclines depends on which mechanism is operative. For example, *S. aureus* strains that are tetracycline resistant on the basis of efflux mediated by *tetK* still may be susceptible to minocycline. Tetracycline resistance due to a ribosomal protection mechanism (*tetM*) produces cross-resistance to doxycycline and minocycline because the target site protected is the same for all tetracyclines.

The glycylylamido moiety characteristic of tigecycline reduces its affinity for most efflux pumps, restoring activity against many organisms displaying tetracycline resistance due to this mechanism. Binding of glycylyclines to ribosomes is also enhanced, improving activity against organisms that harbor ribosomal protection proteins that confer resistance to other tetracyclines (Petersen et al., 1999).

Absorption, Distribution, and Excretion

Absorption. Oral absorption of most tetracyclines is incomplete. The percentage of an oral dose that is absorbed with an empty stomach is modest for demeclocycline and tetracycline (60–80%) and high for doxycycline (95%) and minocycline (100%). The percentage of unabsorbed drug rises as the dose increases. Tigecycline is not appreciably absorbed from the gastrointestinal (GI) tract and is only available for parenteral administration. Absorption of orally administered tetracyclines mostly takes place in the stomach and upper small intestine and is greater in the fasting state. Absorption may be impaired by the concurrent ingestion of divalent and trivalent cations (e.g., Ca^{2+} , Mg^{2+} , Al^{3+} , $\text{Fe}^{2+/3+}$, and Zn^{2+}). Thus, dairy products, antacids, aluminum hydroxide gels; calcium, magnesium, and iron or zinc salts; bismuth subsalicylate (e.g., PEPTO-BISMOL), and dietary Fe and Zn supplements can interfere with absorption of tetracyclines. The decreased absorption apparently results from chelation with these cations and formation of complexes with poor solubility. Doxycycline and minocycline are less affected than tetracyclines and administration with milk or calcium-containing foods is unlikely to impair absorption substantially, but co-administration of antacids or mineral supplements should be avoided.

Variable absorption of orally administered tetracyclines leads to a wide range of plasma concentrations in different individuals. Tetracycline is incompletely absorbed. After a single oral dose, the peak plasma concentration is attained in 2–4 hours. These drugs have half-lives in the range of 6–12 hours and frequently are administered two to four times daily. The administration of 250 mg tetracycline every 6 hours produces peak plasma concentrations of 2–2.5 $\mu\text{g/mL}$. Increasing the dosage above 1 g every 6 hours does not further increase plasma concentrations. Demeclocycline, which also is incompletely absorbed, can be administered in lower daily dosages than the congeners just mentioned because its $t_{1/2}$ of 16 hours provides effective plasma concentrations for 24–48 hours.

Oral doses of doxycycline and minocycline are well absorbed (90-100%) and have half-lives of 16-18 hours; they therefore can be administered less frequently and at lower doses than tetracycline or demeclocycline. After an oral dose of 200 mg of doxycycline, a maximum plasma concentration of 3 µg/mL is achieved at 2 hours, and the plasma concentration remains above 1 µg/mL for 8-12 hours. Plasma concentrations are equivalent whether doxycycline is given orally or parenterally.

Distribution. Tetracyclines distribute widely throughout the body and into tissues and secretions, including urine and prostate. They accumulate in reticuloendothelial cells of the liver, spleen, and bone marrow, and in bone, dentine, and enamel of unerupted teeth. Tigecycline distributes rapidly and extensively into tissues, with an estimated apparent volume of 7-10 L/kg. Because of this extensive distribution, peak serum levels of tigecycline are relatively low (~1 µg/mL).

Inflammation of the meninges is not required for the passage of tetracyclines into the cerebrospinal fluid (CSF). Penetration of these drugs into most other fluids and tissues is excellent. Concentrations in synovial fluid and the mucosa of the maxillary sinus approach that in plasma. Tetracyclines cross the placenta and enter the fetal circulation and amniotic fluid. Relative to the maternal circulation, tetracycline concentrations in umbilical cord plasma and amniotic fluid are 60% and 20%, respectively. Relatively high concentrations of these drugs also are found in breast milk.

Excretion. The primary route of elimination of most older tetracyclines (e.g., demeclocycline, tetracycline) is the kidney, although they also are concentrated in the liver and excreted in bile. After biliary excretion, they are partially reabsorbed via enterohepatic recirculation. Elimination via the intestinal tract occurs even when the drugs are given parenterally. Comparable amounts of tetracycline (i.e., 20-60%) are excreted in the urine within 24 hours following oral or intravenous administration.

Doxycycline is largely excreted unchanged both in the bile and urine, tigecycline is mostly excreted unchanged along with a small amount of glucuronidated metabolites, and minocycline is extensively metabolized by the liver before excretion. Doses of these agents do not require adjustment in patients with renal dysfunction. Decreased hepatic function or obstruction of the common bile duct reduces the biliary excretion of these agents, resulting in longer half-lives and higher plasma concentrations. Specific dosage adjustment recommendations in hepatic disease are available only for tigecycline. Because of their enterohepatic circulation, these drugs may remain in the body for a long time after cessation of therapy. There is some evidence for drug interactions between doxycycline and hepatic enzyme-inducing agents such as phenytoin and rifampin, but not for minocycline or tigecycline.

Therapeutic Uses and Dosage. The tetracyclines have been used extensively to treat infectious diseases and as an additive to animal feeds to facilitate growth. These uses have increased resistance to tetracyclines among gram-positive and gram-negative organisms, limiting their use for a number of common bacterial infections. However, the drugs remain useful as first-line therapy for infections caused by rickettsiae, mycoplasmas, and chlamydiae. The glycyliclones have restored much of

the antibacterial activity lost to the tetracyclines due to resistance and can be used for a number of infections due to gram-positive and gram-negative organisms.

Children >8 years of age should receive 25-50 mg/kg daily in four divided doses. The total daily dose of intravenous tetracycline (no longer available in the U.S.) for most acute infections is 1 g (or 2 g for severe infection), divided into equal doses and administered at 6- or 12-hour intervals. The low pH of tetracycline, but not doxycycline or minocycline, invariably causes phlebitis if infused into a peripheral vein. The recommended dose of demeclocycline is 150 mg every 6 hours or 300 mg every 12 hours for adults and 6.6-13.2 mg/kg in two to four divided doses for children >8 years of age. Demeclocycline is used rarely as an antimicrobial agent because of its higher risks of photosensitivity reactions and nephrogenic diabetes insipidus. The oral or intravenous dose of doxycycline for adults is 100 mg every 12 hours on the first day and then 50 mg every 12 hours, 100 mg once a day, or 100 mg twice daily when severe infection is present; for children >8 years of age, the dose is 4-5 mg/kg per day in two divided doses the first day, then 2-2.5 mg/kg given once or twice daily. The dose of minocycline for adults is 200 mg orally or intravenously initially, followed by 100 mg every 12 hours; for children, it is 4 mg/kg initially followed by 2 mg/kg every 12 hours. Tigecycline is administered intravenously to adults as a 100-mg loading dose, followed by 50 mg every 12 hours. For patients with severe hepatic impairment, the loading dose should be followed by a reduced maintenance dose of 25 mg every 12 hours. Dosage data are not available for tigecycline in pediatrics.

Tetracyclines should not be administered intramuscularly because of local irritation and poor absorption. GI distress, nausea, and vomiting can be minimized by administration of tetracyclines with food. Generally, oral administration of tetracyclines should occur 2 hours before or 2 hours after co-administration with any of the agents listed. Cholestyramine and colestipol also bind orally administered tetracyclines and interfere with the absorption of the antibiotic.

Respiratory Tract Infections. Doxycycline's good activity against *S. pneumoniae* and *H. influenzae* and excellent activity against atypical pathogens such as *Mycoplasma* and *Chlamydia pneumoniae* make it an effective single agent for empirical therapy of community-acquired pneumonia in the outpatient setting or as an adjunct to cephalosporin-based therapy for inpatients (Mandell et al., 2007). Tigecycline has been demonstrated to be effective for use as a single agent for adults hospitalized with community-acquired bacterial pneumonia (Bergallo et al., 2009).

Skin and Soft-Tissue Infections. Community strains of methicillin-resistant *S. aureus* often are susceptible to tetracycline, doxycycline, or minocycline, which appear to be effective for uncomplicated skin and soft-tissue infections, although published data are limited (Cenizal et al., 2007). Tigecycline is approved by the Food and Drug Administration (FDA) for the treatment of complicated skin and soft-tissue infections.

Tetracyclines have been used to treat acne. They may act by inhibiting propionibacteria, which reside in sebaceous follicles and metabolize lipids into irritating free fatty acids. The relatively low doses of tetracycline used for acne (e.g., 250 mg orally twice a day) are associated with few side effects.

Intra-abdominal Infections. Increasing resistance among Enterobacteriaceae and gram-negative anaerobes limit the utility of the tetracyclines for intra-abdominal infections. However, tigecycline possesses excellent activity against these pathogens as well as *Enterococcus* and has demonstrated effectiveness in clinical trials for complicated intra-abdominal infections (Oliva et al., 2005).

GI Infections. Therapy with the tetracyclines is often ineffective in infections caused by *Shigella*, *Salmonella*, or other Enterobacteriaceae because of a high prevalence of drug-resistant strains in many areas. Resistance limits the usefulness of tetracyclines for travelers' diarrhea. Doxycycline (300 mg as a single dose) is effective in reducing stool volume and eradicating *Vibrio cholerae* from the stool within 48 hours. Antimicrobial agents, however, are not substitutes for fluid and electrolyte replacement in this disease. In addition, some strains of *V. cholerae* are resistant to tetracyclines.

Urinary Tract Infections. Tetracyclines are no longer recommended for routine treatment of urinary tract infections because many enteric organisms that cause these infections, including *E. coli*, are resistant. There is little experience in using tigecycline for urinary tract infections; based on its *in vitro* activity, it should be adequate.

Sexually Transmitted Diseases. Because of resistance, doxycycline no longer is recommended for gonococcal infections. If coinfection with *C. trachomatis* has not been excluded, then either doxycycline or azithromycin should be administered in addition to an agent effective for gonococcal urethritis (Workowski and Berman, 2006).

C. trachomatis often is a coexistent pathogen in acute pelvic inflammatory disease, including endometritis, salpingitis, parametritis, and/or peritonitis. Doxycycline, 100 mg intravenously twice daily, is recommended for at least 48 hours after substantial clinical improvement, followed by oral therapy at the same dosage to complete a 14-day course. Doxycycline usually is combined with cefoxitin or cefotetan (Chapter 53) to cover anaerobes and facultative aerobes.

Acute epididymitis is caused by infection with *C. trachomatis* or *N. gonorrhoeae* in men <35 years of age. Effective regimens include a single injection of ceftriaxone (250 mg) plus doxycycline, 100 mg orally twice daily for 10 days. Sexual partners of patients with any of these conditions also should be treated.

Nonspecific urethritis is often due to *Chlamydia trachomatis*. Doxycycline, 100 mg every 12 hours for 7 days, is effective; however, azithromycin is usually preferred because it can be given as a single 1-g dose. Doxycycline (100 mg twice daily for 21 days) is first-line therapy for treatment of lymphogranuloma venereum. The size of buboes decreases within 4 days, and inclusion and elementary bodies entirely disappear from the lymph nodes within 1 week. Rectal pain, discharge, and bleeding of lymphogranulomatous proctitis are decreased markedly. When relapses occur, treatment is resumed with full doses and is continued for longer periods.

Nonpregnant penicillin-allergic patients who have primary, secondary, or latent syphilis can be treated with a tetracycline regimen such as doxycycline, 100 mg orally twice daily for 2 weeks. Tetracyclines should not be used for treatment of neurosyphilis.

Rickettsial Infections. Tetracyclines are effective and may be life-saving in rickettsial infections, including Rocky Mountain spotted fever, recrudescent epidemic typhus (Brill's disease), murine typhus, scrub typhus, rickettsialpox, and Q fever. Clinical improvement often is evident within 24 hours after initiation of therapy. Doxycycline is the drug of choice for treatment of suspected or proven Rocky

Mountain spotted fever in adults and in children, including those <9 years of age, in whom the risk of staining of permanent teeth is outweighed by the seriousness of this potentially fatal infection (Masters et al., 2003).

Anthrax. Doxycycline, 100 mg every 12 hours (2.2 mg/kg every 12 hours for children weighing <45 kg), is indicated for prevention or treatment of anthrax. It should be used in combination with another agent when treating inhalational or GI infection. The recommended duration of therapy is 60 days for exposures occurring as an act of bioterrorism.

Local Application. Except for local use in the eye, topical use of the tetracyclines is not recommended. Their use in ophthalmic therapy is discussed in previous versions of this text. Minocycline sustained-release microspheres for subgingival administration are used in dentistry as an adjunct to scaling and root planing procedures to reduce pocket depth in patients with adult periodontitis.

Other Infections. Tetracyclines in combination with rifampin or streptomycin are effective for acute and chronic infections caused by *Brucella melitensis*, *Brucella suis*, and *Brucella abortus*. Effective regimens are doxycycline, 200 mg per day, plus rifampin, 600-900 mg daily for 6 weeks, or the usual dose of doxycycline plus streptomycin 1 g daily, intramuscularly. Relapses usually respond to a second course of therapy. Although streptomycin is preferable, tetracyclines also are effective in tularemia (Ellis et al., 2002). Both the ulceroglandular and typhoidal types of the disease respond well. Actinomycosis, although most responsive to penicillin G, may be successfully treated with a tetracycline. Minocycline is an alternative for the treatment of nocardiosis, but a sulfonamide should be used concurrently. Yaws and relapsing fever respond favorably to the tetracyclines. Tetracyclines are useful in the acute treatment and for prophylaxis of leptospirosis (*Leptospira* spp.), *Borrelia* spp., including *B. recurrentis* (relapsing fever) and *B. burgdorferi* (Lyme disease), respond to therapy with a tetracycline. The tetracyclines have been used to treat susceptible atypical mycobacterial pathogens, including *M. marinum*.

Untoward Effects

Gastrointestinal. All tetracyclines can produce GI irritation, most commonly after oral administration. GI distress is also characteristic of tigecycline administration. Epigastric burning and distress, abdominal discomfort, nausea, vomiting, and diarrhea may occur. Tolerability can be improved by administering these drugs with food, but tetracyclines should not be taken with dairy products or antacids. Tetracycline has been associated with esophagitis, esophageal ulcers, and pancreatitis.

Many of the tetracyclines are incompletely absorbed from the GI tract, and high concentrations in the bowel can markedly alter enteric flora. Sensitive aerobic and anaerobic coliform microorganisms and gram-positive spore-forming bacteria are suppressed markedly during long-term tetracycline regimens. As the fecal coliform count declines, overgrowth of tetracycline-resistant microorganisms occurs, particularly of yeasts (*Candida* spp.), enterococci, *Proteus*, and *Pseudomonas*. Moniliasis, thrush, or *Candida*-associated esophagitis may arise during therapy with tetracyclines. Tetracyclines and glycyliclones may occasionally produce pseudomembranous colitis caused by *Clostridium difficile*; *pseudomembranous colitis caused by overgrowth of C. difficile is a potentially life-threatening complication.*

Photosensitivity. Demeclocycline, doxycycline, and other tetracyclines and glycylyclines to a lesser extent may produce mild-to-severe photosensitivity reactions in the skin of treated individuals exposed to sunlight. Onycholysis and pigmentation of the nails may develop with or without accompanying photosensitivity.

Hepatic Toxicity. Hepatic toxicity has developed in patients with renal failure receiving ≥ 2 g of drug per day parenterally, but this effect also may occur when large quantities are administered orally. Cases of hepatotoxicity have been reported rarely with doxycycline, minocycline, and tigecycline administration. Pregnant women are particularly susceptible to tetracycline-induced hepatic damage.

Renal Toxicity. Tetracyclines may aggravate azotemia in patients with renal disease because of their catabolic effects. Doxycycline, minocycline, and tigecycline have fewer renal side effects than other tetracyclines. Nephrogenic diabetes insipidus has been observed in some patients receiving demeclocycline, and this phenomenon has been exploited for the treatment of the syndrome of inappropriate secretion of antidiuretic hormone (Chapter 25).

Fanconi syndrome, characterized by nausea, vomiting, polyuria, polydipsia, proteinuria, acidosis, glycosuria, and aminoaciduria, has been observed in patients ingesting outdated and degraded tetracycline. These symptoms presumably result from a toxic effect of the degradation products on proximal renal tubules. Under no circumstances should outdated tetracyclines be administered.

Effects on Teeth. Children receiving long- or short-term therapy with a tetracycline or glycylycline may develop permanent brown discoloration of the teeth. The larger the drug dose relative to body weight, the more intense the enamel discoloration. The duration of therapy appears to be less important than the total quantity of antibiotic administered. The risk of this untoward effect is highest when a tetracycline is given to neonates and infants before the first dentition. However, pigmentation of the permanent teeth may develop if the drug is given between the ages of 2 months and 5 years when these teeth are being calcified. The deposition of the drug in the teeth and bones probably is due to its chelating property and the formation of a tetracycline-calcium orthophosphate complex.

Treatment of pregnant patients with tetracyclines may produce discoloration of the teeth in their children. The period of greatest danger to the teeth is from midpregnancy to ~4-6 months of the postnatal period for the deciduous anterior teeth, and from a few months to 5 years of age for the permanent anterior teeth when the crowns are being formed. However, children up to 8 years old may be susceptible to this complication of tetracycline therapy.

Other Toxic and Irritative Effects. Tetracyclines are deposited in the skeleton during gestation and throughout childhood and may depress bone growth in premature infants. This is readily reversible if the period of exposure to the drug is short.

Thrombophlebitis frequently follows intravenous administration. This irritative effect of tetracyclines has been used therapeutically in patients with malignant pleural effusions, where drug is instilled into the pleural space in a procedure called pleurodesis.

Long-term tetracycline therapy may produce leukocytosis, atypical lymphocytes, toxic granulation of granulocytes, and thrombocytopenic purpura.

The tetracyclines may cause increased intracranial pressure (pseudotumor cerebri) in young infants, even when given in the usual

therapeutic doses. Except for the elevated pressure, the spinal fluid is normal. The pressure promptly returns to normal when therapy is discontinued, and this complication rarely occurs in older individuals.

Patients receiving minocycline may experience vestibular toxicity, manifested by dizziness, ataxia, nausea, and vomiting. The symptoms occur soon after the initial dose and generally disappear within 24-48 hours after drug administration is stopped. Long-term use of minocycline can pigment the skin, producing a brownish discoloration. Various skin reactions, including morbilliform rashes, urticaria, fixed drug eruptions, and generalized exfoliative dermatitis, rarely may follow the use of any of the tetracyclines. Among the more severe allergic responses are angioedema and anaphylaxis; anaphylactoid reactions can occur even after the oral use of these agents. Other hypersensitivity reactions are burning of the eyes, cheilosis, atrophic or hypertrophic glossitis, pruritus ani or vulvae, and vaginitis. Although the exact cause of these reactions is unknown, they can persist for weeks or months after cessation of tetracycline therapy. Fever of varying degrees and eosinophilia may occur when these agents are administered. Asthma also has been observed. Cross-sensitization among the various tetracyclines is common.

Tetracyclines have a variety of effects on mammalian cells unrelated to their capacity to inhibit bacterial protein synthesis. Doxycycline is being studied as an inhibitor of matrix metalloproteinases (Villareal et al., 2003).

CHLORAMPHENICOL

Chloramphenicol, an antibiotic produced by *Streptomyces venezuelae*, was introduced into clinical practice in 1948. With the drug's wide use, it became evident that chloramphenicol could cause serious and fatal blood dyscrasias. For this reason, chloramphenicol is now reserved for treatment of life-threatening infections (e.g., meningitis, rickettsial infections) in patients who cannot take safer alternatives because of resistance or allergies (Wareham and Wilson, 2002).

CHLORAMPHENICOL

The antibiotic is unique among natural compounds in that it contains a nitrobenzene moiety and is a derivative of dichloroacetic acid. The biologically active form is levorotatory.

Antimicrobial Activity. Chloramphenicol possesses a broad spectrum of antimicrobial activity. Strains are considered sensitive if they are inhibited by concentrations of ≤ 8 $\mu\text{g/mL}$, except *S. pneumoniae* where the breakpoint is 4 $\mu\text{g/mL}$, and *H. influenzae*, which has a breakpoint of 2 $\mu\text{g/mL}$. Chloramphenicol is bacteriostatic against most species, although it may be bactericidal against *H. influenzae*, *Neisseria meningitidis*, and *S. pneumoniae*. More than 95% of strains of the following gram-negative bacteria are inhibited *in vitro* by 8 $\mu\text{g/mL}$ or less of chloramphenicol: *H. influenzae*, *N. meningitidis*, *N. gonorrhoeae*, *Brucella* spp., and *Bordetella pertussis*. Likewise,

most anaerobic bacteria, including gram-positive cocci and *Clostridium* spp., and gram-negative rods including *B. fragilis*, are inhibited by this concentration of the drug. Strains of *S. aureus* tend to be less susceptible, with MICs $>8 \mu\text{g/mL}$. Chloramphenicol is active against *Mycoplasma*, *Chlamydia*, and *Rickettsia*.

The Enterobacteriaceae are variably sensitive to chloramphenicol. Most strains of *Escherichia coli* ($\geq 75\%$) and *Klebsiella pneumoniae* are susceptible. *Proteus mirabilis* and indole-positive *Proteus* spp. are susceptible. *P. aeruginosa* is resistant to even very high concentrations of chloramphenicol. Strains of *V. cholerae* have remained largely susceptible to chloramphenicol. Strains of *Shigella* and *Salmonella* resistant to multiple drugs, including chloramphenicol, are prevalent. Of special concern is the increasing prevalence of multiple-drug-resistant strains of *Salmonella* serotype typhi, particularly for strains acquired outside the U.S.

Mechanism of Action. Chloramphenicol inhibits protein synthesis in bacteria, and to a lesser extent, in eukaryotic cells. The drug readily penetrates bacterial cells, probably by facilitated diffusion. Chloramphenicol acts primarily by binding reversibly to the 50S ribosomal subunit (near the binding site for the macrolide antibiotics and clindamycin, which chloramphenicol inhibits competitively). Although binding of tRNA at the codon recognition site on the 30S ribosomal subunit is undisturbed, the drug apparently prevents the binding of the amino acid-containing end of the aminoacyl tRNA to the acceptor site on the 50S ribosomal subunit. The interaction between peptidyltransferase and its amino acid substrate cannot occur, and peptide bond formation is inhibited (Figure 55–2).

Chloramphenicol also can inhibit mitochondrial protein synthesis in mammalian cells, perhaps because mitochondrial ribosomes resemble bacterial ribosomes (both are 70S) more than they do the

80S cytoplasmic ribosomes of mammalian cells. The peptidyltransferase of mitochondrial ribosomes, but not of cytoplasmic ribosomes, is inhibited by chloramphenicol. Mammalian erythropoietic cells are particularly sensitive to the drug.

Resistance to Chloramphenicol. Resistance to chloramphenicol usually is caused by a plasmid-encoded acetyltransferase that inactivates the drug. Resistance also can result from decreased permeability and from ribosomal mutation. Acetylated derivatives of chloramphenicol fail to bind to bacterial ribosomes.

Absorption, Distribution, Fate, and Excretion. Chloramphenicol is absorbed rapidly from the GI tract, and peak concentrations of 10–13 $\mu\text{g/mL}$ occur within 2–3 hours after the administration of a 1-g dose. The product for oral administration is no longer available in the U.S. The preparation of chloramphenicol for parenteral use is the water-soluble, inactive prodrug sodium succinate. Similar concentrations of chloramphenicol succinate in plasma are achieved after intravenous and intramuscular administration. Hydrolysis of chloramphenicol succinate by esterases occurs *in vivo*. Chloramphenicol succinate is rapidly cleared from plasma by the kidneys; this may reduce overall bioavailability of the drug because as much as 30% of the dose may be excreted before hydrolysis. Poor renal function in the neonate and other states of renal insufficiency result in increased plasma concentrations of chloramphenicol succinate. Decreased esterase activity has been observed in the plasma of neonates and infants, prolonging time to peak concentrations of active chloramphenicol (up to 4 hours) and extending the period over which renal clearance of chloramphenicol succinate can occur.

Chloramphenicol is widely distributed in body fluids and readily reaches therapeutic concentrations in CSF, where values are ~60% of those in plasma (range, 45–99%) in the presence or absence of meningitis. The drug actually may accumulate in the brain. Chloramphenicol is present in bile, milk, and placental fluid. It also is found in the aqueous humor after subconjunctival injection.

Hepatic metabolism to the inactive glucuronide is the major route of elimination. This metabolite and chloramphenicol itself are excreted in the urine following filtration and secretion. Patients with cirrhosis or otherwise impaired hepatic function have decreased metabolic clearance, and dosage should be adjusted in these individuals. The $t_{1/2}$ of chloramphenicol correlates with plasma bilirubin concentrations. About 50% of chloramphenicol is bound to plasma proteins; such binding is reduced in cirrhotic patients and in neonates. Half-life is not altered significantly by renal insufficiency or hemodialysis, and dosage adjustment usually is not required. However, if the dose of chloramphenicol has been reduced because of cirrhosis, clearance by hemodialysis may be significant. This effect can be minimized by administering the drug at the end of hemodialysis. Significant variability in the metabolism and pharmacokinetics of chloramphenicol in neonates, infants, and children necessitates monitoring of drug concentrations in plasma.

Therapeutic Uses and Dosage. Therapy with chloramphenicol must be limited to infections for which the benefits of the drug outweigh the risks of the potential toxicities. When other antimicrobial drugs that are equally effective and potentially less toxic are available, they should be used instead of chloramphenicol (Wareham and Wilson, 2002).

Typhoid Fever. Third-generation cephalosporins and quinolones are drugs of choice for the treatment of typhoid fever because they are

Figure 55–2. Inhibition of bacterial protein synthesis by chloramphenicol. Chloramphenicol binds to the 50S ribosomal subunit at the peptidyltransferase site and inhibits the transpeptidation reaction. Chloramphenicol binds to the 50S ribosomal subunit near the site of action of clindamycin and the macrolide antibiotics. These agents interfere with the binding of chloramphenicol and thus may interfere with each other's actions if given concurrently. See Figure 55–1 and its legend for additional information.

less toxic and because strains of *Salmonella typhi* often are resistant to chloramphenicol (Parry, 2003).

The adult dose of chloramphenicol for typhoid fever is 1 g every 6 hours for 4 weeks. Although intravenous and oral routes have been used, the response is more rapid with oral administration. Provided that the primary isolate is sensitive, relapses respond satisfactorily to retreatment.

Bacterial Meningitis. Third-generation cephalosporins have replaced chloramphenicol in the therapy of bacterial meningitis (Quagliarello and Scheld, 1997). Chloramphenicol remains an alternative drug for the treatment of meningitis caused by *H. influenzae*, *N. meningitidis*, and *S. pneumoniae* in patients who have severe allergy to β -lactams and in developing countries (Fuller et al., 2003). The total daily dose for children should be 50 mg/kg of body weight, divided into four equal doses given intravenously every 6 hours. Results with chloramphenicol used for pneumococcal meningitis may be unsatisfactory because some strains are inhibited but not killed. Moreover, penicillin-resistant strains frequently also are resistant to chloramphenicol (Hoban et al., 2001). In the rare situation in which chloramphenicol must be used to treat pneumococcal meningitis, lumbar puncture should be repeated 2-3 days after treatment is initiated to ensure that an adequate response has occurred.

Rickettsial Diseases. The tetracyclines usually are the preferred agents for the treatment of rickettsial diseases. However, in patients allergic to these drugs, in those with reduced renal function, in pregnant women, and in children <8 years of age who require prolonged or repeated courses of therapy, chloramphenicol may be the drug of choice. Rocky Mountain spotted fever, epidemic, murine, scrub, and recrudescent typhus, and Q fever respond well to chloramphenicol. For adults and children with these diseases, a dosage of 50 mg/kg/day divided into 6-hour intervals is recommended. For severe or resistant infections, doses up to 100 mg/kg/day may be used for short intervals, but the dose be reduced to 50 mg/kg/day as soon as possible. Therapy should be continued until the general condition has improved and the patient is afebrile for 24-48 hours.

Untoward Effects. Chloramphenicol inhibits the synthesis of proteins of the inner mitochondrial membrane, probably by inhibiting the ribosomal peptidyltransferase. These include subunits of cytochrome *c* oxidase, ubiquinone-cytochrome *c* reductase, and the proton-translocating ATPase critical for aerobic metabolism. Much of the toxicity observed with this drug can be attributed to these effects.

Hypersensitivity Reactions. Although relatively uncommon, macular or vesicular skin rashes result from hypersensitivity to chloramphenicol. Fever may appear simultaneously or be the sole manifestation. Angioedema is a rare complication. Jarisch-Herxheimer reactions may occur after institution of chloramphenicol therapy for syphilis, brucellosis, and typhoid fever.

Hematological Toxicity. The most important adverse effect of chloramphenicol is on the bone marrow. Chloramphenicol affects the hematopoietic system in two ways: a dose-related toxicity that presents as anemia, leukopenia, or thrombocytopenia, and an idiosyncratic response manifested by aplastic anemia, leading in many cases to fatal pancytopenia. Pancytopenia seems to occur more commonly in individuals who undergo prolonged therapy and especially in those who are exposed to the drug on more than one occasion. A genetic predisposition is suggested by the occurrence of pancytopenia in identical twins. Although the incidence of the reaction is low, ~1 in $\geq 30,000$ courses of therapy, the fatality rate is high when bone

marrow aplasia is complete, and there is an increased incidence of acute leukemia in those who recover. Aplastic anemia accounts for ~70% of cases of blood dyscrasias due to chloramphenicol; hypoplastic anemia, agranulocytosis, and thrombocytopenia make up the remainder. The exact biochemical mechanism has not yet been elucidated but is hypothesized to involve conversion of the nitro group to a toxic intermediate by intestinal bacteria.

The risk of aplastic anemia does not contraindicate the use of chloramphenicol in situations in which it may be lifesaving. The drug should never be used, however, in undefined situations or in diseases readily, safely, and effectively treatable with other antimicrobial agents.

Dose-related, reversible erythroid suppression probably reflects an inhibitory action of chloramphenicol on mitochondrial protein synthesis in erythroid precursors, which in turn impairs iron incorporation into heme. Leukopenia and thrombocytopenia also may occur. Bone marrow suppression occurs regularly when plasma concentrations are ≥ 25 $\mu\text{g/mL}$ and is observed with the use of large doses of chloramphenicol, prolonged treatment, or both. Dose-related suppression of the bone marrow may progress to fatal aplasia if treatment is continued, but most cases of bone marrow aplasia develop suddenly, without prior dose-related marrow suppression. Some patients who developed chronic bone marrow hypoplasia after chloramphenicol treatment subsequently developed acute myeloblastic leukemia. The administration of chloramphenicol in the presence of hepatic disease frequently depresses erythropoiesis. About one-third of patients with severe renal insufficiency exhibit the same reaction.

Other Toxic and Irritative Effects. Nausea and vomiting, unpleasant taste, diarrhea, and perineal irritation may follow the oral administration of chloramphenicol. Blurring of vision and digital paresthesias may rarely occur. Tissues that have a high rate of oxygen consumption may be particularly susceptible to chloramphenicol effects on mitochondrial enzyme systems; encephalopathy and cardiomyopathy have been reported.

Neonates, especially if premature, may develop a serious illness termed *gray baby syndrome* if exposed to excessive doses of chloramphenicol. This syndrome usually begins 2-9 days (average of 4 days) after treatment is started. Within the first 24 hours, vomiting, refusal to suck, irregular and rapid respiration, abdominal distention, periods of cyanosis, and passage of loose green stools occur. The children all are severely ill by the end of the first day, and in the next 24 hours turn an ashen-gray color and become flaccid and hypothermic. A similar "gray syndrome" has been reported in adults who were accidentally overdosed with the drug. Death occurs in ~40% of patients within 2 days of initial symptoms. Those who recover usually exhibit no sequelae.

Two mechanisms apparently are responsible for chloramphenicol toxicity in neonates: (1) a developmental deficiency of glucuronyl transferase, the hepatic enzyme that metabolizes chloramphenicol, in the first 3-4 weeks of life; and (2) inadequate renal excretion of unconjugated drug. At the onset of the clinical syndrome, chloramphenicol concentrations in plasma usually exceed 100 $\mu\text{g/mL}$, although they may be as low as 75 $\mu\text{g/mL}$. Children ≤ 2 weeks of age should receive chloramphenicol in a daily dose no larger than 25 mg/kg of body weight; after this age, full-term infants may be given daily quantities up to 50 mg/kg. Toxic effects have not been observed in the newborns when as much as 1 g of the antibiotic has been given every 2 hours to the mothers during labor.

Drug Interactions. Chloramphenicol inhibits hepatic CYPs and thereby prolongs the half-lives of drugs that are metabolized by this system, including warfarin, dicumarol, phenytoin, chlorpropamide, antiretroviral protease inhibitors, rifabutin, and tolbutamide. Severe toxicity and death have occurred because of failure to recognize such effects. Conversely, other drugs may alter the elimination of chloramphenicol. Concurrent administration of phenobarbital or rifampin, which potently induce CYPs, shortens the $t_{1/2}$ of the antibiotic and may result in subtherapeutic drug concentrations.

MACROLIDES AND KETOLIDES

Erythromycin was discovered in 1952 by McGuire and coworkers in the metabolic products of a strain of *Streptomyces erythreus*. Clarithromycin (BIAXIN, others) and azithromycin (ZITHROMAX, others) are semisynthetic derivatives of erythromycin. Ketolides are semisynthetic derivatives of erythromycin with activity against some macrolide-resistant strains. Telithromycin (Ketek) is the only ketolide currently approved in the U.S. Although the ketolides are promising agents against drug-resistant organisms, substantial hepatotoxicity seen with telithromycin has limited their use.

Macrolide antibiotics contain a many-membered lactone ring (14-membered rings for erythromycin and clarithromycin and a 15-membered ring for azithromycin) to which are attached one or more deoxy sugars. Clarithromycin differs from erythromycin only by methylation of the hydroxyl group at the 6 position, and azithromycin differs by the addition of a methyl-substituted nitrogen atom into the lactone ring. These structural modifications improve acid stability and tissue penetration and broaden the spectrum of activity.

ERYTHROMYCIN

AZITHROMYCIN

Telithromycin differs from erythromycin in that a 3-keto group replaces the α -L-cladinose of the 14-member macrolide ring, and there is a substituted carbamate at C11-C12. These modifications render ketolides less susceptible to methylase-mediated (*erm*) and efflux-mediated (*mef* or *msr*) mechanisms of resistance. Ketolides therefore are active against many macrolide-resistant gram-positive strains. The structural formula of telithromycin is:

TELITHROMYCIN

Antimicrobial Activity. Erythromycin usually is bacteriostatic but may be bactericidal in high concentrations against susceptible organisms. The antibiotic is most active *in vitro* against aerobic gram-positive cocci and bacilli (Table 55-2). Staphylococci are considered susceptible at $\leq 0.5 \mu\text{g/mL}$ and streptococci at $\leq 0.25 \mu\text{g/mL}$. Macrolide resistance among *S. pneumoniae* often co-exists with penicillin resistance. Staphylococci are not reliably sensitive to erythromycin, especially methicillin-resistant strains. Macrolide-resistant strains of *S. aureus* are potentially cross-resistant to clindamycin and streptogramin B (quinupristin). Gram-positive bacilli also are sensitive to erythromycin; typical MICs are $1 \mu\text{g/mL}$ for *Clostridium perfringens*, from 0.2 to $3 \mu\text{g/mL}$ for *Corynebacterium diphtheriae*, and from 0.25 to $4 \mu\text{g/mL}$ for *Listeria monocytogenes*.

Erythromycin is inactive against most aerobic enteric gram-negative bacilli. It has modest activity *in vitro* against other gram-negative organisms, including *H. influenzae* (MIC, 1-32 $\mu\text{g/mL}$) and *N. meningitidis* (MIC, 0.4-1.6 $\mu\text{g/mL}$), and good activity against most strains of *N. gonorrhoeae* (MIC, 0.12-2 $\mu\text{g/mL}$). Useful antibacterial activity also is observed against *Pasteurella multocida*, *Borrelia* spp., and *Bordetella pertussis*. Resistance is common for *B. fragilis* (the MIC ranging from 2-32 $\mu\text{g/mL}$). Macrolides are usually active against *Campylobacter jejuni* (MIC, 0.5-4 $\mu\text{g/mL}$). Erythromycin is active against *M. pneumoniae* (MIC, 0.004-0.02 $\mu\text{g/mL}$) and *Legionella pneumophila* (MIC, 0.01-2 $\mu\text{g/mL}$). Most strains of *C. trachomatis* are inhibited by 0.06-2 $\mu\text{g/mL}$ of erythromycin. Some of the atypical mycobacteria, including *M. scrofulaceum*, are sensitive to erythromycin *in vitro*; *M. kansasii* and *M. avium-intracellulare* vary in sensitivity. *M. fortuitum* is resistant. Macrolides have no effect on viruses, yeasts, or fungi.

