At *intermediate* infusion rates (2–5 $\mu\text{g}/\text{kg}/\text{min}$), dopamine directly stimulates cardiac α receptors and vascular sympathetic neurons that enhance myocardial contractility and neural NE release. At *higher* infusion rates (5–15 $\mu\text{g}/\text{kg}/\text{min}$), α adrenergic receptor stimulation-mediated peripheral arterial and venous constriction occurs. This may be desirable in patients with critically reduced arterial pressure or in those with circulatory failure from severe vasodilation (e.g., sepsis, anaphylaxis). However, high-dose dopamine infusion has little role in the treatment of patients with primary cardiac contractile dysfunction; in this setting, increased vasoconstriction will lead to increased afterload and worsening of LV performance. Tachycardia, which is more pronounced with dopamine than with dobutamine, may actually provoke ischemia (and ischemia-induced malignant arrhythmias) in patients with coronary artery disease.

Dobutamine. Dobutamine is the β agonist of choice for the management of CHF patients with systolic dysfunction. In the formulation available for clinical use, dobutamine is a racemic mixture that stimulates both β_1 and β_2 receptor subtypes. In addition, the (–) enantiomer is an agonist for α adrenergic receptors, whereas the (+) enantiomer is a weak, partial agonist. At infusion rates that result in a positive inotropic effect in humans, the β_1 adrenergic effect in the myocardium predominates. In the vasculature, the α adrenergic agonist effect of the (–) enantiomer appears to be offset by the (+) enantiomer and vasodilating effects of β_2 receptor stimulation. Thus, the principal hemodynamic effect of dobutamine is an increase in stroke volume from

positive inotropy, although β_2 receptor activation may cause a decrease in systemic vascular resistance and, therefore, mean arterial pressure. Despite increases in cardiac output, there is relatively little chronotropic effect.

Continuous dobutamine infusions are typically initiated at 2-3 $\mu\text{g}/\text{kg}/\text{min}$ without a loading dose and uptitrated until the desired hemodynamic response is achieved. Pharmacologic tolerance may limit infusion efficacy beyond 4 days, and, therefore, addition or substitution with a class III PDE inhibitor may be necessary to maintain adequate circulatory support. The major side effects of dobutamine are tachycardia and supraventricular or ventricular arrhythmias, which may require a reduction in dosage. Recent β receptor antagonist use is a common cause of blunted clinical responsiveness to dobutamine.

Phosphodiesterase Inhibitors. The cyclic AMP-PDE inhibitors decrease cellular cyclic AMP degradation, resulting in elevated levels of cyclic AMP in cardiac and smooth muscle myocytes. The physiologic effects of this are positive myocardial inotropism and dilation of resistance and capacitance vessels. Collectively, therefore, PDE inhibition improves cardiac output through ionotropy and by decreasing preload and afterload (thus giving rise to the term *inodilator*). The clinical application of early-generation PDE inhibitors (e.g., theophylline, caffeine) is limited by low cardiovascular specificity and an unfavorable side-effect profile, whereas inamrinone, milrinone, and other more recently developed PDE inhibitors are preferred.

Inamrinone and Milrinone. Parenteral formulations of inamrinone (previously named amrinone) and milrinone are approved for short-term circulation support in advanced CHF. Both drugs are bipyridine derivatives and are selective PDE3 inhibitors, the cyclic GMP-inhibited cyclic AMP-PDE. These drugs directly stimulate myocardial contractility and accelerate myocardial relaxation. In addition, they cause balanced arterial and venous dilation with a consequent fall in systemic and pulmonary vascular resistances and left and right-heart filling pressure. As a result of its effect on LV contractility, the increase in cardiac output from milrinone is superior to that from nitroprusside, despite comparable reductions in systemic vascular resistance. Conversely, the arterial and venodilatory effects of milrinone are greater than those of dobutamine at concentrations that produce similar increases in cardiac output.

Parenteral administration of inamrinone and milrinone in patients with CHF from systolic dysfunction should be initiated with a loading dose followed by continuous infusion. For inamrinone, a 0.75-mg/kg bolus injection administered over 2-3 minutes is typically followed by a 2-20- $\mu\text{g}/\text{kg}/\text{min}$ infusion. The loading dose of milrinone is ordinarily 50 $\mu\text{g}/\text{kg}$, and the continuous infusion rate ranges from 0.25-1 $\mu\text{g}/\text{kg}/\text{min}$. The elimination half-lives of inamrinone and milrinone in normal individuals are 2-3 hours

and 0.5-1 hour, respectively, but are nearly doubled in patients with severe CHF. Clinically significant thrombocytopenia occurs in ~10% of those receiving inamrinone but is rare with milrinone. Because of enhanced selectivity for PDE3, short $t_{1/2}$, and favorable side-effect profile, milrinone is the agent of choice among currently available PDE inhibitors for *short-term*, parenteral inotropic support. However, vasodilation-mediated reductions in mean arterial pressure are one practical barrier to milrinone administration in patients with marginal systemic arterial blood pressure from low cardiac output.

Sildenafil. In contrast to inamrinone and milrinone, sildenafil (REVA-TIO) inhibits PDE5, which is the most common PDE isoform in lung tissue. This characteristic of PDE5 likely accounts for the enhanced pulmonary artery specificity observed with sildenafil use. In fact, until recently, the primary clinical application of sildenafil in CHF has mainly been limited to those with isolated right ventricular systolic failure from pulmonary artery hypertension. However, recently published reports suggest that sildenafil favorably influences exercise capacity and right-heart hemodynamics in patients with pulmonary hypertension from LV systolic dysfunction as well (Lewis et al., 2007). Preclinical experimental models also have raised the possibility that PDE5 inhibition is directly cardioprotective via attenuation of adrenergic stimulation-induced myocardial contraction and by suppressing pressure-overload mediated myocardial hypertrophy and attendant ventricular dysfunction (Kass et al., 2007). The pharmacology of PDE5 inhibitors is presented in Chapter 27.

Chronic Positive Inotropic Therapy

Several orally administered agents with combined inotropic and vasodilator properties are available for clinical use. Although improvements in CHF symptoms, functional status, and hemodynamic profile have been reported, the effect of long-term therapy on mortality is disappointing. In fact, the dopaminergic agonist ibopamine; PDE inhibitors milrinone, inamrinone, and vesnarinone; and pimobendan are associated with increased mortality (Hampton et al., 1997; Packer et al., 1991; Cohn et al., 1998). At present, digoxin remains the only oral inotropic agent available for CHF patient use.

Continuous or intermittent outpatient therapy with intravenous dobutamine or milrinone, administered by a portable or home-based infusion pump through a central venous catheter, is available for end-stage CHF patients with symptoms refractory to optimized medical therapy.

Diastolic Heart Failure

Data from population studies suggest that up to 40% of CHF patients have preserved LV systolic function. The pathogenesis of diastolic CHF includes structural and functional abnormalities of the ventricle(s) that are associated with impaired ventricular relaxation and LV distensibility. These abnormalities are reflected in the

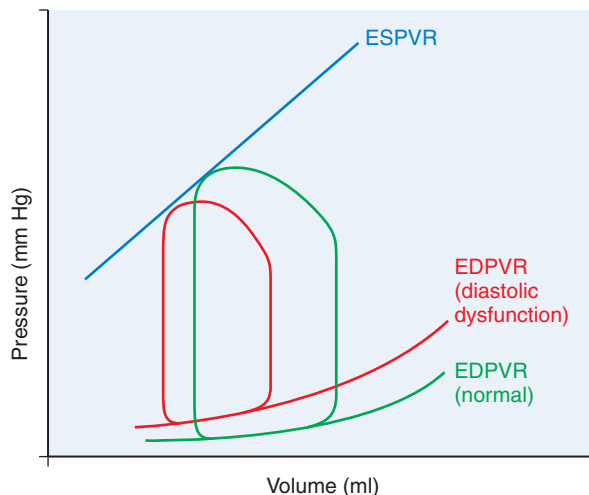

Figure 28–6. Pressure-volume relationships in normal heart and heart with diastolic dysfunction. Normal P-V loop (green) based on normal end diastolic pressure-volume relationship (EDPVR). P-V loop with diastolic dysfunction is shown in red. ESPVR, end-systolic pressure–volume relationship.

LV pressure–volume relationship during diastole, which is shifted upward and to the left relative to normal subjects (Figure 28–6). Consonant with the definition of CHF outlined earlier in this chapter, the diagnosis of diastolic CHF is made when the LV is unable to maintain adequate cardiac output without filling at an abnormally elevated end-diastolic filling pressure.

In patients with *primary* diastolic dysfunction, the myocardial abnormality that accounts for abnormal filling is intrinsic to the myocardium; e.g., by infiltrative disorders including cardiac amyloidosis, hemochromatosis, sarcoidosis, and rarer conditions such as endomyocardial fibrosis and Fabry’s disease. Although not a disease of myocardium infiltration, clinically evident CHF may occur despite intact LV systolic function in familial hypertrophic cardiomyopathy.

Secondary diastolic dysfunction occurs as a consequence of excessive preload (e.g., renal failure), excessive afterload (e.g., systemic hypertension), or changes in LV geometry that occur in response to chronically abnormal loading conditions. Diastolic CHF also is observed in patients with long-standing epicardial coronary artery or pericardial disease. The prevalence of secondary diastolic dysfunction is higher in women and with advanced age. Reported annual mortality rates for diastolic CHF are 5–8%, although this range likely represents an underestimation (Jones et al., 2004).

Patients with diastolic CHF are typically dependent on preload to maintain adequate cardiac output.

Although hypervolemic patients generally benefit from careful intravascular volume reduction, this should be accomplished gradually and treatment goals reassessed frequently. Maintaining synchronous atrial contraction (or at least ventricular rate response control) helps to maintain adequate LV filling during the latter phase of diastole and is therefore a paramount goal in the management of CHF from diastolic dysfunction. Evaluation and treatment of predisposing conditions to impaired diastolic function, such as myocardial ischemia and poorly controlled systemic hypertension, are fundamental to the overall pharmacotherapeutic strategy of this complex form of CHF.

Future Therapies: Targeting Vascular Dysfunction in Congestive Heart Failure from Systolic Dysfunction

Vascular dysfunction is an established component of the CHF syndrome and has evolved into a novel pharmacotherapeutic target for the clinical management of patients with this disease (Varin et al., 2000) (Figure 28–7). Contemporary scientific observations suggest that the blood vessel is a dynamic structure integral to normal myocardial function. This represents a paradigm shift away from the traditional perspective that blood vessels are conduit “tubes” necessary only for blood transport. Elevated levels of oxidant, nitrosative, and other forms of inflammatory stress observed in patients with CHF may impair vascular reactivity by disruption of normal vasodilatory cell signaling pathways (Erwin et al., 2005; Doehner et al., 2001). The precise mechanism by which impaired vascular reactivity is aligned with the progressive natural history of CHF is unresolved; when present, however, vascular dysfunction is associated with decreased exercise tolerance and a poorer clinical outcome. For example, hyperaldosteronism due to overactivation of the renin–angiotensin–aldosterone axis in the setting of LV dysfunction adversely affects both endothelium-dependent and endothelium-independent vascular reactivity (Leopold et al., 2007, Maron et al., 2009) endothelium XO-I zenthine oxidase inhibitor vascular reactivity. This process is in part mediated by increased levels of reactive oxygen species, decreased endogenous levels of antioxidant enzymes, and decreased levels of bioavailable NO (Leopold et al., 2007; Farquharson and Struthers, 2000). As discussed previously, the undesirable effects of hyperaldosteronism on vascular dysfunction are attenuated clinically by aldosterone receptor blockade, resulting in significantly decreased CHF-associated morbidity and mortality (Pitt et al., 1999).

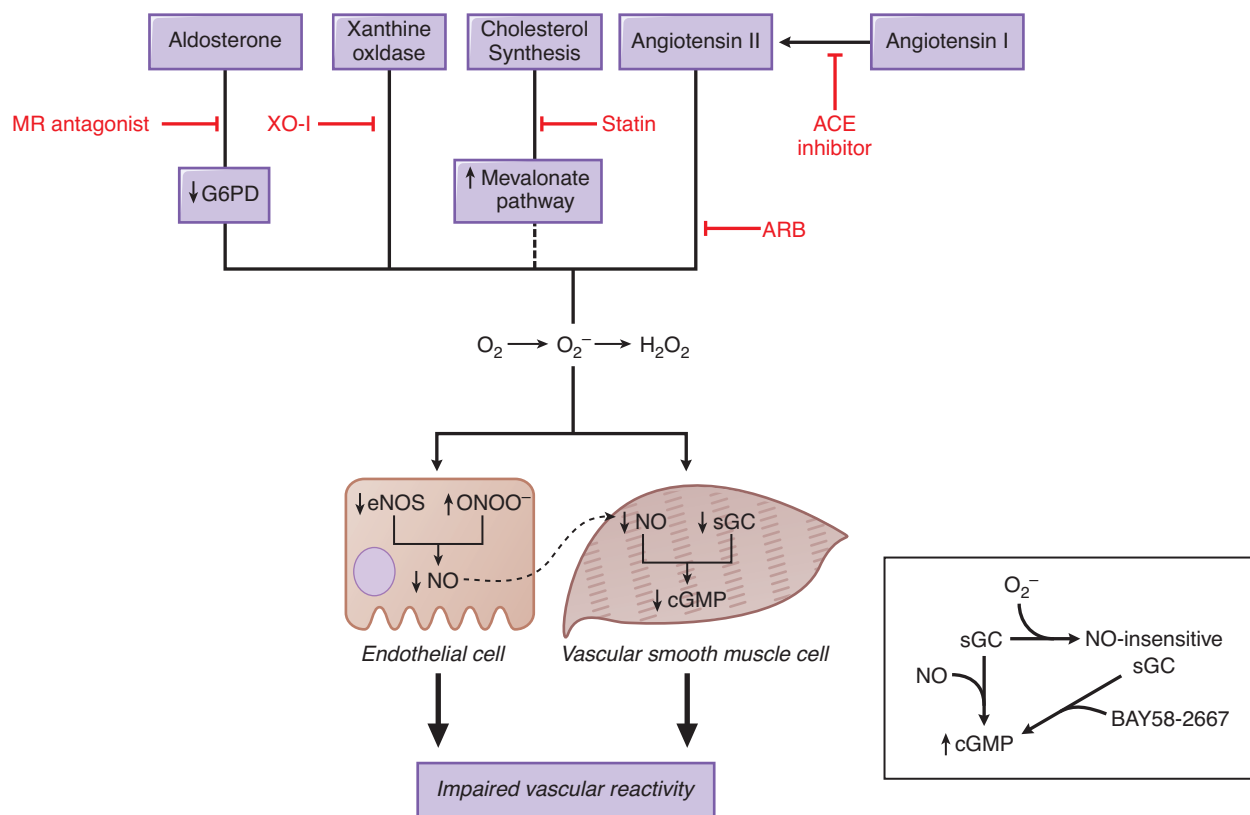

Figure 28–7. Preserving normal vascular reactivity is a target of evolving priority in the treatment of patients with chronic congestive heart failure. Increased levels of reactive oxygen species (ROS), including superoxide (O_2^-) and hydrogen peroxide (H_2O_2) that are generated in both endothelial cells (EC) and vascular smooth muscle cells (VSMC) impair key cell signaling pathways necessary for normal vascular function. Specifically, hyperaldosterone-induced decreased antioxidant enzyme activity in EC, such as glucose-6-phosphate dehydrogenase (G6PD), results in increased ROS formation (Leopold *et al.*, 2007). Likewise, increased xanthine oxidase (XO) activity, AT_1 receptor activation, and upregulation of signaling pathways associated with cholesterol metabolism create a cellular environment favorable for ROS formation. In EC, elevated levels of ROS impair vascular reactivity, in part, by decreasing endothelial nitric oxide synthase (eNOS) activity and increasing peroxynitrite ($ONOO^-$) formation to decrease bioavailable nitric oxide (NO) levels. In VSMC, oxidant stress decreases NO levels and impairs soluble guanylyl cyclase (sGC) sensitivity to NO, thereby decreasing cyclic GMP levels that are necessary for normal VSMC relaxation. Mineralocorticoid (MR)-receptor antagonists, XO inhibitors (XO-I), HMG-coA–reductase inhibitors (statin), AT_1 receptor blockers (ARBs), and angiotensin-converting enzyme (ACE) inhibitors block various cellular reactions associated with elevated levels of ROS and impaired vascular reactivity. The BAY compounds (e.g., BAY 58-2667; *figure inset*), in turn, are a novel group of direct sGC activators that increase enzyme activity despite oxidant stress-induced sGC modifications that convert the enzyme to an NO-insensitive state. XO-I, xanthine oxidase inhibitor.

Xanthine Oxidase and Vascular Dysfunction. Xanthine oxidase (XO) is necessary for normal purine metabolism and catalyzes the oxidation of hypoxanthine to xanthine and xanthine to uric acid in a reaction that generates superoxide. Elevated levels of uric acid are associated with clinically evident CHF (Hare *et al.*, 2008). For example, epidemiologic data support a positive, graded association between impaired exercise capacity and circulating uric acid levels (Doehner *et al.*, 2001). Although the myocardium is rich in XO, vascular endothelial cells also contain high concentrations of

XO, an observation that ultimately led to the hypothesis that increased XO-generated superoxide impairs vascular reactivity in CHF patients (Hare *et al.*, 2008).

Early studies suggested allopurinol (300 mg/day), an XO inhibitor, effectively decreases generation of free oxygen radicals and improves peripheral arterial vasodilation and blood flow in hyperuricemic patients with mild-to-moderate CHF from systolic dysfunction (Doehner *et al.*, 2002). Interestingly, probenecid, which decreases circulating urate levels by enhancing its elimination rather than by inhibiting XO activity, has not been shown to influence vascular reactivity. In patients with advanced CHF, allopurinol-induced serum uric

acid level reduction (over 24 weeks) is associated with functional class improvement, but only in those with baseline serum uric acid levels >9.5 mg/dL. Overall, randomized, placebo-controlled clinical trials examining the long-term efficacy of allopurinol therapy in CHF are sparse, and active investigation in this area continues.

Statins and Vascular Dysfunction. HMG-CoA (3-hydroxy-3-methyl-glutaryl-coenzyme A) reductase catalyzes the formation of L-mevalonic acid, a key biochemical precursor in the cholesterol synthesis pathway (Goldstein and Brown, 1990). Current evidence suggests a role of crosstalk between mevalonate metabolism and cell signaling pathways involved in inflammation and oxidant stress. In this way, HMG-CoA reductase inhibitors, or “statins”, may exert beneficial cardiovascular effects beyond their original intent of low-density lipoprotein reduction; specifically, statins are associated with positive LV remodeling, increased arteriolar blood flow, and decreased circulating platelet aggregation (Liao et al., 2005).