In general, organisms are considered susceptible to clarithromycin and azithromycin at MICs $\leq 2 \mu\text{g/mL}$.

Clarithromycin and azithromycin have some activity against *H. influenzae*, with MIC breakpoints of $\leq 8 \mu\text{g/mL}$ and $\leq 4 \mu\text{g/mL}$, respectively. However, these agents are not drugs of choice for documented *H. influenzae* infections because of their lesser activity compared to β -lactams or fluoroquinolones. Clarithromycin is slightly more potent than erythromycin against sensitive strains of streptococci and staphylococci, and has modest activity against *H. influenzae* and *N. gonorrhoeae*. Azithromycin generally is less active than erythromycin against gram-positive organisms and slightly more active than either erythromycin or clarithromycin against *H. influenzae* and *Campylobacter* spp. Clarithromycin and azithromycin have good activity against *M. catarrhalis*, *Chlamydia* spp., *L. pneumophila*, *B. burgdorferi*, *Mycoplasma pneumoniae*, and *H. pylori*. Azithromycin and clarithromycin have enhanced activity against *M. avium-intracellulare*, as well as against some protozoa (e.g., *Toxoplasma gondii*, *Cryptosporidium*, and *Plasmodium* spp.). Clarithromycin has good activity against *Mycobacterium leprae*.

Telithromycin's spectrum of activity is similar to clarithromycin and azithromycin. MIC breakpoints for telithromycin are $\leq 0.25 \mu\text{g/mL}$ for *S. aureus*, $\leq 1 \mu\text{g/mL}$ for *S. pneumoniae*, and $\leq 4 \mu\text{g/mL}$ for *H. influenzae*. Telithromycin's ability to withstand many macrolide resistance mechanisms increases its activity against macrolide-resistant *S. pneumoniae* and *S. aureus*.

Mechanism of Action. Macrolide antibiotics are bacteriostatic agents that inhibit protein synthesis by binding reversibly to 50S ribosomal subunits of sensitive microorganisms (Figure 55–3), at or very near the site that binds chloramphenicol (Figure 55–2). Erythromycin does not inhibit peptide bond formation per se but rather inhibits the translocation step wherein a newly synthesized peptidyl tRNA molecule moves from the acceptor site on the ribosome to the peptidyl donor site. Gram-positive bacteria accumulate ~ 100 times more erythromycin than do gram-negative bacteria. Cells are considerably more permeable to the unionized form of the drug, which probably explains the increased antimicrobial activity at alkaline pH. Ketolides and macrolides have the same ribosomal target site. The principal difference between the two is that structural modifications within ketolides neutralize the common resistance mechanisms that make macrolides ineffective (Nilius and Ma, 2002).

Resistance to Macrolides and Ketolides. Resistance to macrolides usually results from one of four mechanisms:

- drug efflux by an active pump mechanism (encoded by *mrsA*, *mefA*, or *mefE* in staphylococci, group A streptococci, or *S. pneumoniae*, respectively)
- ribosomal protection by inducible or constitutive production of methylase enzymes, mediated by expression of *ermA*, *ermB*, and *ermC*, which modify the ribosomal target and decrease drug binding

Figure 55–3. Inhibition of bacterial protein synthesis by the macrolide antibiotics erythromycin, clarithromycin, and azithromycin. Macrolide antibiotics are bacteriostatic agents that inhibit protein synthesis by binding reversibly to the 50S ribosomal subunits of sensitive organisms. Erythromycin appears to inhibit the translocation step such that the nascent peptide chain temporarily residing at the A site of the transferase reaction fails to move to the P, or donor, site. Alternatively, macrolides may bind and cause a conformational change that terminates protein synthesis by indirectly interfering with transpeptidation and translocation. See Figure 55–1 and its legend for additional information.

- macrolide hydrolysis by esterases produced by Enterobacteriaceae (Lina et al., 1999; Nakajima, 1999)
- chromosomal mutations that alter a 50S ribosomal protein (found in *B. subtilis*, *Campylobacter* spp., mycobacteria, and gram-positive cocci)

The MLS_B (macrolide-lincosamide-streptogramin B) phenotype is conferred by *erm* genes, which encode methylases that modify the macrolide binding of the ribosome. Because macrolides, lincosamides, and type B streptogramins share the same ribosomal binding site, constitutive expression of *erm* confers cross-resistance to all three drug classes. If resistance is due to inducible expression of *erm*, there is resistance to the macrolides, which are inducers of *erm*, but not to lincosamides and streptogramin B, which are not inducers. Cross-resistance can still occur if constitutive mutants are selected by exposure to lincosamides or streptogramin B. Efflux-mediated resistance to macrolides may not result in cross-resistance to lincosamides or streptogramin B because they are structurally dissimilar to macrolides and are not substrates of the macrolide pump.

Introduction of the 3-keto function converts a methylase-inducing macrolide into a noninducing ketolide. This moiety also prevents drug efflux, probably because it generates a less-desirable substrate. The carbamate substitution at C11-C12 enhances binding to the ribosomal target site, even when the site is methylated, by introducing an extra interaction of the ketolide with the ribosome. Inducible and constitutive methylase-producing strains of *S. pneumoniae* are therefore susceptible to telithromycin. However, constitutive methylase-producing strains of *S. aureus* and *S. pyogenes* are telithromycin resistant because the strength of the ketolide interaction

with the fully methylated ribosomal binding site is insufficient to overcome resistance. Constitutive methylase producers can be selected from strains with the inducible *erm* phenotype.

Absorption, Distribution, and Excretion.

Absorption. Erythromycin base is incompletely but adequately absorbed from the upper small intestine. Because it is inactivated by gastric acid, the drug is administered as enteric-coated tablets, as capsules containing enteric-coated pellets that dissolve in the duodenum, or as an ester. Food, which increases gastric acidity, may delay absorption.

Peak serum concentrations are 0.3-0.5 $\mu\text{g/mL}$, 4 hours after oral administration of 250 mg of the base, and 0.3-1.9 $\mu\text{g/mL}$ after a single dose of 500 mg. Esters of erythromycin base (e.g., stearate, estolate, and ethylsuccinate) have improved acid stability, and their absorption is less altered by food. A single oral 250-mg dose of erythromycin estolate produces peak serum concentrations of $\sim 1.5 \mu\text{g/mL}$ after 2 hours, and a 500-mg dose produces peak concentrations of 4 $\mu\text{g/mL}$. Peak serum concentrations of erythromycin ethylsuccinate are 1.5 $\mu\text{g/mL}$ (0.5 $\mu\text{g/mL}$ of base) 1-2 hours after administration of a 500-mg dose. These peak values include the inactive ester and the free base, the latter of which comprises 20-35% of the total. The concentration of microbiologically active erythromycin base in serum therefore is similar for the various preparations. Higher concentrations of erythromycin can be achieved by intravenous administration. Values are $\sim 10 \mu\text{g/mL}$ 1 hour after intravenous administration of 500-1000 mg of erythromycin lactobionate.

Clarithromycin is absorbed rapidly from the GI tract after oral administration, but first-pass metabolism reduces its bioavailability to 50-55%. Peak concentrations occur ~ 2 hours after drug administration. Clarithromycin may be given with or without food, but the extended-release form, typically given once daily as a 1-g dose, should be administered with food to improve bioavailability. Steady-state peak concentrations in plasma of 2-3 $\mu\text{g/mL}$ are achieved after 2 hours with a regimen of 500 mg every 12 hours, or after 2-4 hours with two 500-mg extended-release tablets given once daily.

Azithromycin administered orally is absorbed rapidly and distributes widely throughout the body, except to the brain and CSF. Concomitant administration of aluminum and magnesium hydroxide antacids decreases the peak serum drug concentrations but not overall bioavailability. Azithromycin should not be administered with food. A 500-mg loading dose will produce a peak plasma drug concentration of $\sim 0.4 \mu\text{g/mL}$. When this loading dose is followed by 250 mg once daily for 4 days, the steady-state peak drug concentration is 0.24 $\mu\text{g/mL}$. Azithromycin also can be administered intravenously, producing plasma concentrations of 3-4 $\mu\text{g/mL}$ after a 1-hour infusion of 500 mg.

Telithromycin is formulated as a 400-mg tablet for oral administration. There is no parenteral form. It is well absorbed with $\sim 60\%$ bioavailability. Peak serum concentrations, averaging 2 $\mu\text{g/mL}$ following a single 800-mg oral dose, are achieved within 30 minutes to 4 hours.

Distribution. Erythromycin diffuses readily into intracellular fluids, achieving antibacterial activity in essentially all sites except the brain and CSF. Erythromycin penetrates into prostatic fluid, achieving concentrations $\sim 40\%$ of those in plasma. Concentrations in middle ear exudate reach only 50% of serum concentrations and thus may be inadequate for the treatment of otitis media caused by *H. influenzae*.

Protein binding is $\sim 70\text{-}80\%$ for erythromycin base and even higher, 96%, for the estolate. Erythromycin traverses the placenta, and drug concentrations in fetal plasma are $\sim 5\text{-}20\%$ of those in the maternal circulation. Concentrations in breast milk are 50% of those in serum.

Clarithromycin and its active metabolite, 14-hydroxycarithromycin, distribute widely and achieve high intracellular concentrations throughout the body. Tissue concentrations generally exceed serum concentrations. Concentrations in middle-ear fluid are 50% higher than simultaneous serum concentrations for clarithromycin and the active metabolite. Protein binding of clarithromycin ranges from 40% to 70% and is concentration dependent.

Azithromycin's unique pharmacokinetic properties include extensive tissue distribution and high drug concentrations within cells (including phagocytes), resulting in much greater concentrations of drugs in tissue or secretions compared to simultaneous serum concentrations. Tissue fibroblasts act as the natural reservoir for the drug *in vivo*. Protein binding is 50% at very low plasma concentrations and less at higher concentrations.

Telithromycin is 60-70% bound by serum protein, principally albumin. It penetrates well into most tissues, exceeding plasma concentrations by ~ 2 -fold to ≥ 10 -fold. Telithromycin is concentrated into macrophages and white blood cells, where concentrations of 40 $\mu\text{g/mL}$ (500 times the simultaneous plasma concentration) are maintained 24 hours after dosing.

Elimination. Only 2-5% of orally administered erythromycin is excreted in active form in the urine; this value is from 12-15% after intravenous infusion. The antibiotic is concentrated in the liver and excreted in the bile, which may contain as much as 250 $\mu\text{g/mL}$ when serum concentrations are very high. The serum elimination $t_{1/2}$ of erythromycin is ~ 1.6 hours. Although the $t_{1/2}$ may be prolonged in patients with anuria, dosage reduction is not routinely recommended in renal failure patients. The drug is not removed significantly by either peritoneal dialysis or hemodialysis.

Clarithromycin is eliminated by renal and nonrenal mechanisms. It is metabolized in the liver to several metabolites; the active 14-hydroxy metabolite is the most significant. Primary metabolic pathways are oxidative *N*-demethylation and hydroxylation at the 14 position. The elimination half-lives are 3-7 hours for clarithromycin and 5-9 hours for 14-hydroxycarithromycin. Metabolism is saturable, resulting in nonlinear pharmacokinetics with higher dosages; longer half-lives are observed after larger doses. The amount of clarithromycin excreted unchanged in the urine ranges from 20% to 40%, depending on the dose administered and the formulation (tablet versus oral suspension). An additional 10-15% of a dose is excreted in the urine as 14-hydroxycarithromycin. Although the pharmacokinetics of clarithromycin are altered in patients with either hepatic or renal dysfunction, dose adjustment is not necessary unless the creatinine clearance is $< 30 \text{ mL/minute}$.

Azithromycin undergoes some hepatic metabolism to inactive metabolites, but biliary excretion is the major route of elimination. Only 12% of drug is excreted unchanged in the urine. The elimination $t_{1/2}$, 40-68 hours, is prolonged because of extensive tissue sequestration and binding.

With a $t_{1/2}$ of 9.8 hours, telithromycin can be given once daily. The drug is cleared primarily by hepatic metabolism, 50% by CYP3A4 and 50% by CYP-independent metabolism. No adjustment of the dose is required for hepatic failure or mild-to-moderate renal

failure. No dose has been established for patients in whom creatinine clearance is <30 mL/minute, although a reduction in dosage probably is advisable (Shi et al., 2004).

Therapeutic Uses and Dosage. Depending on the nature and severity of the infection, the usual oral dose of erythromycin (erythromycin base) for adults ranges from 1-2 g per day, in equally divided and spaced amounts, usually given every 6 hours. Erythromycin base is available as immediate release (film-coated) and delayed-release (enteric-coated) tablets. Daily doses of erythromycin as large as 8 g orally, given for 3 months, have been well tolerated. Food should not be taken concurrently, if possible, with erythromycin base or the stearate formulations, but this is not necessary with erythromycin estolate. The oral dose of erythromycin for children is 30-50 mg/kg per day, divided into four portions; this dose may be doubled for severe infections. Intramuscular administration of erythromycin is not recommended because of pain upon injection. Intravenous administration is generally reserved for the therapy of severe infections, such as legionellosis. The usual dose is 0.5-1 g every 6 hours; 1 g of erythromycin gluceptate (not available in the U.S.) has been given intravenously every 6 hours for as long as 4 weeks with no adverse effects except for thrombophlebitis at the site of injection. Erythromycin lactobionate is available for intravenous injection. The combination of erythromycin and sulfisoxazole appears to have synergistic antibacterial activity; it is available as a suspension used primarily for treatment of otitis media in children.

Clarithromycin (BIAxin, others) usually is given twice daily at a dose of 250 mg for children >12 years and adults with mild to moderate infection. Larger doses (e.g., 500 mg twice daily) are indicated for more severe infection such as pneumonia or when infection is caused by more resistant organisms such as *H. influenzae*. Children <12 years old have received 7.5 mg/kg twice daily in clinical studies. The 500-mg extended-release formulation is given as two tablets once daily. Clarithromycin (500 mg) is also packaged with lansoprazole (30 mg) and amoxicillin (1 g) as a combination regimen (PREVPAC) that is administered twice daily for 10 or 14 days to eradicate *H. pylori* and to reduce the associated risk of duodenal ulcer recurrence (Chapter 45).

Azithromycin (ZITHROMAX, other) should be given 1 hour before or 2 hours after meals when administered orally. For outpatient therapy of community-acquired pneumonia, pharyngitis, or skin and skin-structure infections, a loading dose of 500 mg is given on the first day, and then 250 mg per day is given for days 2 through 5.

A single 2-g dose of extended-release microspheres is an alternative regimen for treatment of community-acquired pneumonia or acute exacerbations of chronic bronchitis. Treatment or prophylaxis of *M. avium-intracellulare* infection in AIDS patients requires higher doses: 600 mg daily in combination with one or more other agents for treatment, or 1200 mg once weekly for primary prevention (Kovacs and Masur, 2000). Azithromycin is useful in treatment of sexually transmitted diseases, especially during pregnancy when tetracyclines are contraindicated. The treatment of uncomplicated nongonococcal urethritis presumed to be caused by *C. trachomatis* consists of a single 1-g dose of azithromycin. This dose also is effective for chancroid. Azithromycin (1 g per week for 3 weeks) is an alternative regimen for treatment of granuloma inguinale or lymphogranuloma venereum.

In children, the recommended dose of azithromycin oral suspension for acute otitis media and pneumonia is 10 mg/kg on the first day (maximum: 500 mg) and 5 mg/kg (maximum: 250 mg per day) on days 2 through 5. A single 30 mg/kg dose is approved as an alternative for otitis media. The dose for tonsillitis or pharyngitis is 12 mg/kg per day, up to 500 mg total, for 5 days.

Respiratory Tract Infections. Macrolides and ketolides are suitable drugs for the treatment of a number of respiratory tract infections due to their activity against *Streptococcus pneumoniae*, *Haemophilus influenzae*, and atypical pathogens (*Mycoplasma*, *Chlamydia*, *Legionella*). Azithromycin and clarithromycin are suitable choices for treatment of mild to moderate community-acquired pneumonia among ambulatory patients. In hospitalized patients, a macrolide is commonly added to a cephalosporin for coverage of atypical respiratory pathogens. Macrolides, fluoroquinolones, and tetracyclines are drugs of choice for treatment of pneumonia caused by *Chlamydia pneumoniae* or *Mycoplasma pneumoniae*. Erythromycin has been considered as the drug of choice for treatment of pneumonia caused by *L. pneumophila*, *L. micdadei*, or other *Legionella* spp. Because of excellent *in vitro* activity, superior tissue concentration, the ease of administration as a single daily dose, and better tolerability compared to erythromycin, azithromycin (or a fluoroquinolone) has supplanted erythromycin as the first-line agent for treatment of legionellosis (Garey and Amsden, 1999). The recommended dose is 500 mg daily, intravenously or orally, for a total of 10-14 days.

Macrolides are also appropriate alternative agents for the treatment of acute exacerbations of chronic bronchitis, acute otitis media, acute streptococcal pharyngitis, and acute bacterial sinusitis. Azithromycin or clarithromycin are generally preferred to erythromycin for these indications due to their broader spectrum and superior tolerability.

Telithromycin has shown to be effective in the treatment of community-acquired pneumonia, acute exacerbations of chronic bronchitis, and acute bacterial sinusitis, and has a potential advantage over macrolides in regions where macrolide-resistant strains are common. However, due to a number of cases of severe hepatotoxicity due to telithromycin, telithromycin's U.S. FDA approval for treatment

of acute exacerbations of chronic bronchitis and sinusitis have been rescinded, leaving only its indication for community-acquired pneumonia. *Because of the substantial risk of serious hepatotoxicity, telithromycin should be used only in circumstances where it provides a substantial advantage over less toxic therapies.*

Skin and Soft-Tissue Infections. Macrolides are alternatives for treatment of erysipelas and cellulitis among patients who have a serious allergy to penicillin. Unfortunately, macrolide-resistant strains of staphylococci and streptococci are increasingly encountered. Erythromycin has been an alternative agent for the treatment of relatively minor skin and soft-tissue infections caused by either penicillin-sensitive or penicillin-resistant *S. aureus*. However, many strains of *S. aureus* are resistant to macrolides, and they no longer can be relied on unless *in vitro* susceptibility has been documented.

Chlamydial Infections. Chlamydial infections can be treated effectively with any of the macrolides. A single 1-g dose of azithromycin is recommended for patients with uncomplicated urethral, endocervical, rectal, or epididymal infections because of the ease of compliance. During pregnancy, erythromycin base, 500 mg four times daily for 7 days, is recommended as first-line therapy for chlamydial urogenital infections. Azithromycin, 1 g orally as a single dose, is a suitable alternative. Erythromycin base is preferred for chlamydial pneumonia of infancy and ophthalmia neonatorum (50 mg/kg per day in four divided doses for 10-14 days). Azithromycin, 1 g/week for 3 weeks, may be effective for lymphogranuloma venereum.

Diphtheria. Erythromycin, 250 mg four times daily for 7 days, is very effective for acute infections or for eradicating the carrier state. The other macrolides also are likely to be effective; because clinical experience with them is lacking, they are not FDA-approved for this indication. The presence of an antibiotic does not alter the course of an acute infection with the diphtheria bacillus or the risk of complications. Antitoxin is indicated in the treatment of acute infection.

Pertussis. Erythromycin is the drug of choice for treating persons with *B. pertussis* disease and for postexposure prophylaxis of household members and close contacts. A 7-day regimen of erythromycin estolate (40 mg/kg per day; maximum: 1 g/day; not available in U.S.) is as effective as the 14-day regimens traditionally recommended (Halperin et al., 1997). Clarithromycin and azithromycin also are effective (Bace et al., 1999). If administered early in the course of whooping cough, erythromycin may shorten the duration of illness; it has little influence on the disease once the paroxysmal stage is reached, although it may eliminate the microorganisms from the nasopharynx. Nasopharyngeal cultures should be obtained from people with pertussis who do not improve with erythromycin therapy because resistance has been reported.

Campylobacter Infections. The treatment of gastroenteritis caused by *C. jejuni* with erythromycin (250-500 mg orally four times a day for 7 days) hastens eradication of the microorganism from the stools and reduces the duration of symptoms. Availability of fluoroquinolones, which are highly active against *Campylobacter* species and other enteric pathogens, largely has replaced the use of erythromycin for this disease in adults. Erythromycin remains useful for treatment of *Campylobacter* gastroenteritis in children.

Helicobacter pylori Infection. Clarithromycin, 500 mg, in combination with omeprazole, 20 mg, and amoxicillin, 1 g (PREVPAC), each administered twice daily for 10-14 days, is effective for treatment

of peptic ulcer disease caused by *H. pylori* (Peterson et al., 2000). Numerous other regimens, some effective as 7-day treatments, have been studied and also are effective. The more effective regimens generally include three agents, one of which usually is clarithromycin (Chapter 45).

Mycobacterial Infections. Clarithromycin or azithromycin is recommended as first-line therapy for prophylaxis and treatment of disseminated infection caused by *M. avium-intracellulare* in AIDS patients and for treatment of pulmonary disease in patients not infected with HIV (Kovacs and Masur, 2000). Azithromycin (1.2 g once weekly) or clarithromycin (500 mg twice daily) is recommended for primary prevention for AIDS patients with <50 CD4 cells/mm³. Single-agent therapy should not be used for treatment of active disease or for secondary prevention in AIDS patients. Clarithromycin (500 mg twice daily) plus ethambutol (15 mg/kg once daily) with or without rifabutin is an effective combination regimen. Azithromycin (500 mg once daily) may be used instead of clarithromycin, but clarithromycin appears to be slightly more efficacious (Ward et al., 1998). Clarithromycin also has been used with minocycline for the treatment of *Mycobacterium leprae* in lepromatous leprosy.

Prophylactic Uses. Penicillin is the drug of choice for the prophylaxis of recurrences of rheumatic fever. Erythromycin is an effective alternative for individuals who are allergic to penicillin. Clarithromycin or azithromycin (or clindamycin) are recommended alternatives for the prevention of bacterial endocarditis in patients undergoing dental procedures who are at high risk for endocarditis (Wilson et al., 2007).

Untoward Effects.

Hepatotoxicity. Cholestatic hepatitis is the most striking side effect. It is caused primarily by erythromycin estolate and rarely by the ethylsuccinate or the stearate. The illness starts after 10-20 days of treatment and is characterized initially by nausea, vomiting, and abdominal cramps. The pain often mimics that of acute cholecystitis. These symptoms are followed shortly thereafter by jaundice, which may be accompanied by fever, leukocytosis, eosinophilia, and elevated transaminases in plasma. Biopsy of the liver reveals cholestasis, periportal infiltration by neutrophils, lymphocytes, and eosinophils, and occasionally, necrosis of neighboring parenchymal cells. Findings usually resolve within a few days after cessation of drug therapy and rarely are prolonged. The syndrome may represent a hypersensitivity reaction to the estolate ester.

Hepatotoxicity has also been observed with clarithromycin and azithromycin, although at a lower rate than with erythromycin. After its regulatory approval and widespread use, a number of post-marketing reports of severe telithromycin-induced hepatotoxicity emerged. These cases tended to have a short latency between drug initiation and manifestation of hepatotoxicity, with some leading to death or liver transplantation (Brinker et al., 2009). Because of this toxicity, telithromycin should only be used in circumstances where it represents a clear advantage over alternative agents.

GI Toxicity. Oral administration of erythromycin, especially of large doses, frequently is accompanied by epigastric distress, which may be quite severe. Intravenous administration of erythromycin may cause similar symptoms, with abdominal cramps, nausea, vomiting, and diarrhea. Erythromycin stimulates GI motility by acting on motilin receptors. Because of this property, erythromycin is used postoperatively to promote peristalsis; it has been exploited to speed

gastric emptying in patients with gastroparesis (Chapter 46). The GI symptoms are dose related and occur more commonly in children and young adults; they may be reduced by prolonging the infusion time to 1 hour or by pretreatment with glycopyrrolate (Bowler et al., 1992). Intravenous infusion of 1-g doses, even when dissolved in a large volume, often is followed by thrombophlebitis. This can be minimized by slow rates of infusion. Clarithromycin, azithromycin, and telithromycin also may cause GI distress, but typically to a lesser degree than that seen with erythromycin.

Cardiac toxicity. Erythromycin, clarithromycin, and telithromycin have been reported to cause cardiac arrhythmias, including QT prolongation with ventricular tachycardia. Most patients have had underlying risk factors, such as prolonged QT syndrome, uncorrected hypokalemia or hypomagnesemia, profound bradycardia, or in patients receiving certain antiarrhythmics (e.g., quinidine, procainamide, amiodarone) or other agents that prolong QTc (e.g., cisapride, pimozone).

Other Toxic and Irritative Effects. Among the allergic reactions observed are fever, eosinophilia, and skin eruptions, which may occur alone or in combination; each disappears shortly after therapy is stopped. Transient auditory impairment is a potential complication of treatment with erythromycin; it has been observed to follow intravenous administration of large doses of the gluceptate or lactobionate (4 g per day) or oral ingestion of large doses of the estolate. Visual disturbances due to slowed accommodation have been reported to occur in ~1% of treatment courses with telithromycin, and they include blurred vision, difficulty focusing, and diplopia. Telithromycin is contraindicated in patients with myasthenia gravis due to reports of exacerbation of neurological symptoms by the antibiotic in these patients. Loss of consciousness and visual disturbances are associated with telithromycin.

Drug Interactions. Erythromycin, clarithromycin, and telithromycin inhibit CYP3A4 and are associated with clinically significant drug interactions (Periti et al., 1992). Erythromycin potentiates the effects of carbamazepine, corticosteroids, cyclosporine, digoxin, ergot alkaloids, theophylline, triazolam, valproate, and warfarin, probably by interfering with CYP-mediated metabolism of these drugs (Chapter 6). Clarithromycin, which is structurally related to erythromycin, has a similar drug interaction profile. Telithromycin is both a substrate and a strong inhibitor of CYP3A4. Co-administration of rifampin, a potent inducer of CYP, decreases the serum concentrations of telithromycin by 80%. CYP3A4 inhibitors (e.g., itraconazole) increase peak serum concentrations of telithromycin. Azithromycin, which differs from erythromycin and clarithromycin because of its 15-membered lactone ring structure, and dirithromycin, which is a longer-acting 14-membered lactone ring analog of erythromycin, appear to be free of these drug interactions. Caution is advised, nevertheless, when using azithromycin in conjunction with drugs known to interact with erythromycin.

LINCOSAMIDES (CLINDAMYCIN)

Clindamycin is a lincosamide, a derivative of the amino acid *trans*-L-4-*n*-propylhygrinic acid, attached to a sulfur-containing derivative of an octose. It is a congener of lincomycin:

Antimicrobial Activity. Bacterial strains are susceptible to clindamycin at MICs of ≤ 0.5 $\mu\text{g/mL}$. Clindamycin generally is similar to erythromycin in its *in vitro* activity against susceptible strains of pneumococci, *S. pyogenes*, and viridans streptococci (Table 55–2). Methicillin-susceptible strains of *S. aureus* usually are susceptible to clindamycin, but methicillin-resistant strains of *S. aureus* and coagulase-negative staphylococci frequently are resistant.

Clindamycin is more active than erythromycin or clarithromycin against anaerobic bacteria, especially *B. fragilis*; some strains are inhibited by < 0.1 $\mu\text{g/mL}$, and most are inhibited by 2 $\mu\text{g/mL}$. The MICs for other anaerobes are as follows: *Bacteroides melaninogenicus*, 0.1 to 1 $\mu\text{g/mL}$; *Fusobacterium*, < 0.5 $\mu\text{g/mL}$ (although most strains of *Fusobacterium varium* are resistant); *Peptostreptococcus*, < 0.1 –0.5 $\mu\text{g/mL}$; *Peptococcus*, 1–100 $\mu\text{g/mL}$ (with 10% of strains resistant); and *C. perfringens*, < 0.1 –8 $\mu\text{g/mL}$. From 10–20% of clostridial species other than *C. perfringens* are resistant. Resistance to clindamycin in *Bacteroides* spp. increasingly is encountered (Hedberg and Nord, 2003). Strains of *Actinomyces israelii* and *Nocardia asteroides* are sensitive. Essentially all aerobic gram-negative bacilli are resistant.

With regard to atypical organisms and parasites, *M. pneumoniae* is resistant. *Chlamydia* spp. are variably sensitive, although the clinical relevance is not established. Clindamycin plus primaquine and clindamycin plus pyrimethamine are second-line regimens for *Pneumocystis jiroveci* pneumonia and *T. gondii* encephalitis, respectively. Clindamycin has been used for treatment of babesiosis.

Mechanism of Action. Clindamycin binds exclusively to the 50S subunit of bacterial ribosomes and suppresses protein synthesis. Although clindamycin, erythromycin, and chloramphenicol are not structurally related, they act at sites in close proximity (Figures 55–2 and 55–3), and binding by one of these antibiotics to the ribosome may inhibit the interaction of the others. There are no clinical indications for the concurrent use of these antibiotics.

Resistance to Clindamycin. Macrolide resistance due to ribosomal methylation by *erm*-encoded enzymes also may produce resistance to clindamycin. Because clindamycin does not induce the methylase, there is cross-resistance only if the enzyme is produced constitutively. However, strains with inducible resistance may develop constitutive production of the methylase during therapy. Thus, many clinicians avoid use of clindamycin in the treatment of deep-seated infections due to organisms displaying an inducible resistance phenotype. Detection of this phenotype can be accomplished by approximating erythromycin and clindamycin on an agar plate with a lawn of the organism; a blunting of the zone of inhibition between clindamycin and erythromycin suggests inducible resistance (this is known as the “D-test”) (Lewis & Jorgensen, 2005). Clindamycin is not a substrate for macrolide efflux pumps; thus strains that are resistant to macrolides by this mechanism are susceptible to clindamycin.

These strains would not display a blunting of inhibition on a D-test, and clindamycin use would be appropriate. Altered metabolism occasionally causes clindamycin resistance (Bozdogan et al., 1999).

Absorption, Distribution, and Excretion

Absorption. Clindamycin is nearly completely absorbed following oral administration. Peak plasma concentrations of 2-3 µg/mL are attained within 1 hour after the ingestion of 150 mg. The presence of food in the stomach does not reduce absorption significantly. The $t_{1/2}$ of the antibiotic is ~2.9 hours, and modest accumulation of drug is thus expected if it is given every 6 hours.

Clindamycin palmitate, an oral preparation for pediatric use, is an inactive prodrug that is hydrolyzed rapidly *in vivo*. Its rate and extent of absorption are similar to those of clindamycin. After several oral doses at 6-hour intervals, children attain plasma concentrations of 2-4 µg/mL with the administration of 8-16 µg/kg.

The phosphate ester of clindamycin, which is given parenterally, also is rapidly hydrolyzed *in vivo* to the active parent compound. After intramuscular injection, peak concentrations in plasma are not attained until 3 hours in adults and 1 hour in children; these values approximate 6 µg/mL after a 300-mg dose and 9 µg/mL after a 600-mg dose in adults.

Distribution. Clindamycin is widely distributed in many fluids and tissues, including bone. Significant concentrations are not attained in CSF, even when the meninges are inflamed. Concentrations sufficient to treat cerebral toxoplasmosis are achievable (Gatti et al., 1998). The drug readily crosses the placental barrier. Ninety percent or more of clindamycin is bound to plasma proteins. Clindamycin accumulates in polymorphonuclear leukocytes, alveolar macrophages, and in abscesses.

Excretion. Only ~10% of the clindamycin administered is excreted unaltered in the urine, and small quantities are found in the feces. However, antimicrobial activity persists in feces for ≥5 days after parenteral therapy with clindamycin is stopped; growth of clindamycin-sensitive microorganisms in colonic contents may be suppressed for up to 2 weeks.

Clindamycin is inactivated by metabolism to *N*-demethylclindamycin and clindamycin sulfoxide, which are excreted in the urine and bile. Accumulation of clindamycin can occur in patients with severe hepatic failure, and dosage adjustments thus may be required.

Therapeutic Uses and Dosage. The oral dose of clindamycin (clindamycin hydrochloride; CLEOCIN, others) for adults is 150-300 mg every 6 hours; for severe infections, it is 300-600 mg every 6 hours. Children should receive 8-12 mg/kg per day of clindamycin palmitate hydrochloride (CLEOCIN PEDIATRIC) in three or four divided doses (some physicians recommend 10-30 mg/kg per day in six divided doses) or for severe infections, 13-25 mg/kg per day. However, children weighing ≤10 kg should receive 1/2 teaspoonful of clindamycin palmitate hydrochloride (37.5 mg) every 8 hours as a minimal dose. Clindamycin phosphate (CLEOCIN PHOSPHATE, others) is available for intramuscular or intravenous use. For serious infections, intravenous or intramuscular administration is recommended in dosages of 1200-2400 mg per day, divided into three or four equal doses for adults. Daily doses as high as 4.8 g have been given intravenously to adults. Children should receive 15-40 mg/kg per day in three or four divided doses; in severe infections, a minimal daily dose of 300 mg is recommended, regardless of body weight.

Skin and Soft-Tissue Infections. Because of clindamycin's good activity against aerobic and anaerobic gram-positive cocci and good oral bioavailability, it is an alternative agent for the treatment of skin

and soft-tissue infections, especially in patients with β-lactam allergies. However, *the high incidence of diarrhea and the occurrence of pseudomembranous colitis should limit its use to infections where it represents a clear therapeutic advantage.* Clindamycin has been employed in the treatment of necrotizing skin and soft-tissue infections based on its potential to reduce toxin expression.

Respiratory Tract Infections. On the basis of one clinical trial which found that clindamycin (600 mg intravenously every 8 hours) was superior to penicillin (1 million units intravenously every 4 hours; Levison et al., 1983), clindamycin has replaced penicillin as the drug of choice for treatment of lung abscess and anaerobic lung and pleural space infections. Clindamycin (600 mg intravenously every 8 hours, or 300-450 mg orally every 6 hours for less severe disease) in combination with primaquine (15 mg of base once daily) is useful for the treatment of mild to moderate cases of *P. jiroveci* pneumonia in AIDS patients.

Other Infections. Clindamycin (600-1200 mg given intravenously every 6 hours) in combination with pyrimethamine (a 200-mg loading dose followed by 75 mg orally each day) and *leucovorin* (folinic acid, 10 mg/day) is effective for acute treatment of encephalitis caused by *T. gondii* in patients with AIDS. Clindamycin also is available as a topical solution, gel, or lotion (CLEOCIN T, others) and as a vaginal cream (CLEOCIN, others). It is effective topically (or orally) for acne vulgaris and bacterial vaginosis. Clindamycin is not predictably useful for the treatment of bacterial brain abscesses because penetration into the CSF is poor; metronidazole, in combination with penicillin or a third-generation cephalosporin, is preferred.

Untoward Effects.

Gastrointestinal Effects. The reported incidence of diarrhea associated with the administration of clindamycin ranges from 2% to 20%. A number of patients (variously reported as 0.01-10%) have developed pseudomembranous colitis caused by the toxin from the organism *C. difficile*. This colitis is characterized by watery diarrhea, fever, and elevated peripheral white blood cell counts. Proctoscopic examination reveals white to yellow plaques on the mucosa of the colon. *This syndrome may be lethal.* Discontinuation of the drug, combined with administration of metronidazole or oral vancomycin usually is curative, but relapses occur in up to 20% of cases. Agents that inhibit peristalsis, such as opioids, may prolong and worsen the condition.

Other Toxic and Irritative Effects. Skin rashes occur in ~10% of patients treated with clindamycin and may be more common in patients with HIV infection. Other reactions, which are uncommon, include exudative erythema multiforme (Stevens-Johnson syndrome), reversible elevation of aspartate aminotransferase and alanine aminotransferase, granulocytopenia, thrombocytopenia, and anaphylactic reactions. Local thrombophlebitis may follow intravenous administration of the drug. Clindamycin can inhibit neuromuscular transmission and may potentiate the effect of a neuromuscular blocking agent administered concurrently.

STREPTOGRAMINS (QUINUPRISTIN/DALFOPRISTIN)

Quinupristin/dalfopristin (SYNERCID) is a combination of quinupristin, a streptogramin B, with dalfopristin, a

streptogramin A, in a 30:70 ratio. These compounds are semisynthetic derivatives of naturally occurring pristinamycins, produced by *Streptomyces pristinaespiralis*. Pristinamycin has been available in France for >30 years for oral treatment of staphylococcal infections. Quinupristin and dalfofpristin are more soluble derivatives of pristinamycin IA and pristinamycin IIA, respectively, and therefore are suitable for intravenous administration.

Antimicrobial Activity. Quinupristin/dalfofpristin is active against gram-positive cocci, including *S. pneumoniae*, beta- and alpha-hemolytic strains of streptococci, *E. faecium* (but not *E. faecalis*), and coagulase-positive and coagulase-negative strains of staphylococci (Table 55–2). Strains are considered sensitive if they are inhibited by concentrations of $\leq 1 \mu\text{g/mL}$. The combination is largely inactive against gram-negative organisms, although *Moraxella catarrhalis* and *Neisseria* spp. are susceptible. It also is active against organisms responsible for atypical pneumonia, *M. pneumoniae*, *Legionella* spp., and *Chlamydia pneumoniae*. The combination is bactericidal against streptococci and many strains of staphylococci but bacteriostatic against *E. faecium*.

Mechanism of Action. Quinupristin and dalfofpristin are protein synthesis inhibitors that bind the 50S ribosomal subunit. Quinupristin binds at the same site as macrolides and has a similar effect, with inhibition of polypeptide elongation and early termination of protein synthesis. Dalfofpristin binds at a site nearby, resulting in a conformational change in the 50S ribosome, synergistically enhancing the binding of quinupristin at its target site. Dalfofpristin directly interferes with polypeptide-chain formation. In many bacterial

species, the net result of the cooperative and synergistic binding of these two molecules to the ribosome is bactericidal activity.

Resistance to Streptogramins. Resistance to quinupristin is mediated by MLS type B resistance determinants (e.g., *ermA* and *ermC* in staphylococci and *ermB* in enterococci), encoding a ribosomal methylase that prevents binding of drug to its target; or *vgb* or *vgbB*, which encode lactonases that inactivate type B streptogramins (Allignet et al., 1998; Bozdogan and Leclercq, 1999). Resistance to dalfofpristin is mediated by *vat*, *vatB*, *vatC*, *vatD*, and *satA*, which encode acetyltransferases that inactivate type A streptogramins (Soltani et al., 2000); or staphylococcal genes *vga* and *vgaB*, which encode ATP-binding efflux proteins that pump type A streptogramins out of the cell (Bozdogan and Leclercq, 1999). These resistance determinants are located on plasmids that may be transferable by conjugative mobilization. Resistance to quinupristin/dalfofpristin always is associated with a resistance gene for type A streptogramins. Genes encoding resistance to type B streptogramins also may be present but are not sufficient by themselves to produce resistance. Methylase-encoding *erm* genes, however, can render the combination bacteriostatic instead of bactericidal, making it ineffective in certain infections in which bactericidal activity is necessary for cure, such as endocarditis.

Absorption, Distribution, and Excretion. The combination of quinupristin/dalfofpristin is administered only by intravenous infusion over at least 1 hour. It is incompatible with saline and heparin and should be dissolved in 5% dextrose in water. Steady-state peak serum concentrations in healthy male volunteers are $\sim 3 \mu\text{g/mL}$ of quinupristin and $7 \mu\text{g/mL}$ of dalfofpristin with a 7.5-mg/kg dose administered every 8 hours. The $t_{1/2}$ is 0.85 hour for quinupristin and 0.7 hour for dalfofpristin. The volume of distribution is 0.87 L/kg for quinupristin and 0.71 L/kg for dalfofpristin. Hepatic metabolism by conjugation is the principal means of clearance for both compounds, with 80% of an administered dose eliminated by biliary excretion. Renal elimination of active compound accounts for most of the remainder. No dosage adjustment is necessary for renal insufficiency. Pharmacokinetics are not significantly altered by peritoneal dialysis or hemodialysis. The area under the plasma concentration curve of active component and its metabolites is increased by 180% for quinupristin and 50% for dalfofpristin by hepatic insufficiency. No adjustment is recommended unless the patient is unable to tolerate the drug, in which case the dosing frequency should be reduced from 8 to 12 hours.

Therapeutic Uses and Dosage. Quinupristin/dalfofpristin is approved in the U.S. for treatment of infections caused by vancomycin-resistant strains of *E. faecium* and complicated skin and skin-structure infections caused by methicillin-susceptible strains of *S. aureus* or *S. pyogenes* (Nichols et al., 1999). In Europe it also is approved for treatment of nosocomial pneumonia and infections caused by methicillin-resistant strains of *S. aureus* (Fagon et al., 2000). In open-label, nonrandomized studies, clinical and microbiological cure rates for a variety of infections caused by vancomycin-resistant *E. faecium* were $\sim 70\%$ with quinupristin/dalfofpristin at a dose of 7.5 mg/kg every 8–12 hours (Moellering et al., 1999). Quinupristin/dalfofpristin should be reserved for treatment of serious infections caused by multiple-drug-resistant gram-positive organisms such as vancomycin-resistant *E. faecium*.

Untoward Effects. The most common side effects are infusion-related events, such as pain and phlebitis at the infusion site and arthralgias and myalgias. Phlebitis and pain can be minimized by infusion of drug through a central venous catheter. Arthralgias and myalgias,

which are more likely to be a problem in patients with hepatic insufficiency and may be due to accumulation of metabolites, are managed by reducing the infusion frequency to every 12 hours.

Drug Interactions. Quinupristin/dalfopristin inhibits CYP3A4. The concomitant administration of other CYP3A4 substrates (Chapter 6) with quinupristin/dalfopristin may raise blood pressure and/or result in significant toxicity. Examples include antihistamines (e.g., azelastine and clemastine); some anticonvulsants (e.g., fosphenytoin and felbamate), macrolide antibiotics; some fluoroquinolones (e.g., moxifloxacin) and ketoconazole; some antimalarials (e.g., chloroquine, mefloquine, and quinine); some antidepressants (e.g., fluoxetine, imipramine, venlafaxine); some antipsychotics (e.g., haloperidol, risperidone, and quetiapine); tacrolimus; and doxepin. Appropriate caution and monitoring are recommended for drugs in which the toxic therapeutic window is narrow or for drugs that prolong the QTc interval.

OXAZOLIDINONES (LINEZOLID)

Linezolid (ZYVOX) is a synthetic antimicrobial agent of the oxazolidinone class (Clemett and Markham, 2000; Diekema and Jones, 2000; Hamel et al., 2000). Several other oxazolidinones are in clinical development.

Antimicrobial Activity. Linezolid is active against gram-positive organisms including staphylococci, streptococci, enterococci, gram-positive anaerobic cocci, and gram-positive rods such as *Corynebacterium* spp. and *Listeria monocytogenes* (Table 55–2). It has poor activity against most gram-negative aerobic or anaerobic bacteria. It is bacteriostatic against enterococci and staphylococci and bactericidal against streptococci. Breakpoints for susceptibility are ≤ 4 $\mu\text{g/mL}$ for staphylococci and ≤ 2 $\mu\text{g/mL}$ for enterococci and streptococci. *Mycobacterium tuberculosis* is moderately susceptible, with MICs of 2 $\mu\text{g/mL}$.

Mechanism of Action and Resistance to Oxazolidinones. Linezolid inhibits protein synthesis by binding to the P site of the 50S ribosomal subunit and preventing formation of the larger ribosomal-fMet-tRNA complex that initiates protein synthesis. Because of its unique mechanism of action, linezolid is active against strains that are resistant to multiple other agents, including penicillin-resistant strains of *S. pneumoniae*; methicillin-resistant, vancomycin-intermediate, and vancomycin-resistant strains of staphylococci; and vancomycin-resistant strains of enterococci. Resistance in enterococci and staphylococci is due to point mutations of the 23S rRNA (Wilson et al., 2003). Because multiple copies of 23S rRNA genes are present in bacteria, resistance generally requires mutations in two or more copies.

Absorption, Distribution, and Excretion. Linezolid is well absorbed after oral administration and may be administered without regard to food. With oral bioavailability approaching 100%, dosing for oral and intravenous preparations is the same. Peak serum concentrations average 13 $\mu\text{g/mL}$ 1–2 hours after a single 600-mg dose in adults and ~ 20 $\mu\text{g/mL}$ at steady state with dosing every 12 hours. The $t_{1/2}$ is

~ 4 –6 hours. Linezolid is 30% protein-bound and distributes widely to well-perfused tissues, with a 0.6–0.7 L/kg volume of distribution.

Linezolid is broken down by nonenzymatic oxidation to aminoethoxyacetic acid and hydroxyethyl glycine derivatives. Approximately 80% of the dose of linezolid appears in the urine, 30% as active compound and 50% as the two primary oxidation products. Ten percent of the administered dose appears as oxidation products in feces. Although serum concentrations and $t_{1/2}$ of the parent compound are not appreciably altered by renal insufficiency, oxidation products accumulate in renal insufficiency, with half-lives increasing by ~ 50 –100%. The clinical significance of this is unknown, and no dose adjustment in renal insufficiency is currently recommended. Linezolid and its breakdown products are eliminated by dialysis; therefore the drug should be administered after hemodialysis. One case report noted sustained therapeutic concentrations of linezolid in peritoneal dialysis fluid with oral administration of 600 mg of linezolid twice daily (DePestel et al., 2003).

Therapeutic Uses and Dosage. Linezolid is FDA approved for treatment of infections caused by vancomycin-resistant *E. faecium*; nosocomial pneumonia caused by methicillin-susceptible and resistant strains of *S. aureus*; community-acquired pneumonia caused by penicillin-susceptible strains of *S. pneumoniae*; complicated skin and skin structure infections caused by streptococci and methicillin-susceptible and -resistant strains of *S. aureus*; and uncomplicated skin and skin-structure infections (Clemett and Markham, 2000). Linezolid is bacteriostatic for staphylococci and enterococci; it should not be first-line therapy for treatment of suspected endocarditis, although there are reports of cure of endocarditis with linezolid in salvage situations (Falagas et al., 2006).

Infections Due to Vancomycin-resistant *E. faecium*. In noncomparative studies, linezolid (600 mg twice daily) has had clinical and microbiological cure rates in the range of 85–90% in treatment of a variety of infections (soft tissue, urinary tract, and bacteremia) caused by vancomycin-resistant *E. faecium*.

Skin and Soft-Tissue Infections. Efficacy of linezolid was similar to that of either oxacillin or vancomycin for complicated and uncomplicated skin and skin-structure infections, most microbiologically documented cases are caused by *S. aureus*. Linezolid, 600 mg twice daily (with or without aztreonam), was as effective as ampicillin/sulbactam (with or without vancomycin or aztreonam) for the management of diabetic foot infections. A 400-mg twice-daily dosage regimen is recommended only for treatment of uncomplicated skin and skin-structure infections.

Respiratory Tract Infections. In randomized, comparative studies, cure rates with linezolid ($\sim 60\%$) were similar to those with vancomycin for nosocomial pneumonia caused by methicillin-resistant or methicillin-susceptible *S. aureus* (Rubinstein et al., 2001; Wunderink et al., 2003a). A post hoc analysis suggested that linezolid may be superior to vancomycin for nosocomial pneumonia caused by methicillin-resistant *S. aureus*, but this needs to be confirmed in a prospective randomized trial (Wunderink et al., 2003b). Linezolid also may be an effective alternative for patients with MRSA infections who are failing vancomycin therapy or whose isolates have reduced susceptibility to vancomycin (Howden et al., 2004).

Linezolid should be reserved as an alternative agent for treatment of infections caused by multiple-drug-resistant strains. It should not be used when other agents are likely to be effective (e.g., community-acquired pneumonia, even though it has the indication).

Untoward Effects

Hematological Toxicity. Myelosuppression, including anemia, leukopenia, pancytopenia, and thrombocytopenia, has been reported in patients receiving linezolid. Thrombocytopenia or a significant reduction in platelet count has been associated with linezolid in 2.4% of treated patients, and its occurrence is related to duration of therapy. Platelet counts should be monitored in patients with risk of bleeding, preexisting thrombocytopenia, or intrinsic or acquired disorders of platelet function (including those potentially caused by concomitant medication) and in patients receiving courses of therapy lasting beyond 2 weeks.

Other Toxic and Irritative Effects. The drug seems to be well tolerated, with generally minor side effects (e.g., GI complaints, headache, rash). Patients receiving long-term (e.g., >8 weeks) treatment with linezolid have developed peripheral neuropathy, optic neuritis, and lactic acidosis (Narita et al., 2007). It is believed that these toxicities may originate from effects of linezolid on the mitochondria. Because these effects have not always been reversible, linezolid should be generally not be used for long-term therapy if there are alternative agents.

Drug Interactions. Linezolid is a weak nonspecific inhibitor of monoamine oxidase. Patients receiving concomitant therapy with an adrenergic or serotonergic agent (including selective serotonin reuptake inhibitors [SSRIs]) or consuming >100 mg of tyramine a day may experience serotonin syndrome, characterized by palpitations, headache, or hypertensive crisis. Co-administration of these agents is best avoided if possible. However, in patients receiving SSRIs who acutely require linezolid therapy for short-term (10-14 days) treatment, co-administration with careful monitoring is reasonable because SSRIs generally require tapering to avoid discontinuation syndrome. Linezolid is neither a substrate nor an inhibitor of CYPs.

AMINOCYCLITOLS (SPECTINOMYCIN)

Spectinomycin is an antibiotic produced by *Streptomyces spectabilis*. The drug is an aminocyclitol:

Antimicrobial Activity, Mechanism of Action, and Resistance to Spectinomycin. Spectinomycin is active against a number of gram-negative bacterial species, but it is inferior to other drugs to which such microorganisms are susceptible. *Its only therapeutic use is in the treatment of gonorrhea caused by strains resistant to first-line drugs or if there are contraindications to the use of these drugs.* Spectinomycin selectively inhibits protein synthesis in gram-negative bacteria. The antibiotic binds to and acts on the 30S ribosomal subunit. Its action is similar to that of the aminoglycosides, but spectinomycin

is not bactericidal and does not cause misreading of messenger RNA. Bacterial resistance may be mediated by mutations in the 16S ribosomal RNA or by modification of the drug by adenylyl-transferase (Clark et al., 1999).

Absorption, Distribution, and Excretion. Spectinomycin is rapidly absorbed after intramuscular injection. A single dose of 2 g produces peak serum concentrations of 100 µg/mL at 1 hour. Eight hours after injection, the concentration is ~15 µg/mL. The drug is not significantly bound to plasma protein, and all of an administered dose is recovered in the urine within 48 hours.

Therapeutic Uses and Dosage. The Centers for Disease Control and Prevention recommends ceftriaxone or cefixime for the treatment of uncomplicated gonococcal infection (Workowski and Berman, 2006). Fluoroquinolones are no longer recommended because of increasing resistance. Spectinomycin is recommended as an alternative regimen in patients who are intolerant or allergic to β-lactam antibiotics; however, the drug is not currently available in the U.S. Spectinomycin also is useful in pregnancy when patients are intolerant to β-lactams. The recommended dose for men and women is a single deep intramuscular injection of 2 g. One of the disadvantages of this regimen is that spectinomycin has no effect on incubating or established syphilis, and it is not active against *Chlamydia* spp. It also is less effective for pharyngeal infections, and follow-up cultures to document cure should be obtained.

Untoward Effects. Spectinomycin, when given as a single intramuscular injection, produces few significant untoward effects. Urticaria, chills, and fever have been noted after single doses, as have dizziness, nausea, and insomnia. The injection may be painful.

POLYMYXINS

The polymyxins, discovered in 1947, are a group of closely related antibiotics elaborated by various strains of *Bacillus polymyxa*. Colistin (polymyxin E) is produced by *Bacillus (Aerobacillus) colistinus*. These drugs, which are cationic detergents, are relatively simple basic peptides with molecular masses of ~1000 Da. Polymyxin B is a mixture of polymyxins B₁ and B₂:

Colistin has a similar structure.

Antimicrobial Activity, Mechanism of Action, and Resistance to Polymyxins. The antimicrobial activities of polymyxin B and colistin are similar and restricted to gram-negative bacteria, including *Enterobacter*, *E. coli*, *Klebsiella*, *Salmonella*, *Pasteurella*, *Bordetella*, and *Shigella*, which usually are sensitive to concentrations of 0.05-2 µg/mL. Most strains of *P. aeruginosa* and *Acinetobacter* are inhibited by <8 µg/mL *in vitro*. *Proteus* and *Serratia* spp. are intrinsically resistant.

Polymyxins are surface-active amphipathic agents. They interact strongly with phospholipids and disrupt the structure of cell

membranes. The permeability of the bacterial membrane changes immediately on contact with the drug. Sensitivity to polymyxin B apparently is related to the phospholipid content of the cell wall–membrane complex. The cell walls of certain resistant bacteria may prevent access of the drug to the cell membrane. Polymyxin B binds to the lipid A portion of endotoxin (the lipopolysaccharide of the outer membrane of gram-negative bacteria) and inactivates this molecule. Polymyxin B attenuates pathophysiological consequences of the release of endotoxin in several experimental systems, but the clinical utility of polymyxin B for this indication has not yet been established.

Although resistance to polymyxins among normally susceptible species is rare (likely owing to the minimal systemic use of this agent for many years), emergence of resistance while on treatment has been documented. Dosing regimens, including combination therapies, able to suppress the emergence of resistance are currently being studied.

Absorption, Distribution, and Excretion. Polymyxin B and colistin are not absorbed when given orally and are poorly absorbed from mucous membranes and the surfaces of large burns. They are cleared renally, and modification of the dose is required in patients with impaired renal function.

Therapeutic Uses and Dosage

Topical Uses. Polymyxin B sulfate is available for ophthalmic, otic, and topical use in combination with a variety of other compounds. Colistin is available as otic drops. Infections of the skin, mucous membranes, eye, and ear due to polymyxin B–sensitive microorganisms respond to local application of the antibiotic in solution or ointment. External otitis, frequently due to *Pseudomonas*, may be cured by the topical use of the drug. *P. aeruginosa* is a common cause of infection of corneal ulcers; local application or subconjunctival injection of polymyxin B often is curative. Polymyxin B, in combination with neomycin (NEOSPORIN G.U. IRRIGANT), is administered as a urinary bladder irrigant in conjunction with the use of indwelling catheters.

Systemic Uses. Colistin is available as colistin sulfate for oral use and as colistimethate sodium for parenteral administration. Due to the emergence of multidrug-resistant gram-negative organisms (especially *Stenotrophomonas maltophilia*, *Acinetobacter* spp., *P. aeruginosa*, and *Klebsiella* spp), there has been a resurgence in the systemic use of polymyxins, despite their toxicity when administered via this route. There are no prospective clinical trials of polymyxin use for systemic infections; however, a number of studies have described their use as salvage therapy for treatment of infections caused by multidrug-resistant organisms (Linden et al., 2003; San Gabriel et al., 2004). Because dosing of these agents varies by drug (polymyxin B or colistin), by the particular commercial preparation, and by the patient's degree of renal dysfunction, expert consultation is recommended before using these agents.

Untoward Effects. Polymyxin B applied to intact or denuded skin or mucous membranes produces no systemic reactions because of its almost complete lack of absorption from these sites. Hypersensitization is uncommon with topical application. Polymyxins are nephrotoxic, and administration with aminoglycosides or other nephrotoxins should be avoided if possible. Polymyxins interfere with neurotransmission at the neuromuscular junction, resulting in muscle weakness and apnea. Other neurological reactions include paresthesias, vertigo, and slurred speech.

GLYCOPEPTIDES (VANCOMYCIN AND TEICOPLANIN)

Vancomycin. Vancomycin is a tricyclic glycopeptide antibiotic produced by *Streptococcus orientalis*. Teicoplanin, a glycopeptide antibiotic produced by *Actinoplanes teichomyetius*, is available in Europe (Biavasco et al., 1997). A number of derivatives, the lipoglycopeptides (including telavancin, oritavancin, and dalbavancin), are in late-stage development.

Teicoplanin. This agent is a mixture of six closely related compounds: One compound has a terminal hydrogen at the oxygen indicated by an asterisk; five compounds have an R substituent of either a decanoic acid [*n*-, 8-methyl-, 9-methyl, (*Z*)-4-] or of a nonanoic acid [8-methyl]. Although not FDA approved for use in the U.S., it is available in Europe. It is similar to vancomycin in chemical structure, mechanism of action, spectrum of activity, and route of elimination (i.e., primarily renal).

Antimicrobial Activity. Vancomycin possesses activity against a broad spectrum of gram-positive bacteria (Table 55–2). Strains are considered susceptible at MICs of ≤ 2 $\mu\text{g/mL}$ for *S. aureus*, ≤ 4 $\mu\text{g/mL}$ for *S. epidermidis*, and ≤ 1 $\mu\text{g/mL}$ for streptococci. *Bacillus* spp., including *B. anthracis*, are inhibited by ≤ 2 $\mu\text{g/mL}$. *Corynebacterium* spp. (diphtheroids) are inhibited by <0.04 – 3.1 $\mu\text{g/mL}$ of vancomycin; most species of *Actinomyces*, by 5–10 $\mu\text{g/mL}$; and *Clostridium* spp., by 0.39–6 $\mu\text{g/mL}$. Essentially all species of gram-negative bacilli and mycobacteria are resistant to vancomycin.

Teicoplanin is active against methicillin-susceptible and methicillin-resistant staphylococci, which typically have MICs of <4 $\mu\text{g/mL}$. The MICs for *Listeria monocytogenes*, *Corynebacterium* spp., *Clostridium* spp., and anaerobic gram-positive cocci range from 0.25–2 $\mu\text{g/mL}$. Nonviridans and viridans streptococci, *S. pneumoniae*, and enterococci are inhibited by concentrations ranging from 0.01–1 $\mu\text{g/mL}$. Some strains of staphylococci, coagulase positive and coagulase negative, as well as enterococci and other organisms that are intrinsically resistant to vancomycin (i.e., *Lactobacillus* spp. and *Leuconostoc* spp.), are resistant to teicoplanin.

Mechanism of Action. Vancomycin and teicoplanin inhibit the synthesis of the cell wall in sensitive bacteria by binding with high affinity to the D-alanyl-D-alanine terminus of cell wall precursor units

(Figure 55–4). Because of their large molecular size, they are unable to penetrate the outer membrane of gram-negative bacteria.

Glycopeptides are generally bactericidal against susceptible strains, except for enterococci. The activity of glycopeptides is best predicted by the ratio of the total drug exposure (area under the curve [AUC]) of glycopeptide to minimum inhibitory concentration (MIC) of the infecting organism. This AUC-to-MIC ratio is established as being predictive of organism killing and cure in *in vitro* and animal models, and in some limited clinical data (Rybak, 2006). An AUC-to-MIC ratio of 400 was predictive of efficacy in patients with MRSA pneumonia (Moise-Broder et al., 2004). One implication of the potential importance of this parameter is that increases in organism MIC, even below the cutoff for susceptibility, can make achieving this target ratio difficult without substantial dosage increases. Thus, although an isolate of *S. aureus* with an MIC of 2 $\mu\text{g/mL}$ would be considered susceptible, it would be difficult to achieve an AUC-to-MIC ratio of 400 at standard doses. The validity and target value of this parameter requires confirmation in further clinical studies with a variety of organisms and infections. The potential contribution to toxicity of using higher doses to achieve these target values also requires consideration (see later in the chapter).

Resistance to Glycopeptides. Strains of enterococci once were uniformly susceptible to glycopeptides. Glycopeptide-resistant strains

Figure 55–4. Inhibition of bacterial cell wall synthesis: vancomycin and β -lactam agents. Vancomycin inhibits the polymerization or transglycosylase reaction (A) by binding to the D-alanyl-D-alanine terminus of the cell wall precursor unit attached to its lipid carrier and blocks linkage to the glycopeptide polymer (indicated by the subscript n). These (NAM–NAG)_n peptidoglycan polymers are located within the cell wall. Van A-type resistance is due to expression of enzymes that modify cell wall precursor by substituting a terminal D-lactate for D-alanine, reducing vancomycin binding affinity by 1000 times. β -Lactam antibiotics inhibit the cross-linking or transpeptidase reaction (B) that links glycopeptide polymer chains by formation of a cross-bridge with the stem peptide (the five glycines in this example) of one chain, displacing the terminal D-alanine of an adjacent chain. See also Figure 53–3.

of enterococci, primarily *Enterococcus faecium*, have emerged as major nosocomial pathogens in hospitals in the U.S. Vancomycin resistance determinants in *E. faecium* and *E. faecalis* are located on a transposon that is part of a conjugative plasmid, rendering it readily transferable among enterococci and, potentially, other gram-positive bacteria. These strains typically are resistant to multiple antibiotics, including streptomycin, gentamicin, and ampicillin, effectively eliminating these as alternative therapeutic agents. Resistance to streptomycin and gentamicin is of special concern because the combination of an aminoglycoside with a cell-wall-synthesis inhibitor is the only reliably bactericidal regimen for treatment of enterococcal endocarditis.

Enterococcal resistance to glycopeptides is the result of alteration of the D-alanyl-D-alanine target to D-alanyl-D-lactate or D-alanyl-D-serine (Arias et al., 2000), which bind glycopeptides poorly, due to the lack of a critical site for hydrogen bonding. Several enzymes within the *van* gene cluster are required for this target alteration to occur. Several phenotypes of resistance to glycopeptides have been described. The *Van A* phenotype confers inducible resistance to teicoplanin and vancomycin in *E. faecium* and *E. faecalis*. The *Van B* phenotype, which tends to be a lower level of resistance, also has been identified in *E. faecium* and *E. faecalis*. The trait is inducible by vancomycin but not teicoplanin, and consequently, many strains remain susceptible to teicoplanin. The *Van C* phenotype, the least important clinically and least well characterized, confers resistance only to vancomycin, is constitutive, and is present in no species of enterococci other than *E. faecalis* and *E. faecium*. *Van D* and *Van E* gene clusters also have been identified, and presumably others will follow.

S. aureus and coagulase-negative staphylococci may express reduced or “intermediate” susceptibility to vancomycin (MIC, 4–8 µg/mL) (Garrett et al., 1999; Hiramatsu et al., 1997; Smith et al., 1999) or high-level resistance (MIC ≥16 µg/mL). Intermediate resistance is associated with (and may be preceded by) a heterogeneous phenotype in which a small proportion of cells within the population (1 in 10⁵ to 1 in 10⁶) will grow in the presence of vancomycin concentrations >4 µg/mL. The genetic and biochemical basis of the intermediate phenotype is unknown. Intermediate strains produce an abnormally thick cell wall, and resistance may be due to false targets for vancomycin. Several genetic elements and multiple mutations are involved, and many of the genes that have been implicated encode enzymes of the cell-wall biosynthetic pathway (Sieradzki and Tomasz, 1999; Sieradzki et al., 1999). Infections caused by vancomycin-intermediate strains have failed to respond to vancomycin clinically and in animal models (Climo et al., 1999; Moore et al., 2003). Prior treatment courses and low vancomycin levels may predispose patients to infection and treatment failure with vancomycin-intermediate strains. These strains typically are resistant to methicillin and multiple other antibiotics; their emergence is a major concern because until recently vancomycin has been the only antibiotic to which staphylococci were reliably susceptible.

The first high-level vancomycin-resistant *S. aureus* strain (MIC ≥32 µg/mL) was isolated in June 2002 (Weigel et al., 2003). This strain, like others that have subsequently been isolated, harbored a conjugative plasmid into which the *Van A* transposon, Tn1546, was integrated as a consequence of an interspecies horizontal gene transfer from *E. faecalis* to a methicillin-resistant strain of *S. aureus*. These isolates have been variably susceptible to teicoplanin and the investigational lipoglycopeptides.

Absorption, Distribution, and Excretion

Absorption. Vancomycin is poorly absorbed after oral administration. For parenteral therapy, the drug should be administered intravenously, never intramuscularly. Teicoplanin can be administered safely by intramuscular injection as well as intravenous administration.

Distribution. A single intravenous dose of 1 g in adults produces plasma concentrations of 15–30 µg/mL 1 hour after a 1- to 2-hour infusion. Approximately 30% of vancomycin is bound to plasma protein. Vancomycin appears in various body fluids, including the CSF when the meninges are inflamed (7–30%); bile; and pleural, pericardial, synovial, and ascitic fluids. Teicoplanin is highly bound by plasma proteins (90–95%).

Elimination. About 90% of an injected dose of vancomycin is excreted by glomerular filtration. The drug has a serum elimination $t_{1/2}$ of ~6 hours. The drug accumulates if renal function is impaired, and dosage adjustments must be made under these circumstances. The drug can be cleared rapidly from plasma with high-flux methods of hemodialysis. In contrast to vancomycin, teicoplanin has an extremely long serum elimination $t_{1/2}$ (up to 100 hours in patients with normal renal function).

Therapeutic Uses and Dosage. Vancomycin and teicoplanin have been used to treat a wide variety of infections, including osteomyelitis and endocarditis, caused by methicillin-resistant and methicillin-susceptible staphylococci, streptococci, and enterococci. Teicoplanin has been found to be comparable to vancomycin in efficacy, except for treatment failures from low doses used for such serious infections as endocarditis. In general, recommendations for teicoplanin follow those of vancomycin, except where noted later. Although extensively studied for >10 years, teicoplanin has not yet been licensed for use in the U.S.

Vancomycin hydrochloride (VANOCIN, others) is marketed for *intravenous* use as a sterile powder for solution. It should be diluted and infused over at least a 60-minute period to avoid infusion-related adverse reactions. The recommended dose of vancomycin for adults is 30–45 mg/kg per day in 2–3 divided doses. The “therapeutic range” for this agent is somewhat controversial. Current recommendations call for monitoring serum trough concentrations (within 30 minutes prior to a dose) at steady state, typically before the fourth dose of a given dosage regimen. A minimum target trough serum concentration of 10 µg/mL is recommended in the most recent consensus guidelines (Rybak et al., 2009). For patients with more serious infections (including endocarditis, osteomyelitis, meningitis, and MRSA pneumonia), trough levels of 15–20 µg/mL are recommended. General pediatric dosage ranges for vancomycin are as follows: for newborns during the first week of life, 15 mg/kg initially, followed by 10 mg/kg every 12 hours; for infants 8–30 days old, 15 mg/kg followed by 10 mg/kg every 8 hours; for older infants (>30 days) and children, 10–15 mg/kg every 6 hours (Frymoyer et al., 2009).

Alteration of dosage is required for patients with impaired renal function. Serum drug concentrations may help guide dose adjustment, but caution should be used in interpreting concentrations in patients with rapidly changing renal function. In functionally anephric patients and patients receiving dialysis with non-high-flux membranes, administration of 1 g (~15 mg/kg) every 5–7 days typically achieves adequate serum levels. In patients receiving intermittent high-efficiency or high-flux dialysis, maintenance doses administered after each dialysis session are typically required

because these modalities clear vancomycin efficiently. Because there is so much variation in how well vancomycin is dialyzed with different membranes, it is recommended that blood levels be monitored to decide how frequently the drug needs to be administered to maintain therapeutic concentrations.

Skin/Soft-Tissue and Bone/Joint Infections. Vancomycin is frequently used in the empirical and definitive treatment of skin/soft-tissue and bone/joint infections, where gram-positive organisms including MRSA are the leading pathogens.

Respiratory Tract Infections. Vancomycin is employed for the treatment of pneumonia when MRSA is suspected, either because of healthcare-associated acquisition or in patients with community-acquired pneumonia with risk factors for staphylococcal infection (e.g., influenza). Because vancomycin penetration into lung tissue is relatively low, aggressive dosing (targeting trough levels of 15-20 µg/mL) is generally recommended.

CNS Infections. Because of vancomycin's excellent activity against *Streptococcus pneumoniae*, it is a key component in the initial empirical treatment of community-acquired bacterial meningitis in locations where penicillin-resistant *Streptococcus pneumoniae* is common (Tunkel et al., 2004). Penetration of vancomycin across inflamed meningitis is modest to poor; thus aggressive dosing is typically warranted. Vancomycin is also used to treat nosocomial meningitis, usually associated with neurosurgical procedures and often caused by staphylococci. Intraventricular administration of vancomycin (via a shunt or reservoir) has been necessary in a few cases of CNS infections due to susceptible microorganisms that did not respond to intravenous therapy alone.

Endocarditis and Vascular Catheter Infections. Vancomycin is standard therapy for staphylococcal endocarditis when the isolate is methicillin resistant or patients have a severe penicillin allergy (Baddour et al., 2005). Administration of an adjunctive aminoglycoside is no longer recommended unless there is a prosthetic valve. Vancomycin is an effective alternative for the treatment of endocarditis caused by viridans streptococci in patients who are allergic to penicillin. In combination with an aminoglycoside, it may be used for enterococcal endocarditis in patients with serious penicillin allergy or for isolates that are not susceptible to penicillins.

Vancomycin is commonly used for the treatment of vascular catheter infections due to gram-positive organisms, such as staphylococci, viridans streptococci, *Corynebacterium* spp, and *Bacillus* spp. In situations when removal of the catheter is not desired, adjunctive treatment with vancomycin as an "antibiotic lock" may aid in salvaging the catheter. In this procedure, a concentrated solution of vancomycin is instilled into the catheter hub and allowed to dwell for variable amounts of time when the catheter is not in use (Carratala, 2002).

Other Infections. Vancomycin can be administered orally to patients with pseudomembranous colitis due to *C. difficile*, and it may be more efficacious than metronidazole in patients with severe disease. The dose for adults is 125-250 mg every 6 hours; the total daily dose for children is 40 mg/kg, given in three to four divided doses. Commercially available capsules can be used for this purpose, or the intravenous formulation can be administered orally with or without compounding into a more palatable oral solution.

The standard dose of teicoplanin in adults is 3-6 mg/kg per day, with higher dosages possible for treatment of serious staphylococcal infections. Once-daily dosing is possible for the treatment of

most infections because of the prolonged serum elimination half-life. As with vancomycin, teicoplanin doses must be adjusted in patients with renal insufficiency. For functionally anephric patients, administration once weekly has been appropriate, but serum drug concentrations should be monitored to determine that the therapeutic range has been maintained (e.g., trough concentration of 15-20 µg/mL). Oral teicoplanin has also been studied for the treatment of *C. difficile* disease, at a dose of 100 mg twice daily.

Untoward Effects. Among the hypersensitivity reactions produced by vancomycin and teicoplanin are macular skin rashes and anaphylaxis. Phlebitis and pain at the site of intravenous injection are relatively uncommon. Chills, rash, and fever may occur. Rapid intravenous infusion of vancomycin may cause erythematous or urticarial reactions, flushing, tachycardia, and hypotension. The extreme flushing that can occur is sometimes called "red-neck" or "red-man" syndrome. This is not an allergic reaction but a direct toxic effect of vancomycin on mast cells, causing them to release histamine. This reaction is generally not observed with teicoplanin.

Auditory impairment, sometimes permanent, may follow the use of vancomycin or teicoplanin. Ototoxicity is associated with excessively high concentrations of these drugs in plasma (60-100 µg/mL of vancomycin). Nephrotoxicity, formerly very problematic due to the impurities in earlier formulations of vancomycin, has become less common with modern formulations at standard dosages. However, the more aggressive dosing regimens recently advocated have been demonstrated to increase nephrotoxicity risk. In a recent observational study, nephrotoxicity occurred in 33% of patients with initial vancomycin trough concentrations of >20 µg/mL, compared to 5% among patients with trough concentrations of <10 µg/mL (Lodise et al., 2009). Thus, careful dosing and monitoring of vancomycin is necessary to balance the risks and benefits. Additionally, caution should be exercised when ototoxic or nephrotoxic drugs, such as aminoglycosides, are administered concurrently with vancomycin.

LIPOPEPTIDES (DAPTOMYCIN)

Daptomycin (CUBICIN) is a cyclic lipopeptide antibiotic derived from *Streptomyces roseosporus*. Discovered >25 years ago, its clinical development has been resumed in response to increasing need for bactericidal antibiotics effective against vancomycin-resistant gram-positive bacteria (Carpenter and Chambers, 2004; Eisenstein and Tally, 2006).

Antimicrobial Activity. Daptomycin is a bactericidal antibiotic selectively active against aerobic, facultative, and anaerobic gram-positive bacteria (Table 55–2) (Jevitt et al., 2003; Streit et al., 2004). The MIC susceptibility breakpoint for staphylococci and streptococci is ≤ 1 $\mu\text{g}/\text{mL}$; for enterococci it is ≤ 4 $\mu\text{g}/\text{mL}$. Daptomycin may be active against vancomycin-resistant strains, although MICs tend to be higher for these organisms than for their vancomycin-susceptible counterparts. MICs of *Corynebacterium* spp., *Peptostreptococcus*, propionibacteria, and *Clostridium perfringens* are generally inhibited by ≤ 0.5 -1 $\mu\text{g}/\text{mL}$ (Goldstein et al., 2004). *Actinomyces* spp. are inhibited over the concentration range of 4-32 $\mu\text{g}/\text{mL}$. *In vitro* activity of daptomycin is Ca^{2+} dependent, and MIC tests should be performed in medium containing 50 mg/L calcium.

Mechanisms of Action and Resistance to Daptomycin.

Daptomycin binds to bacterial membranes resulting in depolarization, loss of membrane potential, and cell death. It has concentration-dependent bactericidal activity. During initial clinical trials for treatment of skin and soft-tissue infections, resistance was rarely observed. Subsequently, during clinical use, daptomycin resistance has been reported to emerge while on therapy, typically during treatment of deep-seated infections (e.g., osteomyelitis, endocarditis, infections of prosthetic material). In a trial of vancomycin for staphylococcal bacteremia and right-sided endocarditis, increases in daptomycin MIC associated with microbiological treatment failure were seen in 6 of 120 patients (5%) (Fowler et al., 2006). The mechanisms of resistance to daptomycin have not been fully characterized, although genetic changes in the *mprF* gene (regulating cell membrane charge) correlating to daptomycin resistance have been described (Yang et al., 2009). Staphylococci with decreased susceptibility to vancomycin have higher daptomycin MICs than fully susceptible strains (Jevitt et al., 2003).