Intermediate byproducts of mevalonate metabolism (i.e., isoprenylated proteins that upregulate activation of Rho, RAS, and other G proteins) are linked to impaired vascular function by increasing levels of oxidant stress and decreasing bioavailable NO levels (Hernandez-Perera et al., 1998). Statins inhibit these intermediary pathways and appear to restore endothelium-dependent (Feron et al., 2001) and endothelium-independent vascular function (Drexler et al., 1993). The pharmacology of the statins and other cholesterol-lowering agents is presented in Chapter 31.

A large number of population studies have demonstrated a favorable effect of statin therapy on outcome in CHF. For example, one retrospective analysis of ischemic- and non-ischemic cardiomyopathy patients with CHF reported a significant reduction in mortality in those treated with a statin for 1 year compared to case-matched patients treated only with standard medical therapy (Horwich et al., 2004). Others have suggested that statins delay CHF in at-risk patients with ischemic heart disease (Kjekshus et al., 1997). Unfortunately, there is a paucity of sufficiently powered prospective, randomized, placebo-controlled clinical trials demonstrating a favorable effect of statin therapy on outcome in patients with CHF. Overall, the evidence in support of statin use in CHF (of either ischemic or non-ischemic etiologies) is primarily based on observational clinical data. The clinical indications for statin therapy in CHF, preferred drug isoform, and optimal drug concentration, for example, remain undefined.

Direct Activators of Soluble Guanylyl Cyclase. Soluble guanylyl cyclase (sGC) is an enzyme that catalyzes the conversion of guanosine triphosphate to cyclic GMP, a second messenger necessary for normal vascular smooth muscle cell relaxation (Koesling, 1999). Under physiologic conditions, NO is the primary biologically

active stimulator of sGC. Elevated levels of oxidant stress deactivate sGC through various molecular mechanisms. For example, aldosterone levels comparable to those observed in patients with decompensated CHF are associated with increased oxidant stress that converts sGC to an NO-insensitive state (Maron et al., 2009), thereby disrupting vasodilatory signaling necessary for normal vascular function.

Organic nitrates, which promote sGC activation by increasing bioavailable NO levels, are subject to pharmacologic tolerance that complicates long-term drug use, dosing, and administration frequency (see the organic nitrates section in Chapter 27). Although the precise mechanism to explain this phenomenon is unknown, it is likely mediated in part by elevated levels of oxidant stress that convert sGC to an NO-insensitive state. BAY compounds (e.g., BAY 58-2667 [cinaciguat]) activate sGC by an NO-independent mechanism, thereby promoting normal sGC function despite conditions of oxidant stress (Stasch et al., 2006). Data from preclinical CHF studies in animals have validated these beneficial molecular effects. In healthy humans, BAY compound administration has not been associated with severe side effects, but hypotension and headache have been reported. Likewise in humans, circulating plasma drug concentrations are decreased to clinically insignificant levels ≤ 30 minutes after infusion termination (Frey et al., 2008).

The utility of BAY 58-2667 in the clinical management of patients with CHF is a topic of ongoing investigation, although early published reports suggest potential for the use of this novel drug class. In a group of patients with acutely decompensated CHF, BAY 58-2667 responders demonstrated a significant decrease in pulmonary capillary wedge pressure, mean right atrial pressure, mean pulmonary artery pressure, pulmonary vascular resistance, and systemic vascular resistance. Cardiac output was significantly increased as well (Lapp et al., 2009). The potential mainstream application of BAY 58-2667 (and other similar compounds) is currently under evaluation in larger clinical trials. Nevertheless, these preliminary observations are encouraging and may expose sustained sGC activity despite enzyme insensitivity to NO[•] as a promising therapeutic target for CHF patients.

CLINICAL SUMMARY

Congestive heart failure is a chronic and usually progressive illness instigated by a primary myocardial insult that impairs myocardial structure and function. Treatment (Figure 28–8) ideally begins with *prevention* of cardiac dysfunction via the identification and remediation of risk factors that predispose individuals to the development of structural heart disease. For example, because coronary artery disease is the most common

Figure 28–8. Stages of heart failure. (Reproduced with permission from Jessup and Brozena, 2003. Copyright © Massachusetts Medical Society. All rights reserved.)

etiology of LV systolic dysfunction, public health tactics to address strategies for prevention of MI through lipid lowering, blood pressure control, and smoking cessation are critical for effective CHF primary prevention.

In asymptomatic patients with LV dysfunction or impaired diastolic dysfunction, neurohormonal compensatory mechanisms that support cardiovascular function are activated, but, paradoxically, further disease progression. Indeed, treatment in this clinical stage is directed at attenuation of sustained neurohormonal activation, with individualized regimens of β adrenergic receptor blockers and ACE inhibitors or AT₁ receptor antagonists.

In most cases, there is unwanted progression to clinically evident CHF, indicating the development of significantly abnormal cardiovascular hemodynamics. Treatment goals in these patients include symptom relief and prevention of disease progression. This may be achieved with diuretics, load-reducing agents, and renin–angiotensin–aldosterone axis antagonists.

Symptomatic patients with hemodynamic decompensation require hospitalization, because oral diuretic and vasodilator therapy alone often are inadequate to reestablish euvolemia and adequate peripheral perfusion. Parenteral vasodilator and inotropic agents are

administered parenterally to restore forward cardiac output and to reverse Na⁺ and water retention. Effective treatment of these patients often is complicated by concurrent renal insufficiency and hypotension, despite evidence of persistently elevated intracardiac filling pressures. In this setting, selection of parenteral agents guided by data obtained from an indwelling pulmonary artery catheter may prove useful.

Consider as an example the clinical scenario in which a decompensated CHF patient presents with normal systemic vascular resistance. In this case, afterload reduction may be contraindicated in the short term and treatment with a parenteral agent such as dobutamine may be preferable. The risk attendant to treatment with sympathomimetic drugs is related to the increase in myocardial O₂ consumption that may occur; this is of particular concern in patients with left-heart failure that occurs as a direct consequence of myocardial ischemia. This clinical quandary has become less common in the era of aggressive myocardial revascularization; when it is encountered, coadministration of dobutamine with parenteral nitroglycerin may be necessary.

In CHF patients who are persistently symptomatic or hemodynamically unstable, referral to a specialized tertiary center with expertise in the evaluation

810 and management of end-stage CHF should be considered. Under these circumstances, resource-intensive treatment, including cardiac resynchronization therapy, mechanical assist devices, high-risk surgical interventions, and cardiac transplantation, may be considered.

Despite the numerous pharmacotherapeutic advances outlined in this chapter, a poor prognosis still remains for patients suffering from severe or end-stage CHF. For these patients, the empathetic initiation of end-of-life discussions may be useful in order to establish appropriate treatment expectations compatible with effective and patient-centered medical care.

Anti-Arrhythmic Drugs

Kevin J. Sampson and
Robert S. Kass

Cardiac cells undergo depolarization and repolarization to form cardiac action potentials ~60 times/minute. The shape and duration of each action potential are determined by the activity of ion channel protein complexes in the membranes of individual cells, and the genes encoding most of these proteins now have been identified. Thus, each heartbeat results from the highly integrated electrophysiologic behavior of multiple proteins on multiple cardiac cells. Ion channel function can be perturbed by inherited mutation/polymorphism, acute ischemia, sympathetic stimulation, or myocardial scarring to create abnormalities of cardiac rhythm, or arrhythmias. Available anti-arrhythmic drugs suppress arrhythmias by blocking flow through specific ion channels or by altering autonomic function. An increasingly sophisticated understanding of the molecular basis of normal and abnormal cardiac rhythm may lead to identification of new targets for anti-arrhythmic drugs and perhaps improved therapies.

Arrhythmias can range from incidental, asymptomatic clinical findings to life-threatening abnormalities. Mechanisms underlying cardiac arrhythmias have been identified in cellular and animal experiments. In some human arrhythmias, precise mechanisms are known, and treatment can be targeted specifically against those mechanisms. In other cases, mechanisms can be only inferred, and the choice of drugs is based largely on the results of prior experience. Anti-arrhythmic drug therapy can have two goals: termination of an ongoing arrhythmia or prevention of an arrhythmia. Unfortunately, anti-arrhythmic drugs not only help to control arrhythmias but also can cause them, especially during long-term therapy. Thus, prescribing anti-arrhythmic drugs requires that precipitating factors be excluded or minimized, that a precise

diagnosis of the type of arrhythmia (and its possible mechanisms) be made, that the prescriber has reason to believe that drug therapy will be beneficial, and that the risks of drug therapy can be minimized.

PRINCIPLES OF CARDIAC ELECTROPHYSIOLOGY

The flow of ions across cell membranes generates the currents that make up cardiac action potentials. The factors that determine the magnitude of individual currents and their modulation by drugs can be explained at the cellular and molecular levels (Priori et al., 1999; Nerbonne and Kass, 2005). However, the action potential is a highly integrated entity wherein changes in one current almost inevitably produce secondary changes in other currents. Most anti-arrhythmic drugs affect more than one ion current, and many exert ancillary effects such as modification of cardiac contractility or autonomic nervous system function. Thus, anti-arrhythmic drugs usually exert multiple actions and can be beneficial or harmful in individual patients (Roden, 1994; Priori et al., 1999).

The Cardiac Cell at Rest: a K^+ -permeable membrane

Ions move across cell membranes in response to electrical and concentration gradients, not through the lipid bilayer but through specific ion channels or transporters. The normal cardiac cell at rest maintains a transmembrane potential ~-80-90 mV negative to the exterior; this gradient is established by pumps, especially the Na^+ , K^+ -ATPase, and fixed anionic charges within cells. There are both an electrical and a concentration gradient that would move Na^+ ions into resting cells (Figure 29-1). However, Na^+ channels, which allow Na^+ to move along this gradient, are closed at negative transmembrane potentials, so Na^+ does not enter normal resting cardiac cells. In contrast, a specific type of K^+ channel protein (the inward rectifier channel) is in an open conformation at negative potentials. Hence, K^+ can move through these channels across the cell membrane at negative potentials in response to either electrical or concentration gradients (Figure 29-1). For each individual ion, there is an equilibrium potential E_x at which there is no net driving force for

Figure 29–1. Electrical and chemical gradients for K^+ and Na^+ in a resting cardiac cell. Inward rectifier K^+ channels are open (left), allowing K^+ ions to move across the membrane and the transmembrane potential to approach E_K . In contrast, Na^+ does not enter the cell despite a large net driving force because Na^+ channel proteins are in the closed conformation (right) in resting cells.

the ion to move across the membrane. E_x can be calculated using the Nernst equation:

$$E_x = - (RT/FZ_x) \ln([x]_i/[x]_o)$$

where Z_x is the valence of the ion, T is the absolute temperature, R is the gas constant, F is Faraday's constant, $[x]_o$ is the extracellular concentration of the ion, and $[x]_i$ is the intracellular concentration. For typical values for K^+ , $[K]_o = 4 \text{ mM}$ and $[K]_i = 140 \text{ mM}$, the calculated K^+ equilibrium potential E_K is -94 mV . There is thus no net force driving K^+ ions into or out of a cell when the transmembrane potential is -94 mV , which is close to the resting potential. If $[K]_o$ is elevated to 10 mM , as might occur in diseases such as renal failure or myocardial ischemia, the calculated E_K rises to -70 mV . In this situation, there is excellent agreement between changes in theoretical E_K owing to changes in $[K]_o$ and the actual measured transmembrane potential, indicating that the normal cardiac cell at rest is permeable to K^+ (because inward rectifier channels are open) and that $[K]_o$ is the major determinant of resting potential.

The Cardiac Action Potential

Transmembrane current through voltage-gated ion channels is the primary determinant of cardiac action potential morphology and duration. Channels are macromolecular complexes consisting of a pore-forming α subunit, as well as β subunits and further accessory proteins. These channels are transmembrane proteins consisting of

Figure 29–2. Voltage dependent conformational changes determine current flow through Na^+ channels. At hyperpolarized potentials, the channel is in a closed conformation and no current can flow (left). As depolarization begins, the pore opens, allowing conduction (middle). And finally, as depolarization is maintained, an intracellular particle blocks current flow, making the channel non-conducting in this inactivated state (right).

a voltage-sensing domain, a selectivity filter, a conducting pore, and often an inactivating particle. In response to changes in local transmembrane potential, ion channels undergo conformational changes allowing for, or preventing, the flow of ions through the conducting pore along their electrochemical gradient (Figure 29–2).

To initiate an action potential, a cardiac myocyte at rest is depolarized above a threshold potential, usually via gap junctions by a neighboring myocyte. Upon membrane depolarization, Na^+ channel proteins change conformation from the “closed” (resting) state to the “open” (conducting) state (Figure 29–2), allowing up to 10^7 Na^+ ions/sec to enter each cell and moving the transmembrane potential toward E_{Na} ($+65 \text{ mV}$). This surge of Na^+ ions lasts only about a millisecond, after which the Na^+ channel protein rapidly changes conformation from the “open” state to an “inactivated,” non-conducting state (Figure 29–2). The maximum upstroke slope of phase 0 (dV/dt_{max} , or V_{max}) of the action potential (Figure 29–3) is largely governed by Na^+ current and plays a role in the conduction velocity of a propagating action potential. Under normal conditions, Na^+ channels, once inactivated, cannot reopen until they reassume the closed conformation. However, a small population of Na^+ channels may continue to open during the action potential plateau in some cells (Figure 29–3), providing further inward current. Certain mutations in the cardiac isoform of the Na^+ channel can further increase the number of channels that do not properly inactivate, thereby prolonging the action potential, and cause one form of the congenital long QT syndrome (Keating and Sanguinetti, 2001). In general, however, as the cell membrane repolarizes, the negative membrane potential moves Na^+ channel proteins from inactivated to “closed” conformations. The relationship between Na^+ channel availability and transmembrane potential is an important determinant of conduction and refractoriness in many cells, as discussed in the following discussion.

The changes in transmembrane potential generated by the inward Na^+ current produce, in turn, a series of openings (and in some cases subsequent inactivation) of other channels (Figure 29–3). For example, when a cell is depolarized by the Na^+ current, “transient outward” K^+ channels quickly change conformation to enter an open, or conducting, state; because the transmembrane potential at the end of phase 0 is positive to E_K , the opening of transient outward channels results in an outward, or repolarizing, K^+ current

Figure 29–3. The relationship between an action potential from the conducting system and the time course of the currents that generate it. The current magnitudes are not to scale; the Na⁺ current is ordinarily 50 times larger than any other current, although the portion that persists into the plateau (phase 2) is small. Multiple types of Ca²⁺ current, transient outward current (I_{TO}), and delayed rectifier (I_K) have been identified. Each represents a different channel protein, usually associated with ancillary (function-modifying) subunits. 4-AP (4-aminopyridine) is a widely used *in vitro* blocker of K⁺ channels. I_{TO2} may be a Cl⁻ current in some species. Components of I_K have been separated on the basis of how rapidly they activate: slowly (I_{Ks}), rapidly (I_{Kr}), or ultra-rapidly (I_{Kur}). The voltage-activated, time-independent current may be carried by Cl⁻ (I_C) or K⁺ (I_{Kp}, *p* for plateau). The genes encoding the major pore-forming proteins have been cloned for most of the channels shown here and are included in the right-hand column. The righthand column lists the primary genes that code for the various ion channels and transporters.

(termed I_{TO}), which contributes to the phase 1 “notch” seen in action potentials from these tissues. Transient outward K⁺ channels, like Na⁺ channels, inactivate rapidly. During the phase 2 plateau of a normal cardiac action potential, inward, depolarizing currents, primarily through Ca²⁺ channels, are balanced by outward, repolarizing currents primarily through K⁺ (“delayed-rectifier”) channels. Delayed-rectifier currents (collectively termed I_K) increase with time, whereas Ca²⁺ currents inactivate (and so decrease with time); as a result, cardiac cells repolarize (phase 3) several hundred milliseconds after the initial Na⁺ channel opening. Mutations in the genes encoding repolarizing K⁺ channels are responsible for the most common forms of the congenital long QT syndrome (Nerbonne and Kass, 2005). Identification of these specific channels has allowed more precise characterization of the pharmacologic effects of anti-arrhythmic drugs. A common mechanism whereby drugs prolong cardiac action potentials and provoke arrhythmias is inhibition of a specific

delayed-rectifier current, I_{Kr}, generated by expression of the *human ether-a-go-go-related gene (HERG)*. The ion channel protein generated by *HERG* expression differs from other ion channels in important structural features that make it much more susceptible to drug block; understanding these structural constraints is an important first step to designing drugs lacking I_{Kr}-blocking properties (Mitcheson et al., 2000). Avoiding I_{Kr}/*HERG* channel block has become a major issue in the development of new anti-arrhythmic drugs (Roden, 2004).

Action Potential Heterogeneity in the Heart

The diversity of action potentials seen throughout different regions of the heart plays a role in understanding the pharmacologic profiles of anti-arrhythmic drugs. This general description of the action potential and the currents that underlie it must be modified for certain cell types (Figure 29–4), primarily due to variability in the expression of ion channels and electrogenic ion transport pumps. In the ventricle, action potential duration (APD) and shape vary across the wall of each chamber, as well as apico-basally (Figure 29–4). In the neighboring His–Purkinje system, action potentials are characterized by a more hyperpolarized plateau potential and prolongation of the action potential due to divergent ion channel expression and differences in intercellular Ca²⁺ handling (Dun and Boyden, 2008). Atrial cells have short action potentials, probably because I_{TO} is larger, and an additional repolarizing K⁺ current, activated by the neurotransmitter acetylcholine, is present. As a result, vagal stimulation further shortens atrial action potentials. Cells of the sinus and atrioventricular (AV) nodes lack substantial Na⁺ currents, and depolarization is achieved by the movement of Ca²⁺ across the membrane. In addition, these cells, as well as cells from the conducting system, normally display the phenomenon of spontaneous diastolic, or phase 4 depolarization and thus spontaneously reach threshold for regeneration of action potentials. The rate of spontaneous firing usually is fastest in sinus node cells, which therefore serve as the natural pacemaker of the heart. Several ionic channels and transport pumps underlie pacemaker currents in the heart. One of the pacemaking currents responsible for this automaticity is generated via specialized K⁺ channels, the hyperpolarization-activated cyclic nucleotide-gated (HCN) channels that are permeable to both potassium and sodium (Cohen and Robinson, 2006). Another major mechanism responsible for automaticity is the repetitive spontaneous Ca²⁺ release from the sarcoplasmic reticulum (SR), a specialized endoplasmic reticulum found in striated muscle cells (Vinogradova and Lakatta, 2009). The rise in cytosolic Ca²⁺ causes membrane depolarizations when Ca²⁺ is extruded from the cell via the electrogenic Na-Ca exchanger (NCX). In addition, sinus node cells lack inward rectifier K⁺ currents that are primarily responsible for protecting working myocardium against spontaneous membrane depolarizations.

Molecular biologic and electrophysiologic techniques have refined the description of ion channels important for the normal functioning of cardiac cells and have identified channels that may be particularly important under pathologic conditions. For example, the transient outward and delayed-rectifier currents actually result from multiple ion channel subtypes (Tseng and Hoffman, 1989; Sanguinetti and Jurkiewicz, 1990) (Figure 29–3).