Absorption, Fate, and Excretion. Daptomycin is poorly absorbed orally and should only be administered intravenously. Direct toxicity to muscle precludes intramuscular injection. The steady-state peak serum concentration following intravenous administration of 4 mg/kg in healthy volunteers is ~ 58 $\mu\text{g}/\text{mL}$. Daptomycin displays linear pharmacokinetics at doses up to 8 mg/kg . It is reversibly bound to albumin; protein binding is 92%. The serum $t_{1/2}$ is 8-9 hours in normal subjects, permitting once-daily dosing. Although the drug penetrates adequately into the lung, the drug is inactivated by pulmonary surfactant (Silverman et al., 2005). Approximately 80% of the administered dose is recovered in urine; a small amount is excreted in feces. Dosage adjustment is required for creatinine clearance < 30 mL/minute ; this is accomplished by administering the recommended dose every 48 hours. For hemodialysis patients the dose should be administered immediately after dialysis.

Therapeutic Uses and Dosage. Daptomycin is indicated for treatment of complicated skin and soft tissue infections (at 4 mg/kg per day) and complicated bacteremia and right-sided endocarditis (at 6 mg/kg per day) (Carpenter and Chambers, 2004). Its efficacy was comparable to that of vancomycin or semisynthetic penicillins. Higher doses (up to 10-12 mg/kg per day) appear to be well tolerated and may be incorporated into future recommendations (Figueroa et al., 2009). Daptomycin was inferior to comparators for treatment of community-acquired pneumonia, likely due to its inactivation in pulmonary surfactant, and it should not be used for this indication (Pertel et al., 2008).

Untoward Effects. The primary toxicity of daptomycin is damage to the musculoskeletal system. In humans, elevations of creatine kinase may occur; this does not require discontinuation of the drug unless there are findings of an otherwise unexplained myopathy. Rhabdomyolysis has been reported to occur rarely. In phase 1 and 2 clinical trials, a few patients had evidence of possible neuropathy, although this was not observed in phase 3 studies.

Drug Interactions. Daptomycin neither inhibits nor induces CYPs, and there are no important drug-drug interactions. However, caution is recommended when administering daptomycin in conjunction with aminoglycosides or statins because of potential risks of nephrotoxicity and myopathy, respectively.

BACITRACIN

Bacitracin is an antibiotic produced by the Tracy-I strain of *Bacillus subtilis*. The bacitracins are a group of polypeptide antibiotics; multiple components have been demonstrated in the commercial products. The major constituent is bacitracin A; its probable structural formula is:

A unit of the antibiotic is equivalent to 26 μg of the USP standard.

Antimicrobial Activity, Mechanism of Action, and Resistance to Bacitracin. Bacitracin inhibits the synthesis of the bacterial cell wall. A variety of gram-positive cocci and bacilli, *Neisseria*, *H. influenzae*, and *Treponema pallidum*, are sensitive to ≤ 0.1 unit of bacitracin per milliliter. *Actinomyces* and *Fusobacterium* are inhibited by concentrations of 0.5-5 units/mL. Enterobacteriaceae, *Pseudomonas*, *Candida* spp., and *Nocardia* are resistant to the drug.

Therapeutic Uses and Dosage. Although bacitracin previously has been employed parenterally, current use is restricted to topical application because of the toxicity of intravenous administration. Bacitracin is available in ophthalmic and dermatologic ointments; the antibiotic also is available as a powder (BACI-RX) for the extemporaneous compounding of topical solutions. The ointments are applied directly to the involved surface one or more times daily. A number of topical preparations of bacitracin, to which neomycin or polymyxin or both have been added, are available, and some contain the three antibiotics plus hydrocortisone.

Topical bacitracin alone or in combination with other antimicrobial agents has no established value in the treatment of furunculosis, pyoderma, carbuncle, impetigo, and superficial and deep abscesses. For open infections such as infected eczema and infected

dermal ulcers, the local application of the antibiotic may be of some help in eradicating sensitive bacteria. Unlike several other antibiotics used topically, bacitracin rarely produces hypersensitivity. Suppurative conjunctivitis and infected corneal ulcer respond well to the topical use of bacitracin when caused by susceptible bacteria. Bacitracin has been used with limited success for eradication of nasal carriage of staphylococci. Oral bacitracin has been used with some success for the treatment of antibiotic-associated diarrhea caused by *C. difficile*. Bacitracin is used by neurosurgeons to irrigate the meninges intraoperatively as an alternative to vancomycin. It has no direct toxicity on neurons.

Untoward Effects. Serious nephrotoxicity results from the parenteral use of this antibiotic. Hypersensitivity reactions rarely result from topical application.

MUPIROCIN

Mupirocin (BACTROBAN) is derived from a fermentation product of *Pseudomonas fluorescens*. It is for topical use only.

Antimicrobial Activity. Mupirocin is active against many gram-positive and selected gram-negative bacteria. It has good activity with MICs ≤ 1 $\mu\text{g/mL}$ against *Streptococcus pyogenes* and methicillin-susceptible and methicillin-resistant strains of *S. aureus*. It is bactericidal at concentrations achieved with topical application.

Mechanism of Action and Mupirocin Resistance. Mupirocin inhibits bacterial protein synthesis by reversible binding and inhibition of isoleucyl transfer-RNA synthetase. There is no cross-resistance with other classes of antibiotics. Low-level resistance, which is not clinically significant, is due to mutations of the host gene encoding isoleucyl transfer-RNA synthetase or an extra chromosomal copy of a gene encoding a modified isoleucyl transfer-RNA synthetase (Ramsey et al., 1996; Udo et al., 2001). High-level resistance (MIC >1 mg/mL) is mediated by a plasmid or chromosomal copy of *mupA*, which encodes a “bypass” synthetase that binds mupirocin poorly (Udo et al., 2001).

Absorption, Fate, and Excretion. Systemic absorption through intact skin or skin lesions is minimal. Any mupirocin that is absorbed is rapidly metabolized to inactive monic acid.

Therapeutic Uses and Dosage. Mupirocin is available as a 2% cream and a 2% ointment for dermatologic use and as a 2% ointment for intranasal use. The dermatologic preparations are indicated for treatment of traumatic skin lesions and impetigo secondarily infected with *S. aureus* or *S. pyogenes*.

The nasal ointment is approved for eradication of *S. aureus* nasal carriage. Mupirocin is highly effective in eradicating *S. aureus* carriage (Laupland and Conly, 2003). Because *S. aureus* colonization

often precedes infection, eradication of carriage by intranasal application of mupirocin might reduce the risk of later infection. However, two clinical trials failed to demonstrate that mupirocin prophylaxis reduces nosocomial *S. aureus* infections (Kalmeijer et al., 2002; Wertheim et al., 2004). A third large study found that *S. aureus* nasal carriers had fewer *S. aureus* nosocomial infections of any site, but it failed to show a reduction in *S. aureus* surgical site infections, the primary end point of the study (Perl et al., 2002). The accumulated evidence indicates that patients who stand to benefit from mupirocin prophylaxis are those with proven *S. aureus* nasal colonization plus risk factors for distant infection or a history of skin or soft-tissue infections. General inpatient populations and individuals lacking specific risk factors for *S. aureus* infection are not likely to benefit from mupirocin prophylaxis.

Untoward Effects. Mupirocin may cause irritation and sensitization at the site of application. Contact with the eyes should be avoided because mupirocin causes tearing, burning, and irritation that may take several days to resolve. Systemic reactions to mupirocin occur rarely, if at all. Polyethylene glycol present in the ointment can be absorbed from damaged skin. Application of the ointment to large surface areas should be avoided in patients with moderate to severe renal failure to avoid accumulation of polyethylene glycol.

CLINICAL SUMMARY

Doxycycline, the most important member of the tetracyclines, is a drug of choice for sexually transmitted diseases, rickettsial infections, plague, brucellosis, tularemia, and spirochetal infections. It is also an important agent for treatment of respiratory tract infections, given its activity against *S. pneumoniae*, *Haemophilus* spp., and atypical pneumonia pathogens; and for skin and soft-tissue infections caused by community strains of methicillin-resistant *S. aureus*, for which minocycline also is particularly active. Glycylcyclines, beginning with tigecycline, have restored much of the activity of the tetracyclines against bacteria that have become refractory to first- and second-generation tetracyclines, including aerobic and anaerobic gram-negative organisms as well as refractory gram-positive organisms.

Macrolides and ketolides are effective for treatment of respiratory tract infections caused by the common pathogens of community-acquired pneumonia, including *S. pneumoniae*, *Haemophilus* spp., *Chlamydia*, mycoplasma, and *Legionella*. They generally are well-tolerated, orally bioavailable, and except for erythromycin, effective in once or twice-daily dosing. All except azithromycin have important drug interactions because they inhibit hepatic CYPs.

Chloramphenicol is rarely indicated in the U.S. and Europe because it can cause irreversible bone marrow toxicity and because less toxic drugs are readily available. However, it continues to be an important

antibiotic in developing nations because it is inexpensive and highly effective for a broad range of infections.

Spectinomycin is indicated only for the treatment of gonococcal infection when a β -lactam or fluoroquinolone cannot be given. Clindamycin has excellent activity against gram-positive cocci but principally is used to treat anaerobic infections. Vancomycin, daptomycin, quinupristin/dalfopristin, and linezolid are indicated for the treatment of gram-positive infections caused by drug-resistant organisms such as penicillin-resistant pneumococci and methicillin-resistant staphylococci. Quinupristin/dalfopristin and linezolid are indicated for the treatment of vancomycin-resistant *E. faecium* infections. These drugs, along with daptomycin, also are active against vancomycin-insensitive strains of *S. aureus*, although clinical trials have not established their clear clinical efficacy to date.

Polymyxins, bacitracin, and mupirocin are effective for the topical treatment of minor skin infections. Colistin (polymyxin E) can be administered systemically and is active against drug-resistant gram-negative bacteria, including *Pseudomonas*, *Stenotrophomonas*, and *Acinetobacter*; its significant toxicity makes it an agent of last resort. Mupirocin is effective for eradication of *S. aureus* nasal colonization.

Chemotherapy of Tuberculosis, *Mycobacterium Avium* Complex Disease, and Leprosy

Tawanda Gumbo

Mycobacteria have caused epic diseases: Tuberculosis (TB) and leprosy have terrorized humankind since antiquity. Although the burden of leprosy has decreased, TB is still the most important infectious killer of humans. *Mycobacterium avium-intracellulare* (or *Mycobacterium avium* complex; MAC) infection continues to be difficult to treat.

Mycobacterium, from the Greek “mycos,” refers to Mycobacteria’s waxy appearance, which is due to the composition of their cell walls. More than 60% of the cell wall is lipid, mainly mycolic acids composed of 2-branched, 3-hydroxy fatty acids with chains made of 76-90 carbon atoms! This extraordinary shield prevents many pharmacological compounds from getting to the bacterial cell membrane or inside the cytosol.

A second layer of defense comes from an abundance of efflux pumps in the cell membrane. These transport proteins pump out potentially harmful chemicals from the bacterial cytoplasm back into the extracellular space and are responsible for the native resistance of mycobacteria to many standard antibiotics (Morris et al., 2005). As an example, ATP binding cassette (ABC) permeases comprise a full 2.5% of the genome of *Mycobacterium tuberculosis*.

A third barrier is the propensity of some of the bacilli to hide inside the patient’s cells, thereby surrounding themselves with an extra physicochemical barrier that antimicrobial agents must cross to be effective.

Mycobacteria are separated into two groups, defined by their rate of growth on agar. A list of pathogenic *rapid* and *slow* growers is shown in Table 56–1. Rapid growers are visible to the naked eye within 7 days; slow growers are visible later. Slow growers tend to be

susceptible to antibiotics specifically developed for Mycobacteria, whereas rapid growers tend to be also susceptible to antibiotics used against many other bacteria. The pharmacology of drugs developed against slow growers is discussed in this chapter.

The mechanisms of action of the anti-mycobacterial drugs are summarized in Figure 56–1. The mycobacterial mechanisms of resistance to these drugs are summarized in Figure 56–2. Pharmacokinetic parameters are presented in terms of Figure 48–1 and Equation 48–1.

History. The first successful drug for treating TB was para-amino salicylic acid (PAS), developed by Lehman in 1943. A more dramatic success came when Waksman and Schatz developed streptomycin. Further efforts led to development of thiacetazone by Domagk in 1946, isoniazid at Squibb, Hoffman La Roche, and Bayer in 1952, pyrazinamide by Kushner and colleagues in 1952, and rifamycins by Sensi and Margalith in 1957. Ethambutol was discovered at Lederle Laboratories in 1961. As might be anticipated, the use of all of these drugs presents problems of drug resistance, adverse events, and drug interactions. Therefore, newer classes of agents are being developed. Moxifloxacin, PA-824, and TMC-207 have reached advanced clinical testing.

ANTI-MYCObACTERIAL DRUGS

Rifamycins: Rifampin, Rifapentine, and Rifabutin

Rifampin or rifampicin (RIFADIN; RIMACTANE, others), rifapentine (PRIFITIN), and rifabutin (MYCOBUTIN) are important in treatment of mycobacterial diseases.

Chemistry. Rifamycins are macrocyclic antibiotics characterized by a chromophoric naphthoquinone group that is spanned by a

RAPID GROWERS

Runyon IV:

Mycobacterium fortuitum complex
Mycobacterium smegmatis group

Slow growers tend to be susceptible to antibiotics specifically developed for Mycobacteria; rapid growers tend to be susceptible to antibiotics also used against many other bacteria.

long aliphatic bridge, with an acetyl group at C25. Rifapentine and rifabutin are derivatives of rifampin, whose structure is:

Mechanism of Action. The mechanism of action for rifamycins is typified by rifampin's action against *M. tuberculosis*. Rifampin enters bacilli in a concentration dependent manner, achieving steady-state concentrations within 15 minutes (Gumbo et al., 2007a). Rifampin binds to the β subunit of DNA-dependent RNA polymerase (*rpoB*) to form a stable drug–enzyme complex. Drug binding suppresses chain formation in RNA synthesis.

Antibacterial Activity. Rifampin inhibits the growth of most gram-positive bacteria as well as many gram-negative microorganisms such as *Escherichia coli*, *Pseudomonas*, indole-positive and

indole-negative *Proteus*, and *Klebsiella*. Rifampin is very active against *Staphylococcus aureus* and coagulase-negative staphylococci. The drug also is highly active against *Neisseria meningitidis* and *Haemophilus influenzae*. Rifampin inhibits the growth of *Legionella* species in cell culture and in animal models.

Rifampin inhibits the growth of many *M. tuberculosis* clinical isolates *in vitro* at concentrations of 0.06–0.25 mg/L (Heifets, 1991). Rifampin is also bactericidal against *M. leprae*. *M. kansasii* is inhibited by 0.25–1 mg/L. Most strains of *Mycobacterium scrofulaceum*, *Mycobacterium intracellulare*, and *M. avium* are suppressed by concentrations of 4 mg/L. *Mycobacterium fortuitum* is highly resistant to the drug. Rifapentine minimum inhibitory concentrations (MICs) are similar to those of rifampin. Rifabutin inhibits the growth of most MAC isolates at concentrations ranging from 0.25–1 mg/L. Rifabutin also inhibits the growth of many strains of *M. tuberculosis* at concentrations of ≤ 0.125 mg/L and *in vitro* has better MICs than rifampin.

Bacterial Resistance. The prevalence of rifampin-resistant isolates are 1 in every 10^7 to 10^8 bacilli. Microbial resistance to rifampin is due to an alteration of the target of this drug, *rpoB*, with resistance in 86% of cases due to mutations at codons 526 and 531 of the *rpoB* gene (Somoskovi et al., 2001). Rifamycin monoresistance occurs at higher rates when patients with AIDS and multi-cavitary TB are treated with either rifapentine or rifabutin (Burman et al., 2006a).

Mutations in genes involved in DNA repair mechanisms will impair the repair of multiple genes, which may lead to hyper-mutable strains (Chapter 48). *M. tuberculosis* Beijing genotype clinical isolates have been associated with higher rates of simultaneous rifampin and isoniazid resistance associated with mutations in the repair genes *mut* and *ogt* (Nouvel et al., 2006; Rad et al., 2003). Inducible or environment-dependent mutators may be a more common phenomenon than these stable mutator phenotypes (Warner and Mizrahi, 2006). Antibiotics, endogenous oxidative and metabolic stressors lead to DNA damage, which induces *dnaE2*. The induction is associated with error-prone DNA repair. This leads to higher rates of rifampin resistance (Boshoff et al., 2003).

Absorption, Distribution, and Excretion. After oral administration, the rifamycins are absorbed to variable extents (Table 56–2) (Burman et al., 2001). Food decreases the rifampin C_{Pmax} by one third; a high-fat meal increases the area under the curve (AUC) of rifapentine by 50%. Food has no effect on rifabutin absorption. Thus rifampin should be taken on an empty stomach, whereas rifapentine should be taken with food, if possible.

Rifamycins are metabolized by microsomal B-esterases and cholinesterases that remove the acetyl group at position 25, resulting in 25-*O*-desacetyl rifamycins. Rifampin is also metabolized by hydrolysis to 3-formyl rifampin, whereas rifapentine is metabolized to 3-formyl rifapentine and 3-formyl-25-*O*-desacetyl-rifapentine. A major pathway for rifabutin elimination is CYP3A. Due to autoinduction, all three rifamycins reduce their own area

Figure 56-1. Mechanisms of action of established and experimental drugs used for the chemotherapy of mycobacterial infections. Shown at the top are the sites of action of approved drugs for the chemotherapy of mycobacterial diseases. Rifamycin is used as a generic term for several drugs, of which rifampin is used most frequently. Also included are two experimental drugs now under investigation: TMC-207 and PA-824. Clofazimine, whose mode of action is not understood, is omitted.

under the concentration-time curves (AUC) with repeated administration (Table 56-3). They have good penetration into many tissues, but levels in the CNS reach only ~5% of those in plasma, likely due to the activity of P-glycoprotein. The drugs and metabolites are excreted by bile and eliminated via feces, with urine elimination accounting for only one-third and less of metabolites.

The population pharmacokinetics (PK) of rifampin are best described using a one-compartment model with transit compartment absorption (Wilkins et al., 2008), using the PK parameters in Table 56-2. Single-drug formulations increase mean transit time during absorption by ~100% and systemic clearance (SCL) by 24% in comparison to fixed-dose combinations of rifampin and other anti-TB drugs. Thus the absorption of rifampin will be slower, and the peak concentration (C_{pmax}) of rifampin lower, with some formulations compared to others (Wilkins et al., 2008).

Rifapentine pharmacokinetics are likewise best described using a one-compartment open model with first-order absorption and elimination (Langdon et al., 2005). The PK parameters are summarized in Table 56-2. However, for each 1-kg weight increase above 50 kg, SCL increases by 0.05 L/hour and V_d by 0.69 L. Thus, C_{pmax} and AUC decrease with increasing patient weight above 50 kg.

Rifabutin pharmacokinetics are best described by a two-compartment open model with first-order absorption and elimination. Rifabutin disposition is biexponential. Rifabutin concentrations are substantially higher in tissue than in plasma due to its lipophilic properties, leading to the very high apparent volumes of distribution (Table 56-2). The consequence is that C_{pmax} values for rifabutin are lower than one would predict by comparison with other rifamycins. The volume of peripheral compartment decreases by 27% with concomitant azithromycin administration; tobacco smoking increases the volume by 39%.

Pharmacokinetics-Pharmacodynamics. Rifampin's bactericidal activity is best optimized by a high AUC/MIC ratio (Gumbo et al., 2007a). However, resistance suppression and rifampin's enduring post-antibiotic effect are best optimized by high C_{max} /MIC. Therefore, the duration of time that the rifampin concentration persists above the MIC is of less importance.

These results predict that the $t_{1/2}$ of a rifamycin is less of an issue in optimizing therapy, and that if patients could tolerate it, higher doses

Figure 56–2. Mechanisms of resistance of *Mycobacteria* to different chemotherapeutic drugs. Shown are the various mechanisms by which mycobacteria resist antibacterial effects of the currently approved chemotherapeutic agents.

would lead to higher bactericidal activities while suppressing resistance. In a recent clinical study, TB patients in South Africa were treated with 20 mg/kg/day of rifampin for 5 days, and the rate of sputum bacillary decline compared to that for doses of 3 mg/kg/day, 6 mg/kg/day, and 12 mg/kg/day (Diacon et al., 2007). There was a linear increase in the rate of kill, with a 2-fold increase between the 600 mg dose and the 1200 mg dose. Currently, efficacy of higher doses of rifampin and rifapentine is being examined in clinical studies.

Therapeutic Uses. Rifampin for oral administration is available alone and as a fixed-dose combination with isoniazid (150 mg of isoniazid, 300 mg of rifampin; rifamate, others) or with isoniazid and pyrazinamide (50 mg of isoniazid, 120 mg of rifampin, and 300 mg pyrazinamide; RIFATER). A parenteral form of rifampin is also available. The dose of rifampin for treatment of tuberculosis in adults is 600 mg, given once daily, either 1 hour before or 2 hours after a meal. Children should receive 10–20 mg/kg given in the same way. Rifabutin is administered at 5 mg/kg/day and rifapentine at 10 mg/kg once a week.

Rifampin is also useful for the prophylaxis of meningococcal disease and *H. influenzae* meningitis. To prevent meningococcal disease, adults may be treated with 600 mg twice daily for 2 days or 600 mg once daily for 4 days; children >1 month of age should receive 10–15 mg/kg, to a maximum of 600 mg. Combined with a β -lactam antibiotic or vancomycin, rifampin may be useful for therapy in selected cases of staphylococcal endocarditis or osteomyelitis,

especially those caused by staphylococci “tolerant” to penicillin. Rifampin may also be indicated for the eradication of the staphylococcal nasal carrier state in patients with chronic furunculosis.

Untoward Effects. Rifampin is generally well tolerated in patients. Usual doses result in <4% of patients with TB developing significant adverse reactions; the most common are rash (0.8%), fever (0.5%), and nausea and vomiting (1.5%). Rarely, hepatitis and deaths due to liver failure have been observed in patients who received other hepatotoxic agents in addition to rifampin or who had preexisting liver disease. Chronic liver disease, alcoholism, and old age appear to increase the incidence of severe hepatic problems. GI disturbances have occasionally required discontinuation of the drug. Various nonspecific symptoms related to the nervous system also have been noted.

Hypersensitivity reactions may be encountered. Hemolysis, hemoglobinuria, hematuria, renal insufficiency, and acute renal failure have been observed rarely; these also are thought to be hypersensitivity reactions. High-dose rifampin should not be administered on a dosing schedule of less than twice weekly because this is associated with a flu-like syndrome of fever, chills, and myalgias in 20% of patients so treated. The syndrome also may include eosinophilia, interstitial nephritis, acute tubular necrosis, thrombocytopenia, hemolytic anemia, and shock. Light chain proteinuria has also been documented with rifampin use. Thrombocytopenia, transient leukopenia, and anemia have occurred during therapy. Because the potential teratogenicity of rifampin is unknown and the drug is known to cross the placenta, it is best to avoid the use of this agent during pregnancy.

Rifabutin is generally well tolerated; primary reasons for discontinuation of therapy include rash (4%), GI intolerance (3%), and neutropenia (2%) (Nightingale et al., 1993). Neutropenia occurred in

Table 56-2

Population Pharmacokinetic Parameter Estimates for Antimycobacterial Drugs in Adult Patients

	PARAMETER ESTIMATE		
	k_a (h^{-1})	SCL (L/h)	V_d (L)
First-line Drugs			
Rifampin	1.15	19	53
Rifapentine	0.6	2.03	37.8
Rifabutin	0.2	61	231/1,050 ^a
Pyrazinamide	3.56	3.4	29.2

Table 56-3

Pharmacokinetic Parameters of Rifampin, Rifabutin, and Rifapentine

	RIFABUTIN	RIFAMPIN	RIFAPENTINE
Protein binding (%)	71	85	97
Oral bioavailability (%)	20	68	—
t_{max} (hours)	2.5-4.0	1.5-2.0	5.0-6.0
C_{max} total (μ g/mL)	0.2-0.6	8-20	8-30
C_{max} free drug (μ g/mL)	0.1	1.5	0.5
Half-life (hours)	32-67	2-5	14-18
Intracellular/extracellular penetration	9	5	24-60
Autoinduction (AUC decrease)	40%	38%	20%
CYP3A induction	Weak	Pronounced	Moderate
CYP3A substrate	Yes	No	No

AUC, area under the curve.

25% of patients with severe HIV infection who received rifabutin. Uveitis and arthralgias have occurred in patients receiving rifabutin doses >450 mg daily in combination with clarithromycin or fluconazole. Patients should be cautioned to discontinue the drug if visual symptoms (pain or blurred vision) occur. Rifabutin causes an

orange-tan discoloration of skin, urine, feces, saliva, tears, and contact lenses, like rifampin. Rarely, thrombocytopenia, a flu-like syndrome, hemolysis, myositis, chest pain, and hepatitis develop in patients treated with rifabutin. Unique side effects include polymyalgia, pseudojaundice, and anterior uveitis.

Rifamycin Overdose. Rifampin overdose is uncommon and has been poorly studied. Doses of up to 12 g have produced serum rifampin concentrations of 400 mg/L with no change in the serum elimination rate. The most prominent symptoms are the orange discoloration of skin, fluids, and mucosal surfaces, leading to the term *red-man syndrome*. Overdose can be life-threatening; treatment consists of supportive measures; there is no antidote.

Drug Interactions. Because rifampin potently induces CYPs 1A2, 2C9, 2C19, and 3A4, its administration results in a decreased $t_{1/2}$ for a number of compounds, including HIV protease and non-nucleoside reverse transcriptase inhibitors, digitoxin, digoxin, quinidine, disopyramide, mexiletine, tocainide, ketoconazole, propranolol, metoprolol, clofibrate, verapamil, methadone, cyclosporine, corticosteroids, coumarin anticoagulants, theophylline, barbiturates, oral contraceptives, halothane, fluconazole, and the sulfonylureas. It leads to therapeutic failure of these agents, with potentially catastrophic consequences. Prior to putting a patient on rifampin, therefore, all the patient's medications should be examined for potential interactions. Rifabutin is a less potent inducer of CYPs than rifampin, both in terms of potency and number of CYP enzymes involved; however, rifabutin does induce hepatic microsomal enzymes and decreases the $t_{1/2}$ of zidovudine, prednisone, digitoxin, quinidine, ketoconazole, propranolol, phenytoin, sulfonylureas, and warfarin. It has less effect than rifampin on serum levels of indinavir and nelfinavir. Compared to rifabutin and rifampin, the CYP-inducing effects of rifapentine are intermediate.

Pyrazinamide

Pyrazinamide is the synthetic pyrazine analog of nicotinamide. Pyrazinamide is also known as pyrazinoic acid amide, pyrazine carboxylamide, and pyrazinecarboxamide.

PYRAZINAMIDE

Mechanism of Action. Pyrazinamide is “activated” by acidic conditions. Initially it was assumed that the acidic conditions under which pyrazinamide works were inside macrophage phagosomes. However, pyrazinamide may not be very effective within macrophages; rather, the acidic conditions for activation may be at the edges of necrotic TB cavities where inflammatory cells produce lactic acid (Blumberg et al., 2003).

Mycobacterium tuberculosis nicotinamidase, or pyrazinamidase deaminates pyrazinamide to pyrazinoic acid (POA), which is then transported to the extracellular milieu by an efflux pump (Zhang et al., 1999). In an acidic extracellular milieu, a fraction of POA⁻ is protonated to POAH, a more lipid-soluble form that enters the bacillus. The Henderson-Hasselbalch equilibrium (Chapter 2) progressively favors the formation of POAH and its equilibration across membranes as the pH of the extracellular medium declines toward the pK_a of pyrazinoic acid, 2.9, a condition that also enhances microbial killing (Zhang et al., 2002). Although the actual mechanism of microbial kill is still unclear, three mechanisms have been proposed (Zhang et al., 2003; Zimhony et al., 2000):

- inhibition of fatty acid synthase type I leading to interference with mycolic acid synthesis
- reduction of intracellular pH
- disruption of membrane transport by HPOA

Antibacterial Activity. Pyrazinamide exhibits antimicrobial activity *in vitro* only at acidic pH. At pH of 5.8-5.95, 80-90% of clinical isolates have an MIC of ≤100 mg/L (Salfinger and Heifets, 1988).

Mechanisms of Resistance. Pyrazinamide-resistant *M. tuberculosis* have pyrazinamidase with reduced affinity for pyrazinamide. This reduced affinity decreases the conversion of pyrazinamide to POA. Single point mutations in the *pncA* gene are encountered in up to 70% of resistant clinical isolates. The mechanisms contributing to resistance in 30% of resistant clinical isolates is unclear.

Absorption, Distribution, and Excretion. Pyrazinamide oral bioavailability is >90%. Pharmacokinetics are best described by a one-compartment model. GI absorption segregates patients into two groups: fast absorbers (56%) with an absorption rate constant of 3.56/hour and slow absorbers (44%) with an absorption rate of 1.25/hour (Wilkins et al., 2006). The drug is concentrated 20-fold in lung epithelial lining fluid (Conte et al., 2000). Pyrazinamide is metabolized by microsomal deamidase to POA and subsequently hydroxylated to 5-hydroxy-POA, which is then excreted by the kidneys. CL (clearance) and V_d (volume of distribution) increase with patient mass (0.5 L/hour and 4.3 L for every 10 kg above 50 kg), and V_d is larger in males (by 4.5 L) (see Table 56–2) This has several implications: The $t_{1/2}$ of pyrazinamide will vary considerably based on weight and gender, and the AUC₀₋₂₄ will decrease with increase in weight for the same dose (same mg drug/kg body weight). Pyrazinamide clearance is reduced in renal failure; therefore, the dosing frequency is reduced to three times a week at low glomerular filtration rates. Hemodialysis removes pyrazinamide; therefore, the drug needs to be re-dosed after each session of hemodialysis (Malone et al., 1999b).

Microbial Pharmacokinetics-Pharmacodynamics. Pyrazinamide's sterilizing effect is closely linked to AUC₀₋₂₄/MIC (Gumbo et al., 2008). However, resistance suppression is linked to the fraction of time that C_p persists above MIC (T > MIC). Because patient weight impacts both SCL and volume, both AUC and $t_{1/2}$ will be impacted by high weight. Clinical trial simulations that account for patient weight reveal that optimal AUC₀₋₂₄/MIC and T > MIC are likely to be achieved only by doses much higher than the currently recommended 15-30 mg/kg/day (Gumbo et al., 2008). The safety of such higher doses in actual patients is unclear.

Therapeutic Uses. The co-administration of pyrazinamide with isoniazid or rifampin has led to a one-third reduction in the duration of anti-TB therapy, and a two-thirds reduction in TB relapse. This led to reduction in length of therapy to 6 months, producing the current “short course” chemotherapy. Pyrazinamide is administered at an oral dose of 15-30 mg/kg/day.

Untoward Effects. Injury to the liver is the most serious side effect of pyrazinamide. When a dose of 40-50 mg/kg is administered orally, signs and symptoms of hepatic disease appear in ~15% of patients, with jaundice in 2-3% and death due to hepatic necrosis in rare instances. However, these rates were determined in an era when

pyrazinamide was administered for durations much longer than the current 2 months. Elevations of plasma alanine/aspartate aminotransferases are the earliest abnormalities produced by the drug. Regimens employed currently (15-30 mg/kg/day) are much safer. Prior to pyrazinamide administration, all patients should undergo studies of hepatic function, and these studies should be repeated at frequent intervals during the entire period of treatment. If evidence of significant hepatic damage becomes apparent, therapy must be stopped. Pyrazinamide should not be given to individuals with hepatic dysfunction unless this is absolutely unavoidable.

Pyrazinamide inhibits excretion of urate, resulting in hyperuricemia in nearly all patients, and may cause acute episodes of gout. Other untoward effects observed with pyrazinamide include arthralgias, anorexia, nausea and vomiting, dysuria, malaise, and fever. In the U.S., the use of pyrazinamide is not approved during pregnancy because of inadequate data on teratogenicity.

There are minimal data on pyrazinamide overdose, and no antidote has been studied.

Isoniazid

Isoniazid (NYDRAZID, others) is a primary drug for the chemotherapy of tuberculosis. All patients infected with isoniazid-sensitive strains of the tubercle bacillus should receive the drug if they can tolerate it. The use of combination therapy (isoniazid + pyrazinamide +

rifampin) provides the basis for “short-course” therapy and improved remission rates.

Chemistry. Isoniazid (*Isonicotinic acid hydrazide*), also called INH, is a small water-soluble molecule (MW = 137) that is structurally related to pyrazinamide (see Figure 56–3).

Mechanism of Action. Isoniazid enters bacilli by passive diffusion. The drug is not directly toxic to the bacillus but must be activated to its toxic form within the bacillus by KatG, a multifunctional catalase-peroxidase. KatG catalyzes the production from isoniazid of an isonicotinoyl radical that subsequently interacts with mycobacterial NAD and NADP to produce a dozen adducts (Argyrou et al., 2007). One of these, a nicotinoyl-NAD isomer, inhibits the activities of enoyl acyl carrier protein reductase (InhA) and β -ketoacyl acyl carrier protein synthase (KasA). Inhibition of these enzymes inhibits synthesis of mycolic acid, an essential component of the mycobacterial cell wall, leading to bacterial cell death. Another adduct, a nicotinoyl-NADP isomer, potently inhibits ($K_i < 1\text{nM}$) mycobacterial dihydrofolate reductase, thereby interfering with nucleic acid synthesis (Argyrou et al., 2006). See Figure 56–3.

Figure 56–3. Metabolism and activation of isoniazid. The pro-drug isoniazid is metabolized in humans by NAT2 isoforms to its principal metabolite, N-acetyl isoniazid, which is excreted by the kidney. Isoniazid diffuses into mycoplasma where it is “activated” by KatG (oxidase/peroxidase) to the nicotinoyl radical, which reacts spontaneously with NAD⁺ or NADP⁺ to produce adducts that inhibit important enzymes in cell-wall and nucleic acid synthesis. DHFR, dihydrofolate reductase.

Other products of KatG activation of INH include superoxide, H_2O_2 , alkyl hydroperoxides, and the NO radical, which may also contribute to the mycobactericidal effects of INH (Timmins and Deretic, 2006). *M. tuberculosis* could be especially sensitive to damage from these radicals because the bacilli have a defect in the central regulator of the oxidative stress response, *oxyR*. Backup defense against radicals is provided by alkyl hydroperoxide reductase (encoded by *ahpC*), which detoxifies organic peroxides. Increased expression of *ahpC* reduces isoniazid effectiveness.

Antibacterial Activity. The isoniazid MICs with clinical *M. tuberculosis* strains vary from country to country. In the U.S., e.g., the MICs are 0.025–0.05 mg/L (Heifets, 1991). Activity against *M. bovis* and *M. kansasii* is moderate. Isoniazid has poor activity against MAC. It has no activity against any other microbial genus.

Mechanisms of Resistance. The prevalence of drug-resistant mutants is ~ 1 in 10^6 bacilli. Because TB cavities may contain as many as 10^7 to 10^9 microorganisms, preexistent resistance can be expected in pulmonary TB cavities of untreated patients. These spontaneous mutants can be selected by monotherapy; indeed, strains resistant to isoniazid will be selected and amplified by isoniazid monotherapy. Thus two or more agents are usually used. Because the mutations resulting in drug resistance are independent events, the probability of resistance to two antimycobacterial agents is small, ~ 1 in 10^{12} ($1 \times 10^6 \times 10^6$), a low probability considering the number of bacilli involved.

Resistance to INH is associated with mutation or deletion of *katG*, overexpression of the genes for *inhA* (confers low-level resistance to INH and some cross-resistance to ethionamide), and *ahpC* and mutations in the *kasA* and *katG* genes. *KatG* mutants exhibit a high level of resistance to isoniazid (Zhang and Yew, 2009). The most common mechanism of isoniazid resistance in clinical isolates is due to single point mutations in the heme binding catalytic domain of *KatG*, especially a serine to asparagine change at position 315. Although isolates with this mutation completely lose the ability to form nicotinoyl-NAD⁺/NADP⁺ adducts, they retain good catalase activity and maintain good biofitness. Compensatory mutations in the *ahpC* promoter occur and increase survival of *katG* mutant strains under oxidative stress.

KatG 315 mutants have a high probability of co-occurrence with ethambutol resistance (Hazbón et al., 2006; Parsons et al., 2005). Mutations in *katG*, *ahpC*, and *inhA* have also been associated with *rpoB* mutations (Hazbón et al., 2006). This suggests that mutations at different loci associated with resistance to different drugs may somehow interact to make multiple drug resistance more likely. In the laboratory, efflux pump induction by isoniazid has been demonstrated, and it also confers resistance to ethambutol (Colangeli et al., 2005). In an *in vitro* pharmacodynamic model, efflux pump-induced resistance developed within 3 days and was followed by development of *katG* mutations (Gumbo et al., 2007b).

Absorption, Distribution, and Excretion. The bioavailability of orally administered isoniazid is $\sim 100\%$ for the 300 mg dose. The pharmacokinetics of isoniazid are best described by a one-compartment model, with the pharmacokinetic parameters in Table 56–2 (Kinzig-Schippers et al., 2005). The ratio of isoniazid in the epithelial lining fluid to that in plasma is 1–2 and for CSF is 0.9 (Conte et al., 2002). Approximately 10% of drug is bound to protein. From 75–95% of a dose of isoniazid

is excreted in the urine within 24 hours, mostly as acetylisoniazid and isonicotinic acid.

Isoniazid is metabolized by hepatic arylamine *N*-acetyltransferase type 2 (NAT2), encoded by a variety of NAT2* alleles (Figure 56–3). The drug is *N*-acetylated to *N*-acetylisoniazid in a reaction that uses acetyl-coA. Isoniazid clearance in patients has been traditionally classified as one of two phenotypic groups: “slow” and “fast” acetylators, as seen in Figure 56–4. Recently, the phenotypic groups have been expanded to fast, intermediate, and slow acetylators, and population pharmacokinetic parameters of isoniazid have been estimated and related to NAT2 genotype; the number of NAT2*4 alleles account for 88% of the variability of INH clearance (Kinzig-Schippers et al., 2005).

The frequency of each acetylation phenotype depends on race but is not influenced by sex or age. Fast acetylation is found in Inuit and Japanese. Slow acetylation is the predominant phenotype in most Scandinavians, Jews, and North African whites. The incidence of “slow acetylators” among various racial types in the U.S. is $\sim 50\%$. Because high acetyltransferase activity (fast acetylation) is inherited as an autosomal dominant trait, “fast acetylators” of isoniazid are either heterozygous or homozygous. Although it has been useful to categorize different “racial” groups dominated by one or the other of these phenotypes, the more precise approach will be to determine the NAT2*4 alleles for each patient to guide therapy for that patient in the future.

Microbial Pharmacokinetics-Pharmacodynamics. Isoniazid’s microbial kill is best explained by the AUC_{0-24} -to-MIC ratio (Gumbo et al., 2007c). Resistance emergence is closely related to both AUC/MIC and C_{max}/MIC (Gumbo et al., 2007c). Because AUC is proportional to dose/CL, this means that efficacy is most dependent on drug dose and CL, and thus on the activity of NAT-2 polymorphic forms. This also suggests that dividing the isoniazid dose into more frequent doses may be detrimental in terms of resistance emergence, and more intermittent dosing would be better (Chapter 48).

Therapeutic Uses. Isoniazid is available as a pill, as an elixir, and for parenteral administration. The commonly used total daily dose of isoniazid is 5 mg/kg, with a maximum of 300 mg; oral and intramuscular doses are identical. Children should receive 10–15 mg/kg/day (300 mg maximum). Dosing information in the treatment of *M. tuberculosis* and *M. kansasii* infections is given in section II and VI.

Untoward Effects. After NAT2 converts isoniazid to acetylisoniazid, which is excreted by the kidney; acetylisoniazid can also be converted to acetylhydrazine (Roy et al., 2008), and then to hepatotoxic metabolites by CYP2E1. Alternatively, acetylhydrazine may be further acetylated by NAT-2 to diacetylhydrazine, which is non-toxic. In this scenario, rapid acetylators will rapidly remove acetylhydrazine while slower acetylators or induction of CYP2E1 will lead to more toxic metabolites. Rifampin is a potent inducer of CYP2E1, which is why it potentiates isoniazid hepatotoxicity.

Elevated serum aspartate and alanine transaminases are encountered commonly in patients on isoniazid. However, the enzyme levels often normalize even when isoniazid therapy is continued (Blumberg et al., 2003). Severe hepatic injury occurs in $\sim 0.1\%$ of all patients taking the drug. Hepatic damage is rare in patients <20 years old but the incidence increases with age to 1.2%

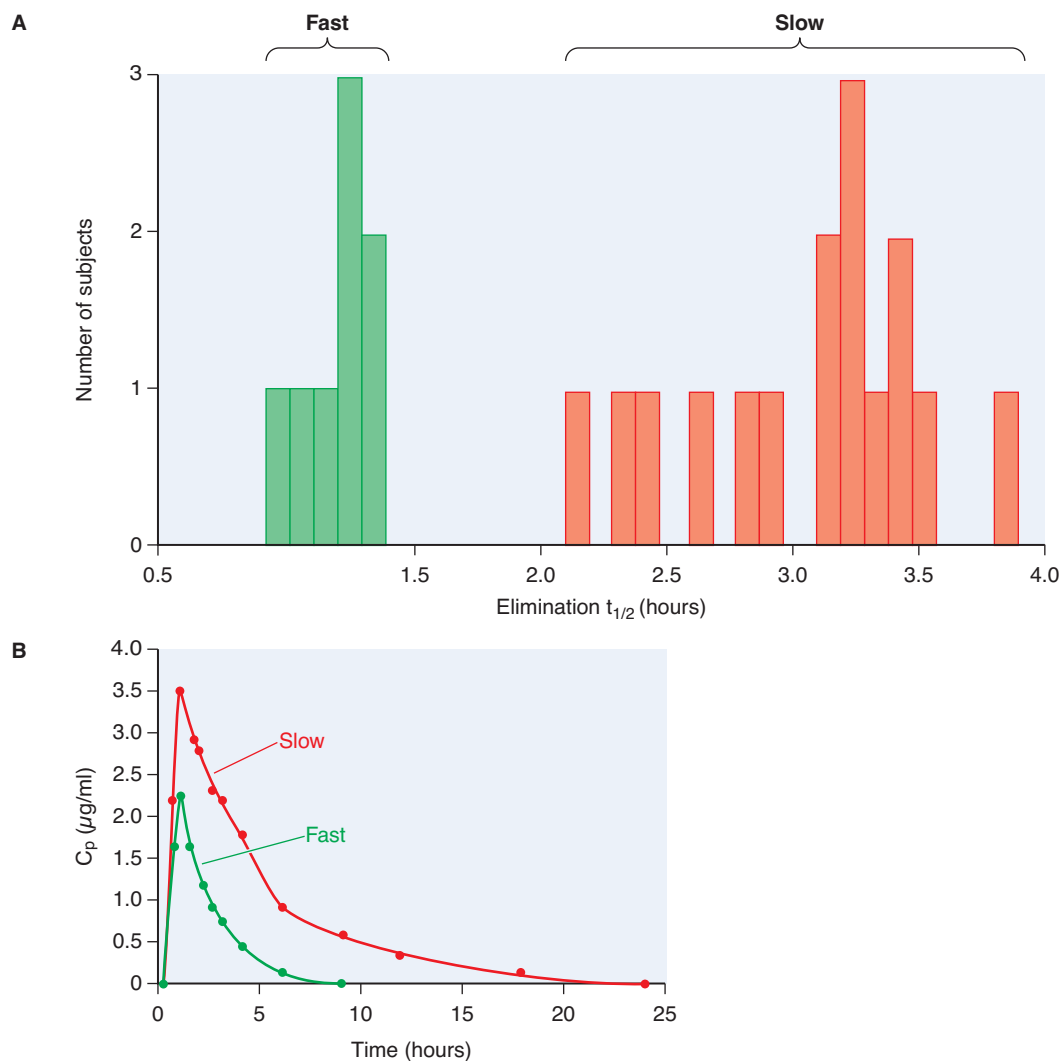

Figure 56-4. Multi-modal distribution of INH clearance due to NAT2 polymorphisms. Twenty-four male volunteers were given INH (250 mg orally [3.3 ± 0.5 mg/kg; all subjects within 10% of estimated lean body mass]) and the time courses of plasma levels (C_p) were assessed. (Modified with permission from Peloquin CA et al. Population pharmacokinetic modeling of isoniazid, rifampin, and pyrazinamide. *Antimicrob Agents Chemother*; 1997, 41:2670. With permission from American Society for Microbiology.) **A.** Frequency distribution of elimination half-times. Plotting elimination half-times ($t_{1/2}$) as a frequency distribution demonstrates a group of 8 subjects with $t_{1/2}$ values < 1.5 hours (mean = 1.2 hours), the *fast acetylators*, and a group of 16 with $t_{1/2}$ values > 2 hours (mean = 3.3 hours), the *slow acetylators*. **B.** Time course of plasma levels. The mean data (C_p vs time after administration) fall into two major groups (see panel A). Both groups reached C_{pmax} at 1 hour. One group (red line) achieved a higher C_p (3.6 $\mu\text{g/mL}$) with a mean elimination $t_{1/2} = 3.3$ hours (*slow acetylators*); the other group (green line) reached a lower maximal C_p (2.3 $\mu\text{g/mL}$) with a mean elimination $t_{1/2} = 1.2$ hours (*fast acetylators*).

Variation in expression of active and defective polymorphic forms of NAT2 characterize the fast and slow acetylators. Slow acetylators may be a greater risk for adverse effects from INH, sulfonamides, and procainamide, whereas fast acetylators may have diminished responses to standard doses of these agents but greater risk from bioactivation by NAT2 of arylamine/hydrazine carcinogens. Recently, researchers have identified three elimination subgroups for INH metabolism, *fast*, *slow*, and *intermediate* (codominant fast and slow alleles).

between 35 and 49 years and to 2.3% over 50 years of age. Overall risk is increased by co-administration with rifampin to ~3%. Fatal hepatitis is even rarer (0.02%). Most cases of hepatitis occur 4-8 weeks after the start of therapy.

If pyridoxine is not given concurrently, peripheral neuritis (most commonly paresthesias of feet and hands) is encountered in

~2% of patients receiving isoniazid 5 mg/kg of the drug daily. Neuropathy is more frequent in “slow” acetylators and in individuals with diabetes mellitus, poor nutrition, or anemia. Other neurological toxicities include convulsions in patients with seizure disorders, optic neuritis and atrophy, muscle twitching, dizziness, ataxia, paresthesias, stupor, and toxic encephalopathy. Mental abnormalities may

appear during the use of this drug, including euphoria, transient impairment of memory, separation of ideas and reality, loss of self-control, and florid psychoses. The prophylactic administration of pyridoxine prevents the development not only of peripheral neuritis, as well as most other nervous system disorders in practically all instances, even when therapy lasts as long as 2 years.

Patients may develop hypersensitivity to isoniazid. Hematological reactions also may occur. Vasculitis associated with antinuclear antibodies may appear during treatment but disappears when the drug is stopped. Arthritic symptoms (back pain; bilateral proximal interphalangeal joint involvement; arthralgia of the knees, elbows, and wrists; and the “shoulder-hand” syndrome) have been attributed to this agent.

Miscellaneous reactions associated with isoniazid therapy include dryness of the mouth, epigastric distress, methemoglobinemia, tinnitus, and urinary retention. In persons predisposed to pyridoxine-deficiency anemia, the administration of isoniazid may result in dramatic anemia. Treatment of the anemia with large doses of vitamin B₆ gradually returns the blood count to normal. A drug-induced syndrome resembling systemic lupus erythematosus has also been reported.

Isoniazid Overdose. Intentional isoniazid overdose occurs most often in young women with concomitant psychiatric problems prescribed isoniazid for latent TB (Sullivan et al., 1998). As little as 1.5 g can be toxic. Isoniazid overdose has been associated with the clinical triad of:

- seizures refractory to treatment with phenytoin and barbiturates
- metabolic acidosis with an anion gap that is resistant to treatment with sodium bicarbonate
- coma

The common early symptoms appear within 0.5-3 hours of ingestion and include ataxia, peripheral neuropathy, dizziness, and slurred speech. The most dangerous are grand mal seizures and coma, encountered when patients ingest ≥ 30 mg/kg of the drug. Mortality in these circumstances is as high as 20%. Intravenous pyridoxine is administered over 5-15 minutes on a gram-to-gram basis

with the ingested isoniazid. If the dose of ingested isoniazid is unknown, then a pyridoxine dose of 70 mg/kg should be used. In patients with seizures, benzodiazepines are utilized.

Isoniazid’s toxicity may be interpreted in terms of effects on pyridoxine metabolism. Isoniazid binds to pyridoxal 5’-phosphate to form isoniazid-pyridoxal hydrazones, thereby depleting neuronal pyridoxal 5’-phosphate and interfering with pyridoxal phosphate-requiring reactions, including the synthesis of the inhibitory neurotransmitter, GABA. Decreased levels of GABA lead to cerebral overexcitability and lowered seizure threshold. The antidote is replenishment of pyridoxal 5’-phosphate.

Drug Interactions. Isoniazid is a potent inhibitor of CYP2C19, CYP3A, and a weak inhibitor of CYP2D6 (Desta et al., 2001). However, isoniazid induces CYP2E1. Drugs that are metabolized by these enzymes will potentially be affected. Table 56–4, based on work by Desta et al. (2001), is a summary of drugs that interact with isoniazid via these mechanisms.

Ethambutol

Ethambutol hydrochloride (MYAMBUTOL) is a water-soluble and heat-stable compound:

ETHAMBUTOL

Mechanism of Action. Ethambutol inhibits arabinosyl transferase III, thereby disrupting the transfer of arabinose into arabinogalactan biosynthesis, which in turn disrupts the assembly of mycobacterial cell wall (Lewis, 1999). The arabinosyl transferases are encoded by *embAB* genes.

Antibacterial Activity. Ethambutol has activity against a wide range of mycobacteria but has no activity against any other genus. Ethambutol MICs are 0.5-2 mg/L in clinical isolates of *M. tuberculosis*, ~0.8 mg/L for *M. kansasii*, and 2-7.5 mg/L for *M. avium* (Heifets, 1991;

Table 56–4

Isoniazid-Drug Interactions via Inhibition and Induction of CYPs

CO-ADMINISTERED DRUG	CYP ISOFORM	ADVERSE EFFECTS
Acetaminophen	CYP2E1 inhibition-induction	Hepatotoxicity
Carbamazepine	CYP3A inhibition	Neurological toxicity
Diazepam	CYP3A and CYP2C19 inhibition	Sedation and respiratory depression
Ethosuximide	CYP3A inhibition	Psychotic behavior
Isoflurane and enflurane	CYP2E1 induction	Decreased effectiveness
Phenytoin	CYP2C19 inhibition	Neurological toxicity
Theophylline	CYP3A inhibition	Seizures, palpitation, nausea
Vincristine	CYP3A inhibition	Limb weakness and tingling
Warfarin	CYP2C9 inhibition	Possibility of increased bleeding (single case reported)

Lewis, 1999). The following species are also susceptible: *M. goodnae*, *M. marinum*, *M. scrofulaceum*, *M. szulgai*. However, the majority of *M. xenopi*, *M. fortuitum*, and *M. chelonae* have been reported as resistant (Lewis, 1999).

Mechanisms of Resistance. *In vitro*, mycobacterial resistance to the drug develops via mutations in the *embB* gene. In 30-70% of clinical isolates that are resistant to ethambutol, mutations are encountered at codon 306 of the *embB* gene. However, mutations in this codon are also encountered in ethambutol-susceptible mycobacteria, as though this mutation is necessary, but not sufficient, to confer ethambutol resistance (Safi et al., 2008). In addition, enhanced efflux pump activity may induce resistance to both isoniazid and ethambutol in the laboratory.

Absorption, Distribution, Metabolism, and Excretion. The oral bioavailability of ethambutol is ~80%. Approximately 10-40% of the drug is bound to plasma protein. Ethambutol drug concentrations have been modeled using a two-compartment open model, with first-order absorption and elimination (Peloquin et al., 1999; Zhu et al., 2004). The decline in ethambutol is biexponential, with a $t_{1/2}$ of 3 hours in the first 12 hours, and a $t_{1/2}$ of 9 hours between 12 and 24 hours, due to redistribution of drug. Clearance and V_d are greater in children than in adults on a per kilogram basis. Slow and incomplete absorption is common in children, so that good peak concentrations of drug are often not achieved with standard dosing (Zhu et al., 2004). In addition, these C_{max} values are not very impressive given the typical MIC values for most clinical isolates of mycobacteria. See Table 56-2 for PK data on this drug.

Alcohol dehydrogenase oxidizes ethambutol to an aldehyde, which is then oxidized by aldehyde dehydrogenase to dicarboxylic acid. However, 80% of the drug is not metabolized at all and is renally excreted. Therefore, in renal failure ethambutol should be dosed at 15-25 mg/kg, three times a week instead of daily, even in patients receiving hemodialysis.

Microbial pharmacokinetics-pharmacodynamics. Ethambutol's microbial kill of *M. tuberculosis* is optimized by AUC/MIC, while that against disseminated MAC is optimized by C_{max} /MIC (Srivastava et al., 2010; Deshpande et al., 2010). Thus, to optimize microbial kill, high intermittent doses such as 25 mg/kg every other day to 50 mg/kg twice a week may be superior to daily doses of 15 mg/kg.

Therapeutic Uses. Ethambutol is available for oral administration in tablets containing the D-isomer. It is used for the treatment of TB, disseminated MAC, and in *M. kansasii* infection. Ethambutol is administered at 15-25 mg/kg per day for both adults and children.

Untoward Effects. Ethambutol produces very few serious untoward reactions. Fewer than 2% of patients who receive daily doses of 15 mg/kg of ethambutol have adverse reactions: ~1% experience diminished visual acuity, 0.5% a rash, and 0.3% drug fever. Other side effects that have been observed are pruritus, joint pain, GI upset, abdominal pain, malaise, headache, dizziness, mental confusion, disorientation, and possible hallucinations. Numbness and tingling of the fingers owing to peripheral neuritis are infrequent. Anaphylaxis and leukopenia are rare. Therapy with ethambutol results in an

increased concentration of urate in the blood in ~50% of patients, owing to decreased renal excretion of uric acid.

The most important side effect is optic neuritis, resulting in decreased visual acuity and loss of ability to differentiate red from green. The incidence of this reaction is proportional to the dose of ethambutol and is observed in 15% of patients receiving 50 mg/kg/day, in 5% of patients receiving 25 mg/kg/day, and in <1% of patients receiving daily doses of 15 mg/kg. The intensity of the visual difficulty is related to the duration of therapy after the decreased visual acuity first becomes apparent and may be unilateral or bilateral. Tests of visual acuity and red-green discrimination prior to the start of therapy and periodically thereafter are thus recommended. Recovery usually occurs when ethambutol is withdrawn; the time required is a function of the degree of visual impairment.

Cases of ethambutol overdose are rare; drug interactions involving ethambutol are not significant.

Aminoglycosides: Streptomycin, Amikacin, and Kanamycin

The aminoglycosides streptomycin, amikacin, and kanamycin are used for the treatment of mycobacterial diseases. The MICs for *M. tuberculosis* in Middlebrook broth are 0.25-3.0 mg/L for all three aminoglycosides (Heifets, 1991). For *M. avium* streptomycin and amikacin, MICs are 1-8 mg/L; those of kanamycin are 3-12 mg/L. *M. kansasii* is frequently susceptible to these agents, but other nontuberculous mycobacteria are only occasionally susceptible. The pharmacological properties and therapeutic uses of aminoglycosides are discussed in full in Chapter 54.

Bacterial Resistance. Primary resistance to streptomycin is found in 2-3% of *M. tuberculosis* clinical isolates. Streptomycin and the two other aminoglycosides inhibit protein synthesis by binding to the 30S ribosomal subunit and causing misreading of the genetic code during translation. The 30S ribosomal unit is made of the 16S mRNA (encoded by *rpsL*), which binds to the ribosomal protein S12 (encoded by *rrs*) to optimize tRNA binding and mRNA decoding. Mutations in *rpsL* and *rrs* are associated with high-level aminoglycoside resistance in mycobacteria. However, mutations in these genes are only encountered in half of clinical isolates with aminoglycoside resistance. GidB is an rRNA methyltransferase for 16S rRNA, and mutations in *gidB* gene are associated with low-level streptomycin resistance (Okamoto et al., 2007). The *gidB* mutations lead to high-level streptomycin resistant mutants at a rate 2000 times that in wild type. Mutations in *gidB* are encountered in 33% of streptomycin-resistant clinical isolates of *M. tuberculosis*. Finally, efflux pump-mediated resistance was recently demonstrated in clinical isolates with low-level streptomycin-resistant *M. tuberculosis* and interacted with chromosomal mutations in *gidB* (Spies et al., 2008). Thus resistance to aminoglycosides involves several genetic loci, as well as efflux pumps.

Therapeutic Uses. Therapeutic uses of aminoglycosides in treatment of mycobacterial infections are discussed later.

Clofazimine (LAMPRENE) is a fat-soluble riminophenazine dye. It was discontinued in 2005 but remains licensed as an orphan drug.

Mechanism of Action. The biochemical basis for the antimicrobial actions of clofazimine remains to be established (Anonymous, 2008a). Possible mechanisms of action include:

- membrane disruption
- inhibition of mycobacterial phospholipase A₂
- inhibition of microbial K⁺ transport
- generation of hydrogen peroxide
- interference with the bacterial electron transport chain

However, it is known that clofazimine has both antibacterial activity as well as anti-inflammatory effects via inhibition of macrophages, T cells, neutrophils, and complement.

Antibacterial Activity. The MICs for *M. avium* clinical isolates are 1-5 mg/L. The MICs for *M. tuberculosis* are ~1.0 mg/L. The compound also is useful for treatment of chronic skin ulcers (Buruli ulcer) produced by *Mycobacterium ulcerans*. It has activity against many gram-positive bacteria with an MIC ≤1.0 mg/L against *S. aureus*, coagulase-negative Staphylococci, *Streptococcus pyogenes*, and *Listeria monocytogenes*. Gram-negative bacteria have MICs >32 mg/L.

Bacterial Resistance. Mechanisms of resistance are unknown.

Absorption, Distribution, and Excretion. Clofazimine's oral bioavailability is highly variable, 45-60%; bioavailability is increased 2-fold by high-fat meals and decreased 30% by antacids (Nix et al., 2004). After a single dose, clofazimine is best modeled using a one-compartment model and has a prolonged absorption phase; after 200 mg of clofazimine, the t_{max} is 5.3-7.8 hours. After prolonged repeated dosing, the $t_{1/2}$ is ~70 days. For PK data, see Table 56-2 and Nix et al. (2004). As a result of the good penetration into many tissues, a reddish black discoloration of skin and body secretions may occur and take a long time to resolve. Crystalline deposits of the drug have been encountered in many tissues at autopsy (Anonymous, 2008a). Clofazimine is metabolized in the liver in four steps: hydrolytic dehalogenation, hydrolytic deamination, glucuronidation, and hydroxylation.

Dosing. Clofazimine is administered orally at doses up to 300 mg a day.

Untoward Effects. GI problems are encountered in 40-50% of patients and include abdominal pain, diarrhea, nausea, and vomiting.

In patients who have died following the abdominal pain, crystal deposition in intestinal mucosa, liver, spleen, and abdominal lymph nodes has been demonstrated (Anonymous, 2008a). Body secretion discoloration, eye discoloration, and skin discoloration occur in most patients and can lead to depression in some patients.

Drug interactions. Anti-inflammatory effects may be inhibited by dapsone.

Fluoroquinolones

Fluoroquinolones are DNA gyrase inhibitors. Their chemistry, spectrum of activity, pharmacology, and adverse events are discussed in greater detail in Chapter 52. Drugs such as ofloxacin and ciprofloxacin have been second-line anti-TB agents for many years, but they are limited by the rapid development of resistance. Adding C8 halogen and C8 methoxy groups markedly reduces the propensity for drug resistance. Of the C8 methoxy quinolones, moxifloxacin (approved by the Food and Drug Administration for nontubercular infections) is furthest along in clinical testing as an anti-TB agent. Moxifloxacin is being studied to replace either isoniazid or ethambutol.

Microbial Pharmacokinetics-Pharmacodynamics Relevant to TB.

Fluoroquinolone microbial kill is best explained by AUC₀₋₂₄/MIC ratio. In preclinical models, moxifloxacin AUC₀₋₂₄/MIC exposures equivalent to those from the standard 400-mg dose were associated with good microbial kill but amplified the drug-resistant subpopulation, so that resistance emerged in 7-13 days with monotherapy (Gumbo et al., 2004). This time to emergence of resistance harmonizes well with speed of resistance emergence in patients (Ginsburg et al., 2003). Moxifloxacin exposure best associated with minimizing emergence of resistance was an AUC₀₋₂₄/MIC of 53. Clinical trial simulations revealed that doses >400 mg a day might better achieve this AUC/MIC, which experiments in mice substantiate (Almeida et al., 2007). Given that rifamycins reduce moxifloxacin AUC, these results point to a potential concern of quinolone resistance. Unfortunately, the safety of moxifloxacin doses >400 mg has not been established.

Therapeutic Uses in Treatment of TB. In TB patients, moxifloxacin (400 mg/day) has bactericidal effects similar to that of standard doses of isoniazid (Johnson et al., 2006). When replacing ethambutol in the standard multi-drug regimen, 400 mg/day of moxifloxacin produces faster sputum conversion at 4 weeks than ethambutol (Burman et al., 2006b). In a comparison study of moxifloxacin, gatifloxacin, ofloxacin, and ethambutol as the fourth drug administered concurrently with isoniazid, rifampin, and pyrazinamide (Rustomjee et al., 2008b), moxifloxacin led to faster rates of bacterial kill during the early phases, gatifloxacin was equivalent by the eighth week, and ofloxacin was no better than ethambutol. Moxifloxacin is currently being studied in a phase 3 trial that may eventually lead to 4-month duration of anti-TB therapy compared to the current 6 months.

Drug Interactions Relevant to TB. In a study of volunteers treated with rifampin, moxifloxacin, or both drugs, rifampin reduced the moxifloxacin AUC₀₋₂₄ by 27% via induction of sulfate conjugation (Weiner et al., 2007). In another study, rifapentine reduced moxifloxacin AUC₀₋₂₄ by 17% (Dooley et al., 2008). These studies suggest that the most important cause of pharmacokinetic variability for moxifloxacin is concomitantly administered drugs for tuberculosis.

TMC-207 (R207910)

TMC-207 is a diarylquinone discovered by Andries et al. in 2005.

Mechanism of Action. TMC-207 acts by targeting subunit *c* of the ATP synthase of *M. tuberculosis*, leading to inhibition of the proton pump activity of the ATP synthase (Andries et al., 2005; Koul et al., 2007). Thus, the compound targets bacillary energy metabolism.

Antibacterial Activity. The TMC-207 MIC for *M. tuberculosis* is 0.03–0.12 mg/L. It has good activity against MAC, *M. leprae*, *M. bovis*, *M. marinum*, *M. kansasii*, *M. ulcerans*, *M. fortuitum*, *M. szulgai*, and *M. abscessus* (Andries et al., 2005; Huitric et al., 2007).

Bacterial Resistance. The proportion of *M. tuberculosis* mutants resistant to four times the MIC is 5×10^{-7} to 2×10^{-8} . Resistance is associated with two point mutations: D32V and A63P. This region of the gene encodes the membrane-spanning domain of the ATP synthase *c* subunit.

Absorption, Distribution, and Excretion. After oral ingestion of 400 mg of TMC-207, the t_{\max} was 4 hours, the C_{\max} was 5.5 mg/L after 400 mg/day, and the AUC_{0-24} was 65 mg·h/L. Based on these data, the CL is ~6.2 L/h, although systemic clearance reportedly is “triexponential.” Population pharmacokinetic studies have not been published.

Pharmacokinetics, Efficacy, and Therapeutic Use. The anti-TB activity of TMC-207 is correlated with time above MIC. In murine TB, TMC-207 had superior bactericidal activity compared to isoniazid and rifampin, and accelerated sterilization when combined with rifampin, isoniazid, and pyrazinamide (Andries et al., 2005). In patients with drug-susceptible TB, the rate of sputum bacillary decline was similar to rifampin and isoniazid (Rustomjee et al., 2008a). A regimen of TMC207 400 mg daily for 2 weeks followed by 200 mg three times day thereafter was added to a background second-line regimen of either kanamycin or amikacin, ofloxacin with or without ethambutol in patients with TB resistant to both isoniazid and rifampin (MDR-TB), and led to an 8-week sputum conversion of ~50% with TMC207 compared to 9% without (Diacon et al., 2009).

Untoward Effects. The adverse events encountered with TMC207 are mild and include nausea in 26% of patients and diarrhea in 13% of patients, with others such as arthralgia, pain in extremities, and hyperuricemia in a small proportion of patients (Diacon et al., 2009). However, only a limited number of patients have been exposed to this drug, so that the full side-effect profile is unclear.

PA-824

PA-824 is a nitroimidazopyran discovered by Stover et al. in 2000.

Mechanism of Action. PA-824 inhibits *M. tuberculosis* mycolic acid and protein synthesis at the step between hydroxymycolate and ketomycolate (Stover et al., 2000). Similar to the structurally related metronidazole, PA-824 is a pro-drug that requires activation by the bacteria via a nitro-reduction step that requires, among other factors, a specific glucose-6-phosphate dehydrogenase, FGD1, and the reduced deazaflavin co-factor F_{420} (Bashiri et al., 2008). Another mechanism involves generation of reactive nitrogen species such as NO by PA-824's des-nitro metabolite, which then augment the kill of intracellular nonreplicating persistent bacilli by the innate immune system (Singh et al., 2008).

Antibacterial Activity. *In vitro*, the drug kills both nonreplicating *M. tuberculosis* that are under anaerobic conditions as well as replicating bacteria in ambient air. The MICs of PA-824 against *M. tuberculosis* range from 0.015–0.25 mg/L, but the drug lacks activity against other mycobacteria.

Bacterial Resistance. The proportion of mutants resistant to 5 mg/L of PA-824 is 10^{-6} . Resistance arises due to changes in structure of FGD, which is due to a variety of point mutations in *fgd* gene. However, resistant isolates have also been identified that lack *fgd* mutations, so that resistance may also be due to other mechanisms (Stover et al., 2000).

Pharmacokinetics and Efficacy. In murine and guinea pig TB, PA-824 was equivalent to standard doses of isoniazid (Stover et al., 2000). In a recent murine TB study, 100 mg/kg/day of PA-824 with pyrazinamide and rifampin showed total sterilization at 2 months and no relapse, versus 15% relapse with the standard isoniazid, rifampin, and pyrazinamide regimen (Tasneen et al., 2008). Phase 1 studies have been performed, but the pharmacokinetic data have not been published. Phase 2 studies are in progress.

Ethionamide

Ethionamide (TRECATOR) is a congener of thioisonicotinamide.

Mechanism of Action. Mycobacterial EthA, an NADPH-specific, FAD-containing monooxygenase, converts ethionamide to a sulfoxide, and then to 2-ethyl-4-aminopyridine (Vannelli et al., 2002). Although these products are not toxic to mycobacteria, it is believed that a closely related and transient intermediate is the active antibiotic. Ethionamide inhibits mycobacterial growth by inhibiting the activity of the *inhA* gene product, the enoyl-ACP reductase of fatty

acid synthase II (Larsen et al., 2002). This is the same enzyme that activated isoniazid inhibits. Although the exact mechanisms of inhibition may differ, the results are the same: inhibition of mycolic acid biosynthesis and consequent impairment of cell-wall synthesis.

Antibacterial Activity. The multiplication of *M. tuberculosis* is suppressed by concentrations of ethionamide ranging from 0.6-2.5 mg/L. A concentration of ≤ 10 mg/L will inhibit $\sim 75\%$ of photochromogenic mycobacteria; the scotochromogens are more resistant.

Bacterial Resistance. Resistance occurs mainly via changes in the enzyme that activates ethionamide, and mutations are encountered in a transcriptional repressor gene that controls its expression, *etaR*. Mutations in *inhA* gene lead to resistance to both ethionamide and isoniazid.

Absorption, Distribution, and Excretion. The oral bioavailability of ethionamide approaches 100%. The pharmacokinetics are adequately explained by a one-compartment model with first-order absorption and elimination (Zhu et al., 2002); see PK values in Table 56-2. After oral administration of 500 mg of ethionamide, a C_{\max} of 1.4 mg/L is achieved in 2 hours. The $t_{1/2}$ is ~ 2 hours. The concentrations in the blood and various organs are approximately equal. Ethionamide is cleared by hepatic metabolism; six metabolites have been identified. Metabolites are eliminated in the urine, with $< 1\%$ of ethionamide excreted in an active form.

Therapeutic Uses. Ethionamide is administered only orally. The initial dosage for adults is 250 mg twice daily; it is increased by 125 mg/day every 5 days until a dose of 15-20 mg/kg/day is achieved. The maximal dose is 1 g daily. The drug is best taken with meals in divided doses to minimize gastric irritation. Children should receive 10-20 mg/kg/day in two divided doses, not to exceed 1 g/day.

Untoward effects. Approximately 50% of patients are unable to tolerate a single dose larger than 500 mg because of GI upset. The most common reactions are anorexia, nausea and vomiting, gastric irritation, and a variety of neurologic symptoms. Severe postural hypotension, mental depression, drowsiness, and asthenia are common. Convulsions and peripheral neuropathy are rare. Other reactions referable to the nervous system include olfactory disturbances, blurred vision, diplopia, dizziness, paresthesias, headache, restlessness, and tremors. Pyridoxine (vitamin B₆) relieves the neurologic symptoms, and its concomitant administration is recommended. Severe allergic skin rashes, purpura, stomatitis, gynecomastia, impotence, menorrhagia, acne, and alopecia have also been observed. A metallic taste also may be noted. Hepatitis has been associated with the use of the ethionamide in $\sim 5\%$ of cases. Hepatic function should be assessed at regular intervals in patients receiving the drug.

Para-Aminosalicylic Acid

Para-aminosalicylic acid (PAS), discovered by Lehman in 1943, was the first effective treatment for TB.

AMINOSALICYLIC ACID

Mechanism of Action. PAS is a structural analog of *para*-aminobenzoic acid, the substrate of dihydropteroate synthase (*folP1/P2*). As a result, PAS is thought to be a competitive inhibitor *folP1*. However, *in vitro* the inhibitory activity against *folP1* is very poor. However, mutation of the thymidylate synthase gene (*thyA*) results in resistance to PAS, but only 37% of the PAS-resistant clinical isolates or spontaneous mutants encode a mutation in *thyA* gene, or in any genes encoding enzymes in the folate pathway or biosynthesis of thymine nucleotides (Mathys et al., 2009). Unidentified actions of PAS likely play more important roles in its anti-TB effects.

Antibacterial Activity. PAS is bacteriostatic. *In vitro*, most strains of *M. tuberculosis* are sensitive to a concentration of 1 mg/L. It has no activity against other bacteria.

Bacterial Resistance. Mutations in *thyA* gene lead to drug resistance in a minority of drug-resistant isolates.

Absorption, Distribution, and Excretion. PAS oral bioavailability is $> 90\%$. PAS pharmacokinetics are described by a one-compartment model (Peloquin et al., 2001); see the PK values in Table 56-2. The C_{\max} increases 1.5-fold and AUC 1.7-fold with food compared to fasting (Peloquin et al., 2001). These results mean that PAS should be administered with food, which also greatly reduces gastric irritation. Protein binding is 50-60%. PAS is N-acetylated in the liver to N-acetyl PAS, a potential hepatotoxin. Over 80% of the drug is excreted in the urine; $> 50\%$ is in the form of the acetylated compound. Excretion of PAS acid is reduced by renal dysfunction; thus the dose must be reduced in renal dysfunction.

Therapeutic Uses. PAS is administered orally in a daily dose of 12 g. The drug is best administered after meals, with the daily dose divided into three equal portions. Children should receive 150-300 mg/kg/day in 3-4 divided doses.

Untoward Effects. The incidence of untoward effects associated with the use of PAS is $\sim 10-30\%$. GI problems predominate and often limit patient adherence. Hypersensitivity reactions to PAS are seen in 5-10% of patients and manifest as skin eruptions, fever, eosinophilia, and other hematological abnormalities.

Cycloserine

Cycloserine (SEROMYCIN) is D-4-amino-3-isoxazolidone. It is a broad-spectrum antibiotic produced by *Streptococcus orchidaceus*.

CYCLOSERINE

Mechanism of Action. Cycloserine and d-alanine are structural analogs; thus cycloserine inhibits alanine racemase which converts L-alanine to d-alanine and d-alanine: d-alanine ligase, stopping reactions in which d-alanine is incorporated into bacterial cell-wall synthesis (Anonymous, 2008b).

Antibacterial Activity. Cycloserine is a broad-spectrum antibiotic. It inhibits *M. tuberculosis* at concentrations of 5-20 mg/L. It has good activity against MAC, enterococci, *E. coli*, *S. aureus*, *Nocardia* species, and *Chlamydia*.

Mechanisms of Resistance. Mutations involved in cycloserine resistance to pathogenic *Mycobacteria* are currently unknown. However, resistance in clinical isolates of *M. tuberculosis* has been detected in 10-82% of isolates (Anonymous, 2008b).