Figure 29–4. Normal impulse propagation. A schematic of the human heart with example action potentials from different regions of the heart (*top*) for a normal beat and their corresponding contributions to the macroscopic ECG (*bottom*). AV, atrioventricular; LV, left ventricle; RV, right ventricle; SA, sinoatrial. (Used with permission from The Am Physiol Soc. Nerbonne and Kass, *Physiol Rev*, 2005.)

The acetylcholine-evoked hyperpolarization results from activation of a K^+ channel formed by hetero-oligomerization of multiple, distinct channel proteins (Krapivinsky et al., 1995). The understanding that molecularly diverse entities subserve regulation of the cardiac action potential is important because drugs may target one channel subtype selectively. Furthermore, ancillary function-modifying proteins (the products of diverse genes) have been identified for most ion channels.

Maintenance of Intracellular Ion Homeostasis

With each action potential, the cell interior gains Na^+ ions and loses K^+ ions. An ATP-requiring Na^+-K^+ exchange mechanism, or pump, is activated in most cells to maintain intracellular homeostasis. This $Na^+,K^+-ATPase$ extrudes three Na^+ ions for every two K^+ ions shuttled from the exterior of the cell to the interior; as a result, the act of pumping itself generates a net outward (repolarizing) current.

Normally, basal intracellular Ca^{2+} is maintained at very low levels (<100 nM). In cardiac myocytes, the entry of Ca^{2+} during each action potential through L-type Ca^{2+} channels is a signal to the sarcoplasmic reticulum to release its Ca^{2+} stores. The efflux of Ca^{2+} from the sarcoplasmic reticulum occurs through ryanodine-receptor (RyR2) Ca^{2+} release channels, and the resulting increase in intracellular Ca^{2+} subsequently triggers Ca^{2+} -dependent contractile processes

(= excitation-contraction coupling). Removal of intracellular Ca^{2+} occurs by both Ca^{2+} -ATPase (which moves Ca^{2+} ions back into the sarcoplasmic reticulum) and NCX, which exchanges three Na^+ ions from the exterior for each Ca^{2+} ion extruded. Abnormal regulation of intracellular Ca^{2+} is increasingly well described in heart failure and contributes to arrhythmias in this setting. Furthermore, mutations that disrupt the normal activity of the RyR2 channels and the cardiac isoform of calsequestrin have been linked to catecholaminergic polymorphic ventricular tachycardia (CPVT), thereby demonstrating a direct link between spontaneous sarcoplasmic reticulum Ca^{2+} release and cardiac arrhythmias (Mohamed et al., 2007). Inhibiting RyR2 channels with flecainide appears to prevent CPVT in mouse models and in humans (Watanabe et al., 2009). Thus, in both CPVT and heart disease, the cardiac ryanodine receptor has become an intriguing target for future anti-arrhythmic drug therapies.

Impulse Propagation and the Electrocardiogram

Normal cardiac impulses originate in the sinus node. Impulse propagation in the heart depends on two factors: the magnitude of the depolarizing current (usually Na^+ current) and the geometry of cell–cell electrical connections. Cardiac cells are relatively long and thin and well coupled through specialized gap junction proteins at their ends, whereas lateral (“transverse”) gap junctions are sparser.

As a result, impulses spread along cells two to three times faster than across cells. This “anisotropic” (direction-dependent) conduction may be a factor in the genesis of certain arrhythmias described later (Priori et al., 1999). Once impulses leave the sinus node, they propagate rapidly throughout the atria, resulting in atrial systole and the P wave of the surface electrocardiogram (ECG; Figure 29–4). Propagation slows markedly through the AV node, where the inward current (through Ca^{2+} channels) is much smaller than the Na^+ current in atria, ventricles, or the subendocardial conducting system. This conduction delay allows the atrial contraction to propel blood into the ventricle, thereby optimizing cardiac output. Once impulses exit the AV node, they enter the conducting system, where Na^+ currents are larger than elsewhere and propagation is correspondingly faster, up to 0.75 m/s longitudinally. Activation spreads from the His–Purkinje system on the endocardium of the ventricles throughout the rest of the ventricles, stimulating coordinated ventricular contraction. This electrical activation manifests itself as the QRS complex on the ECG. Due to the aforementioned heterogeneity in ventricular APDs, the T wave of the ECG, which represents ventricular repolarization, is broader than the QRS complex and of opposite polarity to what one would expect if repolarization directly followed activation.

The ECG can be used as a rough guide to some cellular properties of cardiac tissue (Figure 29–4):

- Heart rate reflects sinus node automaticity.
- PR-interval duration reflects AV nodal conduction time.
- QRS duration reflects conduction time in the ventricle.
- The QT interval is a measure of ventricular APD.

Refractoriness and Conduction Failure

In atrial, ventricular, and His–Purkinje cells, if a single action potential is restimulated very early during the plateau, no Na^+ channels are available to open, so no inward current results, and no action potential is generated: At this point, the cell is termed refractory (Figure 29–5). On the other hand, if a stimulus occurs after the cell has repolarized completely, Na^+ channels have recovered from inactivation, and a normal Na^+ channel–dependent upstroke results with the same amplitude as the previous upstroke (Figure 29–5A). When a stimulus occurs during phase 3 of the action potential, the upstroke of the premature action potential is slower and of smaller magnitude. The magnitude depends on the number of Na^+ channels that have recovered from inactivation (Figure 29–5B). The recovery from inactivation is faster at more hyperpolarized membrane potentials. Thus, refractoriness is determined by the voltage-dependent recovery of Na^+ channels from inactivation. Refractoriness frequently is measured by assessing whether premature stimuli applied to tissue preparations (or the whole heart) result in propagated impulses. Although the magnitude of the Na^+ current is one major determinant of propagation of premature beats, cellular geometry also is important in multicellular preparations. Propagation from cell to cell requires current flow from the first site of activation and consequently can fail if inward current is insufficient to drive activation in many neighboring cells. The *effective refractory period* (ERP) is the longest interval at which a premature stimulus fails to generate a propagated response and often is used to describe drug effects in intact tissue.

Figure 29–5. Qualitative differences in responses of nodal and conducting tissues to premature stimuli. **A.** With a very early premature stimulus (*black arrow*) in ventricular myocardium, all Na^+ channels still are in the inactivated state, and no upstroke results. As the action potential repolarizes, Na^+ channels recover from the inactivated to the resting state, from which opening can occur. The phase 0 upstroke slope of the premature action potentials (*purple*) are greater with later stimuli because recovery from inactivation is voltage dependent. **B.** The relationship between transmembrane potential and degree of recovery of Na^+ channels from inactivation. The dotted line indicates 25% recovery. Most Na^+ channel–blocking drugs shift this relationship to the left. **C.** In nodal tissues, premature stimuli delivered even after full repolarization of the action potential are depressed; recovery from inactivation is time dependent.

The situation is different in tissue whose depolarization is largely controlled by Ca^{2+} channel current such as the AV node. As Ca^{2+} channels have a slower recovery from inactivation, these tissues often are referred to as slow response, in contrast to fast response in the remaining cardiac tissues (Figure 29–5C). Even after a Ca^{2+} channel–dependent action potential has repolarized to its initial resting potential, not all Ca^{2+} channels are available for re-excitation. Therefore, an extra stimulus applied shortly after repolarization is complete and generates a reduced Ca^{2+} current, which may propagate slowly to adjacent cells prior to extinction. An extra stimulus applied later will result in a larger Ca^{2+} current and faster propagation. Thus, in Ca^{2+} channel–dependent tissues, which include not only the AV node but also tissues whose underlying characteristics have been altered by factors such as myocardial ischemia, refractoriness is prolonged and propagation occurs slowly. Conduction that exhibits such dependence on the timing of premature stimuli is termed *decremental*. Slow conduction in the heart, a critical factor in the genesis of re-entrant arrhythmias (see next section), also can occur when Na^+ currents are depressed by disease or membrane depolarization (e.g., elevated $[\text{K}]_o$), resulting in decreased steady-state Na^+ channel availability (Figure 29–5B).

When the normal sequence of impulse initiation and propagation is perturbed, an arrhythmia occurs. Failure of impulse initiation, in the sinus node, may result in slow heart rates (bradyarrhythmias), whereas failure in the normal propagation of action potentials from atrium to ventricle results in dropped beats (commonly referred to as heart block) that usually reflect an abnormality in either the AV node or the His–Purkinje system. These abnormalities may be caused by drugs (Table 29–1) or by structural heart disease; in the latter case, permanent cardiac pacing may be required.

Abnormally rapid heart rhythms (tachyarrhythmias) are common clinical problems that may be treated with anti-arrhythmic drugs. Three major underlying mechanisms have been identified: enhanced automaticity, triggered automaticity, and re-entry. These often are interrelated mechanisms, as the first two often serve to initiate re-entry.

Enhanced Automaticity

Enhanced automaticity may occur in cells that normally display spontaneous diastolic depolarization—the sinus and AV nodes and the His–Purkinje system. β Adrenergic stimulation, hypokalemia, and mechanical stretch of cardiac muscle cells increase phase 4 slope and so accelerate pacemaker rate, whereas acetylcholine reduces pacemaker rate both by decreasing phase 4 slope and through hyperpolarization (making the maximum diastolic potential more negative). In addition, automatic behavior may occur in sites that ordinarily lack spontaneous pacemaker activity; for example, depolarization of ventricular cells (e.g., by ischemia) may produce “abnormal” automaticity. When impulses propagate from a region of enhanced normal or abnormal automaticity to excite the rest of the heart, more complex arrhythmias may result from the induction of functional re-entry.

Afterdepolarizations and Triggered Automaticity

Under some pathophysiologic conditions, a normal cardiac action potential may be interrupted or followed by an abnormal depolarization (Figure 29–6). If this abnormal depolarization reaches threshold, it may, in turn, give rise to secondary upstrokes that can propagate and create abnormal rhythms. These abnormal secondary upstrokes occur only after an initial normal, or “triggering,” upstroke and so are termed *triggered rhythms*.

Two major forms of triggered rhythms are recognized. In the first case, under conditions of intracellular or sarcoplasmic reticulum Ca^{2+} overload (e.g., myocardial ischemia, adrenergic stress, digitalis intoxication, heart failure), a normal action potential may be followed by a *delayed afterdepolarization* (DAD; Figure 29–6A). If this afterdepolarization reaches threshold, a secondary triggered beat or beats may occur. DAD amplitude is increased *in vitro* by rapid pacing, and clinical arrhythmias thought to correspond to DAD-mediated triggered beats are more frequent when the underlying cardiac rate is rapid (Priori et al., 1999). DADs are also responsible for exercise-induced ventricular tachycardia in congenital CPVT syndrome caused by mutations in RyR channels (Knollmann and Roden, 2008). In the second type of triggered activity, the key abnormality is marked prolongation of the cardiac action potential. When this occurs, phase 3 repolarization may be interrupted by an *early afterdepolarization* (EAD; Figure 29–6B). EAD-mediated triggering *in vitro* and clinical arrhythmias are most common when the underlying heart rate is slow, extracellular K^+ is low, and certain drugs that prolong APD (antiarrhythmics and others) are present. EAD-related triggered upstrokes probably reflect inward current through Na^+ or Ca^{2+} channels. EADs are induced much more readily in Purkinje cells than in epicardial or endocardial cells. When cardiac repolarization is markedly prolonged, polymorphic ventricular tachycardia with a long QT interval, known as the *torsades de pointes* syndrome, may occur. This arrhythmia is thought to be caused by EADs, which trigger functional re-entry (discussed in the following discussion) owing to heterogeneity of APDs across the ventricular wall (Priori et al., 1999). Congenital long QT syndrome, a disease in which torsades de pointes is common, can most often be caused by mutations in the genes encoding the Na^+ channels or the channels underlying the repolarizing currents I_{Kr} and I_{Ks} (Nerbonne and Kass, 2005).

Re-entry

Re-entry occurs when a cardiac impulse travels in a path such as to return to its original site and reactivate the original site and self-perpetuate rapid activation independent of the normal sinus node conduction. This abnormal activation path (or re-entrant circuit) requires anisotropic conduction slowing (or failure) due to either an anatomic or functional barrier.

Anatomically Defined Re-entry. Re-entry can occur when impulses propagate by more than one pathway

Table 29–1

Drug-Induced Cardiac Arrhythmias

ARRHYTHMIA	DRUG	LIKELY MECHANISM	TREATMENT*	CLINICAL FEATURES
Sinus bradycardia	Digoxin	↑Vagal tone	Antidigoxin antibodies	Atrial tachycardia may also be present
AV block			Temporary pacing	
Sinus bradycardia	Verapamil	Ca ²⁺ channel block	Ca ²⁺	
AV block	Diltiazem		Temporary pacing	
Sinus bradycardia	β Blockers	Sympatholytic	Isoproterenol	
AV block	Clonidine		Temporary pacing	
	Methyldopa			
Sinus tachycardia	β Blocker	Upregulation of β receptors with chronic therapy;	β Blockade	Hypertension, angina also possible
Any other tachycardia	withdrawal	β blocker withdrawal ⇒ ↑ β effects		
↑ Ventricular rate in atrial flutter	Quinidine Flecainide Propafenone	Conduction slowing in atrium, with enhanced (quinidine) or unaltered AV conduction	AV nodal blockers	QRS complexes often widened at fast rates
↑ Ventricular rate in atrial fibrillation in patients with WPW syndrome	Digoxin Verapamil	↓ accessory pathway refractoriness	IV procainamide DC cardioversion	Ventricular rate can exceed 300 beats/min
Multifocal atrial tachycardia	Theophylline	↑ intracellular Ca ²⁺ and DADs	Withdraw theophylline ?Verapamil	Often in advanced lung disease
Polymorphic VT with ↑ QT interval (torsades de pointes)	Quinidine Sotalol Procainamide Disopyramide Dofetilide Ibutilide “Noncardioactive” drugs (see text) Amiodarone (rare)	EAD-related triggered activity	Cardiac pacing Isoproterenol Magnesium	Hypokalemia, bradycardia frequent Related to ↑ plasma concentrations, except for quinidine
Frequent or difficult to terminate VT (“incessant” VT)	Flecainide Propafenone Quinidine (rarer)	Conduction slowing in re-entrant circuits	Na ⁺ bolus reported effective in some cases	Most often in patients with advanced myocardial scarring
Atrial tachycardia with AV block; ventricular bigeminy, others	Digoxin	DAD-related triggered activity (± ↑ vagal tone)	Antidigoxin antibodies	Co-existence of abnormal impulses with abnormal sinus or AV nodal function
Ventricular fibrillation	Inappropriate use of IV verapamil	Severe hypotension and/or myocardial ischemia	Cardiac resuscitation (DC cardioversion)	Misdiagnosis of VT as PSVT and inappropriate use of verapamil

*In each of these cases, recognition and withdrawal of the offending drug(s) are mandatory. AV, atrioventricular; DAD, delayed afterdepolarization; DC, direct current; EAD, early afterdepolarization; IV, intravenous; PSVT, paroxysmal supraventricular tachycardia; VT, ventricular tachycardia; WPW, Wolff–Parkinson–White supraventricular tachycardia; ↑, increase; ↓, decrease; ?, unclear.

Figure 29-6. Afterdepolarizations and triggered activity. **A.** Delayed afterdepolarization (DAD) arising after full repolarization. DADs are typically caused by spontaneous Ca^{2+} release from the sarcoplasmic reticulum under conditions of Ca^{2+} overload. The extra cytosolic Ca^{2+} is removed from the cytosol by the electrogenic Na-Ca exchanger (NCX), which produces Na^+ influx and causes a cell membrane depolarization in the form of a DAD. A DAD that reaches threshold results in a triggered upstroke (black arrow, right). **B.** Early afterdepolarization (EAD) interrupting phase 3 repolarization. Multiple ion channels and transporters can contribute to EADs (e.g., Na^+ channel, L-type Ca^{2+} channel, NCX). Under some conditions, triggered beat(s) can arise from an EAD (black arrow, right).

between two points in the heart, and those pathways have heterogeneous electrophysiologic properties. Patients with Wolff–Parkinson–White (WPW) syndrome have accessory connections between the atrium and ventricle (Figure 29-7). With each sinus node depolarization, impulses can excite the ventricle via the normal structures (AV node) or the accessory pathway. However, the electrophysiologic properties of the AV node and accessory pathways are different: Accessory pathways usually consist of non-nodal tissue and consequently vastly differ in refractoriness with the AV node. Thus, with a premature atrial beat, conduction may fail in the accessory pathway but continue, albeit slowly, in the AV node and then through the His–Purkinje system; there, the propagating impulse may encounter the ventricular end of the accessory pathway when it is no longer refractory. The likelihood that the accessory pathway is no longer refractory increases as AV nodal conduction slows. When the impulse re-enters the atrium, it then can re-enter the ventricle via the AV node, re-enter the atrium via the accessory pathway, and so on (Figure 29-7). Re-entry of this type, referred to as *AV re-entrant tachycardia*, is determined by:

- the presence of an anatomically defined circuit
- heterogeneity in refractoriness among regions in the circuit
- slow conduction in one part of the circuit

Figure 29-7. Atrioventricular re-entrant tachycardia in the Wolff–Parkinson–White syndrome. In these patients, an accessory atrioventricular (AV) connection is present (light blue). A premature atrial impulse blocks in the accessory pathway (1) and propagates slowly through the AV node and conducting system. On reaching the accessory pathway (by now no longer refractory), the impulse re-enters the atrium (2), where it then can re-enter the ventricle via the AV node and become self-sustaining (see Figure 29-9C). AV nodal blocking drugs readily terminate this tachycardia. Recurrences can be prevented by drugs that prevent atrial premature beats, by drugs that alter the electrophysiologic characteristics of tissue in the circuit (e.g., they prolong AV nodal refractoriness), and by nonpharmacologic techniques that section the accessory pathway.

Similar “anatomically defined” re-entry commonly occurs in the region of the AV node (*AV nodal re-entrant tachycardia*) and in the atrium (*atrial flutter*). The term *paroxysmal supraventricular tachycardia* (PSVT) includes both AV re-entry and AV nodal re-entry, which share many clinical features.

The primary therapy for anatomically defined re-entry is radiofrequency ablation, as its consistent pathway (or automatic foci) often makes it possible to identify and ablate critical segments of this pathway, effectively curing the patient and obviating the need for long-term drug therapy. Radiofrequency ablation is carried out through a catheter advanced to the interior of the heart and requires minimal convalescence.