Absorption, Distribution, and Excretion. Oral cycloserine is almost completely absorbed. The population pharmacokinetics are best described using a one-compartment model with first-order absorption and elimination (Zhu et al., 2001). The drug's $t_{1/2}$ is 9 hours. C_{max} in plasma is reached in 45 minutes in fasting subjects, but is delayed for up to 3.5 hours with a high-fat meal. See Table 56–2 for PK values. Cycloserine is well distributed throughout body. There is no appreciable barrier to CNS entry for cycloserine, and cerebrospinal fluid (CSF) concentrations are approximately the same as those in plasma. About 50% of cycloserine is excreted unchanged in the urine in the first 12 hours; a total of 70% is recoverable in the active form over a period of 24 hours. The drug may accumulate to toxic concentrations in patients with renal failure. About 60% of it is removed by hemodialysis, and the drug must be re-dosed after each hemodialysis session (Malone et al., 1999a).

Therapeutic Uses. Cycloserine is available for oral administration. The usual dose for adults is 250-500 mg twice daily.

Untoward Effects. Neuropsychiatric symptoms are common and occur in 50% of patients on 1 g/day, so much so that the drug has earned the nickname “psych-serine.” Symptoms range from headache and somnolence to severe psychosis, seizures, and suicidal ideas. Large doses of cycloserine or the concomitant ingestion of alcohol increases the risk of seizures. Cycloserine is contraindicated in individuals with a history of epilepsy and should be used with caution in individuals with a history of depression.

Capreomycin

Capreomycin (CAPASTAT) is an antimycobacterial cyclic peptide. It consists of four active components: capreomycins IA, IB, IIA, and IIB. The agent used clinically contains primarily IA and IB. Antimycobacterial activity is similar to that of aminoglycosides as are adverse effects, and capreomycin should not be administered with other drugs that damage cranial nerve VIII.

Bacterial resistance to capreomycin develops when it is given alone; such microorganisms show cross-resistance with kanamycin and neomycin. The adverse reactions associated with the use of capreomycin are hearing loss, tinnitus, transient proteinuria, cylindruria, and nitrogen retention. Severe renal failure is rare. Eosinophilia is common. Leukocytosis, leukopenia, rashes, and fever have also been observed. Injections of the drug may be painful. Capreomycin is a second-line antituberculosis agent. The recommended daily dose is 1g (no more than 20 mg/kg) per day for 60-120 days, followed by 1g two to three times a week.

Macrolides

The pharmacology, bacterial activity, resistance mechanisms of macrolides are discussed in Chapter 55. Azithromycin and clarithromycin are used for the treatment of MAC.

Dapsone

Dapsone (DDS, diamino-diphenylsulfone) or 4'-diaminodiphenylsulfone, was synthesized by Fromm and Wittman in 1908, and its similarity to sulphonamides led to the establishment of anti-streptococcal effects by Buttle et al. and Forneau et al. in 1937.

Mechanism of Action. Dapsone is a structural analog of *para*-aminobenzoic acid (PABA) and a competitive inhibitor of dihydropteroate synthase (*folP1/P2*) in the folate pathway, shown in Figure 56–5. The effect on this evolutionarily conserved pathway also explains why dapsone is a broad-spectrum agent with antibacterial, anti-protozoal, and antifungal effects.

The anti-inflammatory effects of dapsone occur via inhibition of tissue damage by neutrophils (summarized by Wolf et al., 2002). First, dapsone inhibits neutrophil myeloperoxidase activity and respiratory burst. Second, it inhibits activity of neutrophil lysosomal enzymes. Third, it may also act as a free radical scavenger, counteracting the effect of free radicals generated by neutrophils. Fourth, dapsone may also inhibit migration of neutrophils to inflammatory lesions (Wolf et al., 2002). Dapsone is extensively used for acne, but this therapy is not recommended.

Antimicrobial Effects. *Antibacterial.* Dapsone is bacteriostatic against *M. leprae* at concentrations of 1-10 mg/L. More than 90% of clinical isolates of MAC and *M. kansasii* have an MIC of ≤ 8 mg/L, but the MICs for *M. tuberculosis* isolates are high. It has little activity against other bacteria.

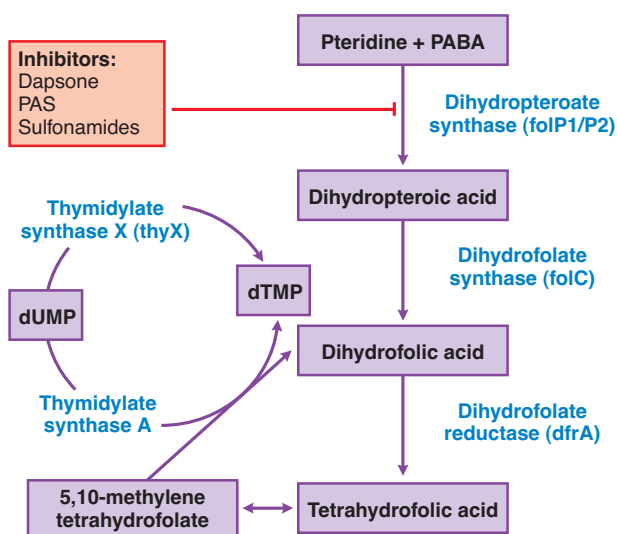

Figure 56–5. Effects of antimicrobials on folate metabolism and deoxynucleotide synthesis.

Anti-parasitic. Dapsone is also highly effective against *Plasmodium falciparum* with IC_{50} of 0.006-0.013 mg/mL (0.6-1.3 mg/L) even in sulfadoxine-pyrimethamine-resistant strains. Dapsone has an IC_{50} of 0.55 mg/L against *Toxoplasma gondii* tachyzoites.

Antifungal. Dapsone is effective at concentrations of 0.1/mg/L against the fungus *Pneumocystis jiroveci*.

Drug Resistance. Resistance to dapsone in *P. falciparum*, *P. jiroveci*, and *M. leprae* results primarily from mutations in genes encoding dihydropteroate synthase (Figure 56–5). In *P. falciparum* mutations occur at several positions such as 436, 437, 540, 58, and 613. In *P. jiroveci* isolates, mutations are often amino acid substitutions at positions 55 and 57. In *M. leprae*, mutations are encountered at codons 53 and 55.

Absorption, Distribution, and Excretion. After oral administration, absorption is complete; the elimination $t_{1/2}$ is 20-30 hours. The population pharmacokinetics of dapsone are shown in Table 56–2 (Simpson et al., 2006). CL increases 0.03 L/hour and V_d 0.7 L increases for each 1-kg increase in body weight above 62.3 kg. Dapsone undergoes N-acetylation by NAT2. N-oxidation to dapsone hydroxylamine is via CYP2E1, and to a lesser extent by CYP2C. Dapsone hydroxylamine enters red blood cells, leading to methemoglobin formation. Sulfones tend to be retained for up to 3 weeks in skin and muscle and especially in liver and kidney. Intestinal reabsorption of sulfones excreted in the bile contributes to long-term retention in the bloodstream; periodic interruption of treatment is advisable for this reason. Epithelial lining fluid to plasma ratio is between 0.76 and 2.91; CSF-to-plasma ratio is 0.21-2.01 (Gatti et al., 1997). Approximately 70-80% of a dose of dapsone is excreted in the urine as an acid-labile mono-N-glucuronide and mono-N-sulfamate.

Therapeutic Uses. Dapsone is administered as an oral agent. Therapeutic uses of dapsone in the treatment of leprosy are described later. Dapsone is combined with chlorproguanil for the treatment of malaria. Dapsone is also used for *P. jiroveci* infection and prophylaxis, and for the prophylaxis for *T. gondii*, as discussed in chapters devoted to these infections. The anti-inflammatory effects are the basis for therapy for pemphigoid, dermatitis herpetiformis, linear IgA bullous disease, relapsing chondritis, and ulcers caused by the brown recluse spider (Wolf et al., 2002).

Dapsone and Glucose-6-Phosphate Dehydrogenase Deficiency. Glucose-6-phosphate dehydrogenase (G6PD) protects red cells against oxidative damage. However, G6PD deficiency is encountered in nearly half a billion people worldwide, the most common of 100 variants being G6PD-A⁻. Dapsone, an oxidant, causes severe hemolysis in patients with G6PD deficiency. Thus, G6PD deficiency testing should be performed prior to use of dapsone wherever possible.

Other Untoward Effects. Hemolysis develops in almost every individual treated with 200-300 mg of dapsone per day. Doses of ≤ 100 mg in healthy persons and ≤ 50 mg in healthy individuals with a G6PD deficiency do not cause hemolysis. Methemoglobinemia also is common. A genetic deficiency in the NADH-dependent methemoglobin reductase can result in severe methemoglobinemia after administration of dapsone. Isolated instances of headache, nervousness, insomnia, blurred vision, paresthesias, reversible peripheral neuropathy (thought to be due to axonal degeneration), drug fever, hematuria,

pruritus, psychosis, and a variety of skin rashes have been reported. An infectious mononucleosis-like syndrome, which may be fatal, occurs occasionally.

PRINCIPLES OF ANTITUBERCULOSIS CHEMOTHERAPY

Evolution and Pharmacology. *Mycobacterium tuberculosis* is not a single species, but a complex of species with 99.9% similarity at nucleotide level. The complex includes *M. tuberculosis (typus humanus)*, *M. canettii*, *M. africanum*, *M. bovis*, and *M. microti*. They all cause tuberculosis (TB), with *M. microti* responsible for only a handful of human cases.

Antituberculosis Therapy. Isoniazid, pyrazinamide, rifampin, ethambutol, and streptomycin are currently considered first-line anti-TB agents. Moxifloxacin is being studied as a first-line agent. First-line agents are more efficacious and better tolerated, relative to second-line agents. Second-line agents are used in case of poor tolerance or resistance to first-line agents. Second-line drugs include ethionamide, PAS, cycloserine, amikacin, kanamycin, and capreomycin.

When anti-TB drug monotherapy was administered to TB patients, resistance emergence terminated the effectiveness of these drugs. The mutation rates to first-line anti-TB drugs are between 10^{-7} and 10^{-10} , so that the likelihood of resistance is high to any single anti-TB drugs in patients with cavitary TB who have $\sim 10^9$ CFU of bacilli in a 3-cm pulmonary lesion. However, the likelihood that bacilli would develop mutations to two or more different drugs is the product of two mutation rates (between 1 in 10^{14} and 1 in 10^{20}), which makes the probability of resistance emergence to more than two drugs acceptably small. Thus, only combination therapy anti-TB therapy is currently recommended for treatment of TB. Multidrug therapy has led to a reduction in length of therapy.

Types of Antituberculosis Therapy

Prophylaxis. After infection with *M. tuberculosis*, $\sim 10\%$ of people will develop active disease over a lifetime. The highest risk of reactivation TB is in patients with Mantoux tuberculin skin test reaction ≥ 5 mm who also fall into one of the following categories: recently exposed to TB, have HIV co-infection, have fibrotic changes on chest radiograms, or are immunosuppressed due to HIV infection, post-transplantation, or are taking immunosuppressive medications for any reason. If the tuberculin skin test is ≥ 10 mm, high risk of TB is encountered in recent (≤ 5 years) immigrants from areas of high TB prevalence, children < 4 years of age, children exposed to adults with TB, intravenous drug users, as well as residents and

employees of high-risk congregate settings. Any person with a skin test >15 mm is also at high risk of disease. In these patients at high risk of active TB, prophylaxis is recommended to prevent active disease. Prophylaxis consists of oral isoniazid, 300 mg daily or twice weekly, for 6 months in adults. Those who cannot take isoniazid should be given rifampin, 10 mg/kg daily, for 4 months. In children, isoniazid 10-15 mg/kg daily (maximum 300 mg) is administered, or 20-30 mg/kg two times a week directly observed, for 9 months. In children who cannot tolerate isoniazid, rifampin 10-20 mg/kg daily for 6 months is recommended.

Definitive Therapy. All active TB cases should be confirmed by culture and have antimicrobial susceptibilities determined. The current standard regimen for drug-susceptible TB consists of isoniazid (5 mg/kg, maximum 300 mg/day), rifampin (10 mg/kg, maximum 600 mg/day), and pyrazinamide (15-30 mg/kg, maximum of 2 g/day) for 2 months, followed by intermittent 10 mg/kg rifampin and 15 mg/kg isoniazid two or three times a week for 4 months. Children should receive 10-20 mg/kg isoniazid per day (300 mg maximum). Rifabutin 5 mg/kg/day can be used for the entire 6 months of therapy in adult HIV-infected patients because rifampin can adversely interact with some antiretroviral agents to reduce their effectiveness. In case there is resistance to isoniazid, initial therapy also may include ethambutol (15-20 mg/kg/day) or streptomycin (1 g/day) until isoniazid susceptibility is documented. Ethambutol doses in children are 15-20 mg/kg/day (maximum 1 g) or 50 mg/kg twice weekly (2.5 g). Because monitoring of visual acuity is difficult in children <5 years old, caution should be exercised in using ethambutol in these children.

The first 2 months of the four-drug regimen is termed the initial phase of therapy, and the last 4 months the continuation phase of therapy. Rifapentine (10 mg/kg once a week) may be substituted for rifampin in the continuation phase in patients with no evidence of HIV infection or cavitary TB. Pyridoxine, vitamin B₆, (10-50 mg/day) should be administered with isoniazid to minimize the risks of neurological toxicity in patients predisposed to neuropathy (e.g., the malnourished, elderly, pregnant women, HIV-infected individuals, diabetic patients, alcoholic patients, and uremic patients). To ensure compliance, therapy is administered as directly observed therapy (DOT). Although DOT is the standard of care, an analysis of a series of 11 randomized clinical trials found no difference in outcome between DOT and self-administered therapy (Volmink and Garner, 2007).

The duration of therapy for drug-susceptible pulmonary TB is 6 months. A 9-month duration should be used for patients with cavitary disease who are still sputum culture positive at 2 months. HIV-infected patients with CD4+ lymphocyte cell counts <100/mm³ are at increased risk of developing rifamycin resistance. Therefore, daily therapy is recommended during the continuation phase. Most cases of extrapulmonary TB are treated for 6 months. TB meningitis

is an exception that requires a 9- to 12-month duration. In addition, corticosteroids are recommended for TB pericarditis, and results of a meta-analysis suggest they should also be used in TB meningitis (Prasad and Singh, 2008).

Drug-Resistant TB. According to the fourth global report of the World Health Organization (WHO), from 2002 to 2006, the proportion of new TB cases resistant to at least one anti-TB drug was 17%; isoniazid resistance was 10%, and MDR (multidrug resistant) was 3%. MDR-TB is said to be present if an isolate is resistant simultaneously to isoniazid and rifampin. According to the CDC, in the U.S., resistance to isoniazid was 8% and MDR was 1%. In previously treated patients, resistance to at least one drug was 35%, isoniazid resistance was 28%, and MDR was 15%; resistance to isoniazid in previously treated cases was 13%, and MDR was 4%; of the MDR, only 3% was extensively drug resistant TB [XDR]. XDR-TB is MDR-TB that is also resistant to fluoroquinolones and at least one of three injectable second-line drugs (i.e., amikacin, kanamycin, or capreomycin).

In documented drug resistance, therapy should be based on evidence of susceptibility and should include:

- at least three drugs to which the pathogen is susceptible, with at least one of the injectable anti-TB agents
- in the case of MDR-TB, use of four to six medications for better outcomes
- at least 18 months of therapy (Blumberg et al., 2003; Orenstein et al., 2009)

The addition to the regimen of a fluoroquinolone and surgical resection of the main lesions have been associated with improved outcome (Chan et al., 2004). There are currently no data to support intermittent therapy.

PRINCIPLES OF THERAPY AGAINST MYCOBACTERIUM AVIUM COMPLEX

The *Mycobacterium avium* complex (MAC) is made up of at least two species: *M. intracellulare* and *M. avium*. *M. intracellulare* causes pulmonary disease often in immunocompetent individuals. *M. avium* is further divided into a number of subspecies: *M. avium* subsp. *hominissuis* causes disseminated disease in immunocompromised patients, *M. avium* subsp. *paratuberculosis* has been implicated in the etiology of Crohn's disease, and *M. avium* subsp. *avium* causes TB of birds. These bacteria are ubiquitous in the environment and can be encountered in water, food, and soil. Therefore, when MAC bacteria are isolated from a nonsterile site in patient's body, one cannot assume they are causing an infection.

M. intracellulare often infects immunocompetent patients. The first decision after isolating MAC from pulmonary specimens is to determine whether disease is actually present or if the organism is merely part of environmental contamination. Criteria in favor of therapy includes bacteriological evidence, which consists of positive cultures from at least two sputums, or one positive culture from bronchoalveolar lavage or pulmonary biopsy with a positive culture or histopathological features, and clinical evidence of infection, and radiological evidence of infection such as pulmonary cavitation, nodular lesions, and/or bronchiectasis (Griffith et al., 2007).

In newly diagnosed patients with MAC pneumonia, triple drug therapy is recommended. These include a rifamycin, ethambutol, and a macrolide (Griffith et al., 2007; Kasperbauer and Daley, 2008). For the macrolides, either oral clarithromycin or azithromycin may be used. Rifampin is often the rifamycin of choice. Clarithromycin, 1000 mg, or azithromycin, 500 mg, are combined with ethambutol, 25 mg/kg, and rifampin, 600 mg, and administered three times a week for nodular and bronchiectatic disease. Therapy is continued for 12 months after the last negative culture. The same drugs are administered for patients with cavitary disease, but the dosing regimens are azithromycin 250 mg, ethambutol 15 mg/kg, and rifampin 600 mg. Parenteral streptomycin or amikacin at 15 mg/kg are recommended as a fourth drug. The effect of the aminoglycosides on clinical outcomes is unclear. Duration of therapy is as for nodular disease. In advanced pulmonary disease or during re-treatment, rifabutin 300 mg daily may replace rifampin. Because clarithromycin susceptibility correlates with outcome, risk of failure is high when high clarithromycin MICs are documented. Patients at risk for failure also include those with cavitary disease, presumably due to higher bacillary load. Even with these therapies, long-term success is still fairly limited. Only half of patients have successful outcomes as defined by both culture conversion and clinical outcomes.

Therapy for Disseminated *M. Avium* Complex

Disseminated MAC disease is caused by *M. avium* in 95% of patients. This is a disease of the immunocompromised patient, especially with reduced cell-mediated immunity. MAC usually occurs in patients whose CD4 cell count is $<50/\text{mm}^3$. Patients at risk for infection are those who have had other opportunistic infections, are colonized with MAC, or have an HIV RNA burden >5 log copies/ mm^3 .

The symptoms and laboratory findings of disseminated disease are nonspecific and include fever, night sweats, weight loss, elevated serum alkaline phosphates, and anemia at the time of diagnosis. However, when disease occurs in patients already on antiretroviral therapy, it may manifest as a focal disease of the lymph nodes, osteomyelitis, pneumonitis, pericarditis, skin or soft-tissue abscesses, genital ulcers, or CNS infection (DHHS Panel, 2008). In addition to a compatible clinical picture, isolation of MAC from cultures of blood, lymph node, bone marrow, or other normally sterile tissue or body fluids is required for diagnosis.

Prophylactic Therapy. The goals of prophylactic therapy are to prevent the development of disease during the time when a patient's CD4 count is low. Monotherapy with either oral azithromycin 1200 mg once a week or clarithromycin 500 mg twice a day is started when patients present with a CD4 count $<50/\text{mm}^3$ (DHHS Panel, 2008). For patients intolerant to macrolides, rifabutin 300 mg a day is administered. Once the CD4 count is >100 per mm^3 for ≥ 3 months, MAC prophylaxis should be discontinued.

Definitive and Suppressive Therapy. In patients with disease due to MAC, the goals of therapy include suppression of symptoms and conversion to negative blood cultures. The infection itself is not completely eradicated until immune reconstitution. Therapy is divided into initial therapy and chronic suppressive therapy. Recommended therapy consists of a combination of clarithromycin 500 mg twice a day with ethambutol 15 mg/kg daily, administered orally (DHHS Panel, 2008). Azithromycin 500-600 mg daily is an acceptable alternative to clarithromycin, especially in those patients in whom clarithromycin would adversely interact with other drugs. The addition of rifabutin 300 mg a day may improve outcomes. Mortality in disseminated MAC is high in patients with either a CD4 cell count $<50/\text{mm}^3$ or a MAC burden of $>2 \log_{10}$ CFU/ mm^3 of blood, or in the absence of effective antiretroviral therapy. In these patients, a fourth drug may be added, based on susceptibility testing. Potential fourth agents include amikacin, 10-15 mg/kg intravenously daily; streptomycin, 1 g intravenously or intramuscularly daily; ciprofloxacin, 500-750 mg orally twice daily; levofloxacin, 500 mg orally daily; or moxifloxacin, 400g orally daily. Patients should be continued on suppressive therapy until all three of the following criteria are met:

- therapy duration of at least 12 months
- CD4 count $>100/\text{mm}^3$ for at least 6 months
- asymptomatic for MAC infection

PRINCIPLES OF ANTI-LEPROSY THERAPY

The global prevalence of leprosy has markedly declined, largely due to the global initiative of the WHO to eliminate leprosy (Hansen's disease) as a public health problem by providing multidrug therapy (rifampin, clofazimine, and dapsone) free of charge. Prevalence of the disease has dropped by $\sim 90\%$ since 1985. Nevertheless, there are pockets of disease around the world, especially in Africa, Asia, and South America. In the U.S., <200 new cases were reported in 2005, mainly among immigrants.

Four major clinical types of leprosy impact therapy. At one end of the spectrum is *tuberculoid leprosy*, also termed paucibacillary leprosy because the bacterial burden is low and *M. leprae* is rarely found in smears. On the other end of the spectrum is the *lepromatous* form of the disease (Levis and Ernst, 2005). This is characterized by a disseminated infection and a high bacillary burden. Two major intermediate forms of the disease are recognized: borderline (dimorphous) tuberculoid disease, which has features of both tuberculoid and lepromatous leprosy, and indeterminate

disease, which has early hypopigmented lesions without features of the lepromatous and tuberculoid leprosy.

Mycobacterium leprae was discovered by Armauer Hansen in 1873. The *M. leprae* genome has undergone reductive evolution and has radically downsized its genome (Cole et al., 2001). As a result, *M. leprae* cannot produce ATP from NADH or utilize acetate or galactose as carbon sources; moreover, it has lost the anaerobic electron transfer system and cannot survive under hypoxic conditions. It has a long doubling time (14 days) and is an obligate intracellular pathogen. As a result, *M. leprae* is difficult to culture on synthetic media, an impediment to basic research on the disease.

Types of Anti-Leprosy Therapy

Therapy for leprosy is based on multi-drug regimens using rifampin, clofazimine, and dapsone. The reasons for using combinations of agents include reduction in the development of resistance, the need for adequate therapy when primary resistance already exists, and reduction in the duration of therapy. The most bactericidal drug in current regimens is rifampin. Because of high kill rates and massive release of bacterial antigens, rifampin is not often given during a “reversal” reaction (see below) or in patients with erythema nodosum leprosum. Clofazimine is only bacteriostatic against *M. leprae*. However, it also has anti-inflammatory effects and can treat reversal reactions and erythema nodosum leprosum. The third major agent in the regimen

is dapsone. The objective of administering these drugs is total cure.

Definitive Therapy; Standard Therapy

Pauci-Bacillary Leprosy. The WHO regimen consists of a single dose of oral rifampin, 600 mg, combined with dapsone, 100 mg, administered under direct supervision once every month for 6 months, and dapsone, 100 mg a day, in between for 6 months. In the U.S., the regimen consists of dapsone, 100 mg, and rifampin, 600 mg, daily for 6 months, followed by dapsone monotherapy for 3-5 years.

Multibacillary Therapy. The WHO recommends the same regimen as for paucibacillary leprosy, with two major changes. First, clofazimine, 300 mg a day, is added for the entirety of therapy. Second, the regimen lasts 1 year instead of 6 months. In the U.S., the regimen is also the same as for paucibacillary, but dual therapy continues for 3 years, followed by dapsone monotherapy for 10 years. Clofazimine (an orphan drug) is added when there is dapsone resistance or chronically reactional patients.

The duration of therapy for multi-bacillary leprosy is a drawback. Studies in murine leprosy, and in patients, have demonstrated that viable bacilli are killed within 3 months of therapy (Ji et al., 1996) suggesting that the length of current therapy for multibacillary leprosy may be unnecessarily long. Recently, the WHO proposed that all forms of leprosy be treated with the same dose as for paucibacillary leprosy; a clinical trial was promising (Kroger et al., 2008). This new shorter regimen promises to reduce duration of therapy radically.

Treatment of Reactions in Leprosy. Patients with tuberculoid leprosy may develop “reversal reactions,” manifestations of delayed

Table 56–5

Drugs Used in the Treatment of Mycobacteria Other Than for Tuberculosis, Leprosy, or MAC

MYCOBACTERIAL SPECIES	FIRST-LINE THERAPY	ALTERNATIVE AGENTS
<i>M. kansasii</i>	Isoniazid + rifampin ^a + ethambutol	Trimethoprim-sulfamethoxazole; ethionamide; cycloserine; clarithromycin; amikacin; streptomycin; moxifloxacin or gatifloxacin
<i>M. fortuitum</i> complex	Amikacin + doxycycline	Cefoxitin; rifampin; a sulfonamide; moxifloxacin or gatifloxacin; clarithromycin; trimethoprim-sulfamethoxazole; imipenem
<i>M. marinum</i>	Rifampin + ethambutol	Trimethoprim-sulfamethoxazole; clarithromycin; minocycline; doxycycline
<i>Mycobacterium ulcerans</i>	Rifampin + streptomycin ^c	Clarithromycin ^b ; rifapentine ^b
<i>M. malmoense</i>	Rifampin + ethambutol ± clarithromycin	Fluoroquinolone
<i>M. haemophilum</i>	Clarithromycin + rifampin + quinolone	-

^aIn HIV-infected patients, the substitution of rifabutin for rifampin minimizes drug interactions with the HIV protease inhibitors and non-nucleoside reverse transcriptase inhibitors. ^bBased on animal models. ^cFor *Mycobacterium ulcerans*, surgery is the primary therapy.

hypersensitivity to antigens of *M. leprae*. Cutaneous ulcerations and deficits of peripheral nerve function may occur. Early therapy with corticosteroids or clofazimine is effective. Reactions in the lepromatous form of the disease (erythema nodosum leprosum) are characterized by the appearance of raised, tender, intracutaneous nodules, severe constitutional symptoms, and high fever. This reaction may be triggered by several conditions but is often associated with therapy. It is thought to be an Arthus-type reaction related to release of microbial antigens in patients harboring large numbers of bacilli. Treatment with clofazimine or thalidomide is effective.

Therapy for Other Nontuberculous Mycobacteria

Mycobacteria other than those already discussed can be recovered from a variety of lesions in humans. Because they frequently are resistant to many of the commonly used agents, they must be examined for sensitivity *in vitro* and drug therapy selected on this basis. Therapy for infections from these organisms is summarized in Table 56–5. In some instances, surgical removal of the infected tissue followed by long-term treatment with effective agents is necessary. *M. kansasii* causes disease similar to that caused by *M. tuberculosis*, but it may be milder. The microorganisms may be resistant to isoniazid. Therapy with isoniazid, rifampin, and ethambutol has been successful.

CLINICAL SUMMARY

Combination therapy is almost always the desirable approach for mycobacterial disease, to ensure effective eradication and to prevent the emergence of resistance. Isoniazid, rifampin, ethambutol, streptomycin, and pyrazinamide are first-line agents for the treatment of tuberculosis. Moxifloxacin promises to replace either isoniazid or ethambutol and shorten therapy. Antimicrobial agents with excellent activity against *Mycobacterium avium* complex include rifabutin, clarithromycin, azithromycin, and fluoroquinolones. Clinical monitoring of patients with mycobacterial infections is important because drug interactions and adverse drug reactions are common with the multiple-drug regimens used. Considerable progress has been achieved in eliminating leprosy through the use of multiple-drug chemotherapy including dapsone, rifampin, and clofazimine.

57 chapter

Antifungal Agents

John E. Bennett

There are 200,000 known species of fungi, and estimates of the total size of Kingdom Fungi range to well over a million. Residents of the kingdom are quite diverse and include yeasts, molds, mushrooms, smuts, the pathogens *Aspergillus fumigatus* and *Candida albicans*, and the source of penicillin, *Penicillium chrysogenum*. Fortunately, only ~400 fungi cause disease in animals, and even fewer cause significant human disease. However, fungal infections are becoming more common: Patients with AIDS and patients whose immune systems are compromised by drug therapy are especially susceptible to mycotic infections. Fungi are eukaryotes with unique cell walls containing glucans and chitin, and their eradication requires different strategies than those for treatment of bacterial infections. Available agents have effects on the synthesis of membrane and cell-wall components, on membrane permeability, on the synthesis of nucleic acids, and on microtubule/mitotic spindle function (Figure 57-1).

Antifungal agents described in this chapter are discussed under two major headings, systemic and topical, although this distinction is somewhat arbitrary. The imidazole, triazole, and polyene antifungal agents may be used either systemically or topically, and many superficial mycoses can be treated either systemically or topically.

Although *Pneumocystis jirovecii*, responsible for life-threatening pneumonia in immunocompromised patients, is a fungus and not a protozoan, its treatment is

discussed elsewhere because the drugs used are primarily antibacterial or antiprotozoal rather than antifungal.

Major pharmaceutical companies have closed their antifungal development programs, although a few small firms continue to sponsor research in this field. Thus, the near future in this area is likely to be limited to expansion of experience with existing compounds (Table 57-1). The most recent systemic antifungals to reach clinical development, posaconazole (NOXAFIL) and isavuconazole (in phase III trials in the U.S.), are both triazoles.

SYSTEMIC ANTIFUNGAL AGENTS: SYSTEMIC DRUGS FOR DEEPLY INVASIVE FUNGAL INFECTIONS

Amphotericin B

Chemistry. Amphotericin B is one of a family of some 200 polyene macrolide compounds with antifungal activity. Those studied to date share the characteristics of four to seven conjugated double bonds, an internal cyclic ester, poor aqueous solubility, substantial toxicity on parenteral administration, and a common mechanism of antifungal action. Amphotericin B (see following structure) is a heptaene macrolide containing seven conjugated double bonds in the *trans* position and 3-amino-3,6-dideoxymannose (mycosamine) connected to the main ring by a glycosidic bond. The amphoteric behavior for which the drug is named derives from the presence of a carboxyl group on the main ring and a primary amino group on mycosamine; these groups confer aqueous solubility at extremes of pH. X-ray crystallography has shown the molecule to be rigid and rod-shaped, with the hydrophilic hydroxyl groups of the macrolide ring forming an opposing face to the lipophilic polyenic portion.

AMPHOTERICIN B

Figure 57–1. Sites of action of antifungal drugs. Amphotericin B and other polyenes, such as nystatin, bind to ergosterol in fungal cell membranes and increase membrane permeability. The imidazoles and triazoles, such as itraconazole and fluconazole, inhibit 14- α -sterol demethylase, prevent ergosterol synthesis, and lead to the accumulation of 14- α -methylsterols. The allylamines, such as naftifine and terbinafine, inhibit squalene epoxidase and prevent ergosterol synthesis. The echinocandins, such as caspofungin, inhibit the formation of glucans in the fungal cell wall.

Drug Formulations. There are currently four formulations of amphotericin B commercially available: conventional amphotericin B (C-AMB), liposomal amphotericin B (L-AMB), amphotericin B lipid complex (ABLC), and amphotericin B colloidal dispersion (ABCD). Table 57–2 summarizes the pharmacokinetic properties of these preparations.

C-AMB (Conventional amphotericin B, FUNGIZONE). Amphotericin B is insoluble in water but is formulated for intravenous infusion by complexing it with the bile salt deoxycholate. The complex is marketed as a lyophilized powder for injection. C-AMB forms a colloid in water, with particles largely $<0.4 \mu\text{m}$ in diameter. Filters in intravenous infusion lines that trap particles $>0.22 \mu\text{m}$ in diameter will remove significant amounts of drug. Addition of electrolytes to infusion solutions causes the colloid to aggregate.

ABCD. Amphotericin B colloidal dispersion (AMPHOTEC, AMPHOCIL) contains roughly equimolar amounts of amphotericin B and cholesterol sulfate formulated for injection. Like C-AMB, ABCD forms a colloidal solution when dispersed in aqueous solution. ABCD provides much lower blood levels than C-AMB in mice and humans. In a study in patients with neutropenic fever comparing daily ABCD (4 mg/kg) with C-AMB (0.8 mg/kg), chills and hypoxia were significantly more common with ABCD than with C-AMB (White et al., 1998). Hypoxia was associated with severe febrile reactions. In a comparison of ABCD (6 mg/kg) and C-AMB (1–1.5 mg/kg) in invasive aspergillosis patients, ABCD was less nephrotoxic than C-AMB (49% vs. 15%) but caused more fever (27% vs. 16%) and chills (53% vs. 30%) (Bowden et al., 2002). Administration of the recommended ABCD dose over 3–4 hours and use of premedication to reduce febrile reactions are advised, particularly with initial infusions. ABCD is approved at a recommended dose of 3–4 mg/kg intravenously daily

for patients with invasive aspergillosis who are not responding to or are unable to tolerate C-AMB.

L-AMB. Liposomal amphotericin B is a small, unilamellar vesicle formulation of amphotericin B (AMBISOME). The drug is supplied as a lyophilized powder, which is reconstituted with sterile water for injection. Blood levels following intravenous infusion are almost equivalent to those obtained with C-AMB, and because L-AMB can be given at higher doses, blood levels have been achieved that exceed those obtained with C-AMB (Boswell et al., 1998) (Table 57–2). Amphotericin B accumulation in the liver and spleen is higher with L-AMB than with C-AMB. Adverse effects include nephrotoxicity, hypokalemia, and infusion-related reactions, such as fever, chills, hypoxia, hypotension, and hypertension, but these do not commonly lead to drug discontinuation. Infusion-related pain in the back, abdomen, or chest occurs in occasional patients, usually with the first few doses. Anaphylaxis also has been reported. As empirical therapy or prophylaxis in febrile neutropenic patients, C-AMB and L-AMB are equivalent. As induction therapy of disseminated histoplasmosis in AIDS patients, L-AMB 3 mg/kg was superior to C-AMB 0.7 mg/kg (Johnson, 2002). L-AMB is approved for initial therapy of cryptococcal meningitis of AIDS patients and is listed as an alternative to C-AMB for induction therapy of both disseminated histoplasmosis and cryptococcal meningoencephalitis in AIDS patients (Kaplan et al., 2009). L-AMB is approved for empirical therapy of fever in the neutropenic host not responding to appropriate antibacterial agents, as well as for salvage therapy of aspergillosis and candidiasis. The recommended daily intravenous dose for empirical therapy is 3 mg/kg; for treatment of mycoses, the dosage is 3–5 mg/kg. L-AMB also is effective in visceral leishmaniasis at doses of 3–4 mg/kg daily. The drug is administered in 5% dextrose in water, with initial doses infused over 2 hours. If well tolerated, infusion duration can be shortened to 1 hour. Doses up to 10 mg/kg have been used but are associated with higher toxicity and, in one randomized trial of aspergillosis, no improvement in efficacy (Cornely, 2007a).

ABLC (ABELCET). Amphotericin B lipid complex is a complex of amphotericin B with lipids (dimyristoylphosphatidylcholine and dimyristoylphosphatidylglycerol). ABLC is given in a dose of 5 mg/kg in 5% dextrose in water, infused intravenously once daily over 2 hours. Blood levels of amphotericin B are much lower with ABLC than with the same dose of C-AMB. ABLC is effective in a variety of mycoses, with the possible exception of cryptococcal meningitis. The drug is approved for salvage therapy of deep mycoses.

The three lipid formulations collectively appear to reduce the risk of the patient's serum creatinine doubling during therapy by 58% (Barrett et al., 2003). In patients at high risk for nephrotoxicity, ABLC is more nephrotoxic than L-AMB (Wingard et al., 2000). In some patients, the additive burden of amphotericin B nephrotoxicity can help precipitate advanced renal failure, with attendant morbidity. Infusion-related reactions are not consistently reduced with the use of lipid preparations. ABCD causes more infusion-related reactions than C-AMB. Although L-AMB reportedly causes fewer infusion-related reactions than ABLC during the first dose (Wingard et al., 2000), the difference depends on whether premedication is given and varies considerably between patients. Infusion-related reactions typically decrease with subsequent infusions.