Functionally Defined Re-entry. Re-entry also may occur in the absence of a distinct, anatomically defined pathway (Figure 29-8). For example, a premature beat (from an EAD or DAD) from within the ventricular wall may experience refractory tissue in only one direction, allowing for conduction throughout the rest of the wall until the originally refractory area recovers, re-excites, and then propagates back through the original location of the premature beat. Another example is

Figure 29–8. *Two types of re-entry.* The border of a propagating wavefront is denoted by a heavy black arrowhead. In anatomically defined re-entry (*top*), a fixed pathway is present (e.g., Figure 29–7). The black area denotes tissue in the re-entrant circuit that is completely refractory because of the recent passage of the propagating wavefront; the gray area denotes tissue in which depressed upstrokes can be elicited (see Figure 29–5A), and the red area represents tissue in which restimulation would result in action potentials with normal upstrokes. The red area is termed an *excitable gap*. In functionally defined, or “leading circle,” re-entry (*bottom*), there is no anatomic pathway and no excitable gap. Rather, the circulating wavefront creates an area of inexcitable tissue at its core. In this type of re-entry, the circuit does not necessarily remain in the same anatomic position during consecutive beats, and multiple such “rotors” may be present.

localized ischemia or other electrophysiologic perturbations that result in an area of sufficiently slow conduction in the ventricle that impulses exiting from that area, find the rest of the myocardium re-excitable in which case re-entry may ensue. Atrial or ventricular fibrillation (VF) is an extreme example of “functionally defined” (or “leading circle”) re-entry: Cells are re-excited as soon as they are repolarized sufficiently to allow

enough Na^+ channels to recover from inactivation. The abnormal activation pathway subsequently provides abnormal spatial heterogeneity of repolarization that can cause other re-entrant circuits to form; this perpetuates until neither organized activation patterns nor coordinated contractile activity is present.

Common Arrhythmias and Their Mechanisms

The primary tool for diagnosis of arrhythmias is the ECG. More sophisticated approaches sometimes are used, such as recording from specific regions of the heart during artificial induction of arrhythmias by specialized pacing techniques. Table 29–2 lists common arrhythmias, their likely mechanisms, and approaches that should be considered for their acute termination and for long-term therapy to prevent recurrence. Examples of some arrhythmias discussed here are shown in Figure 29–9. Some arrhythmias, notably VF, are best treated not with drugs but with direct current (DC) cardioversion—the application of a large electric current across the chest. This technique also can be used to immediately restore normal rhythm in less serious cases; if the patient is conscious, a brief period of general anesthesia is required. Implanted cardioverter-defibrillators (ICDs), devices that are capable of detecting VF and automatically delivering a defibrillating shock, are used increasingly in patients judged to be at high risk for VF. Often drugs are used with these devices if defibrillating shocks, which are painful, occur frequently.

MECHANISMS OF ANTI-ARRHYTHMIC DRUG ACTION

Anti-arrhythmic drugs almost invariably have multiple effects in patients, and their effects on arrhythmias can be complex. A drug can modulate additional targets in addition to its primary mode of action. At the same time, a single arrhythmia may result from multiple underlying mechanisms (e.g., torsades de pointes (Figure 29–9H) can result either from increased Na^+ channel late currents or decreased inward rectifier currents). Thus, anti-arrhythmic therapy should be tailored to target the most relevant underlying arrhythmia mechanism. Drugs may be anti-arrhythmic by suppressing the initiating mechanism or by altering the re-entrant circuit. In some cases, drugs may suppress the initiator but nonetheless promote re-entry.

Table 29–2

A Mechanistic Approach to Anti-Arrhythmic Therapy

ARRHYTHMIA	COMMON MECHANISM	ACUTE THERAPY ^a	CHRONIC THERAPY ^a
Premature atrial, nodal, or ventricular depolarizations Atrial fibrillation	Unknown Disorganized “functional” re-entry	None indicated	None indicated
Atrial flutter	Continual AV node stimulation and irregular, often rapid, ventricular rate Stable re-entrant circuit in the right atrium Ventricular rate often rapid and irregular	1. Control ventricular response: AV node block ^b 2. Restore sinus rhythm: DC cardioversion Same as atrial fibrillation	1. Control ventricular response: AV nodal block ^b 2. Maintain normal rhythm: K ⁺ channel block, Na ⁺ channel block, Na ⁺ channel block with $\tau_{\text{recovery}} > 1$ second Same as atrial fibrillation
Atrial tachycardia	Enhanced automaticity, DAD-related automaticity, or re-entry in atrium	Same as atrial fibrillation	AV nodal blocking drugs especially desirable to avoid \uparrow ventricular rate Ablation in selected cases ^c Same as atrial fibrillation Ablation of tachycardia “focus” ^c
AV nodal reentrant tachycardia (PSVT)	Re-entrant circuit within or near AV node	*Adenosine AV nodal block Less commonly: \uparrow vagal tone (digitalis, edrophonium, phenylephrine)	*AV nodal block Flecainide Propafenone *Ablation ^c
Arrhythmias associated with WPW syndrome: 1. AV re-entry (PSVT)	Re-entry (Figure 29–7)	Same as AV nodal reentry	K ⁺ channel block Na ⁺ channel block with $\tau_{\text{recovery}} > 1$ second *Ablation ^c
2. Atrial fibrillation with atrioventricular conduction via accessory pathway	Very rapid rate due to nondecremental properties of accessory pathway	*DC cardioversion *Procainamide	K ⁺ channel block Na ⁺ channel block with $\tau_{\text{recovery}} > 1$ second (AV nodal blockers can be harmful)
VT in patients with remote myocardial infarction	Re-entry near the rim of the healed myocardial infarction	Lidocaine Amiodarone Procainamide DC cardioversion Adenosine ^c Verapamil ^e β Blockers ^c DC cardioversion *DC cardioversion	*ICD ^d Amiodarone K ⁺ channel block Na ⁺ channel block Verapamil ^e β Blockers ^e
VT in patients without structural heart disease	DADs triggered by \uparrow sympathetic tone		
VF	Disorganized reentry	Lidocaine Amiodarone Procainamide Pacing Magnesium Isoproterenol	*ICD ^d Amiodarone K ⁺ channel block Na ⁺ channel block β Blockade Pacing
Torsades de pointes, congenital or acquired; (often drug related)	EAD-related triggered activity		

*Indicates treatment of choice. ^aAcute drug therapy is administered intravenously; chronic therapy implies long-term oral use. ^bAV nodal block can be achieved clinically by adenosine, Ca²⁺ channel block, β adrenergic receptor blockade, or increased vagal tone (a major anti-arrhythmic effect of digitalis glycosides). ^cAblation is a procedure in which tissue responsible for the maintenance of a tachycardia is identified by specialized recording techniques and then selectively destroyed, usually by high-frequency radio waves delivered through a catheter placed in the heart. ^dICD, implanted cardioverter–defibrillator: a device that can sense VT or VF and deliver pacing and/or cardioverting shocks to restore normal rhythm. ^eThese may be harmful in reentrant VT and so should be used for acute therapy only if the diagnosis is secure. DAD, delayed afterdepolarization; EAD, early afterdepolarization; WPW, Wolff–Parkinson–White syndrome; PSVT, paroxysmal supraventricular tachycardia; VT, ventricular tachycardia; VF, ventricular fibrillation.

Figure 29–9. ECGs showing normal and abnormal cardiac rhythms. The P, QRS, and T waves in normal sinus rhythm are shown in panel **A**. Panel **B** shows a premature beat arising in the ventricle (*arrow*). Paroxysmal supraventricular tachycardia (PSVT) is shown in panel **C**; this most likely is re-entry using an accessory pathway (see Figure 29–7) or re-entry within or near the atrioventricular (AV) node. In atrial fibrillation (panel **D**), there are no P waves, and the QRS complexes occur irregularly (and at a slow rate in this example); electrical activity between QRS complexes shows small undulations (*arrow*) corresponding to fibrillatory activity in the atria. In atrial flutter (panel **E**), the atria beat rapidly, ~250 beats/minute (*arrows*) in this example, and the ventricular rate is variable. If a drug that slows the rate of atrial flutter is administered, 1:1 AV conduction (panel **F**) can occur. In monomorphic ventricular tachycardia (VT, panel **G**), identical wide QRS complexes occur at a regular rate, 180 beats/min. The electrocardiographic features of the torsades de pointes syndrome (panel **H**) include a very long QT interval (>600 ms in this example, *arrow*) and ventricular tachycardia in which each successive beat has a different morphology (polymorphic VT). Panel **I** shows the disorganized electrical activity characteristic of ventricular fibrillation.

Drugs may slow automatic rhythms by altering any of the four determinants of spontaneous pacemaker discharge (Figure 29–10):

- decrease phase 4 slope
- increase threshold potential
- increase maximum diastolic potential
- increase APD

Adenosine and acetylcholine may increase maximum diastolic potential, and β receptor antagonists (see Chapter 12) may decrease phase 4 slope. Blockade of Na^+ or Ca^{2+} channels usually results in altered threshold, and blockade of cardiac K^+ channels prolongs the action potential.

Anti-arrhythmic drugs may block arrhythmias owing to DADs or EADs by two major mechanisms:

- inhibition of the development of afterdepolarizations
- interference with the inward current (usually through Na^+ or Ca^{2+} channels), which is responsible for the upstroke

Thus, arrhythmias owing to digitalis-induced DADs may be inhibited by verapamil (which blocks the development of DAD by reducing Ca^{2+} influx into the cell, thereby decreasing sarcoplasmic reticulum Ca^{2+} load and the likelihood of spontaneous Ca^{2+} release from the sarcoplasmic reticulum) or by quinidine (which blocks Na^+ channels, thereby elevating the threshold required to produce the abnormal upstroke). Similarly, two approaches are used in arrhythmias related to EAD-triggered beats (Tables 29–1 and 29–2). EADs can be inhibited by shortening APD; in practice, heart rate is accelerated by isoproterenol infusion or by pacing. Triggered beats arising from EADs can be inhibited by Mg^{2+} , without normalizing repolarization *in vitro* or QT interval, through mechanisms that are not well understood. In patients with a congenitally prolonged QT interval, torsades de pointes often occurs with adrenergic stress; therapy includes β adrenergic blockade (which does not shorten the QT interval) as well as pacing.

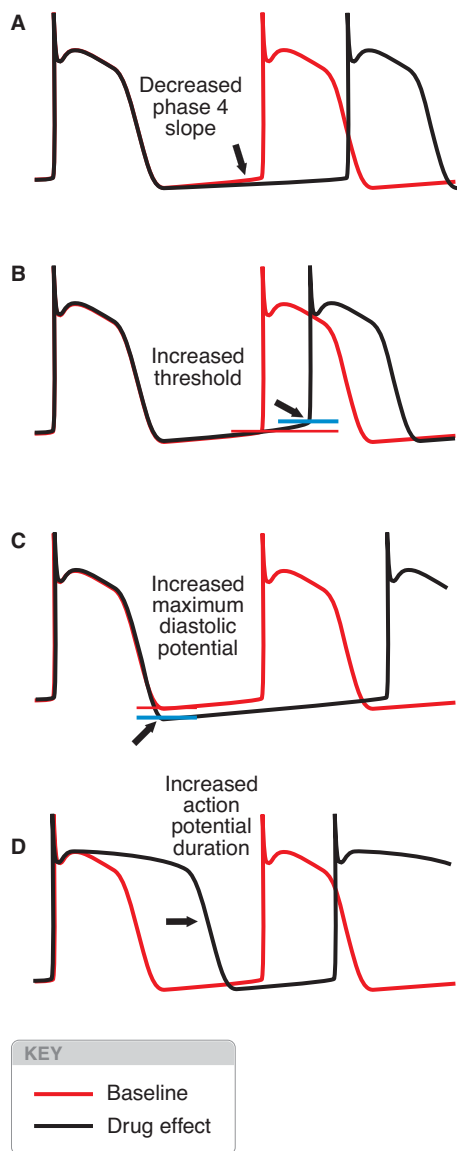

Figure 29-10. Four ways to reduce the rate of spontaneous discharge. The blue horizontal line represents threshold potential.

In anatomically determined re-entry, drugs may terminate the arrhythmia by blocking propagation of the action potential. Conduction usually fails in a “weak link” in the circuit. In the example of the WPW-related arrhythmia described earlier, the weak link is the AV node, and drugs that prolong AV nodal refractoriness and slow AV nodal conduction, such as Ca^{2+} channel blockers, β adrenergic receptor antagonists, or digitalis glycosides, are likely to be effective. On the other hand, slowing conduction in functionally determined re-entrant circuits may change the pathway without extinguishing the circuit. In fact, slow conduction generally promotes the development of re-entrant arrhythmias, whereas the most likely approach for terminating functionally determined re-entry is prolongation of

refractoriness (Task Force, 1991). In atrial and ventricular myocytes, refractoriness can be prolonged by delaying the recovery of Na^+ channels from inactivation. Drugs that act by blocking Na^+ channels generally shift the voltage dependence of recovery from block (Figure 29-5B) and so prolong refractoriness (Figure 29-11).

Drugs that increase APD without direct action on Na^+ channels (e.g., by blocking delayed-rectifier currents) also will prolong refractoriness (Figure 29-11). Particularly in sinoatrial or AV nodal tissues, Ca^{2+} channel blockade prolongs refractoriness. Drugs that interfere with cell-cell coupling also theoretically should increase refractoriness in multicellular preparations; amiodarone may exert this effect in diseased tissue (Levine et al., 1988). Acceleration of conduction in an area of slow conduction also could inhibit re-entry; lidocaine may exert such an effect, and peptides that suppress

Figure 29-11. Two ways to increase refractoriness. In this figure, the black dot indicates the point at which a sufficient number of Na^+ channels (an arbitrary 25%; see Figure 29-5B) have recovered from inactivation to allow a premature stimulus to produce a propagated response in the absence of a drug. Block of Na^+ channels (A) shifts voltage dependence of recovery (see Figure 29-5B) and so delays the point at which 25% of channels have recovered (red diamond), prolonging refractoriness. Note that if the drug also dissociates slowly from the channel (see Figure 29-12), refractoriness in fast-response tissues actually can extend beyond full repolarization (“postrepolarization refractoriness”). Drugs that prolong the action potential (B) also will extend the point at which an arbitrary percentage of Na^+ channels have recovered from inactivation, even without directly interacting with Na^+ channels. ERP, effective refractory period.

experimental arrhythmias by increasing gap junction conductance have been described.

State-Dependent Ion Channel Block

Recent advances have elucidated the structural and molecular determinants of ion channel permeation and drug block. This information has begun to play an increasing role in analyzing the actions of available and new anti-arrhythmic compounds (MacKinnon, 2003). A key concept is that ion channel–blocking drugs bind to specific sites on the ion channel proteins to modify function (e.g., decrease current) and that the affinity of the ion channel protein for the drug on its target site will vary as the ion channel protein shuttles among functional conformations (or ion channel “states”; see Figure 29–2). Physicochemical characteristics, such as molecular weight and lipid solubility, are important determinants of state-dependent binding. State-dependent binding has been studied most extensively in the case of Na⁺ channel–blocking drugs. Most useful agents of this type block open and/or inactivated Na⁺ channels and have very little affinity for channels in the resting state. Most Na⁺ channel blockers bind to a local anesthetic binding site in the pore of Nav1.5, and drug affinity is reduced with mutation to critical residues in the pore (Fozzard et al., 2005). Thus, with each action potential, drugs bind to Na⁺ channels and block them, and with each diastolic interval, drugs dissociate, and the block is released.

As illustrated in Figure 29–12, the dissociation rate is a key determinant of steady-state block of Na⁺

channels. When heart rate increases, the time available for dissociation decreases, and steady-state Na⁺ channel block increases. The rate of recovery from block also slows as cells are depolarized, as in ischemia. This explains the finding that Na⁺ channel blockers depress Na⁺ current, and hence conduction, to a greater extent in ischemic tissues than in normal tissues. Open versus inactivated-state block also may be important in determining the effects of some drugs. Increased APD, which results in a relative increase in time spent in the inactivated state, may increase block by drugs that bind to inactivated channels, such as lidocaine or amiodarone.

The rate of recovery from block often is expressed as a time constant (τ_{recovery} , the time required for ~63% of an exponentially determined process to be complete; Courtney, 1987). In the case of drugs such as lidocaine, τ_{recovery} is so short ($\ll 1$ s) that recovery from block is very rapid, and substantial Na⁺ channel block occurs only in rapidly driven tissues, particularly in ischemia. Conversely, drugs such as flecainide have such long τ_{recovery} values (> 10 s) that roughly the same number of Na⁺ channels is blocked during systole and diastole. As a result, marked slowing of conduction occurs even in normal tissues at normal rates.

Classifying Anti-Arrhythmic Drugs

Classifying drugs by common electrophysiologic properties emphasizes the connection between basic electrophysiologic actions and anti-arrhythmic effects (Vaughan Williams, 1992). To the extent that the clinical actions of drugs can be predicted from their basic electrophysiologic properties, such classification schemes have merit. However, as each compound is

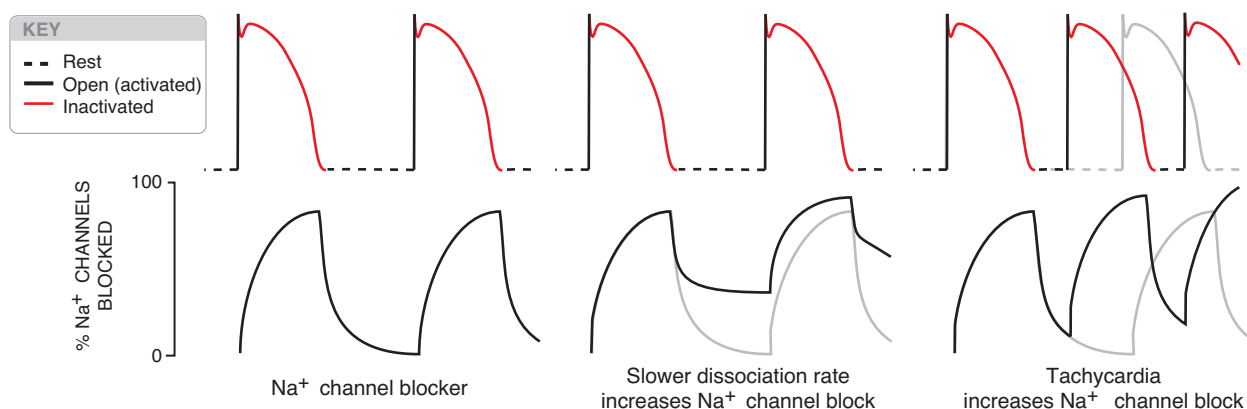

Figure 29–12. Recovery from block of Na⁺ channels during diastole. This recovery is the critical factor determining extent of steady-state Na⁺ channel block. Na⁺ channel blockers bind to (and block) Na⁺ channels in the open and/or inactivated states, resulting in phasic changes in the extent of block during the action potential. As shown in the *middle* panel, a decrease in the rate of recovery from block increases the extent of block. Different drugs have different rates of recovery, and depolarization reduces the rate of recovery. The *right* panel shows that increasing heart rate, which results in relatively less time spent in the rest state, also increases the extent of block. (Modified from Roden et al., 1993, with permission from Wiley-Blackwell Publishing.)

better characterized in a range of *in vitro* and *in vivo* test systems, it becomes apparent that differences in pharmacologic effects occur even among drugs that share the same classification, some of which may be responsible for the observed clinical differences in responses to drugs of the same broad “class” (Table 29–3). An alternative way of approaching anti-arrhythmic therapy is to classify arrhythmia mechanisms and then to target drug therapy to the electrophysiologic mechanism most likely to terminate or prevent the arrhythmia (Task Force, 1991) (Table 29–2). Most recently, a genetic framework of arrhythmia mechanisms has been suggested as a new approach for classifying anti-arrhythmic drug therapy (Knollmann and Roden, 2008).

Na⁺ Channel Block. The extent of Na⁺ channel block depends critically on heart rate and membrane potential, as well as on drug-specific physicochemical characteristics that determine τ_{recovery} (Figure 29–12). The following description applies when Na⁺ channels are blocked (i.e., at rapid heart rates in diseased tissue with a rapid-recovery drug such as lidocaine or even at normal rates in normal tissues with a slow-recovery drug such as flecainide). When Na⁺ channels are blocked, threshold for excitability is decreased (i.e., greater membrane depolarization is required to open enough Na⁺ channels to overcome K⁺ currents at the resting membrane potential and elicit an action potential). This change in threshold probably contributes to the clinical findings that Na⁺ channel blockers tend to increase both pacing threshold and the energy required to defibrillate the fibrillating heart (Echt et al., 1989). These deleterious effects may be important if anti-arrhythmic drugs are used in patients with pacemakers or implanted defibrillators. Na⁺ channel block decreases conduction velocity in non-nodal tissue and increases QRS duration. Usual doses of flecainide prolong QRS intervals by 25% or more during normal rhythm, whereas lidocaine increases QRS intervals only at very fast heart rates. Drugs with τ_{recovery} values greater than 10 s (e.g., flecainide) also tend to prolong the PR interval; it is not known whether this represents additional Ca²⁺ channel block (see “Ca²⁺ Channel Block”) or block of fast-response tissue in the region of the AV node. Drug effects on the PR interval also are highly modified by autonomic effects. For example, quinidine actually tends to shorten the PR interval largely as a result of its vagolytic properties. Action potential duration either is unaffected or shortened by Na⁺ channel block; some Na⁺ channel-blocking drugs do prolong cardiac action potentials but by other mechanisms, usually K⁺ channel block (Table 29–3).

By increasing threshold, Na⁺ channel block decreases automaticity (Figure 29–10B) and can inhibit triggered activity arising from DADs or EADs. Many Na⁺ channel blockers also decrease phase 4 slope (Figure 29–10A). In anatomically defined re-entry, Na⁺ channel blockers may decrease conduction sufficiently to extinguish the propagating re-entrant wavefront. However, as described earlier, conduction slowing owing to Na⁺ channel block may exacerbate re-entry. Block of Na⁺ channels also shifts the voltage dependence of recovery from inactivation (Figure 29–5B) to more negative potentials, thereby tending to increase refractoriness. Thus, whether a given drug exacerbates or suppresses re-entrant arrhythmias depends on the balance between its effects on refractoriness and on conduction in a particular re-entrant circuit. Lidocaine and mexiletine have short τ_{recovery} values and are not useful in atrial fibrillation or flutter, whereas quinidine, flecainide, propafenone, and similar agents are effective in some patients. Many of these agents owe part of their anti-arrhythmic activity to blockade of K⁺ channels.

Late Na⁺ Channel Current Block. The long QT syndrome variant 3 (LQT3) is characterized by late inward Na⁺ current caused by defects in the inactivation of the cardiac isoform of the Na⁺ channel. This late current prolongs the APD and predisposes to arrhythmia. Many drugs with local anesthetic effects, including mexiletine, preferentially block this late current and can be used to successfully treat LQT3 patients. The lessons learned from LQT3 have led to a better understanding of blocking late Na⁺ current, which may be a more common pathologic condition than previously thought. Recently, a number of animal models of heart failure have been shown to have a similar increase in late Na⁺ current, and consequently late Na⁺ blockade is an attractive candidate for anti-arrhythmic drugs in this setting. Interestingly, recent studies have shown the local anesthetic late current blockade is not unique to selective Na⁺ channel blockers and other drugs bind to the same binding site, including commonly used β adrenergic antagonists (including propranolol) and an anti-anginal therapeutic (ranolazine), preferentially inhibiting late current, which may in turn play a role in their anti-arrhythmic utility in both LQT3 and heart failure patients (Fredj et al., 2006; Bankston and Kass, 2010).

Na⁺ Channel-Blocker Toxicity. Conduction slowing in potential re-entrant circuits can account for toxicity of drugs that block the Na⁺ channel (Table 29–1). For example, Na⁺ channel block decreases conduction velocity and hence slows atrial flutter rate. Normal AV

Table 29–3

Major Electrophysiologic Actions of Anti-Arrhythmic Drugs

DRUG	NA ⁺ CHANNEL BLOCK		↑APD	Ca ²⁺ CHANNEL BLOCK	AUTONOMIC EFFECTS	OTHER EFFECTS
	$\tau_{RECOVERY}^1$, SECONDS	STATE DEPENDENCE ¹				
Lidocaine	0.1	I > O				
Phenytoin	0.2	I

Adenosine				✓	✓: Adenosine receptor activation	✓: Activation of outward K ⁺ current
Magnesium				? ✓		Mechanism not well understood

✓Indicates an effect that is important in mediating the clinical action of a drug. (x)Indicates a demonstrable effect whose relationship to drug action in patients is less well established. ^aIndicates drugs prescribed as racemates, and the enantiomers are thought to exert similar electrophysiologic effects. ^bIndicates racemates for which clinically relevant differences in the electrophysiologic properties of individual enantiomers have been reported (see text). One approach to classifying drugs is:

Class	Major action
I	Na ⁺ channel block
II	β blockade
III	action potential prolongation (usually by K ⁺ channel block)
IV	Ca ²⁺ channel block

Drugs are listed here according to this scheme. It is important to bear in mind, however, that many drugs exert multiple effects that contribute to their clinical actions. It is occasionally clinically useful to subclassify Na⁺ channel blockers by their rates of recovery from drug-induced block ($\tau_{recovery}$) under physiologic conditions. Because this is a continuous variable and can be modulated by factors such as depolarization of the resting potential, these distinctions can become blurred: class Ib, $\tau_{recovery} < 1$ s; class Ia, $\tau_{recovery} 1-10$ s; class Ic, $\tau_{recovery} > 10$ s. These class and subclass effects are associated with distinctive ECG changes, characteristic “class” toxicities, and efficacy in specific arrhythmia syndromes (see text). ¹These data are dependent on experimental conditions, including species and temperature. The $\tau_{recovery}$ values cited here are from Courtney (1987). O, open-state blocker; I, inactivated-state blocker; APD, action potential duration.

nodal function permits a greater number of impulses to penetrate the ventricle, and heart rate actually may increase (Figure 29–9). Thus, atrial flutter rate may drop from 300/minute, with 2:1 or 4:1 AV conduction (i.e., a heart rate of 150 or 75 beats/minute), to 220 per minute, but with 1:1 transmission to the ventricle (i.e., a heart rate of 220 beats/minute), with potentially disastrous consequences. This form of drug-induced arrhythmia is especially common during treatment with quinidine because the drug also increases AV nodal conduction through its vagolytic properties; flecainide and propafenone also have been implicated. Therapy with Na⁺ channel blockers in patients with re-entrant ventricular tachycardia after a myocardial infarction (MI) can increase the frequency and severity of arrhythmic episodes. Although the mechanism is unclear, slowed conduction allows the re-entrant wavefront to persist within the tachycardia circuit. Such drug-exacerbated arrhythmia can be very difficult to manage, and deaths owing to intractable drug-induced ventricular tachycardia have been reported. In this setting, Na⁺ infusion may be beneficial. Several Na⁺ channel blockers (e.g., procainamide, quinidine) have been reported to exacerbate neuromuscular paralysis by D-tubocurarine (Chapter 11).

Action Potential Prolongation. Most drugs that prolong the action potential do so by blocking K⁺ channels, although enhanced inward Na⁺ current also can cause prolongation. Enhanced inward current may underlie QT prolongation (and arrhythmia suppression) by ibutilide. Block of cardiac K⁺ channels increases APD and reduces normal automaticity (Figure 29–10D). Increased APD, seen as an increase in QT interval, increases refractoriness (Figure 29–11) and therefore should be an effective way of treating re-entry (Task Force, 1991). Experimentally, K⁺ channel block produces a series of desirable effects: reduced defibrillation energy requirement, inhibition of VF owing to acute ischemia, and increased contractility (Roden, 1993). As shown in Table 29–3, most K⁺ channel-blocking drugs also interact with β adrenergic receptors (sotalol) or other channels (e.g., amiodarone, quinidine). Amiodarone and sotalol appear to be at least as effective as drugs with predominant Na⁺ channel-blocking properties in both atrial and ventricular arrhythmias. “Pure” action potential-prolonging drugs (e.g., dofetilide, ibutilide) also are available (Murray, 1998; Torp-Pedersen et al., 1999).

Toxicity of Drugs That Prolong QT Interval. Most of these agents disproportionately prolong cardiac action

potentials when underlying heart rate is slow and can cause *torsades de pointes* (Table 29–1 and Figure 29–9). While this effect usually is seen with QT-prolonging anti-arrhythmic drugs, it can occur more rarely with drugs that are used for noncardiac indications. For such agents, the risk of torsades de pointes may become apparent only after widespread use postmarketing, and recognition of this risk has been a common cause for drug withdrawal (Roden, 2004). Recent research has shown that sex hormones modify cardiac ion channels and help account for the clinically observed increased incidence of drug-induced torsades de pointes in women (Kurokawa et al., 2009).

Ca²⁺ Channel Block. The major electrophysiologic effects resulting from block of cardiac Ca²⁺ channels are in nodal tissues. Dihydropyridines, such as nifedipine, which are used commonly in angina and hypertension (Chapter 28), preferentially block Ca²⁺ channels in vascular smooth muscle; their cardiac electrophysiologic effects, such as heart rate acceleration, result principally from reflex sympathetic activation secondary to peripheral vasodilation. Only verapamil, diltiazem, and bepridil block Ca²⁺ channels in cardiac cells at clinically used doses. These drugs generally slow heart rate (Figure 29–10A), although hypotension, if marked, can cause reflex sympathetic activation and tachycardia. The velocity of AV nodal conduction decreases, so the PR interval increases. AV nodal block occurs as a result of decremental conduction, as well as increased AV nodal refractoriness. These latter effects form the basis of the anti-arrhythmic actions of Ca²⁺ channel blockers in re-entrant arrhythmias whose circuit involves the AV node, such as AV re-entrant tachycardia (Figure 29–7).

Another important indication for anti-arrhythmic therapy is to reduce ventricular rate in atrial flutter or fibrillation. Rare forms of ventricular tachycardia appear to be DAD-mediated and respond to verapamil (Sung et al., 1983). Parenteral verapamil and diltiazem are approved for rapid conversion of PSVTs to sinus rhythm and for temporary control of rapid ventricular rate in atrial flutter or fibrillation. Oral verapamil may be used in conjunction with digoxin to control ventricular rate in chronic atrial flutter or fibrillation and for prophylaxis of repetitive PSVT. Unlike β adrenergic receptor antagonists, Ca²⁺ channel blockers have not been shown to reduce mortality after MI (Singh, 1990). In contrast to other Ca²⁺ channel blockers, bepridil increases APD in many tissues and can exert an anti-arrhythmic effect in atria and ventricles. However, because bepridil can cause torsades de pointes, it is not prescribed widely and has been discontinued in the U.S.

Verapamil and Diltiazem. The major adverse effect of intravenous verapamil or diltiazem is hypotension, particularly with bolus administration. This is a particular problem if the drugs are used mistakenly in patients with ventricular tachycardia (in whom Ca^{2+} channel blockers usually are not effective) misdiagnosed as AV nodal re-entrant tachycardia (Stewart et al., 1986). Hypotension also is frequent in patients receiving other vasodilators, including quinidine, and in patients with underlying left ventricular dysfunction, which the drugs can exacerbate. Severe sinus bradycardia or AV block also occurs, especially in susceptible patients, such as those also receiving β blockers. With oral therapy, these adverse effects tend to be less severe. Constipation can occur with oral verapamil.

Verapamil (CALAN, ISOPTIN, VERELAN, COVERA-HS, and others) is prescribed as a racemate. L-Verapamil is a more potent calcium channel blocker than is D-verapamil. However, with oral therapy, the L-enantiomer undergoes more extensive first-pass hepatic metabolism. For this reason, a given concentration of verapamil prolongs the PR interval to a greater extent when administered intravenously (where concentrations of the L- and D-enantiomers are equivalent) than when administered orally (Echizen et al., 1985). Diltiazem (CARDIZEM, TIAZAC, DILACOR XR, and others) also undergoes extensive first-pass hepatic metabolism, and both drugs have metabolites that exert Ca^{2+} channel-blocking actions. In clinical practice, adverse effects during therapy with verapamil or diltiazem are determined largely by underlying heart disease and concomitant therapy; plasma concentrations of these agents are not measured routinely. Both drugs can increase serum digoxin concentration, although the magnitude of this effect is variable; excess slowing of ventricular response may occur in patients with atrial fibrillation.

Blockade of β Adrenergic Receptors. β Adrenergic stimulation increases the magnitude of the Ca^{2+} current and slows its inactivation, increases the magnitude of repolarizing K^+ and Cl^- currents (Sanguinetti et al., 1991), increases pacemaker current (thereby increasing sinus rate; DiFrancesco, 1993), increases the Ca^{2+} stored in the sarcoplasmic reticulum (thereby increasing likelihood of spontaneous Ca^{2+} release and DADs), and under pathophysiologic conditions, can increase both DAD- and EAD-mediated arrhythmias. The increases in plasma epinephrine associated with severe stress (e.g., acute MI, resuscitation after cardiac arrest) lower serum K^+ , especially in patients receiving chronic diuretic therapy (Brown et al., 1983). β Adrenergic receptor antagonists inhibit these effects and can be anti-arrhythmic

by reducing heart rate, decreasing intracellular Ca^{2+} overload, and inhibiting afterdepolarization-mediated automaticity. Epinephrine-induced hypokalemia appears to be mediated by β_2 adrenergic receptors and is blocked by “noncardioselective” antagonists such as propranolol (Chapter 12). In acutely ischemic tissue, β blockers increase the energy required to fibrillate the heart, an anti-arrhythmic action (Anderson et al., 1983). These effects may contribute to the reduced mortality observed in trials of chronic therapy with β blockers—including propranolol, timolol, and metoprolol—after MI (Singh, 1990). Atenolol and metoprolol have been shown to decrease mortality in the first week following MI.

As with Ca^{2+} channel blockers and digitalis, β blockers increase AV nodal conduction time (increased PR interval) and prolong AV nodal refractoriness; hence, they are useful in terminating re-entrant arrhythmias that involve the AV node and in controlling ventricular response in atrial fibrillation or flutter. In many (but not all) patients with the congenital long QT syndrome, as well as in many other patients, arrhythmias are triggered by physical or emotional stress; β blockers may be useful in these cases (Schwartz et al., 2000). β Adrenergic receptor antagonists also reportedly are effective in controlling arrhythmias Na^+ channel blockers; this effect may be due in part to slowing of the heart rate, which then decreases the extent of rate-dependent conduction slowing by Na^+ channel block (Myerburg et al., 1989).

Adverse effects of β blockade include fatigue, bronchospasm, hypotension, impotence, depression, aggravation of heart failure, worsening of symptoms owing to peripheral vascular disease, and masking of the symptoms of hypoglycemia in diabetic patients (Chapter 12). In patients with arrhythmias owing to excess sympathetic stimulation (e.g., pheochromocytoma, *clonidine* withdrawal), β blockers can result in unopposed α adrenergic stimulation, with resulting severe hypertension and/or α adrenergic-mediated arrhythmias. In such patients, arrhythmias should be treated with both α and β adrenergic antagonists or with a drug such as labetalol that combines α and β blocking properties. Abrupt discontinuation of chronic β blocker therapy can lead to “rebound” symptoms, including hypertension, increased angina, and arrhythmias; thus, β receptor antagonists are tapered over 2 weeks prior to discontinuation of chronic therapy (Chapters 12 and 25 through 28).

Selected β Adrenergic Receptor Blockers. It is likely that most β adrenergic antagonists share anti-arrhythmic properties. Some, such as propranolol, also exert Na^+ channel-blocking effects at high concentrations. Similarly, drugs with intrinsic sympathomimetic activity may be less useful as anti-arrhythmics, at least in theory (Singh, 1990). Acebutolol is as effective as quinidine in suppressing ventricular ectopic beats, an arrhythmia that many clinicians no longer treat. Sotalol (see later in this chapter) is more effective for

832 many arrhythmias than other β blockers, probably because of its K^+ channel–blocking actions. Esmolol (see later in this chapter) is a β_1 -selective agent that has a very short elimination $t_{1/2}$. Intravenous esmolol is useful in clinical situations in which immediate β adrenergic blockade is desired.

PRINCIPLES IN THE CLINICAL USE OF ANTI-ARRHYTHMIC DRUGS

Drugs that modify cardiac electrophysiology often have a very narrow margin between the doses required to produce a desired effect and those associated with adverse effects. Moreover, anti-arrhythmic drugs can induce new arrhythmias with possibly fatal consequences. Nonpharmacologic treatments, such as cardiac pacing, electrical defibrillation, or ablation of targeted regions, are indicated for some arrhythmias; in other cases, no therapy is required, even though an arrhythmia is detected. Therefore, the fundamental principles of therapeutics described here must be applied to optimize anti-arrhythmic therapy.

1. Identify and Remove Precipitating Factors

Factors that commonly precipitate cardiac arrhythmias include hypoxia, electrolyte disturbances (especially hypokalemia), myocardial ischemia, and certain drugs. Anti-arrhythmics, including cardiac glycosides, are not the only drugs that can precipitate arrhythmias (Table 29–1). For example, theophylline can cause multifocal atrial tachycardia, which sometimes can be managed simply by reducing the dose of theophylline. Torsades de pointes can arise not only during therapy with action potential–prolonging anti-arrhythmics but also with other drugs not ordinarily classified as having effects on ion channels. These include the antibiotic erythromycin (Chapter 55); the antiprotozoal pentamidine (Chapter 50); some antipsychotics, notably thioridazine, ziprasidone, risperidone, and quetiapine (Chapter 16); some analgesics, notably methadone and celecoxib; some antiemetics (e.g., droperidol, dolasetron); anti-histamines such as diphenhydramine;azole antifungals such as voriconazole and fluconazole; bronchodilators such as albuterol, foterol, and salmeterol; prednisone; cisapride; famotidine; tacrolimus; some selective serotonin reuptake inhibitors (including citalopram, fluoxetine, paroxetine, sertraline, and venlafaxine); haloperidol; trazodone; some serotonin 5-HT₁ antagonists (e.g., sumatriptan, zolmitriptan); some antiretrovirals (e.g., efavirenz); most quinolone antibiotics (e.g., levofloxacin); tizanidine; and certain tricyclic antidepressants (Chapter 15).