Table 57–1

Pharmacotherapy of Mycoses

DEEP MYCOSES		DRUGS	SUPERFICIAL MYCOSES		DRUGS
Invasive aspergillosis			Candidiasis		
Immunosuppressed		Voriconazole, amphotericin B	Vulvovaginal	<i>Topical</i>	Butoconazole, clotrimazole, miconazole, nystatin, terconazole, tioconazole
Non-immunosuppressed		Voriconazole, amphotericin B, itraconazole		<i>Oral</i>	Fluconazole
Blastomycosis			Oropharyngeal	<i>Topical</i>	Clotrimazole, nystatin
Rapidly progressive or CNS		Amphotericin B		<i>Oral (systemic)</i>	Fluconazole, itraconazole
Indolent and non-CNS		Itraconazole			Posaconazole
Candidiasis			Cutaneous	<i>Topical</i>	Amphotericin B, clotrimazole, ciclopirox, econazole, ketoconazole, miconazole, nystatin
Deeply invasive		Amphotericin B, fluconazole, voriconazole, caspofungin, micafungin, anidulafungin		Ringworm	<i>Topical</i>
Coccidioidomycosis					Butenafine, ciclopirox, clotrimazole, econazole, haloprogin, ketoconazole, miconazole, naftifine, oxiconazole, sertaconazole, sulconazole, terbinafine, tolnaftate, undecylenate
Rapidly progressing		Amphotericin B			<i>Systemic</i>
Indolent		Itraconazole, fluconazole			Griseofulvin, itraconazole, terbinafine
Meningeal		Fluconazole, intrathecal amphotericin B			
Cryptococcosis					
Non-AIDS and initial AIDS		Amphotericin B, flucytosine			
Maintenance AIDS		Fluconazole			
Histoplasmosis					
Chronic pulmonary		Itraconazole			
Disseminated					
<i>Rapidly progressing or CNS</i>		Amphotericin B			
<i>Indolent non-CNS</i>		Itraconazole			
<i>Maintenance AIDS</i>		Itraconazole			
Mucormycosis					
		Amphotericin B			
Pseudallescheriasis					
		Voriconazole, itraconazole			
Sporotrichosis					
Cutaneous		Itraconazole			
Extracutaneous		Amphotericin B, itraconazole			
Prophylaxis in the immunocompromised host					
		Fluconazole			
		Posaconazole			
		Micafungin			
Empirical therapy in the immunocompromised host (category not recognized by FDA)					
		Amphotericin B			
		Caspofungin			
		Fluconazole			

The cost of the lipid formulations of amphotericin B greatly exceeds that of C-AMB, making them unavailable in many countries.

Mechanism of Action. The antifungal activity of amphotericin B depends principally on its binding to a sterol moiety, primarily ergosterol in the membrane of sensitive fungi. By virtue of their interaction with these sterols, polyenes appear to form pores or channels

that increase the permeability of the membrane, allowing leakage of a variety of small molecules (Figure 57–1).

Absorption, Distribution, and Excretion. Gastrointestinal (GI) absorption of all amphotericin B formulations is negligible. Pharmacokinetic properties differ markedly between preparations with L-AMB having the highest plasma concentrations at therapeutic doses

Table 57-2

Pharmacokinetic Parameters for Amphotericin B Formulations after Multiple Administrations in Humans

PRODUCT	DOSE (MG/KG)	C _{MAX} (µg/mL)	AUC _(1-24hr) (µg.hr/mL)	V (L/kg)	Cl (mL/hr/kg)
AmBisome (L-AMB)	5	83±35.2	555±311	0.11±0.08	11±6
Amphotec (ABCD)	5	3.1	43	4.3	117
Ablecet (ABLC)	5	1.7±0.8	14±7	131±7.7	426±188.5
Fungizone (C-AMB)	0.6	1.1±0.2	17.1±5	5±2.8	38±15

For details, see Boswell et al. (1998). From Boswell GW, Buell D, Bekersky I. AmBisome (liposomal amphotericin B): A comparative review. *J Clin Pharmacol*, 1998, 38:583–592. ©1998 The American College of Clinical Pharmacology. Reprinted by permission of SAGE Publications.

(Table 57–2). C-AMB is released from its complex with deoxycholate in the bloodstream, and the amphotericin B that remains in plasma is more than 90% bound to proteins, largely β -lipoprotein. Excretion into the urine is negligible with all the formulations. Azotemia, liver failure, or hemodialysis does not have a measurable impact on plasma concentrations. Concentrations of amphotericin B (via C-AMB) in fluids from inflamed pleura, peritoneum, synovium, and aqueous humor are approximately two-thirds of trough concentrations in plasma. Little amphotericin B from any formulation penetrates into cerebrospinal fluid (CSF), vitreous humor, or normal amniotic fluid.

Antifungal Activity. Amphotericin B has useful clinical activity against *Candida* spp., *Cryptococcus neoformans*, *Blastomyces dermatitidis*, *Histoplasma capsulatum*, *Sporothrix schenckii*, *Coccidioides* spp., *Paracoccidioides braziliensis*, *Aspergillus* spp., *Penicillium marneffei*, and the agents of mucormycosis. Amphotericin B has limited activity against the protozoa *Leishmania* spp. and *Naegleria fowleri*. The drug has no antibacterial activity.

Fungal Resistance. Some isolates of *Candida lusitanae* have been relatively resistant to amphotericin B. *Aspergillus terreus* and perhaps *Aspergillus nidulans* may be more resistant to amphotericin B than other *Aspergillus* species (Steinbach et al., 2004). Mutants selected *in vitro* for resistance to nystatin (a polyene antifungal discussed later) or amphotericin B replace ergosterol with certain precursor sterols. The rarity of significant amphotericin B resistance arising during therapy has left it unclear whether ergosterol-deficient mutants retain sufficient pathogenicity to survive in deep tissue.

Therapeutic Uses. The recommended doses were given earlier for each formulation. *Candida* esophagitis responds to much lower doses than deeply invasive mycoses. Intrathecal infusion of C-AMB is useful in patients with meningitis caused by *Coccidioides*. Too little is known about intrathecal administration of lipid formulations to recommend them. C-AMB can be injected into the CSF of the lumbar spine, cisterna magna, or lateral cerebral ventricle. Fever and headache are common reactions that may be decreased by intrathecal administration of 10–15 mg of hydrocortisone. Local injections of amphotericin B into a joint or peritoneal dialysate fluid commonly produce irritation and pain. Intraocular injection following pars plana vitrectomy has been used successfully for fungal endophthalmitis.

Intravenous administration of amphotericin B is the treatment of choice for mucormycosis and is used for initial treatment of

cryptococcal meningitis, severe or rapidly progressing histoplasmosis, blastomycosis, coccidioidomycosis, and penicilliosis marneffei, as well as in patients not responding to azole therapy of invasive aspergillosis, extracutaneous sporotrichosis, fusariosis, alternariosis, and trichosporonosis. Amphotericin B (C-AMB or L-AMB) is often given to selected patients with profound neutropenia who have fever that does not respond to broad-spectrum antibacterial agents over 5–7 days.

Untoward Effects. The major acute reactions to intravenous amphotericin B formulations are fever and chills. Infusion-related reactions are worst with ABCD, slightly less with C-C-AMB, even less with ABLC, and least with L-AMB. Tachypnea and respiratory stridor or modest hypotension also may occur, but true bronchospasm or anaphylaxis is rare. Patients with pre-existing cardiac or pulmonary disease may tolerate the metabolic demands of the reaction poorly and develop hypoxia or hypotension. The reaction ends spontaneously in 30–45 minutes; meperidine may shorten it. Pretreatment with oral acetaminophen or use of intravenous hydrocortisone hemisuccinate, 0.7 mg/kg, at the start of the infusion decreases reactions. Febrile reactions abate with subsequent infusions. Infants, children, and patients receiving therapeutic doses of glucocorticoids are less prone to reactions.

Azotemia occurs in 80% of patients who receive C-AMB for deep mycoses (Carlson and Condon, 1994). Lipid formulations are less nephrotoxic, being much less with ABLC, even less with L-AMB, and minimal with ABCD. Toxicity is dose-dependent and usually transient and increased by concurrent therapy with other nephrotoxic agents, such as aminoglycosides or cyclosporine. Although permanent histological changes in renal tubules occur even during short courses of C-AMB, permanent functional impairment is uncommon in adults with normal renal function prior to treatment unless the cumulative dose exceeds 3–4 g. Renal tubular acidosis and renal wasting of K⁺ and Mg²⁺ also may be seen during and for several weeks after therapy. Supplemental K⁺ is required in one-third of patients on prolonged therapy. Saline loading has decreased nephrotoxicity, even in the absence of water or salt deprivation. Administration of 1 L of normal saline intravenously on the day that C-AMB is to be given has been recommended for adults who are able to tolerate the Na⁺ load and who are not already receiving that amount in intravenous fluids.

Hypochromic, normocytic anemia commonly occurs during treatment with C-AMB. Anemia is less with lipid formulations and usually not seen over the first 2 weeks. The anemia is most likely

due to decreased production of erythropoietin. Patients with low plasma erythropoietin may respond to administration of recombinant erythropoietin. Anemia reverses slowly following cessation of therapy. Headache, nausea, vomiting, malaise, weight loss, and phlebitis at peripheral infusion sites are common. Thrombocytopenia or mild leukopenia is observed rarely. Hepatotoxicity is not firmly established with any amphotericin B formulation. Arachnoiditis has been observed as a complication of injecting C-AMB into the CSF.

Flucytosine

Chemistry. Flucytosine is 5-fluorocytosine, a fluorinated pyrimidine related to fluorouracil and floxuridine.

FLUCYTOSINE

Mechanism of Action. All susceptible fungi are capable of deaminating flucytosine to 5-fluorouracil (Figure 57–2), a potent antimetabolite that is used in cancer chemotherapy (Chapter 61). Fluorouracil is metabolized first to 5-fluorouracil-ribose monophosphate (5-FUMP) by the enzyme uracil phosphoribosyl transferase (UPRTase; also called uridine monophosphate pyrophosphorylase). As in mammalian cells, 5-FUMP then is either incorporated into RNA (via synthesis of 5-fluorouridine triphosphate) or metabolized to 5-fluoro-2'-deoxyuridine-5'-monophosphate (5-FdUMP), a potent inhibitor of thymidylate synthetase. DNA synthesis is impaired as the ultimate result of this latter reaction. The selective action of flucytosine is due to the lack of cytosine deaminase in mammalian cells, which prevents metabolism to fluorouracil.

Antifungal Activity. Flucytosine has clinically useful activity against *Cryptococcus neoformans*, *Candida* spp., and the agents of chromoblastomycosis. Within these species, determination of susceptibility *in vitro* has been extremely dependent on the method employed, and susceptibility testing performed on isolates obtained prior to treatment has not correlated with clinical outcome.

Fungal Resistance. Drug resistance arising during therapy (secondary resistance) is an important cause of therapeutic failure when flucytosine is used alone for cryptococcosis and candidiasis. In chromoblastomycosis, resurgence of lesions after an initial response has led to the presumption of secondary drug resistance. In isolates of *Cryptococcus* and *Candida* species, secondary drug resistance has been accompanied by a change in the minimal inhibitory concentration from <2.5 µg/mL to >360 µg/mL. The mechanism for this resistance can be loss of the permease necessary for cytosine transport or decreased activity of either UPRTase or cytosine deaminase (Figure 57–2). In *Candida albicans*, substitution of thymidine for cytosine at nucleotide 301 in the gene encoding UPRTase (*FUR1*) causes a cysteine to become an arginine, modestly increasing flucytosine resistance (Dodgson et al., 2004). Flucytosine resistance is further increased if both *FUR1* alleles in the diploid fungus are mutated.

Absorption, Distribution, and Excretion. Flucytosine is absorbed rapidly and well from the GI tract. It is widely distributed in the body,

Figure 57–2. Action of flucytosine in fungi. Flucytosine is transported by cytosine permease into the fungal cell, where it is deaminated to 5-fluorouracil (5-FU). The 5-FU is then converted to 5-fluorouracil-ribose monophosphate (5-FUMP) and then is either converted to 5-fluorouridine triphosphate (5-FUTP) and incorporated into RNA or converted by ribonucleotide reductase to 5-fluoro-2'-deoxyuridine-5'-monophosphate (5-FdUMP), which is a potent inhibitor of thymidylate synthase. 5-FUDP, 5-fluorouridine-5'-diphosphate; dUMP, deoxyuridine-5'-monophosphate; dTMP, deoxythymidine-5'-monophosphate.

with a volume of distribution that approximates total body water, and is minimally bound to plasma proteins. The peak plasma concentration in patients with normal renal function is ~70–80 µg/mL, achieved 1–2 hours after a dose of 37.5 mg/kg. Approximately 80% of a given dose is excreted unchanged in the urine; concentrations in the urine range from 200–500 µg/mL. The $t_{1/2}$ of the drug is 3–6 hours in normal individuals. In renal failure, the $t_{1/2}$ may be as long as 200 hours. The clearance of flucytosine is approximately equivalent to that of creatinine. Reduction of dosage is necessary in patients with decreased renal function, and concentrations of drug in plasma should be measured periodically. Peak concentrations should range between 50 and 100 µg/mL. Flucytosine is cleared by hemodialysis, and patients undergoing such treatment should receive a single dose of 37.5 mg/kg after dialysis; the drug also is removed by peritoneal dialysis.

Flucytosine concentration in CSF is ~65–90% of that found simultaneously in the plasma. The drug also appears to penetrate into the aqueous humor.

Therapeutic Uses. Flucytosine (ANCOBON) is given orally at 50–150 mg/kg per day, in four divided doses at 6-hour intervals. Dosage must be adjusted for decreased renal function. Flucytosine is used predominantly in combination with amphotericin B. Flucytosine caused no added toxicity when added to 0.7 mg/kg of amphotericin B for the initial 2 weeks of therapy of cryptococcal meningitis in AIDS patients. Although the CSF colony count diminished more rapidly with combination therapy, there was no apparent impact on mortality or morbidity (van der Horst et al., 1997). An all-oral regimen of flucytosine plus fluconazole also has been advocated for therapy of AIDS patients

with cryptococcosis, but the combination has substantial GI toxicity with no evidence that flucytosine adds benefit (Larsen et al., 1994). In cryptococcal meningitis of non-AIDS patients, the role of flucytosine is more conjectural. The addition of flucytosine to ≥ 6 weeks of therapy with C-AMB runs the risk of substantial bone marrow suppression or colitis if the flucytosine dose is not promptly adjusted downward as amphotericin B–induced azotemia occurs. In the 2008 IDSA guidelines for the treatment of cryptococcal meningitis, addition of flucytosine (100 mg/kg orally in four divided doses) is recommended for the first 2 weeks of treatment with amphotericin B in AIDS patients. A similar practice is often used in HIV-negative patients but the benefit is unknown (Pappas et al., 2001).

Untoward Effects. Flucytosine may depress the bone marrow and lead to leukopenia and thrombocytopenia; patients are more prone to this complication if they have an underlying hematological disorder, are being treated with radiation or drugs that injure the bone marrow, or have a history of treatment with such agents. Other untoward effects—including rash, nausea, vomiting, diarrhea, and severe enterocolitis—have been noted. In ~5% of patients, plasma levels of hepatic enzymes are elevated, but this effect reverses when therapy is stopped. Toxicity is more frequent in patients with AIDS or azotemia (including those who are receiving amphotericin B concurrently) and when plasma drug concentrations exceed 100 $\mu\text{g/mL}$. Toxicity may result from conversion of flucytosine to 5-fluorouracil by the microbial flora in the intestinal tract of the host.

Imidazoles and Triazoles

The azole antifungals include two broad classes, imidazoles and triazoles, which share the same antifungal spectrum and mechanism of action. The systemic triazoles are metabolized more slowly and have less effect on human sterol synthesis than the imidazoles. Because of these advantages, new congeners under development are mostly triazoles. Of the drugs now on the market in the U.S., clotrimazole, miconazole, ketoconazole, econazole, butoconazole, oxiconazole, sertaconazole, and sulconazole are imidazoles; terconazole, itraconazole, fluconazole, voriconazole, posaconazole, and isavuconazole (an experimental drug) are triazoles. The topical use of azole antifungals is described in the second section of this chapter. The basic triazole structure is:

Mechanism of Action. At concentrations achieved following systemic administration, the major effect of imidazoles and triazoles on fungi is inhibition of 14- α -sterol demethylase, a microsomal CYP (Figure 57–1). Imidazoles and triazoles thus impair the biosynthesis of ergosterol for the cytoplasmic membrane and lead to the accumulation of 14- α -methylsterols. These methylsterols may disrupt the close packing of acyl chains of phospholipids, impairing the functions of certain membrane-bound enzyme systems, thus inhibiting growth of

the fungi. Some azoles directly increase permeability of the fungal cytoplasmic membrane, but the concentrations required are likely only obtained with topical use.

Antifungal Activity. Azoles as a group have clinically useful activity against *Candida albicans*, *Candida tropicalis*, *Candida parapsilosis*, *Candida glabrata*, *Cryptococcus neoformans*, *Blastomyces dermatitidis*, *Histoplasma capsulatum*, *Coccidioides* spp., *Paracoccidioides brasiliensis*, and ringworm fungi (dermatophytes). *Aspergillus* spp., *Scedosporium apiospermum* (*Pseudallescheria boydii*), *Fusarium*, and *Sporothrix schenckii* are intermediate in susceptibility. *Candida krusei* and the agents of mucormycosis are more resistant. Thus, these drugs do not have any useful antibacterial or antiparasitic activity, with the possible exception of antiprotozoal effects against *Leishmania major*. Posaconazole has slightly improved activity *in vitro* against the agents of mucormycosis.

Resistance. Azole resistance emerges gradually during prolonged azole therapy, causing clinical failure in patients with far-advanced HIV infection and oropharyngeal or esophageal candidiasis. The primary mechanism of resistance in *C. albicans* is accumulation of mutations in *ERG11*, the gene coding for the 14- α -sterol demethylase. These mutations protect heme in the enzyme pocket from binding to the azole but allow access of the natural substrate for the enzyme lanosterol. Cross-resistance is conferred to all azoles. Increased azole efflux by both ATP-binding cassette (ABC) and major facilitator superfamily transporters can add to fluconazole resistance in *C. albicans* and *C. glabrata*. Increased production of C14- α -sterol demethylase is another potential cause of resistance. Mutation of the C5,6 sterol reductase gene *ERG3* also can increase azole resistance in some species.

Primary azole resistance has been described in some isolates of *Aspergillus fumigatus* with increased azole transport and decreased ergosterol content, but the clinical significance is unknown. Decreased fluconazole susceptibility has been described in *Cryptococcus neoformans* isolated from AIDS patients failing prolonged therapy.

Interaction of Azole Anti-Fungals with Other Drugs. The azoles interact with hepatic CYPs as substrates and inhibitors (Table 57–3), providing myriad possibilities for the interaction of azoles with many other medications. Thus, azoles can elevate plasma levels of some co-administered drugs (Table 57–4). Other co-administered drugs can decrease plasma concentrations of azole antifungal agents (Table 57–5). As a consequence of myriad interactions, combinations of certain drugs with azole antifungal medications may be contraindicated (Table 57–6).

Ketoconazole

Ketoconazole, administered orally, has been replaced by itraconazole for the treatment of all mycoses except when the lower cost of ketoconazole outweighs the advantage of itraconazole. Itraconazole lacks ketoconazole's corticosteroid suppression while retaining most of ketoconazole's pharmacological properties and expanding the antifungal spectrum. Ketoconazole sometimes is used to inhibit excessive production of glucocorticoids in patients with Cushing's syndrome (Chapter 42) and is available for topical use, as described later.

Itraconazole

This synthetic triazole is an equimolar racemic mixture of four diastereoisomers (two enantiomeric pairs), each

Table 57-3

Interaction of Azole Antifungal Agents with Hepatic CYPs

FLUCONAZOLE	VORICONAZOLE	ITRACONAZOLE	POSACONAZOLE
CYP3A4 inhibitor	CYP2C9 inhibitor and substrate	CYP3A4 inhibitor	CYP3A4 inhibitor
CYP2C9 inhibitor	CYP3A4 inhibitor		
CYP2C19 inhibitor	CYP2C19 inhibitor		

Table 57-4

Drugs Exhibiting Elevated Plasma Concentrations When Co-Administered with Azole Anti-Fungal Agents

Alfentanil	Eplerenone	Losartan	Saquinavir
Alprazolam	Ergot alkaloids	Lovastatin	Sildenafil
Astemizole	Erlotinib	Methadone	Sirolimus
Buspirone	Eszopiclone	Methylprednisolone	Solifenacin
Busulfan	Felodipine	Midazolam	Sunitinib
Carbamazepine	Fexofenadine	Nevirapine	Tacrolimus
Cisapride	Gefitinib	Omeprazole	Triazolam
Cyclosporine	Glimepiride	Phenytoin	Vardenafil
Digoxin	Glipizide	Pimozide	Vinca alkaloids
Docetaxel	Halofantrine	Quinidine	Warfarin
Dofetilide	Haloperidol	Ramelteon	Zidovudine
Efavirenz	Imatinib	Ranolazine	Zolpidem
Eletriptan	Irinotecan	Risperidone	

Mechanism of interaction presumably occurs largely at the level of hepatic CYPs, especially CYPs 3A4, 2C9, and 2D6, but can also involve P-glycoprotein and other mechanisms. Not all drugs listed interact equally with all azoles. For details, see Chapter 6 and Zonios (2008).

Table 57-5

Some Drugs that Decrease Azole Concentration When Co-Administered

DRUG	FLUCONAZOLE	VORICONAZOLE	ITRACONAZOLE	POSACONAZOLE
Antacids (simultaneous)	—		+	—

possessing three chiral centers. The structure is similar to that of the imidazole ketoconazole.

Absorption, Distribution, and Excretion. Itraconazole (SPORANOX, others) is available as a capsule and a solution in hydroxypropyl- β -cyclodextrin for oral use. The capsule form of the drug is best absorbed in the fed state, but the oral solution is better absorbed in the fasting state, providing peak plasma concentrations >150% of

those obtained with the capsule. Itraconazole is metabolized in the liver. It is both a substrate for and a potent inhibitor of CYP3A4. Itraconazole is present in plasma with an approximately equal concentration of a biologically active metabolite, hydroxy-itraconazole. Bioassays may report up to 3.3 times as much itraconazole in plasma as do physical methods such as high-performance liquid chromatography, depending on the susceptibility of the bioassay organism to hydroxy-itraconazole. The native drug and metabolite are >99%

ITRACONAZOLE

bound to plasma proteins. Neither appears in urine or CSF. The $t_{1/2}$ of itraconazole at steady state is ~30–40 hours. Steady-state levels of itraconazole are not reached for 4 days and those of hydroxy-itraconazole for 7 days; thus, loading doses are recommended when treating deep mycoses. Severe liver disease will increase itraconazole plasma concentrations, but azotemia and hemodialysis have no effect. Itraconazole is not carcinogenic but is teratogenic in rats and contraindicated for the treatment of onychomycosis during pregnancy or for women contemplating pregnancy (Category C).

Drug Interactions. Tables 57–4, 57–5, and 57–6 list select interactions of azoles with other drugs. Many of the interactions can result in serious toxicity from the companion drug, such as inducing potentially fatal cardiac arrhythmias when used with quinidine, halofantrine (an orphan drug used for malaria), levomethadyl (an orphan drug used for heroin addiction), pimozide (ORAP) or cisapride (only available under an investigational limited access program in the U.S.). Other drugs may decrease itraconazole serum levels below therapeutic concentrations (Table 57–5).

Therapeutic Uses. Itraconazole is the drug of choice for patients with indolent, nonmeningeal infections due to *B. dermatitidis*, *H. capsulatum*, *P. brasiliensis*, and *C. immitis*. The drug also is useful in the therapy of indolent invasive aspergillosis outside the CNS, particularly after the infection has been stabilized with amphotericin B. Approximately half the patients with distal subungual onychomycosis respond to itraconazole (Evans and Sigurgeirsson, 1999). Although not an approved use, itraconazole is a reasonable choice for the treatment of pseudallescheriasis, an infection not responding to amphotericin B therapy, as well as cutaneous and extracutaneous sporotrichosis, tinea corporis, and extensive tinea versicolor. HIV-infected patients with disseminated histoplasmosis or *Penicillium marneffei* infections have a decreased incidence of relapse if given prolonged itraconazole “maintenance” therapy. According to the 2008 CDC/IDSA guidelines, discontinuation of itraconazole may be considered in AIDS patients with disseminated histoplasmosis who have completed 1 year of itraconazole, have responded to highly active antiretroviral therapy (HAART) with a CD4 >150/mm³ for 6 months, have a urine histoplasma antigen <2 units and a negative blood culture for histoplasma (Kaplan et al., 2009) (Chapter 59). Itraconazole is not recommended for maintenance therapy of cryptococcal meningitis in HIV-infected patients because of a high incidence of relapse. Long-term therapy has been used in non-HIV-infected patients with allergic bronchopulmonary aspergillosis to decrease the dose of glucocorticoids and reduce attacks of acute bronchospasm (Salez et al., 1999).

Itraconazole solution is effective and approved for use in oropharyngeal and esophageal candidiasis. Because the solution has more GI side effects than fluconazole tablets, itraconazole solution usually is reserved for patients not responding to fluconazole.

Untoward Effects. Adverse effects of itraconazole therapy can occur as a result of interactions with many other drugs (Tables 57–3 and 57–4). Serious hepatotoxicity has rarely led to hepatic failure and death. If symptoms of hepatotoxicity occur, the drug should be discontinued and liver function assessed. Intravenous itraconazole causes a dose-dependent inotropic effect that can lead to congestive heart failure in patients with impaired ventricular function. In the

absence of interacting drugs, itraconazole capsules and suspension are well tolerated at 200 mg daily. Some patients complain of the taste of the solution, and GI side effects are common, although adherence is generally unimpaired. Diarrhea, abdominal cramps, anorexia, and nausea are more common than with the capsules. In one series of patients receiving 50–400 mg of the capsules per day, nausea and vomiting were recorded in 10%, hypertriglyceridemia in 9%, hypokalemia in 6%, increased serum aminotransferase in 5%, rash in 2%, and at least one side effect in 39%. Occasionally, rash necessitates drug discontinuation, but most adverse effects can be handled with dose reduction. Profound hypokalemia has been seen in patients receiving ≥600 mg daily and in those who recently have received prolonged amphotericin B therapy. Doses of 300 mg twice daily have led to other side effects, including adrenal insufficiency, lower limb edema, hypertension, and in at least one case, rhabdomyolysis. Doses >400 mg per day are not recommended for long-term use. Anaphylaxis has been observed rarely, as well as severe rash, including Stevens-Johnson syndrome.

Dosage. In treating deep (life-threatening) mycoses, a loading dose of 200 mg of itraconazole is administered three times daily for the first 3 days. After the loading doses, two 100-mg capsules are given twice daily with food. The divided doses are alleged to increase the area under the plasma concentration versus time curve (AUC), even though the $t_{1/2}$ is ~30 hours. For maintenance therapy of HIV-infected patients with disseminated histoplasmosis, 200 mg once daily is used. Onychomycosis can be treated with either 200 mg once daily for 12 weeks or for infections isolated to fingernails, two monthly cycles consisting of 200 mg twice daily for 1 week followed by a 3-week period of no therapy—so-called pulse therapy (Evans and Sigurgeirsson, 1999). Retention of active drug in the nail keratin permits intermittent treatment. Daily therapy is preferred by some authorities for infections likely to be more refractory, but it costs twice as much as pulse therapy. Once-daily terbinafine (250 mg), however, is superior to pulse therapy with itraconazole. For oropharyngeal candidiasis, itraconazole oral solution should be taken fasting in a dose of 100 mg (10 mL) once daily and swished vigorously in the mouth before swallowing to optimize any topical effect. Patients with esophageal thrush unresponsive or refractory to treatment with fluconazole tablets are given 100 mg of the solution twice a day for 2–4 weeks.

Fluconazole

Fluconazole is a fluorinated bistriazole.

FLUCONAZOLE

Absorption, Distribution, and Excretion. Fluconazole is almost completely absorbed from the GI tract. Plasma concentrations are essentially the same whether the drug is given orally or intravenously, and its bioavailability is unaltered by food or gastric acidity. Peak plasma concentrations are 4–8 µg/mL after repetitive doses of 100 mg. Renal

excretion accounts for >90% of elimination, and the elimination $t_{1/2}$ is 25-30 hours. Fluconazole diffuses readily into body fluids, including breast milk, sputum, and saliva; concentrations in CSF can reach 50-90% of the simultaneous values in plasma. The dosage interval should be increased from 24-48 hours with a creatinine clearance of 21-40 mL/minute and to 72 hours at 10-20 mL/minute. A dose of 100-200 mg should be given after each hemodialysis. About 11-12% of drug in the plasma is protein bound.

Drug Interactions. Fluconazole is an inhibitor of CYP3A4 and CYP2C9. Fluconazole's drug-drug interactions are shown in Tables 57-3 and 57-4. Patients who receive >400 mg daily or azotemic patients who have elevated fluconazole blood levels may experience drug interactions not otherwise seen.

Therapeutic Uses. Candidiasis. Fluconazole, 200 mg on the first day and then 100 mg daily for at least 2 weeks, is effective in oropharyngeal candidiasis. Doses of 100-200 mg daily have been used to decrease candiduria in high-risk patients. A single dose of 150 mg is effective in uncomplicated vaginal candidiasis. A dose of 400 mg daily decreases the incidence of deep candidiasis in allogeneic bone marrow transplant recipients and is useful in treating candidemia of nonimmunosuppressed patients. In patients who have not been receiving fluconazole prophylaxis, the drug has been used successfully as empirical treatment of febrile neutropenia in patients not responding to antibacterial agents and who are not judged to be at high risk of mould infections. Although response to *C. glabrata* bloodstream infections in randomized trials using fluconazole has been comparable to that with *C. albicans*, *C. glabrata* becomes resistant upon prolonged exposure to fluconazole. Empirical use of fluconazole for suspected candidemia may not be advisable in patients who have been receiving long-term fluconazole prophylaxis and may be colonized with azole-resistant *C. glabrata*. Based on resistance *in vitro*, *Candida krusei* would not be expected to respond to fluconazole or other azoles.

Cryptococcosis. Following IDSA guidelines (Perfect et al., 2010), fluconazole, 400 mg daily, is used for the initial 8 weeks in the treatment of cryptococcal meningitis in patients with AIDS after the patient's clinical condition has been stabilized with at least 2 weeks of intravenous amphotericin B. After 8 weeks in patients no longer symptomatic, the dose is decreased to 200 mg daily and continued indefinitely. If the patient has completed 12 months of treatment for cryptococcosis, responds to HAART, has a CD4 count maintained >200/mm³ for at least 6 months, and is asymptomatic from cryptococcal meningitis, it is reasonable to discontinue maintenance fluconazole as long as the CD4 response is maintained. Some would add that an undetectable viral load for 3 months is required. Fluconazole, 400 mg daily, has been recommended as continuation therapy in non-AIDS patients with cryptococcal meningitis who have responded to an initial course of C-AMB or L-AMB and for patients with pulmonary cryptococcosis.

Other Mycoses. Fluconazole is the drug of choice for treatment of coccidioid meningitis because of good penetration into the CSF and much less morbidity than with intrathecal amphotericin B. In other forms of coccidioidomycosis, fluconazole is comparable to itraconazole. Fluconazole has no useful activity against histoplasmosis, blastomycosis, or sporotrichosis. Fluconazole is not effective in the prevention or treatment of aspergillosis. Fluconazole has some activity in ringworm but is not approved for that indication. As with other azoles, with the possible exception of posaconazole, there is no activity in mucormycosis.

Untoward Effects. Side effects in patients receiving >7 days of drug, regardless of dose, include the following: nausea 3.7%, headache 1.9%, skin rash 1.8%, vomiting 1.7%, abdominal pain 1.7%, and diarrhea 1.5%. Use of high doses may be limited by nausea. Reversible alopecia may occur with prolonged therapy at 400 mg daily. Rare cases of deaths due to hepatic failure or Stevens-Johnson syndrome have been reported. Fluconazole is teratogenic in rodents and has been associated with skeletal and cardiac deformities in at least three infants born to two women taking high doses during pregnancy. Fluconazole is a Category C agent that should be avoided during pregnancy unless the potential benefit justifies the possible risk to the fetus.

Dosage. Fluconazole (DIFLUCAN, others) is marketed in the U.S. as tablets of 50, 100, 150, and 200 mg for oral administration, powder for oral suspension providing 10 and 40 mg/mL, and intravenous solutions containing 2 mg/mL in saline and in dextrose solution. The daily dose of fluconazole should be based on the infecting organism and the patient's response to therapy. Generally recommended dosages are 50-400 mg once daily for either oral or intravenous administration. A loading dose of twice the daily maintenance dose is generally administered on the first day of therapy. Prolonged maintenance therapy may be required to prevent relapse. Children are treated with 3-12 mg/kg once daily (maximum: 600 mg/day).

Voriconazole

Voriconazole (VFEND) is a triazole with a structure similar to fluconazole but with increased activity *in vitro*, an expanded spectrum, and poor aqueous solubility.

VORICONAZOLE

Absorption, Distribution, and Excretion. Oral bioavailability is 96% and protein binding 56% (Jeu et al., 2003). Volume of distribution is high (4.6 L/kg), with extensive drug distribution in tissues. Metabolism occurs through CYP2C19 and to a lesser extent CYP2C9; CYP3A4 plays a limited role. Less than 2% of parent drug is recovered from urine, although 80% of the inactive metabolites are excreted in the urine. The oral dose does not have to be adjusted for azotemia or hemodialysis. Peak plasma concentrations after oral doses of 200 mg orally twice daily are ~3 µg/mL. CSF concentrations of 1-3 µg/mL have been reported in a patient with fungal meningitis.

Plasma elimination $t_{1/2}$ is 6 hours. Voriconazole exhibits non-linear metabolism so that higher doses cause greater-than-linear increases in systemic drug exposure. Genetic polymorphisms in CYP2C19 can cause up to 4-fold differences in drug exposure; 15-20% of Asians are homozygous poor metabolizers, compared with 2% of whites and African Americans. Patients >65 years and patients with mild or moderate hepatic insufficiency have elevated areas under the curve (AUCs). Patients with mild-to-moderate cirrhosis should receive the same loading dose of voriconazole but half

the maintenance dose. There are no data to guide dosing in patients with severe hepatic insufficiency.

The intravenous formulation of voriconazole contains sulbutyl ether β -cyclodextrin (SBECD). When voriconazole is given intravenously, SBECD is excreted completely by the kidney. Significant accumulation of SBECD occurs with a creatinine clearance <50 mL/minute. Because toxicity of SBECD at high plasma concentrations is unclear, oral voriconazole is preferred in azotemic patients.

Drug Interactions. Voriconazole is metabolized by, and inhibits, CYPs 2C19, 2C9, and CYP3A4 (in that order of decreasing potency). The major metabolite of voriconazole, the voriconazole N-oxide, also inhibits these CYPs. Inhibitors or inducers of these CYPs may increase or decrease voriconazole plasma concentrations, respectively. In addition, there is potential for voriconazole and its major metabolite to increase the plasma concentrations of other drugs metabolized by these enzymes (Tables 57-3, 57-4, and 57-5). Because the sirolimus AUC increases 11-fold when voriconazole is given, co-administration is contraindicated. *When starting voriconazole in a patient receiving ≥ 40 mg/day of omeprazole, the dose of omeprazole should be reduced by half.*

Therapeutic Uses. In an open randomized trial, voriconazole provided superior efficiency to C-AMB in the primary therapy of invasive aspergillosis (Herbrecht et al., 2002). In a secondary analysis, survival also was superior in the voriconazole arm. Voriconazole was compared to L-AMB in an open randomized trial in the empirical therapy of neutropenic patients whose fever did not respond to >96 hours of antibacterial therapy. Because the 95% confidence interval in this noninferiority trial permitted the possibility that voriconazole might be $>10\%$ worse than L-AMB, the Food and Drug Administration did not approve voriconazole for this use (Walsh et al., 2002). However, in a secondary analysis, there were fewer breakthrough infections with voriconazole (1.9%) than with L-AMB (5%). Voriconazole is approved for use in esophageal candidiasis on the basis of a double-blind randomized comparison with fluconazole (Ally et al., 2001). In non-neutropenic patients with candidemia, voriconazole was comparable in efficacy and less toxic than initial C-AMB followed by fluconazole (Kullberg, 2005). Voriconazole is approved for initial treatment of candidemia and invasive aspergillosis, as well as for salvage therapy in patients with *Pseudallescheria boydii* (*Scedosporium apiospermum*) and *Fusarium* infections. Positive response of patients with cerebral fungal suggest that the drug penetrates infected brain.

Untoward Effects. Voriconazole is teratogenic in animals and generally contraindicated in pregnancy (Category D). Women of child-bearing potential should use effective contraception during treatment. Although voriconazole is generally well tolerated, occasional cases of hepatotoxicity have been reported, and liver function should be monitored. Voriconazole, like some other azoles, causes a prolongation of the QTc interval, which can become significant in patients with other risk factors for torsades de pointes. Patients must be warned about possible visual effects. Transient visual or auditory hallucinations are frequent after the first dose, usually at night and particularly with intravenous administration. Symptoms diminish with time (Zonios et al., 2008). Patients receiving their first intravenous infusion have had anaphylactoid reactions, with faintness, nausea, flushing, feverishness, and rash.

In such patients, the infusion should be stopped. Rash has been reported in 5.8% of patients.