2. Establish the Goals of Treatment

Some Arrhythmias Should Not Be Treated: The CAST Example. Abnormalities of cardiac rhythm are readily detectable by a variety of recording methods. However, the mere detection of an abnormality does not equate with the need for therapy. This was illustrated in

the Cardiac Arrhythmia Suppression Trial (CAST). The presence of asymptomatic ventricular ectopic beats is a known marker for increased risk of sudden death owing to VF in patients convalescing from MI. In the CAST, patients whose ventricular ectopic beats were suppressed by the potent Na^+ channel blockers encainide (no longer marketed) or flecainide were randomly assigned to receive those drugs or placebo. Unexpectedly, the mortality rate was 2- to 3-fold higher among patients treated with the drugs than those treated with placebo (CAST Investigators, 1989). Although the explanation for this effect is not known, several lines of evidence suggest that in the presence of these drugs, transient episodes of myocardial ischemia and/or sinus tachycardia can cause marked conduction slowing (because these drugs have a very long $\tau_{recovery}$), resulting in fatal re-entrant ventricular tachyarrhythmias (Ruskin, 1989; Akiyama et al., 1991). One consequence of this pivotal clinical trial was to re-emphasize the concept that therapy should be initiated only when a clear benefit to the patient can be identified. When symptoms are obviously attributable to an ongoing arrhythmia, there usually is little doubt that termination of the arrhythmia will be beneficial; when chronic therapy is used to prevent recurrence of an arrhythmia, the risks may be greater (Roden, 1994). *Among the anti-arrhythmic drugs discussed here, only β adrenergic blockers and, to a lesser extent, amiodarone (Connolly, 1999) have been shown to reduce mortality during long-term therapy.*

Symptoms Due to Arrhythmias. Some patients with an arrhythmia may be asymptomatic; in this case, establishing any benefit for treatment will be very difficult. Some patients may present with presyncope, syncope, or even cardiac arrest, which may be due to brady- or tachyarrhythmias. Other patients may present with a sensation of irregular heartbeats (i.e., palpitations) that can be minimally symptomatic in some individuals and incapacitating in others. The irregular heartbeats may be due to intermittent premature contractions or to sustained arrhythmias such as atrial fibrillation (which results in an irregular ventricular rate) (Figure 29–9). Finally, patients may present with symptoms owing to decreased cardiac output attributable to arrhythmias. The most common symptom is breathlessness either at rest or on exertion. Rarely, sustained tachycardias may produce no “arrhythmia” symptoms (such as palpitations) but will depress contractile function; these patients may present with congestive heart failure that can be controlled by treating the arrhythmia.

Choosing Among Therapeutic Approaches. In choosing among available therapeutic options, it is important to establish clear therapeutic goals. For example, three options are available in patients with atrial fibrillation: (1) reduce the ventricular response using AV nodal blocking agents such as digitalis, verapamil, diltiazem, or β adrenergic antagonists (Table 29–1); (2) restore and maintain normal rhythm using drugs such as quinidine, flecainide, or amiodarone; or (3) decide not to implement anti-arrhythmic therapy, especially if the patient truly is asymptomatic. Most patients with atrial fibrillation also benefit from anticoagulation to reduce stroke incidence regardless of symptoms (Singer, 1996) (Chapter 30).

Factors that contribute to choice of therapy include not only symptoms but also the type and extent of structural heart disease, the QT interval prior to drug therapy, the co-existence of conduction system disease, and the presence of noncardiac diseases (Table 29–4). In the rare patient with the WPW syndrome and

Table 29–4

Patient-Specific Anti-Arrhythmic Drug Contraindications

CONDITION	EXCLUDE/USE WITH CAUTION
Cardiac	
Heart failure Sinus or AV node dysfunction	Disopyramide, flecainide Digoxin, verapamil, diltiazem, β receptor antagonists, amiodarone
Wolff–Parkinson–White syndrome (risk of extremely rapid rate if atrial fibrillation develops)	Digoxin, verapamil, diltiazem
Infranodal conduction disease	Na^+ channel blockers, amiodarone
Aortic/subaortic stenosis	Bretylium
History of myocardial infarction	Flecainide
Prolonged QT interval	Quinidine, procainamide, disopyramide, sotalol, dofetilide, ibutilide, amiodarone
Cardiac transplant	Adenosine
Noncardiac	
Diarrhea	Quinidine
Prostatism, glaucoma	Disopyramide
Arthritis	Chronic procainamide
Lung disease	Amiodarone
Tremor	Mexiletine
Constipation	Verapamil
Asthma, peripheral vascular disease, hypoglycemia	β blockers, propafenone

atrial fibrillation, the ventricular response can be extremely rapid and can be accelerated paradoxically by AV nodal blocking drugs such as digitalis or Ca^{2+} channel blockers; deaths owing to drug therapy have been reported under these circumstances.

The frequency and reproducibility of arrhythmia should be established prior to initiating therapy because inherent variability in the occurrence of arrhythmias can be confused with a beneficial or adverse drug effect. Techniques for this assessment include recording cardiac rhythm for prolonged periods or evaluating the response of the heart to artificially induced premature beats. It is important to recognize that drug therapy may be only partially effective. A marked decrease in the duration of paroxysms of atrial fibrillation may be sufficient to render a patient asymptomatic even if an occasional episode still can be detected.

3. Minimize Risks

Anti-Arrhythmic Drugs Can Cause Arrhythmias. One well-recognized risk of anti-arrhythmic therapy is the possibility of provoking new arrhythmias, with potentially life-threatening consequences. Anti-arrhythmic drugs can provoke arrhythmias by different mechanisms (Table 29–1). These drug-provoked arrhythmias must be recognized because further treatment with anti-arrhythmic drugs often exacerbates the problem, whereas withdrawal of the causative agent often is curative. Thus, establishing a precise diagnosis is critical, and targeting therapies at underlying mechanisms of the arrhythmias may be required. For example, treating a ventricular tachycardia with verapamil not only may be ineffective but also can cause catastrophic cardiovascular collapse (Stewart et al., 1986).

Monitoring of Plasma Concentration. Some adverse effects of anti-arrhythmic drugs result from excessive plasma drug concentrations. Measuring plasma concentration and adjusting the dose to maintain the concentration within a prescribed therapeutic range may minimize some adverse effects. In many patients, serious adverse reactions relate to interactions involving anti-arrhythmic drugs (often at usual plasma concentrations), transient factors such as electrolyte disturbances or myocardial ischemia, and the type and extent of the underlying heart disease (Ruskin, 1989; Roden, 1994). Factors such as generation of unmeasured active metabolites, variability in elimination of enantiomers (which may exert differing pharmacologic effects), and disease- or enantiomer-specific abnormalities in drug binding to plasma proteins can complicate the interpretation of plasma drug concentrations.

Patient-Specific Contraindications. Another way to minimize the adverse effects of anti-arrhythmic drugs is to avoid certain drugs in certain patient subsets altogether. For example, patients with a history of congestive heart failure are particularly prone to develop heart failure during disopyramide therapy. In other cases, adverse effects of drugs may be difficult to distinguish from exacerbations of underlying disease. Amiodarone may cause interstitial lung disease; its use therefore is undesirable in a patient with advanced pulmonary disease in whom the development of this potentially fatal adverse effect would be difficult to detect. Specific diseases that constitute relative or absolute contraindications to specific drugs are listed in Table 29–4.

4. Consider the Electrophysiology of the Heart as a “Moving Target”

Cardiac electrophysiology varies dynamically in response to external influences such as changing autonomic tone, myocardial ischemia, and myocardial stretch (Priori et al., 1999). For example, myocardial ischemia results in changes in extracellular K^+ that make the resting potential less negative, inactivate Na^+ channels, decrease Na^+ current, and slow conduction (Weiss et al., 1991). In addition, myocardial ischemia can result in the formation and release of metabolites such as lysophosphatidylcholine, which can alter ion channel function; ischemia also may activate channels that otherwise are quiescent, such as the ATP-inhibited K^+ channels. Thus, in response to myocardial ischemia, a normal heart may display changes in resting potential, conduction velocity, intracellular Ca^{2+} concentrations, and repolarization, any one of which then may create arrhythmias or alter response to anti-arrhythmic therapy.

Summaries of important electrophysiologic and pharmacokinetic features of the drugs considered here are presented in Tables 29–3 and 29–5, respectively. Ca^{2+} channel blockers and β adrenergic antagonists are discussed in Chapters 12 and 25 to 28. The drugs are presented in alphabetical order.

Adenosine. Adenosine (ADENOCARD, others) is a naturally occurring nucleoside that is administered as a rapid intravenous bolus for the acute termination of re-entrant supraventricular arrhythmias (Lerman and Belardinelli, 1991). Adenosine also has been used to produce controlled hypotension during some surgical procedures and in the diagnosis of coronary artery disease. Intravenous ATP appears to produce effects similar to those of adenosine.

Pharmacologic Effects. The effects of adenosine are mediated by its interaction with specific G protein-coupled adenosine receptors. Adenosine activates acetylcholine-sensitive K^+ current in the atrium and sinus and AV nodes, resulting in shortening of APD, hyperpolarization, and slowing of normal automaticity (Figure 29–10C). Adenosine also inhibits the electrophysiologic effects of increased intracellular cyclic AMP that occur with sympathetic stimulation. Because adenosine thereby reduces Ca^{2+} currents, it can be anti-arrhythmic by increasing AV nodal refractoriness and by inhibiting DADs elicited by sympathetic stimulation.

Administration of an intravenous bolus of adenosine to humans transiently slows sinus rate and AV nodal conduction velocity and increases AV nodal refractoriness. A bolus of adenosine can produce transient sympathetic activation by interacting with carotid baroreceptors (Biaggioni et al., 1991); a continuous infusion can cause hypotension.

Adverse Effects. A major advantage of adenosine therapy is that adverse effects are short lived because the drug is transported into cells and deaminated so rapidly. Transient asystole (lack of any cardiac rhythm whatsoever) is common but usually lasts less than 5 seconds

and is in fact the therapeutic goal. Most patients feel a sense of chest fullness and dyspnea when therapeutic doses (6–12 mg) of adenosine are administered. Rarely, an adenosine bolus can precipitate bronchospasm or atrial fibrillation presumably by heterogeneously shortening atrial action potentials.

Clinical Pharmacokinetics. Adenosine is eliminated with a $t_{1/2}$ of seconds by carrier-mediated uptake, which occurs in most cell types, including the endothelium, and subsequent metabolism by adenosine deaminase. Adenosine probably is the only drug whose efficacy requires a rapid bolus dose, preferably through a large central intravenous line; slow administration results in elimination of the drug prior to its arrival at the heart.

The effects of adenosine are potentiated in patients receiving dipyridamole, an adenosine uptake inhibitor, and in patients with cardiac transplants owing to denervation hypersensitivity. Methylxanthines (Chapter 36) such as theophylline and caffeine block adenosine receptors; therefore, larger than usual doses are required to produce an anti-arrhythmic effect in patients who have consumed these agents in beverages or as therapy.

Amiodarone. Amiodarone (CORDARONE, PACERONE, others) exerts a multiplicity of pharmacologic effects, none of which is clearly linked to its arrhythmia-suppressing properties (Mason, 1987). Amiodarone is a structural analog of thyroid hormone, and some of its anti-arrhythmic actions and its toxicity may be attributable to interaction with nuclear thyroid hormone receptors. Amiodarone is highly lipophilic, is concentrated in many tissues, and is eliminated extremely slowly; consequently, adverse effects may resolve very slowly. In the U.S., the drug is indicated for oral therapy in patients with recurrent ventricular tachycardia or fibrillation resistant to other drugs. Oral amiodarone also is effective in maintaining sinus rhythm in patients with atrial fibrillation (Connolly, 1999). An intravenous form is indicated for acute termination of ventricular tachycardia or fibrillation (Kowey et al., 1995) and is supplanting lidocaine as first-line therapy for out-of-hospital cardiac arrest (Dorian et al., 2002). Trials of oral amiodarone have shown a modest beneficial effect on mortality after acute MI (Amiodarone Trials Meta-Analysis Investigators, 1997). Despite uncertainties about its mechanisms of action and the potential for serious toxicity, amiodarone now is used very widely in the treatment of common arrhythmias such as atrial fibrillation (Roy et al., 2000).

Pharmacologic Effects. Studies of the acute effects of amiodarone in *in vitro* systems are complicated by its insolubility in water, necessitating the use of solvents

Table 29–5

Pharmacokinetic Characteristics and Doses of Anti-Arrhythmic Drugs

DRUG	BIOAVAILABILITY	PROTEIN BINDING >80%	ELIMINATION			ELIMINATION $t_{1/2}$	ACTIVE METABOLITE(S)	THERAPEUTIC ^b PLASMA CONCENTRATION	USUAL DOSES ^c

✓ Indicates an effect that affects the clinical action of the drug. (x): metabolite or route of elimination probably of minor clinical importance. *The elimination $t_{1/2}$ is one, but not the only, determinant of how frequently a drug must be administered to maintain a therapeutic effect and avoid toxicity (Chapter 2). For some drugs with short elimination half-lives, infrequent dosing is nevertheless possible, e.g., verapamil. Formulations that allow slow release into the GI tract of a rapidly eliminated compound (available for many drugs, including procainamide, disopyramide, verapamil, diltiazem, and propranolol) also allow infrequent dosing. ^bThe therapeutic range is bounded by a plasma concentration below which no therapeutic effect is likely, and an upper concentration above which the risk of adverse effects increases. Many serious adverse reactions to anti-arrhythmic drugs can occur at “therapeutic” concentrations in susceptible individuals. When only an upper limit is cited, a lower limit has not been well defined. Variable generation of active metabolites may further complicate the interpretation of plasma concentration data (Chapter 2). ^cOral doses are presented unless otherwise indicated. Doses are presented as suggested ranges in adults of average build; lower doses are less likely to produce toxicity. Lower maintenance dosages may be required in patients with renal or hepatic disease. Loading doses are only indicated when a therapeutic effect is desired before maintenance therapy would bring drug concentrations into a therapeutic range—that is, for acute therapy (e.g., lidocaine, verapamil, adenosine) or when the elimination $t_{1/2}$ is extremely long (amiodarone). ^dBioavailability reduced by incomplete absorption. ^eIndicates suggested dosage using slow-release formulation. ^fThis drug is available only in a restricted distribution system (see text). IV, intravenous.

such as dimethyl sulfoxide. Amiodarone's effects may be mediated by perturbation of the lipid environment of the ion channels (Herbette et al., 1988). Amiodarone blocks inactivated Na^+ channels and has a relatively rapid rate of recovery (time constant ~ 1.6 s) from block. It also decreases Ca^{2+} current and transient outward delayed-rectifier and inward rectifier K^+ currents and exerts a noncompetitive adrenergic blocking effect. Amiodarone potently inhibits abnormal automaticity and, in most tissues, prolongs APD. Amiodarone decreases conduction velocity by Na^+ channel block and by a poorly understood effect on cell-cell coupling that may be especially important in diseased tissue (Levine et al., 1988). Prolongations of the PR, QRS, and QT intervals and sinus bradycardia are frequent during chronic therapy. Amiodarone prolongs refractoriness in all cardiac tissues; Na^+ channel block, delayed repolarization owing to K^+ channel block, and inhibition of cell-cell coupling all may contribute to this effect.

Adverse Effects. Hypotension owing to vasodilation and depressed myocardial performance are frequent with the intravenous form of amiodarone and may be due in part to the solvent. Although depressed contractility can occur during long-term oral therapy, it is unusual. Despite administration of high doses that would cause serious toxicity if continued long term, adverse effects are unusual during oral drug-loading regimens, which typically require several weeks. Occasionally during the loading phase, patients develop nausea, which responds to a decrease in daily dose.

Adverse effects during long-term therapy reflect both the size of daily maintenance doses and the cumulative dose, suggesting that tissue accumulation may be responsible. The most serious adverse effect during chronic amiodarone therapy is pulmonary fibrosis, which can be rapidly progressive and fatal. Underlying lung disease, doses of 400 mg/day or more, and recent pulmonary insults such as pneumonia appear to be risk factors (Dusman et al., 1990). Serial chest X-rays or pulmonary function studies may detect early amiodarone toxicity, but monitoring plasma concentrations has not been useful. With low doses, such as 200 mg/day or less used in atrial fibrillation, pulmonary toxicity is unusual. Other adverse effects during long-term therapy include corneal microdeposits (which often are asymptomatic), hepatic dysfunction, neuromuscular symptoms (most commonly peripheral neuropathy or proximal muscle weakness), photosensitivity, and hypo- or hyperthyroidism. The multiple effects of amiodarone on thyroid function are discussed further in Chapter 39. Treatment consists of withdrawal of the drug and supportive measures, including corticosteroids, for life-threatening pulmonary toxicity; reduction of dosage may be sufficient if the drug is deemed necessary and the adverse effect is not life-threatening. Despite the marked QT prolongation and bradycardia typical of chronic amiodarone therapy, torsades de pointes and other drug-induced tachyarrhythmias are unusual.

Clinical Pharmacokinetics. Amiodarone's oral bioavailability is $\sim 30\%$, presumably because of poor absorption. This incomplete bioavailability is important in calculating equivalent dosing regimens when converting from intravenous to oral therapy. The drug is distributed in lipid; e.g., heart-tissue-to-plasma concentration

ratios of greater than 20:1 and lipid-to-plasma ratios of greater than 300:1 have been reported. After the initiation of amiodarone therapy, increases in refractoriness, a marker of pharmacologic effect, require several weeks to develop. Amiodarone undergoes hepatic metabolism by CYP3A4 to desethyl-amiodarone, a metabolite with pharmacologic effects similar to those of the parent drug. When amiodarone therapy is withdrawn from a patient who has been receiving therapy for several years, plasma concentrations decline with a $t_{1/2}$ of weeks to months. The mechanism whereby amiodarone and desethyl-amiodarone are eliminated is not well established.

A therapeutic plasma amiodarone concentration range of 0.5-2 $\mu\text{g}/\text{mL}$ has been proposed. However, efficacy apparently depends as much on duration of therapy as on plasma concentration, and elevated plasma concentrations do not predict toxicity (Dusman et al., 1990). Because of amiodarone's slow accumulation in tissue, a high-dose oral loading regimen (e.g., 800-1600 mg/day) usually is administered for several weeks before maintenance therapy is started. Maintenance dose is adjusted based on adverse effects and the arrhythmias being treated. If the presenting arrhythmia is life-threatening, dosages of >300 mg/day normally are used unless unequivocal toxicity occurs. On the other hand, maintenance doses of ≤ 200 mg/day are used if recurrence of an arrhythmia would be tolerated, as in patients with atrial fibrillation. Because of its very slow elimination, amiodarone is administered once daily, and omission of one or two doses during chronic therapy rarely results in recurrence of arrhythmia.