Dosage. Voriconazole for intravenous infusion is packaged as 200 mg with 3.2 g SBECD. Treatment is usually initiated with an intravenous infusion of 6 mg/kg every 12 hours for two doses, followed by 3-4 mg/kg every 12 hours. It should be administered no faster than 3 mg/kg/hr (e.g., over 1-2 hours, not as an intravenous bolus). As the patient improves, oral administration is continued as 200 mg every 12 hours. Patients failing to respond may be given 300 mg every 12 hours. Voriconazole is available as 50- or 200-mg tablets or a suspension of 40 mg/mL when hydrated. The tablets, but not the suspension, contain lactose. Because high-fat meals reduce voriconazole bioavailability, oral drug should be given either 1 hour before or 1 hour after meals. Children metabolize voriconazole more rapidly than adults (Walsh, 2004a).

Posaconazole

Posaconazole (NOXAFIL) is a synthetic structural analog of itraconazole with the same broad antifungal spectrum but with up to 4-fold greater activity *in vitro* against yeasts and filamentous fungi, including the agents of mucormycosis (Guinea et al., 2008; Frampton, 2008). Activity against yeasts *in vitro* is similar to voriconazole. The mechanism of action is the same as other imidazoles, inhibition of sterol 14- α demethylase.

Absorption, Distribution, and Excretion. Posaconazole is available as a cherry-flavored suspension containing 40 mg/mL. Bioavailability is significantly enhanced by the presence of food (Courtney et al., 2003; Krieter, 2004). The drug has a long terminal phase $t_{1/2}$ (25-31 hours), a large volume of distribution (331-1341 L), and extensive binding ($>98\%$) to protein, predominantly albumin. Systemic exposure is four times higher in homozygous CYP2C19 slow metabolizers than in homozygous wild-type metabolizers. Steady-state concentrations are reached in 7-10 days when dosed four times daily. Saturation of absorption occurs at 800 mg/day (Ezzet et al., 2005; Ullmann et al., 2006). Renal impairment does not alter plasma concentrations; hepatic impairment causes a modest increase (Moton, 2008). With radiolabeled drug given to volunteers, 77% was excreted in the stool, with 66% of the administered dose appearing as unchanged drug. The major metabolic pathway is hepatic UDP glucuronidation (Krieter, 2004). Hemodialysis does not remove detectable amounts of this highly protein-bound drug from the circulation. Gastric acid improves absorption in that an acidic beverage, ginger ale, increased the AUC by 70% in the fasting state (Krishna et al., 2009b). Drugs that reduce gastric acid (e.g., cimetidine and esomeprazole) decreased posaconazole exposure by 32-50% (Frampton and Scott, 2008). Diarrhea reduced the average plasma concentration by 37% (Smith et al., 2009). Plasma concentrations in allogeneic stem cell transplant recipients were 52% lower than in patients not receiving a stem cell transplant (Ullmann et al., 2006). Although monitoring plasma concentrations has been advocated (Smith et al., 2009), the lower limit of therapeutic effect for any indication is unknown.

Therapeutic Use. Posaconazole is not inferior to fluconazole for treatment of oropharyngeal candidiasis, although fluconazole is the preferred drug because of safety, cost, and extensive experience. The dose is 100 mg twice daily the first day and once daily thereafter for

13 days. Posaconazole is approved for prophylaxis against candidiasis and aspergillosis in patients >13 years of age who have prolonged neutropenia or severe graft-vs-host disease (GVHD) (Ullmann et al., 2007). Posaconazole and other “azoles” have recently been compared for prophylaxis effect in patients with neutropenia (Cornely et al., 2007b). The broad applicability of posaconazole for prophylaxis of patients with prolonged neutropenia or GVHD remains unsettled, although the drug clearly remains an option for those indications (De Pauw, 2007).

Posaconazole is approved in the E.U. as salvage therapy for aspergillosis and several other infections, as are itraconazole and voriconazole. A number of clinical reports of favorable response to posaconazole as salvage therapy in mucormycosis have appeared in the literature, leaving the issue unresolved (Dannaoui et al., 2003; Greenberg et al., 2006). Lack of an intravenous formulation continues to limit studies of critically ill patients.

Drug Interactions. Posaconazole inhibits CYP3A4. Co-administration with rifabutin or phenytoin increases the plasma concentration of these drugs and decreases posaconazole exposure by 2-fold. The mechanism of induced posaconazole clearance is unknown but may involve hepatic phase 2 glucuronidation, rather than phase 1 oxidative enzymes. Oxidative products have not been recovered in the serum of treated patients. Posaconazole increases the AUC of cyclosporine, tacrolimus (121%), sirolimus (790%), midazolam (83%) and other CYP3A4 substrates (Table 57–4) (Frampton and Scott, 2008; Krishna et al., 2009a; Moton et al., 2009). Posaconazole is not known to prolong cardiac repolarization, as other azoles may, but posaconazole should not be co-administered with drugs that are CYP3A4 substrates and prolong the QTc interval, such as methadone, haloperidol, pimozide, quinidine, risperidone, sunitinib, tacrolimus, and halofantrine (Table 57–6).

Untoward Effects. The safety profile of posaconazole is good, with nausea, vomiting, diarrhea, abdominal pain, and headache the most commonly reported adverse effects (Smith et al., 2009). Although adverse effects occur in at least a third of patients, discontinuation due to adverse effects in long-term studies has been only 8%. Posaconazole causes fetal bone malformation in pregnant rats and is pregnancy Category C. Safety in children <8 years of age has not been established.

Dosage. Dosage for adults and children >8 years of age is 200 mg (5 mL suspension) three times daily for prophylaxis. Treatment of active infection is begun at 200 mg four times daily and changed to 400 mg twice daily once infection has improved. All doses should be taken with a full meal.

Isavuconazole

Isavuconazole (BAL8557) is an investigational water-soluble pro-drug of the synthetic triazole, BAL4815.

The pro-drug is readily cleaved by esterases in the human body to release the active triazole. *In vitro* activity is comparable to voriconazole (Guinea et al., 2008; Perkhofer et al., 2009).

Absorption, Distribution, and Excretion. Oral administration of once-daily doses equivalent to 100 mg BAL4815 for loading followed by 50 mg daily and 200 mg loading followed by 100 mg resulted in peak plasma concentrations at 21 days of 1.37 µg/mL and 3.5 µg/mL

at 2.25 and 3.5 hours, respectively. The AUCs_{0-24h} were 21.6 and 40.3 µg·h/mL, respectively (Schmitt-Hoffman et al., 2006). With intravenous administration there was close to a linear dose response, with a 5-fold accumulation over 14 days, a t_{1/2} of 84.5–117 hours, and a volume of distribution at steady state of 308–542 L. Excretion is by the liver with most drug appearing in feces.

Therapeutic Use. Isavuconazole has been found comparable to fluconazole in *Candida* esophagitis with all three isavuconazole regimens tested: loading dose of 200 followed by 50 mg daily, loading dose of 400 mg followed by 100 mg daily, or 400 mg once weekly for 14 days (Odds, 2006). The drug was well tolerated. Phase III trials are enrolling patients with deeply invasive candidiasis and aspergillosis.

Echinocandins

Screening natural products of fungal fermentation in the 1970s led to the discovery that *echinocandins* had activity against *Candida* and that the biological activity was directed against formation of 1,3-β-D-glucans in the fungal cell wall (Wiederhold and Lewis, 2003). The inhibition of glucan synthesis reduces structural integrity of the fungal cell wall (Figure 57–3), resulting in osmotic instability and cell death. Three echinocandins are approved for clinical use: caspofungin, anidulafungin, and micafungin. All are cyclic lipopeptides with a hexapeptide nucleus. All have the same mechanism of action but differ in pharmacological properties. Susceptible fungi include *Candida* species and *Aspergillus* species (Bennett, 2006).

General Pharmacological Characteristics. Echinocandins differ somewhat pharmacokinetically (Table 57–7) but all share lack of oral bioavailability, extensive protein binding (>97%), inability to penetrate into CSF, lack of renal clearance, and only a slight to modest effect of hepatic insufficiency on plasma drug concentration (Kim et al., 2007; Wagner et al., 2006). Adverse effects are minimal and rarely lead to drug discontinuation (Kim et al., 2007). All three agents are pregnancy Category C. For a review of the basic and clinical pharmacology of the echinocandins, see Wiederhold and Lewis (2007).

The minimum inhibitory concentration (MIC) of *Candida albicans* and several other *Candida* species are in the range of 0.015–0.5 µg/mL, higher for caspofungin than micafungin or anidulafungin. In *Candida* spp., echinocandins cause cell death at concentrations only 2- to 4-fold higher than that needed to inhibit growth. Azole-resistant *Candida* species remain susceptible to echinocandins. MIC of *Candida parapsilosis* and *C. guilliermondii* are consistently higher than other *Candida* spp., usually 2 µg/mL with all three echinocandins. In none of the clinical trials of the three echinocandins has the higher MIC of *C. parapsilosis* been reflected in lower response rates. An unexplained and paradoxical effect of increased growth at concentrations above the MIC has been seen more often in *C. parapsilosis* than with other *Candida* spp. and more commonly with caspofungin than micafungin or anidulafungin (Chamilos et al., 2007). In *Aspergillus*, echinocandins are not cidal but change the shape of hyphae; thus, *in vitro* susceptibility testing is done with a “morphological” end point (change in hyphal shape). Animal models do not suggest activity against dimorphic fungi such

Figure 57–3. *The fungal cell wall and membrane and the action of echinocandins.* The strength of the fungal cell wall is maintained by fibrillar polysaccharides, largely β -1,3-glucan and chitin, which bind covalently to each other and to proteins. A glucan synthase complex in the plasma membrane catalyzes the synthesis of beta-1,3-glucan; the glucan is extruded into the periplasm and incorporated into the cell wall. Echinocandins inhibit the activity of the glucan synthase complex, resulting in loss of the structural integrity of the cell wall. A subunit of glucan synthase designated Fks1p is thought to be the target of the echinocandin. Mutations in Fks1p, coded for by *FKS1*, cause resistance to echinocandins.

as *Histoplasma capsulatum*. Echinocandins have no activity against *Cryptococcus neoformans*, *Trichosporon* spp., or agents of mucormycosis. *In vitro* studies have consistently failed to show synergism or antagonism between echinocandins and amphotericin B. There is no antagonism between echinocandins and azoles; an additive effect has been reported with *Aspergillus* in some *in vitro* systems and animals models. Echinocandin resistance can be selected in *Candida albicans* under drug pressure both *in vitro* and clinically during prolonged echinocandin therapy. Resistance is from mutations in a conserved region of the *FKS1* gene, coding for amino acids Phe⁶⁴¹-Asp⁶⁵⁸ (Park et al., 2005). FKS1p is an essential component of the 1,3- β -D-glucan synthase complex (Figure 57–3).

Caspofungin

Caspofungin acetate (CANCIDAS) is a water-soluble, semisynthetic lipopeptide synthesized from the fermentation product of *Glarea lozoyensis* (Johnson and Perfect, 2003; Keating and Figgit, 2003).

CASPOFUNGIN

Table 57-7

Pharmacokinetics of Echinocandins in Humans

DRUG	DOSE (mg)	C _{max} (μg/mL)	AUC _{0-24h} (mg•h/L)	t _{1/2} (h)	Cl (mL/min/kg)	V _d (L)
Caspofungin	70	12	93.5	10	0.15	9.5
Micafungin	75	7.1	59.9	13	0.16	14
Anidulafungin	200	7.5	104.5	25.6	0.16	33.4

For details, see Wagner et al. (2006).

Metabolism and Excretion. Catabolism is largely by hydrolysis and *N*-acetylation, with excretion of the metabolites in the urine and feces. Mild and moderate hepatic insufficiency increases the AUC by 55% and 76%, respectively.

Drug Interactions. Caspofungin increase tacrolimus levels by 16%, which should be managed by standard monitoring. Cyclosporine slightly increases caspofungin levels. Rifampin and other drugs activating CYP3A4 can cause a slight reduction in caspofungin levels.

Therapeutic Use. Caspofungin is approved for initial therapy of deeply invasive candidiasis and as salvage therapy for patients with invasive aspergillosis who are failing or intolerant of approved drugs, such as amphotericin B formulations or voriconazole. Approval for salvage therapy of aspergillosis was based on a study of 63 patients in a noncomparative salvage trial. Caspofungin is also approved for esophageal candidiasis, based on randomized trials that found noninferiority to fluconazole and C-AMB (Villanueva et al., 2001). A blinded randomized clinical trial of caspofungin in deeply invasive candidiasis found noninferiority to C-AMB, leading to approval for that indication (Mora-Duarte et al., 2002). Most patients in that multicenter study were not neutropenic and had catheter-acquired candidemia. Efficacy was comparable to that of fluconazole in other studies of the same general patient population. Caspofungin is also approved for the treatment of persistently febrile neutropenic patients with suspected fungal infections, based on noninferiority to L-AMB in a randomized trial (Walsh et al., 2004b).

Untoward Effects. Caspofungin has been remarkably well tolerated, with the exception of phlebitis at the infusion site. Histamine-like effects have been reported with rapid infusions. Other symptoms have been equivalent to those observed in patients receiving fluconazole in the comparator arm.

Dosage. Caspofungin is administered intravenously once daily over 1 hour. In candidemia and salvage therapy of aspergillosis, the initial dose is 70 mg, followed by 50 mg daily. The dose should be increased to 70 mg daily in patients receiving rifampin as well as in those failing to respond to 50 mg. Esophageal candidiasis is treated with 50 mg daily. In moderate hepatic failure, the dose should be reduced to 35 mg daily.

Micafungin

Micafungin (MYCAMINE) is a water-soluble semisynthetic echinocandin derived from the fungus *Coleophoma empedri*.

Absorption, Distribution, and Excretion. Micafungin has linear pharmacokinetics over a large range of doses (1-3 mg/kg) and ages (premature infants to elderly). Feces contain 71% of intravenously administered radiolabeled drug, including both native drug and metabolites (Wiederhold and Lewis, 2007). Small amounts of drug are metabolized in the liver by arylsulfatase and catechol *O*-methyltransferase. Hydroxylation by CYP3A4 is barely detectable. Reduction of dose in moderate hepatic failure is not required. Clearance is more rapid in premature infants and intermediate in children 2-8 years of age, compared to older children and adults.

Drug Interactions. In normal volunteers, micafungin appears to be a mild inhibitor of CYP3A4, increasing AUC of nifedipine by 18%

and sirolimus by 21%. Micafungin has no effect on tacrolimus clearance.

Therapeutic Use. Micafungin is approved for the treatment of deeply invasive candidiasis (Fritz et al., 2008). Doses of 100 mg and 150 mg daily of micafungin were equivalent to caspofungin (Pappas et al., 2007). Micafungin, 100 mg/day, was also not inferior to L-AMB, 3 mg/kg (Kuse et al., 2007). Micafungin is also approved for treatment of esophageal candidiasis and prophylaxis of deeply invasive candidiasis in hematopoietic stem cell transplant recipients.

Doses. Micafungin is given intravenously as 100 mg daily over 1 hour for adults, with 50 mg recommended for prophylaxis and 150 mg for esophageal candidiasis. No loading dose is needed.

Anidulafungin

Anidulafungin (ERAXIS) is a water-insoluble semisynthetic compound extracted from the fungus *Aspergillus nidulans*, from which the drug's name derives.

Absorption, Distribution and Excretion. Anidulafungin is cleared from the body by slow chemical degradation, first by opening the hexapeptide ring and then proteolysis of peptide bonds (Vazquez and Sobel, 2006). No metabolism by the liver or renal excretion of active drug occurs. No dose adjustment for hepatic or renal failure is needed. The drug diluent for intravenous infusion contains 3 mg ethanol for every 50 mg anidulafungin, an amount of ethanol insufficient to have a pharmacological effect.

Drug interactions. None are known.

Therapeutic Use. In a randomized double-blinded clinical trial, anidulafungin was noninferior to fluconazole in candidemia of non-neutropenic patients (Reboli et al., 2007). Anidulafungin is also approved for the treatment of esophageal candidiasis.

Dose. Drug dissolved in the supplied diluent is infused once daily in saline or 5% dextrose in water at a rate not exceeding 1.1 mg/minute. For deeply invasive candidiasis, anidulafungin is given daily as a loading dose of 200 mg followed by 100 mg daily. For esophageal candidiasis, a loading dose of 100 mg is followed by 50 mg daily.

Griseofulvin

The drug is practically insoluble in water.

Mechanism of Action. Griseofulvin inhibits microtubule function and thereby disrupts assembly of the mitotic spindle. Thus, a prominent morphological manifestation of the action of griseofulvin is the production of multinucleate cells as the drug inhibits fungal mitosis. Although the effects of the drug are similar to those of *colchicine* and the vinca alkaloids, griseofulvin's binding sites on the microtubular protein are distinct. In addition to its binding to tubulin, griseofulvin interacts with microtubule-associated protein.

Absorption, Distribution, and Excretion. The oral administration of a 0.5 g dose of griseofulvin produces peak plasma concentrations of ~1 µg/mL in ~4 hours. Blood levels are quite variable, however. Some studies have shown improved absorption when the drug is taken with a fatty meal. Because the rates of dissolution and disaggregation limit the bioavailability of griseofulvin, micro-sized and ultra-micro-sized powders are now used in preparations (GRIFULVIN V and GRIS-PEG, respectively). Although the bioavailability of the ultra-microcrystalline preparation is said to be 50% greater than that of the conventional micro-sized powder, this may not always be true. Griseofulvin has a plasma $t_{1/2}$ of ~1 day, and ~50% of the oral dose can be detected in the urine within 5 days, mostly in the form of metabolites. The primary metabolite is 6-methylgriseofulvin. Barbiturates decrease griseofulvin absorption from the GI tract.

Griseofulvin is deposited in keratin precursor cells; when these cells differentiate, the drug is tightly bound to, and persists in, keratin, providing prolonged resistance to fungal invasion. For this

reason, the new growth of hair or nails is the first to become free of disease. As the fungus-containing keratin is shed, it is replaced by normal tissue. Griseofulvin is detectable in the stratum corneum of the skin within 4-8 hours of oral administration. Sweat and transepidermal fluid loss play an important role in the transfer of the drug in the stratum corneum. Only a very small fraction of a dose of the drug is present in body fluids and tissues.

Antifungal Activity. Griseofulvin is fungistatic *in vitro* for various species of the dermatophytes *Microsporum*, *Epidermophyton*, and *Trichophyton*. The drug has no effect on bacteria or on other fungi. Although failure of ringworm lesions to improve is not rare, isolates from these patients usually are still susceptible to griseofulvin *in vitro*.

Therapeutic Uses. Mycotic disease of the skin, hair, and nails due to *Microsporum*, *Trichophyton*, or *Epidermophyton* responds to griseofulvin therapy. For tinea capitis in children, griseofulvin remains the drug of choice for efficacy, safety, and availability as an oral suspension; efficacy is best for tinea capitis caused by *Microsporum canis*, *Microsporum audouinii*, *Trichophyton schoenleinii*, and *Trichophyton verrucosum*. Griseofulvin is also effective for ringworm of the glabrous skin; tinea cruris and tinea corporis caused by *M. canis*, *Trichophyton rubrum*, *T. verrucosum*, and *Epidermophyton floccosum*; and tinea of the hands (*T. rubrum* and *T. mentagrophytes*) and beard (*Trichophyton* species). Griseofulvin also is highly effective in tinea pedis, the vesicular form of which is most commonly due to *T. mentagrophytes* and the hyperkeratotic type to *T. rubrum*. Topical therapy is sufficient for most cases of tinea pedis. *T. rubrum* and *T. mentagrophytes* infections may require higher-than-conventional doses of griseofulvin.

Dosage. The recommended daily dose of griseofulvin is 2.3 mg/kg (up to 500 mg) for children and 500 mg to 1 g for adults. Doses of 1.5-2 g daily may be used for short periods in severe or extensive infections. Best results are obtained when the daily dose is divided and given at 6-hour intervals, although the drug often is given once or twice per day. Treatment must be continued until infected tissue is replaced by normal hair, skin, or nails, which requires 1 month for scalp and hair ringworm, 6-9 months for fingernails, and at least a year for toenails. Itraconazole or terbinafine is much more effective for onychomycosis.

Untoward Effects. The incidence of serious reactions due to griseofulvin is very low. One of the minor effects is headache (incidence as high as 15%), which is sometimes severe and usually disappears as therapy is continued. Other nervous system manifestations include peripheral neuritis, lethargy, mental confusion, impairment of performance of routine tasks, fatigue, syncope, vertigo, blurred vision, transient macular edema, and augmentation of the effects of alcohol. Among the side effects involving the alimentary tract are nausea, vomiting, diarrhea, heartburn, flatulence, dry mouth, and angular stomatitis. Hepatotoxicity also has been observed. Hematological effects include leukopenia, neutropenia, punctate basophilia, and monocytosis; these often disappear despite continued therapy. Blood studies should be carried out at least once a week during the first month of treatment or longer. Common renal effects include albuminuria and cylindruria without evidence of renal insufficiency. Reactions involving the skin are cold and warm urticaria, photosensitivity, lichen planus, erythema, erythema multiforme-like rashes, and vesicular and morbilliform eruptions. Serum sickness syndromes

and severe angioedema develop rarely during treatment with griseofulvin. Estrogen-like effects have been observed in children. A moderate but inconsistent increase of fecal protoporphyrins has been noted with chronic use.

Griseofulvin induces hepatic CYPs, thereby increasing the rate of metabolism of warfarin; adjustment of the dosage of the latter agent may be necessary in some patients. The drug may reduce the efficacy of low-estrogen oral contraceptive agents, probably by a similar mechanism.

Terbinafine

Terbinafine is a synthetic allylamine, structurally similar to the topical agent naftifine.

TERBINAFINE

Terbinafine is well absorbed, but bioavailability is decreased to ~40% because of first-pass metabolism in the liver. Proteins bind >99% of the drug in plasma. Drug accumulates in skin, nails, and fat. The initial $t_{1/2}$ is ~12 hours but extends to 200–400 hours at steady state. Terbinafine is not recommended in patients with azotemia or hepatic failure because in the latter condition, terbinafine plasma levels are increased by unpredictable amounts. Rifampin decreases and cimetidine increases plasma terbinafine concentrations. The drug is well tolerated, with a low incidence of GI distress, headache, or rash. Very rarely, fatal hepatotoxicity, severe neutropenia, Stevens-Johnson syndrome, or toxic epidermal necrolysis may occur. The drug is pregnancy Category B and it is recommended that systemic terbinafine therapy for onychomycosis be postponed until after pregnancy is complete. Its mechanism of action is inhibition of fungal squalene epoxidase, blocking ergosterol biosynthesis. Increased intracellular squalene also impairs cell growth.

Terbinafine (LAMISIL, others), given as one 250-mg tablet daily for adults, is somewhat more effective for nail onychomycosis than 200 mg daily of itraconazole, and definitely more effective than pulse itraconazole therapy (Fernandez-Obregon et al., 2007). Duration of treatment varies with the site being treated but typically is 6–12 weeks. Efficacy in onychomycosis can be improved by the simultaneous use of amorolfine 5% nail lacquer (Baran et al., 2007). Terbinafine (250 mg daily) also is effective in tinea capitis and is used off-label for ringworm elsewhere on the body. Oral granules are available for use against tinea capitis, usually a disease of children. The recommended dose is 125–250 mg (depending on weight) daily for 6 weeks. The topical use of terbinafine is discussed later.

Topical Antifungal Agents

Topical treatment is useful in many superficial fungal infections, i.e., those confined to the stratum corneum, squamous mucosa, or cornea. Such diseases include dermatophytosis (ringworm), candidiasis, tinea versicolor,

pie-dra, tinea nigra, and fungal keratitis. Topical administration of antifungal agents usually is not successful for mycoses of the nails (onychomycosis) and hair (tinea capitis) and has no place in the treatment of subcutaneous mycoses, such as sporotrichosis and chromoblastomycosis. The efficacy of topical agents in the treatment of superficial mycoses depends not only on the type of lesion and the mechanism of action of the drug but also on the viscosity, hydrophobicity, and acidity of the formulation. Regardless of formulation, penetration of topical drugs into hyperkeratotic lesions often is poor. Removal of thick, infected keratin is sometimes a useful adjunct to therapy and is the principal mode of action of Whitfield's ointment. Similarly, 40% urea paste can be applied under occlusion to soften infected nails.

Among the topical agents, the preferred formulation for cutaneous application usually is a cream or solution. Ointments are messy and are too occlusive for macerated or fissured intertriginous lesions. The use of powders, whether applied by shake containers or aerosols, is largely confined to the feet and moist lesions of the groin and other intertriginous areas.

The systemic agents used for the treatment of superficial mycoses were discussed earlier. Some of these agents also are administered topically; their uses are described here and also in Chapter 65.

Imidazoles and Triazoles for Topical Use

These closely related classes of drugs are synthetic antifungal agents that are used both topically and systemically. Indications for their topical use include ringworm, tinea versicolor, and mucocutaneous candidiasis. Resistance to imidazoles or triazoles is very rare among the fungi that cause ringworm. Selection of one of these agents for topical use should be based on cost and availability because testing *in vitro* for fungal susceptibility to these drugs does not predict clinical responses.

Cutaneous Application. The preparations for cutaneous use described below are effective for tinea corporis, tinea pedis, tinea cruris, tinea versicolor, and cutaneous candidiasis. They should be applied twice a day for 3–6 weeks. Despite some activity *in vitro* against bacteria, this effect is not clinically useful. The cutaneous formulations are not suitable for oral, vaginal, or ocular use.

Vaginal Application. Vaginal creams, suppositories, and tablets for vaginal candidiasis are all used once a day for 1–7 days, preferably at bedtime to facilitate retention. None is useful in trichomoniasis, despite some activity *in vitro*. Most vaginal creams are administered in 5-g amounts. Three vaginal formulations—clotrimazole tablets, miconazole suppositories, and terconazole cream—come in both low- and high-dose preparations. A shorter duration of therapy is recommended for the higher dose of each. These preparations are administered for 3–7 days. Approximately 3–10% of the vaginal dose is absorbed. Although some imidazoles are teratogenic in rodents, no adverse effects on the human fetus have been attributed to the vaginal use of imidazoles or triazoles. The most common side effect is vaginal burning or itching. A male sexual partner may experience

mild penile irritation. Cross-allergenicity among these compounds is assumed to exist, based on their structural similarities.

Oral Use. Use of the oral troche of clotrimazole is properly considered as topical therapy. The only indication for this 10-mg troche is oropharyngeal candidiasis. Antifungal activity is due entirely to the local concentration of the drug; there is no systemic effect.

Clotrimazole

CLOTRIMAZOLE

Absorption of clotrimazole is <0.5% after application to the intact skin; from the vagina, it is 3-10%. Fungicidal concentrations remain in the vagina for as long as 3 days after application of the drug. The small amount absorbed is metabolized in the liver and excreted in bile. In adults, an oral dose of 200 mg/day will give rise initially to plasma concentrations of 0.2-0.35 µg/mL, followed by a progressive decline.

In a small fraction of recipients, clotrimazole on the skin may cause stinging, erythema, edema, vesication, desquamation, pruritus, and urticaria. When it is applied to the vagina, ~1.6% of recipients complain of a mild burning sensation, and rarely of lower abdominal cramps, a slight increase in urinary frequency, or skin rash. Occasionally, the sexual partner may experience penile or urethral irritation. By the oral route, clotrimazole can cause GI irritation. In patients using troches, the incidence of this side effect is ~5%.

Therapeutic Uses. Clotrimazole is available as a 1% cream, lotion, powder, aerosol solution, and solution (LOTTRIMIN AF, MYCELEX, others), 1% or 2% vaginal cream, or vaginal tablets of 100, 200, or 500 mg (GYNE-LOTTRIMIN, others), and 10-mg troches (MYCELEX, others). On the skin, applications are made twice a day. For the vagina, the standard regimens are one 100-mg tablet once a day at bedtime for 7 days, one 200-mg tablet daily for 3 days, one 500-mg tablet inserted only once, or 5 g of cream once a day for 3 days (2% cream) or 7 days (1% cream). For oropharyngeal candidiasis, troches are to be dissolved slowly in the mouth five times a day for 14 days.

Topical clotrimazole cures dermatophyte infections in 60-100% of cases. The cure rates in cutaneous candidiasis are 80-100%. In vulvovaginal candidiasis, the cure rate is usually >80% when the 7-day regimen is used. A 3-day regimen of 200 mg once a day appears to be similarly effective, as does single-dose treatment (500 mg). Recurrences are common after all regimens. The cure rate with oral troches for oral and pharyngeal candidiasis may be as high as 100% in the immunocompetent host.

Econazole

Econazole is the deschloro derivative of miconazole. Econazole readily penetrates the stratum corneum and is found in effective concentrations down to the mid-dermis. However, <1% of an applied

dose appears to be absorbed into the blood. Approximately 3% of recipients have local erythema, burning, stinging, or itching. Econazole nitrate (SPECTAZOLE, ECOSTATIN, others) is available as a water-miscible cream (1%) to be applied twice a day.

Miconazole

MICONAZOLE

Miconazole readily penetrates the stratum corneum of the skin and persists there for >4 days after application. Less than 1% is absorbed into the blood. Absorption is no more than 1.3% from the vagina.

Adverse effects from topical application to the vagina include burning, itching, or irritation in ~7% of recipients, and infrequently, pelvic cramps (0.2%), headache, hives, or skin rash. Irritation, burning, and maceration are rare after cutaneous application. Miconazole is considered safe for use during pregnancy, although some authors avoid its vaginal use during the first trimester.

Therapeutic Uses. Miconazole nitrate is available as a 2% cream, ointment, lotion, powder, gel, aerosol powder, and aerosol solution (MICATIN, ZEASORB-AF, others). To avoid maceration, only the lotion should be applied to intertriginous areas. Miconazole is available as a 2% and 4% vaginal cream, and as 100-mg, 200-mg, or 1200-mg vaginal suppositories (MONISTAT 7, MONISTAT 3, MONISTAT 1, others), to be applied high in the vagina at bedtime for 7, 3, or 1 day(s), respectively.

In the treatment of tinea pedis, tinea cruris, and tinea versicolor, the cure rate may be >90%. In the treatment of vulvovaginal candidiasis, the mycologic cure rate at the end of 1 month is ~80-95%. Pruritus sometimes is relieved after a single application. Some vaginal infections caused by *Candida glabrata* also respond.

Terconazole and Butoconazole

Terconazole (TERAZOL, others) is a ketal triazole. The mechanism of action of terconazole is similar to that of the imidazoles. The 80-mg vaginal suppository is inserted at bedtime for 3 days; the 0.4% vaginal cream is used for 7 days and the 0.8% cream for 3 days. Clinical efficacy and patient acceptance of both preparations are at least as good as for clotrimazole in patients with vaginal candidiasis.

Butoconazole is an imidazole that is pharmacologically quite comparable to clotrimazole. Butoconazole nitrate (FEMSTAT 3, others) is available as a 2% vaginal cream; it is used at bedtime in nonpregnant females. Because of the slower response during pregnancy, a 6-day course is recommended (during the second and third trimester).

Tioconazole

Tioconazole (VAGISTAT 1, others) is an imidazole marketed for treatment of *Candida* vulvovaginitis. A single 4.6-g dose of ointment (300 mg) is given at bedtime.

These imidazole derivatives are used for the topical treatment of infections caused by the common pathogenic dermatophytes. Oxiconazole nitrate (OXISTAT) is available as a 1% cream and lotion; sulconazole nitrate (EXELDERM, SULCOSYN) is supplied as a 1% solution and/or cream. Sertaconazole (ERTACZO) is a 2% cream marketed for tinea pedis.

Ketoconazole

This imidazole is available as a 0.5% cream, foam, gel, and shampoo (NIZORAL, others) for common skin dermatophytes infections, for tinea versicolor, and seborrheic dermatitis.

Ciclopirox Olamine

CICLOPIROX OLAMINE

Ciclopirox olamine (LOPROX, others) has broad-spectrum antifungal activity. It is fungicidal to *C. albicans*, *E. floccosum*, *M. canis*, *T. mentagrophytes*, and *T. rubrum*. It also inhibits the growth of *Malassezia furfur*. After application to the skin, it penetrates through the epidermis into the dermis, but even under occlusion, <1.5% is absorbed into the systemic circulation. Because the $t_{1/2}$ is 1.7 hours, no systemic accumulation occurs. The drug penetrates into hair follicles and sebaceous glands. It can sometimes cause hypersensitivity. It is available as a 0.77% cream, gel, suspension, and lotion for the treatment of cutaneous candidiasis and for tinea corporis, cruris, pedis, and versicolor. An 8% nail lacquer is available for onychomycosis. Cure rates in the dermatomycoses and candidal infections are 81-94%. No topical toxicity has been noted.

Ciclopirox 0.77% gel and 1% shampoo are also used for the treatment of seborrheic dermatitis of the scalp. An 8% topical solution (PENLAC NAIL LACQUER, others) is an effective treatment for mild to moderate superficial white onychomycosis. An oral agent would be preferred for distal or lateral onychomycosis.

Haloprogin

Haloprogin is a halogenated phenolic ether:

HALOPROGIN

It is fungicidal to various species of *Epidermophyton*, *Pityrosporum*, *Microsporum*, *Trichophyton*, and *Candida*. During treatment with this drug, irritation, pruritus, burning sensations, vesiculation, increased maceration, and "sensitization" (or exacerbation of the lesion) occasionally occur, especially on the foot if occlusive footwear is worn. Haloprogin is poorly absorbed through the skin; it is converted to trichlorophenol in the body. The systemic toxicity from topical application appears to be low.

Haloprogin (HALOTEX) cream or solution is applied twice a day for 2-4 weeks. Its principal use is against tinea pedis, for which the cure rate is ~80%; it is thus approximately equal in efficacy to tolnaftate. It also is used against tinea cruris, tinea corporis, tinea manuum, and tinea versicolor. Haloprogin is no longer available in the U.S.

Tolnaftate

Tolnaftate is a thiocarbamate with the following structure:

TOLNAFTATE

Tolnaftate is effective in the treatment of most cutaneous mycoses caused by *T. rubrum*, *T. mentagrophytes*, *T. tonsurans*, *E. floccosum*, *M. canis*, *M. audouinii*, *Microsporum gypseum*, and *M. furfur*, but it is ineffective against *Candida*. In tinea pedis, the cure rate is ~80%, compared with ~95% for miconazole. Toxic or allergic reactions to tolnaftate have not been reported.

Tolnaftate (AFTATE, TINACTIN, others) is available in a 1% concentration as a cream, gel, powder, aerosol powder, and topical solution, or as a topical aerosol liquid. The preparations are applied locally twice a day. Pruritus is usually relieved in 24-72 hours. Involution of interdigital lesions caused by susceptible fungi is very often complete in 7-21 days.

Naftifine

NAFTIFINE

Naftifine is representative of the allylamine class of synthetic agents that inhibit squalene-2,3-epoxidase and thus inhibit fungal biosynthesis of ergosterol. The drug has broad-spectrum fungicidal activity *in vitro*. Naftifine hydrochloride (NAFTIN) is available as a 1% cream or gel. It is effective for the topical treatment of tinea cruris and tinea corporis; twice-daily application is recommended. The drug is well tolerated, although local irritation has been observed in 3% of treated patients. Allergic contact dermatitis also has been reported. Naftifine also may be efficacious for cutaneous candidiasis and tinea versicolor, although the drug is not approved for these uses.

Terbinafine

Terbinafine 1% cream or spray is applied twice daily and is effective in tinea corporis, tinea cruris, and tinea pedis. Terbinafine is less active against *Candida* species and *Malassezia furfur*, but the cream also can be used in cutaneous candidiasis and tinea versicolor. The systemic use of terbinafine was discussed earlier.

Butenafine

Butenafine hydrochloride (MENTAX, LOTRIMIN ULTRA) is a benzylamine derivative with a mechanism of action similar to that of terbinafine and naftifine. Its spectrum of antifungal activity and use also are similar to those of the allylamines.

Polyene Antifungal Antibiotics

Nystatin. Nystatin was discovered in the New York State Health Laboratory and was named accordingly; it is a tetraene macrolide produced by *Streptomyces noursei*, is structurally similar to amphotericin B, and has the same mechanism of action. The drug is not absorbed from the GI tract, skin, or vagina. A liposomal formulation (NYOTRAN) is in clinical trials for candidemia.

Nystatin (MYCOSTATIN, NILSTAT, others) is useful only for candidiasis and is supplied in preparations intended for cutaneous, vaginal, or oral administration for this purpose. Infections of the nails and hyperkeratinized or crusted skin lesions do not respond. Powders are preferred for moist lesions and are applied two to three times daily. Creams or ointments are used twice daily. Combinations of nystatin with antibacterial agents or corticosteroids also are available. Allergic reactions to nystatin are very uncommon. Although vaginal tablets of nystatin are well tolerated, imidazoles or triazoles are more effective agents than nystatin for vaginal candidiasis.

Nystatin suspension is usually effective for oral candidiasis of the immunocompetent host. Patients should be instructed to swish the drug around in the mouth and then swallow; otherwise, the patient may expectorate the bitter liquid and fail to treat the infected mucosa in the posterior pharynx or esophagus. Other than the bitter taste and occasional complaints of nausea, adverse effects are uncommon.

Miscellaneous Antifungal Agents