Dosage adjustments are not required in hepatic, renal, or cardiac dysfunction. Amiodarone potently inhibits the hepatic metabolism or renal elimination of many compounds. Mechanisms identified to date include inhibition of CYP3A4, CYP2C9 and P-glycoprotein (Chapters 5 and 6). Dosages of warfarin, other anti-arrhythmics (e.g., flecainide, procainamide, quinidine), or digoxin usually require reduction during amiodarone therapy.

Bretylum. Bretylum is a quaternary ammonium compound that prolongs cardiac action potentials and interferes with reuptake of norepinephrine by sympathetic neurons. In the past, bretylum was used to treat VF and prevent its recurrence; the drug is currently not available in the U.S.

Digoxin

DIGOXIN

Digitoxin has H at C12 in place of the OH.

838 *Pharmacologic Effects.* Digitalis glycosides exert positive inotropic effects and are used in heart failure (Chapter 28). Their inotropic action results from increased intracellular Ca^{2+} (Smith, 1988), which also forms the basis for arrhythmias related to cardiac glycoside intoxication. Cardiac glycosides increase phase 4 slope (i.e., increase the rate of automaticity), especially if $[\text{K}]_o$ is low. These drugs (e.g., digoxin) also exert prominent vagotonic actions, resulting in inhibition of Ca^{2+} currents in the AV node and activation of acetylcholine-mediated K^+ currents in the atrium. Thus, the major “indirect” electrophysiologic effects of cardiac glycosides are hyperpolarization, shortening of atrial action potentials, and increases in AV nodal refractoriness. The latter action accounts for the utility of digoxin in terminating re-entrant arrhythmias involving the AV node and in controlling ventricular response in patients with atrial fibrillation. Cardiac glycosides may be especially useful in the latter situation because many such patients have heart failure, which can be exacerbated by other AV nodal blocking drugs such as Ca^{2+} channel blockers or β adrenergic receptor antagonists. However, sympathetic drive is increased markedly in many patients with advanced heart failure, so digitalis is not very effective in decreasing the rate; on the other hand, even a modest decrease in rate can ameliorate heart failure. Similarly, in other conditions in which high sympathetic tone drives rapid AV conduction (e.g., chronic lung disease, thyrotoxicosis), digitalis therapy may be only marginally effective in slowing the rate. In heart transplant patients, in whom innervation has been ablated, cardiac glycosides are ineffective for rate control. Increased sympathetic activity and hypoxia can potentiate digitalis-induced changes in automaticity and DADs, thus increasing the risk of digitalis toxicity. A further complicating feature in thyrotoxicosis is increased digoxin clearance. The major ECG effects of cardiac glycosides are PR prolongation and a nonspecific alteration in ventricular repolarization (manifested by depression of the ST segment), whose underlying mechanism is not well understood.

Adverse Effects. Because of the low therapeutic index of cardiac glycosides, their toxicity is a common clinical problem (Chapter 28). Arrhythmias, nausea, disturbances of cognitive function, and blurred or yellow vision are the usual manifestations. Elevated serum concentrations of digitalis, hypoxia (e.g., owing to chronic lung disease), and electrolyte abnormalities (e.g., hypokalemia, hypomagnesemia, hypercalcemia) predispose patients to digitalis-induced arrhythmias. Although digitalis intoxication can cause virtually any arrhythmia, certain types of arrhythmias are characteristic. Arrhythmias that should raise a strong suspicion of digitalis intoxication are those in which DAD-related tachycardias occur

along with impairment of sinus node or AV nodal function. Atrial tachycardia with AV block is classic, but ventricular bigeminy (sinus beats alternating with beats of ventricular origin), “bidirectional” ventricular tachycardia (a very rare entity), AV junctional tachycardias, and various degrees of AV block also can occur. With severe intoxication (e.g., with suicidal ingestion), severe hyperkalemia owing to poisoning of Na^+, K^+ -ATPase and profound bradyarrhythmias, which may be unresponsive to pacing therapy, are seen. In patients with elevated serum digitalis levels, the risk of precipitating VF by DC cardioversion probably is increased; in those with therapeutic blood levels, DC cardioversion can be used safely.

Minor forms of cardiac glycoside intoxication may require no specific therapy beyond monitoring cardiac rhythm until symptoms and signs of toxicity resolve. Sinus bradycardia and AV block often respond to intravenous atropine, but the effect is transient. Mg^{2+} has been used successfully in some cases of digitalis-induced tachycardia. Any serious arrhythmia should be treated with antidigoxin Fab fragments (DIGIBIND, DIGIFAB), which are highly effective in binding digoxin and digitoxin and greatly enhance their renal excretion (Chapter 28). Serum glycoside concentrations rise markedly with antidigitalis antibodies, but these represent bound (pharmacologically inactive) drug. Temporary cardiac pacing may be required for advanced sinus node or AV node dysfunction. Digitalis exerts direct arterial vasoconstrictor effects, which can be especially deleterious in patients with advanced atherosclerosis who receive intravenous drug; mesenteric and coronary ischemia have been reported.

Clinical Pharmacokinetics. The only digitalis glycoside used in the U.S. is digoxin (LANOXIN). Digitoxin (various generic preparations) also is used for chronic oral therapy outside the U.S. Digoxin tablets are incompletely (75%) bioavailable. In some patients, intestinal microflora may metabolize digoxin, markedly reducing bioavailability. In these patients, higher than usual doses are required for clinical efficacy; toxicity is a serious risk if antibiotics that destroy intestinal microflora are administered. Inhibition of P-glycoprotein (see “Adverse effects and Drug Interactions” under “Dronaderone”) also may play a role in cases of toxicity. Digoxin is 20-30% protein bound. The anti-arrhythmic effects of digoxin can be achieved with intravenous or oral therapy. However, digoxin undergoes relatively slow distribution to effector site(s); therefore, even with intravenous therapy, there is a lag of several hours between drug administration and the development of measurable anti-arrhythmic effects such as PR-interval prolongation or slowing of the ventricular rate in atrial fibrillation. To avoid intoxication, a loading dose of ~0.6-1 mg digoxin is administered over 24 hours. Measurement of postdistribution serum digoxin concentration and adjustment of the daily dose (0.0625-0.5 mg) to maintain concentrations of 0.5-2 ng/mL are useful during chronic digoxin therapy (Table 29-5). Some patients may require and tolerate higher concentrations but with an increased risk of adverse effects.

The elimination $t_{1/2}$ of digoxin ordinarily is ~36 hours, so maintenance doses are administered once daily. Renal elimination of unchanged drug accounts for less than 80% of digoxin elimination. Digoxin doses should be reduced (or dosing interval increased) and serum concentrations monitored closely in patients with impaired excretion owing to renal failure or in patients who

are hypothyroid. Digitoxin undergoes primarily hepatic metabolism and may be useful in patients with fluctuating or advanced renal dysfunction. Digitoxin metabolism is accelerated by drugs such as phenytoin and rifampin that induce hepatic metabolism (Chapter 6). Digitoxin's elimination $t_{1/2}$ is even longer than that of digoxin (~7 days); it is highly protein bound, and its therapeutic range is 10–30 ng/mL.

Amiodarone, quinidine, verapamil, diltiazem, cyclosporine, itraconazole, propafenone, and flecainide decrease digoxin clearance, likely by inhibiting P-glycoprotein, the major route of digoxin elimination (Fromm et al., 1999). New steady-state digoxin concentrations are approached after 4–5 $t_{1/2}$ (i.e., in about a week). Digitalis toxicity results so often with quinidine or amiodarone that it is routine to decrease the dose of digoxin if these drugs are started. In all cases, digoxin concentrations should be measured regularly and the dose adjusted if necessary. Hypokalemia, which can be caused by many drugs (e.g., diuretics, *amphotericin B*, corticosteroids), will potentiate digitalis-induced arrhythmias.

Disopyramide. Disopyramide (NORPACE, others) exerts electrophysiologic effects very similar to those of quinidine, but the drugs have different adverse effect profiles (Morady et al., 1982). Disopyramide is used to maintain sinus rhythm in patients with atrial flutter or atrial fibrillation and to prevent recurrence of ventricular tachycardia or VF. Disopyramide is prescribed as a racemate. Its structure is as follows.

Pharmacologic Actions and Adverse Effects. The *in vitro* electrophysiologic actions of *S*-(+)-disopyramide are similar to those of quinidine. The *R*-(-)-enantiomer produces similar Na^+ channel block but does not prolong cardiac action potentials. Unlike quinidine, racemic disopyramide is not an α adrenergic receptor antagonist, but it does exert prominent anticholinergic actions that account for many of its adverse effects. These include precipitation of glaucoma, constipation, dry mouth, and urinary retention; the latter is most common in males with prostatism but also can occur in females. Disopyramide commonly depresses contractility, which can precipitate heart failure (Podrid et al., 1980) and also can cause torsades de pointes.

Clinical Pharmacokinetics. Disopyramide is well absorbed. Binding to plasma proteins is concentration dependent, so a small increase in

total concentration may represent a disproportionately larger increase in free drug concentration (Lima et al., 1981). Disopyramide is eliminated by both hepatic metabolism (to a weakly active metabolite) and renal excretion of unchanged drug. The dose should be reduced in patients with renal dysfunction. Higher than usual dosages may be required in patients receiving drugs that induce hepatic metabolism, such as phenytoin.

Dofetilide. Dofetilide (TIKOSYN) is a potent and “pure” I_{Kr} blocker. As a result of this specificity, it has virtually no extracardiac pharmacologic effects. Dofetilide is effective in maintaining sinus rhythm in patients with atrial fibrillation. In the DIAMOND studies (Torp-Pedersen et al., 1999), dofetilide did not affect mortality in patients with advanced heart failure or in those convalescing from acute MI. Dofetilide currently is available through a restricted distribution system that includes only physicians, hospitals, and other institutions that have received special educational programs covering proper dosing and in-hospital treatment initiation.

Adverse Effects. Torsades de pointes occurred in 1–3% of patients in clinical trials where strict exclusion criteria (e.g., hypokalemia) were applied and continuous ECG monitoring was used to detect marked QT prolongation in the hospital. The incidence of this adverse effect during more widespread use of the drug, marketed since 2000, is unknown. Other adverse effects were no more common than with placebo during premarketing clinical trials.

Clinical Pharmacokinetics. Most of a dose of dofetilide is excreted unchanged by the kidneys. In patients with mild to moderate renal failure, decreases in dosage based on creatinine clearance are required to minimize the risk of torsades de pointes. The drug should not be used in patients with advanced renal failure or with inhibitors of renal cation transport. Dofetilide also undergoes minor hepatic metabolism.

Dronedarone. Dronedarone (MULTAQ) is a noniodinated benzofuran derivative of amiodarone that was approved by the FDA in 2009 for the treatment of atrial fibrillation and atrial flutter. In randomized placebo-controlled trials, it was effective in maintaining sinus rhythm and reducing the rate of ventricular response during episodes of atrial fibrillation (drug reviewed by Patel et al., 2009). Compared to amiodarone, dronedarone treatment is associated with significantly fewer adverse events, but it also is significantly less effective in maintaining sinus rhythm. Dronedarone reduces morbidity and mortality in patients with high-risk

840 atrial fibrillation. However, dronedarone *increases* mortality in patients with severe heart failure and is contraindicated in patients with NYHA class 4 heart failure and in patients with a recent decompensation of heart failure requiring hospitalization.

Pharmacologic Effects. Similar to amiodarone, dronedarone is a potent blocker of multiple ion currents, including the rapidly activating delayed-rectifier K⁺ current (I_{Kr}), the slowly activating delayed-rectifier K⁺ current (I_{Ks}), the inward rectifier K⁺ current (I_{K1}), the acetylcholine activated K⁺ current, the peak Na⁺ current, and the L-type Ca²⁺ current. It has stronger antiadrenergic effects than amiodarone.

Adverse Effects and Drug Interactions. The most common adverse reactions are diarrhea, nausea, abdominal pain, vomiting, and asthenia. Dronedarone causes dose-dependent prolongation of QTc interval, but torsades de pointes is rare. Dronedarone is metabolized by CYP3A and is a moderate inhibitor of CYP3A, CYP2D6, and P-glycoprotein. A potent CYP3A4 inhibitor such as ketoconazole may increase dronedarone exposure by as much as 25-fold. Consequently, dronedarone should not be co-administered with potent CYP3A4 inhibitors (e.g., antifungals, macrolide antibiotics). Co-administration with other drugs metabolized by CYP2D6 (e.g., metoprolol) or P-glycoprotein (e.g., digoxin) may result in increased drug concentrations.

Esmolol. (BREVIBLOC, others) is a β₁-selective agent that is metabolized by erythrocyte esterases and so has a very short elimination t_{1/2} (9 minutes). Intravenous esmolol is useful in clinical situations in which immediate β adrenergic blockade is desired (e.g., for rate control of rapidly conducted atrial fibrillation). Because of esmolol's very rapid elimination, adverse effects due to β adrenergic blockade—should they occur—dissipate rapidly when the drug is stopped. Although methanol is a metabolite of esmolol, methanol intoxication has not been a clinical problem. Its pharmacology is described in detail in Chapter 12.

Flecainide. The effects of flecainide (TAMBOCOR, others) therapy are thought to be attributable to the drug's very long τ_{recovery} from Na⁺ channel block (Roden and Woosley, 1986). In the CAST study, flecainide increased mortality in patients convalescing from MI (CAST Investigators, 1989). However, it continues to be approved for the maintenance of sinus rhythm in patients with supraventricular arrhythmias, including atrial fibrillation, in whom structural heart disease is

absent (Anderson et al., 1989; Henthorn et al., 1991) and for life-threatening ventricular arrhythmias, such as sustained ventricular tachycardia.

Pharmacologic Effects. Flecainide blocks Na⁺ current and delayed-rectifier K⁺ current (I_{Kr}) *in vitro* at similar concentrations, 1 to 2 μM (Ikeda et al., 1985; Follmer and Colatsky, 1990). It also blocks Ca²⁺ currents *in vitro*. APD is shortened in Purkinje cells, probably owing to block of late-opening Na⁺ channels, but prolonged in ventricular cells, probably owing to block of delayed-rectifier current (Ikeda et al., 1985). Flecainide does not cause EADs *in vitro* but has been associated with rare cases of torsades de pointes. In atrial tissue, flecainide disproportionately prolongs action potentials at fast rates, an especially desirable anti-arrhythmic drug effect; this effect contrasts with that of quinidine, which prolongs atrial action potentials to a greater extent at slower rates (Wang et al., 1990). Flecainide prolongs the duration of PR, QRS, and QT intervals even at normal heart rates. Flecainide also is an open channel blocker of RyR2 Ca²⁺ release channels and prevents arrhythmogenic Ca²⁺ release from the sarcoplasmic reticulum in isolated myocytes (Hilliard et al., 2010). The blockade of the RyR2 channel by flecainide targets directly the underlying molecular defect in patients with mutations in the ryanodine receptor and cardiac calsequestrin, which may explain why flecainide suppresses ventricular arrhythmias in CPVT patients refractory to standard drug therapy (Watanabe et al., 2009).

Adverse Effects. Flecainide produces few subjective complaints in most patients; dose-related blurred vision is the most common non-cardiac adverse effect. It can exacerbate congestive heart failure in patients with depressed left ventricular performance. The most serious adverse effects are provocation or exacerbation of potentially lethal arrhythmias. These include acceleration of ventricular rate in patients with atrial flutter, increased frequency of episodes of re-entrant ventricular tachycardia, and increased mortality in patients convalescing from MI (Crijns et al., 1988; CAST Investigators, 1989). As discussed earlier, it is likely that all these effects can be attributed to Na⁺ channel block. Flecainide also can cause heart block in patients with conduction system disease.

Clinical Pharmacokinetics. Flecainide is well absorbed. The elimination t_{1/2} is shorter with urinary acidification (10 hours) than with urinary alkalinization (17 hours), but it is nevertheless sufficiently long to allow dosing twice daily (Table 29–5). Elimination occurs by both renal excretion of unchanged drug and hepatic metabolism

to inactive metabolites. The latter is mediated by the polymorphically distributed enzyme CYP2D6 (Gross et al., 1989) (Chapter 6). However, even in patients in whom this pathway is absent because of genetic polymorphism or inhibition by other drugs (i.e., quinidine, fluoxetine), renal excretion ordinarily is sufficient to prevent drug accumulation. In the rare patient with renal dysfunction and lack of active CYP2D6, flecainide may accumulate to toxic plasma concentrations. Flecainide is a racemate, but there are no differences in the electrophysiologic effects or disposition kinetics of its enantiomers (Kroemer et al., 1989). Some reports have suggested that plasma flecainide concentrations greater than 1 $\mu\text{g/mL}$ should be avoided to minimize the risk of flecainide toxicity; however, in susceptible patients, the adverse electrophysiologic effects of flecainide therapy can occur at therapeutic plasma concentrations.

Ibutilide. Ibutilide (CORVERT) is an I_{Kr} blocker that in some systems also activates an inward Na^+ current (Murray, 1998). The action potential–prolonging effect of the drug may arise from either mechanism.

Ibutilide is administered as a rapid infusion (1 mg over 10 minutes) for the immediate conversion of atrial fibrillation or flutter to sinus rhythm. The drug's efficacy rate is higher in patients with atrial flutter (50-70%) than in those with atrial fibrillation (30-50%). In atrial fibrillation, the conversion rate is lower in those in whom the arrhythmia has been present for weeks or months compared with those in whom it has been present for days. The major toxicity with ibutilide is torsades de pointes, which occurs in up to 6% of patients and requires immediate cardioversion in up to one-third of these. The drug undergoes extensive first-pass metabolism and so is not used orally. It is eliminated by hepatic metabolism and has a $t_{1/2}$ of 2-12 hours (average of 6 hours).

Lidocaine. Lidocaine (XYLOCAINE, others) is a local anesthetic that also is useful in the acute intravenous therapy of ventricular arrhythmias. When lidocaine was administered to all patients with suspected MI, the incidence of VF was reduced (Lie et al., 1974). However, survival to hospital discharge tended to be decreased (Hine et al., 1989), perhaps because of lidocaine-exacerbated heart block or congestive heart failure. Therefore, lidocaine no longer is administered routinely to all patients in coronary care units.

Pharmacologic Effects. Lidocaine blocks both open and inactivated cardiac Na^+ channels. *In vitro* studies suggest that lidocaine-induced block reflects an increased likelihood that the Na^+ channel protein assumes a nonconducting conformation in the presence of drug (Balsler et al., 1996). Recovery from block is very rapid, so lidocaine exerts greater effects in depolarized (e.g., ischemic) and/or rapidly driven tissues. Lidocaine is not useful in atrial arrhythmias possibly because atrial action potentials are so short that the Na^+ channel is in the inactivated state only briefly compared with diastolic (recovery) times, which are relatively long. In some studies, lidocaine increased current through inward rectifier channels; however, the clinical significance of this effect is not known. Lidocaine can hyperpolarize Purkinje fibers depolarized by low $[\text{K}]_o$ or stretch; the resulting increased conduction velocity may be anti-arrhythmic in re-entry.

Lidocaine decreases automaticity by reducing the slope of phase 4 and altering the threshold for excitability. APD usually is unaffected or is shortened; such shortening may be due to block of the few Na^+ channels that inactivate late during the cardiac action potential. Lidocaine usually exerts no significant effect on PR or QRS duration; QT is unaltered or slightly shortened. The drug exerts little effect on hemodynamic function, although rare cases of lidocaine-associated exacerbations of heart failure have been reported, especially in patients with very poor left ventricular function. For additional information on lidocaine, see Chapter 20.

Adverse Effects. When a large intravenous dose of lidocaine is administered rapidly, seizures can occur. When plasma concentrations of the drug rise slowly above the therapeutic range, as may occur during maintenance therapy, tremor, dysarthria, and altered levels of consciousness are more common. Nystagmus is an early sign of lidocaine toxicity.

Clinical Pharmacokinetics. Lidocaine is well absorbed but undergoes extensive though variable first-pass hepatic metabolism; thus, oral use of the drug is inappropriate. In theory, therapeutic plasma concentrations of lidocaine may be maintained by intermittent intramuscular administration, but the intravenous route is preferred (Table 29-5). Lidocaine's metabolites, glycine xylidide (GX) and monoethyl GX, are less potent as Na^+ channel blockers than the parent drug. GX and lidocaine appear to compete for access to the Na^+ channel, suggesting that with infusions during which GX accumulates, lidocaine's efficacy may be diminished (Bennett et al., 1988). With infusions lasting longer than 24 hours, the clearance of lidocaine falls—an effect that has been attributed to competition between parent drug and metabolites for access to hepatic drug-metabolizing enzymes.

Plasma concentrations of lidocaine decline biexponentially after a single intravenous dose, indicating that a multicompartment model is necessary to analyze lidocaine disposition. The initial drop in plasma lidocaine following intravenous administration occurs rapidly, with a $t_{1/2}$ of ~8 minutes, and represents distribution from the central compartment to peripheral tissues. The terminal elimination $t_{1/2}$, usually ~110 minutes, represents drug elimination by hepatic metabolism. Lidocaine's efficacy depends on maintenance of therapeutic plasma concentrations in the central compartment. Therefore, the administration of a single bolus dose of lidocaine can result in transient arrhythmia suppression that dissipates rapidly as the drug is distributed and concentrations in the central compartment

fall. To avoid this distribution-related loss of efficacy, a loading regimen of 3-4 mg/kg over 20-30 minutes is used—e.g., an initial 100 mg followed by 50 mg every 8 minutes for three doses. Subsequently, stable concentrations can be maintained in plasma with an infusion of 1-4 mg/min, which replaces drug removed by hepatic metabolism. The time to steady-state lidocaine concentrations is ~8-10 hours. If the maintenance infusion rate is too low, arrhythmias may recur hours after the institution of apparently successful therapy. On the other hand, if the rate is too high, toxicity may result. In either case, routine measurement of plasma lidocaine concentration at the time of expected steady state is useful in adjusting the maintenance infusion rate.

In heart failure, the central volume of distribution is decreased, so the total loading dose should be decreased. Because lidocaine clearance also is decreased, the rate of the maintenance infusion should be decreased. Lidocaine clearance also is reduced in hepatic disease, during treatment with *cimetidine* or β blockers and during prolonged infusions (Nies et al., 1976). Frequent measurement of plasma lidocaine concentration and dose adjustment to ensure that plasma concentrations remain within the therapeutic range (1.5-5 $\mu\text{g/mL}$) are necessary to minimize toxicity in these settings. Lidocaine is bound to the acute-phase reactant α_1 -acid glycoprotein. Diseases such as acute MI are associated with increases in β_1 -acid glycoprotein and protein binding and hence a decreased proportion of free drug. These findings may explain why some patients require and tolerate higher than usual total plasma lidocaine concentrations to maintain anti-arrhythmic efficacy (Kessler et al., 1984).

Magnesium. The intravenous administration of 1-2 g MgSO_4 reportedly is effective in preventing recurrent episodes of torsades de pointes, even if the serum Mg^{2+} concentration is normal (Tzivoni et al., 1988). However, controlled studies of this effect have not been performed. The mechanism of action is unknown because the QT interval is not shortened; an effect on the inward current, possibly a Ca^{2+} current, responsible for the triggered upstroke arising from EADs (*black arrow*, Figure 29-6B) is possible. Intravenous Mg^{2+} also has been used successfully in arrhythmias related to digitalis intoxication.

Large placebo-controlled trials of intravenous magnesium to improve outcome in acute MI have yielded conflicting results (Woods and Fletcher, 1994; ISIS-4 Collaborative Group, 1995). Although oral Mg^{2+} supplements may be useful in preventing hypomagnesemia, there is no evidence that chronic Mg^{2+} ingestion exerts a direct anti-arrhythmic action.

Mexiletine. Mexiletine (MEXITIL, others) is an analog of lidocaine that has been modified to reduce first-pass hepatic metabolism and permit chronic oral therapy (Campbell, 1987). The electrophysiologic actions are similar to those of lidocaine. Tremor and nausea, the major dose-related adverse effects, can be minimized by taking the drugs with food.

Mexiletine undergoes hepatic metabolism, which is inducible by drugs such as phenytoin. Mexiletine is approved for treating ventricular arrhythmias; combinations of mexiletine with quinidine or sotalol may increase efficacy while reducing adverse effects. *In vitro* studies and clinical case reports have suggested a role for mexiletine (or flecainide) in correcting the aberrant late inward Na^+ current in congenital LQT3 (Napolitano et al., 2006).

Procainamide. Procainamide (PROCAN SR, others) is an analog of the local anesthetic procaine (Chapter 20). It exerts electrophysiologic effects similar to those of quinidine but lacks quinidine's vagolytic and α adrenergic blocking activity. Procainamide is better tolerated than quinidine when given intravenously. Loading and maintenance intravenous infusions are used in the acute therapy of many supraventricular and ventricular arrhythmias. However, long-term oral treatment is poorly tolerated and often is stopped owing to adverse effects.

Pharmacologic Effects. Procainamide is a blocker of open Na^+ channels with an intermediate τ_{recovery} from block. It also prolongs cardiac action potentials in most tissues, probably by blocking outward K^+ current(s). Procainamide decreases automaticity, increases refractory periods, and slows conduction. Its major metabolite, *N*-acetyl procainamide, lacks the Na^+ channel-blocking activity of the parent drug but is equipotent in prolonging action potentials. Because the plasma concentrations of *N*-acetyl procainamide often exceed those of procainamide, increased refractoriness and QT prolongation during chronic procainamide therapy may be partly attributable to the metabolite. However, it is the parent drug that slows conduction and produces QRS-interval prolongation. Although hypotension may occur at high plasma concentrations, this effect usually is attributable to ganglionic blockade rather than to any negative inotropic effect, which is minimal.

Adverse Effects. Hypotension and marked slowing of conduction are major adverse effects of high concentrations ($>10 \mu\text{g/mL}$) of procainamide, especially during intravenous use. Dose-related nausea is frequent during oral therapy and may be attributable in part to high plasma concentrations of *N*-acetyl procainamide. Torsades de pointes can occur, particularly when plasma concentrations of

N-acetyl procainamide rise to >30 $\mu\text{g/mL}$. Procainamide produces potentially fatal bone marrow aplasia in 0.2% of patients; the mechanism is not known, but high plasma drug concentrations are not suspected.

During long-term therapy, most patients will develop biochemical evidence of the drug-induced lupus syndrome, such as circulating antinuclear antibodies (Woosley et al., 1978). Therapy need not be interrupted merely because of the presence of antinuclear antibodies. However, 25-50% of patients eventually develop symptoms of the lupus syndrome; common early symptoms are rash and small-joint arthralgias. Other symptoms of lupus, including pericarditis with tamponade, can occur, although renal involvement is unusual. The lupuslike symptoms resolve on cessation of therapy or during treatment with *N*-acetyl procainamide (see next section).

Clinical Pharmacokinetics. Procainamide is eliminated rapidly ($t_{1/2} = 3\text{-}4$ hours) by both renal excretion of unchanged drug and hepatic metabolism. The major pathway for hepatic metabolism is conjugation by *N*-acetyl transferase, whose activity is determined genetically, to form *N*-acetyl procainamide. *N*-Acetyl procainamide is eliminated by renal excretion ($t_{1/2} = 6\text{-}10$ hours) and is not significantly converted back to procainamide. Because of the relatively rapid elimination rates of both the parent drug and its major metabolite, oral procainamide usually is administered as a slow-release formulation. In patients with renal failure, procainamide and/or *N*-acetyl procainamide can accumulate to potentially toxic plasma concentrations. Reduction of procainamide dose and dosing frequency and monitoring of plasma concentrations of both compounds are required in this situation. Because the parent drug and metabolite exert different pharmacologic effects, the past practice of using the sum of their concentrations to guide therapy is inappropriate.

In individuals who are “slow acetylators,” the procainamide-induced lupus syndrome develops more often and earlier during treatment than among rapid acetylators (Woosley et al., 1978). In addition, the symptoms of procainamide-induced lupus resolve during treatment with *N*-acetyl procainamide. Both these findings support results of *in vitro* studies, suggesting that it is chronic exposure to the parent drug (or an oxidative metabolite) that results in the lupus syndrome; these findings also provided one rationale for the further development of *N*-acetyl procainamide and its analogs as anti-arrhythmic agents (Roden, 1993).

Propafenone. Propafenone (RYTHMOL, others) is a Na^+ channel blocker with a relatively slow time constant for recovery from block (Funck-Brentano et al., 1990). Some data suggest that, like flecainide, propafenone also blocks K^+ channels. Its major electrophysiologic effect is to slow conduction in fast-response tissues. The drug is prescribed as a racemate; although the enantiomers do not differ in their Na^+ channel-blocking properties, *S*-(+)-propafenone is a β receptor antagonist *in vitro* and in some patients. Propafenone prolongs PR and QRS durations. Chronic therapy with oral propafenone is used to maintain sinus rhythm in patients with supraventricular tachycardias, including atrial fibrillation; like other Na^+ channel blockers, it

also can be used in ventricular arrhythmias, but with only modest efficacy.

Adverse Effects. Adverse effects during propafenone therapy include acceleration of ventricular response in patients with atrial flutter, increased frequency or severity of episodes of re-entrant ventricular tachycardia, exacerbation of heart failure, and the adverse effects of β adrenergic blockade, such as sinus bradycardia and bronchospasm (see earlier in this chapter and Chapter 12).

Clinical Pharmacokinetics. Propafenone is well absorbed and is eliminated by both hepatic and renal routes. The activity of CYP2D6, an enzyme that functionally is absent in $\sim 7\%$ of Caucasians and African Americans (Chapter 6), is a major determinant of plasma propafenone concentration and thus the clinical action of the drug. In most subjects (“extensive metabolizers”), propafenone undergoes extensive first-pass hepatic metabolism to 5-hydroxy propafenone, a metabolite equipotent to propafenone as a Na^+ channel blocker but much less potent as a β adrenergic receptor antagonist. A second metabolite, *N*-desalkyl propafenone, is formed by non-CYP2D6-mediated metabolism and is a less potent blocker of Na^+ channels and β adrenergic receptors. CYP2D6-mediated metabolism of propafenone is saturable, so small increases in dose can increase plasma propafenone concentration disproportionately. In “poor metabolizer” subjects, in whom functional CYP2D6 is absent, first-pass hepatic metabolism is much less than in extensive metabolizers, and plasma propafenone concentrations will be much higher after an equal dose. The incidence of adverse effects during propafenone therapy is significantly higher in poor metabolizers.

CYP2D6 activity can be inhibited markedly by a number of drugs, including quinidine and fluoxetine. In extensive metabolizer subjects receiving such drugs or in poor metabolizer subjects, plasma propafenone concentrations of more than 1 $\mu\text{g/mL}$ are associated with clinical effects of β receptor blockade, such as reduction of exercise heart rate (Lee et al., 1990). It is recommended that dosage in patients with moderate to severe liver disease should be reduced to $\sim 20\text{-}30\%$ of the usual dose, with careful monitoring. It is not known if propafenone doses must be decreased in patients with renal disease. A slow-release formulation allows twice-daily dosing.

Quinidine. As early as the 18th century, the bark of the cinchona plant was used to treat “rebellious palpitations” (Levy and Azoulay, 1994). Studies in the early 20th century identified quinidine, a diastereomer of the antimalarial quinine, as the most potent of the anti-arrhythmic substances extracted from the cinchona plant, and by the 1920s, quinidine was used as an anti-arrhythmic agent. Quinidine is used to maintain sinus rhythm in patients with atrial flutter or atrial fibrillation and to prevent recurrence of ventricular tachycardia or VF (Grace and Camm, 1998).

Pharmacologic Effects. Quinidine blocks Na^+ current and multiple cardiac K^+ currents. It is an open-state blocker of Na^+ channels, with a τ_{recovery} in the intermediate (~ 3 s) range; as a consequence, QRS duration increases modestly, usually by 10–20%, at therapeutic dosages. At therapeutic concentrations, quinidine commonly prolongs the QT interval up to 25%, but the effect is highly variable. At concentrations as low as $1 \mu\text{M}$, quinidine blocks Na^+ current and the rapid component of delayed rectifier (I_{Kr}); higher concentrations block the slow component of delayed rectifier, inward rectifier, transient outward current, and L-type Ca^{2+} current.

Quinidine's Na^+ channel-blocking properties result in an increased threshold for excitability and decreased automaticity. As a consequence of its K^+ channel-blocking actions, quinidine prolongs action potentials in most cardiac cells, most prominently at slow heart rates. In some cells, such as midmyocardial cells and Purkinje cells, quinidine consistently elicits EADs at slow heart rates, particularly when $[\text{K}]_o$ is low (Priori et al., 1999). Quinidine prolongs refractoriness in most tissues, probably as a result of both prolongation of APD and Na^+ channel blockade.

In intact animals and humans, quinidine also produces β receptor blockade and vagal inhibition. Thus, the intravenous use of quinidine is associated with marked hypotension and sinus tachycardia. Quinidine's vagolytic effects tend to inhibit its direct depressant effect on AV nodal conduction, so the effect of drug on the PR interval is variable. Moreover, quinidine's vagolytic effect can result in increased AV nodal transmission of atrial tachycardias such as atrial flutter (Table 29–1).

Adverse Effects—Noncardiac. Diarrhea is the most common adverse effect during quinidine therapy, occurring in 30–50% of patients; the mechanism is not known. Diarrhea usually occurs within the first several days of quinidine therapy but can occur later. Diarrhea-induced hypokalemia may potentiate torsades de pointes due to quinidine.

A number of immunologic reactions can occur during quinidine therapy. The most common is thrombocytopenia, which can be severe but resolves rapidly with discontinuation of the drug.

Hepatitis, bone marrow depression, and lupus syndrome occur rarely. None of these effects is related to elevated plasma quinidine concentrations.

Quinidine also can produce cinchonism, a syndrome that includes headache and tinnitus. In contrast to other adverse responses to quinidine therapy, cinchonism usually is related to elevated plasma quinidine concentrations and can be managed by dose reduction.

Adverse Effects—Cardiac. Of patients receiving quinidine therapy, 2–8% will develop marked QT-interval prolongation and torsades de pointes. In contrast to effects of sotalol, *N*-acetyl procainamide, and many other drugs, quinidine-associated torsades de pointes generally occurs at therapeutic or even subtherapeutic plasma concentrations. The reasons for individual susceptibility to this adverse effect are not known.

At high plasma concentrations of quinidine, marked Na^+ channel block can occur, with resulting ventricular tachycardia. This adverse effect occurs when very high doses of quinidine are used to try to convert atrial fibrillation to normal rhythm; this aggressive approach to quinidine dosing has been abandoned, and quinidine-induced ventricular tachycardia is unusual.

Quinidine can exacerbate heart failure or conduction system disease. However, in most patients with congestive heart failure, quinidine is well tolerated, perhaps because of its vasodilating actions.

Clinical Pharmacokinetics. Quinidine is well absorbed and is 80% bound to plasma proteins, including albumin and, like lidocaine, the acute-phase reactant β_1 -acid glycoprotein. As with lidocaine, greater than usual doses (and total plasma quinidine concentrations) may be required to maintain therapeutic concentrations of free quinidine in high-stress states such as acute MI (Kessler et al., 1984). Quinidine undergoes extensive hepatic oxidative metabolism, and $\sim 20\%$ is excreted unchanged by the kidneys. One metabolite, 3-hydroxyquinidine, is nearly as potent as quinidine in blocking cardiac Na^+ channels and prolonging cardiac action potentials. Concentrations of unbound 3-hydroxyquinidine equal to or exceeding those of quinidine are tolerated by some patients. Other metabolites are less potent than quinidine, and their plasma concentrations are lower; thus, they are unlikely to contribute significantly to the clinical effects of quinidine.

There is substantial individual variability in the range of dosages required to achieve therapeutic plasma concentrations of 2–5 $\mu\text{g}/\text{mL}$. Some of this variability may be assay dependent because not all assays exclude quinidine metabolites. In patients with advanced renal disease or congestive heart failure, quinidine clearance is decreased only modestly. Thus, dosage requirements in these patients are similar to those in other patients.

Drug Interactions. Quinidine is a potent inhibitor of CYP2D6. As a result, the administration of quinidine to patients receiving drugs that undergo extensive CYP2D6-mediated metabolism may result in altered drug effects owing to accumulation of parent drug and failure of metabolite formation. For example, inhibition of CYP2D6-mediated metabolism of *codeine* to its active metabolite *morphine* results in decreased analgesia. On the other hand, inhibition of CYP2D6-mediated metabolism of propafenone results in elevated plasma propafenone concentrations and increased β adrenergic receptor blockade. Quinidine reduces the clearance of digoxin; inhibition of P-glycoprotein-mediated digoxin transport has been implicated (Fromm et al., 1999).

Quinidine metabolism is induced by drugs such as *phenobarbital* and *phenytoin* (Data et al., 1976). In patients receiving these agents, very high doses of quinidine may be required to achieve therapeutic concentrations. If therapy with the inducing agent is then stopped, quinidine concentrations may rise to very high levels, and its dosage must be adjusted downward. *Cimetidine* and *verapamil* also elevate plasma quinidine concentrations, but these effects usually are modest.

Sotalol. Sotalol (BETAPACE, BETAPACE AF) is a nonselective β adrenergic receptor antagonist that also prolongs cardiac action potentials by inhibiting delayed-rectifier and possibly other K^+ currents (Hohnloser and Woosley, 1994). Sotalol is prescribed as a racemate; the L-enantiomer is a much more potent β adrenergic receptor antagonist than the D-enantiomer, but the two are equipotent as K^+ channel blockers. Its structure is shown below:

In the U.S., sotalol is an orphan drug approved for use in patients with both ventricular tachyarrhythmias (BETAPACE) and atrial fibrillation or flutter (BETAPACE AF). Clinical trials suggest that it is at least as effective as most Na^+ channel blockers in ventricular arrhythmias (Mason, 1993).

Sotalol prolongs APD throughout the heart and QT interval on the ECG. It decreases automaticity, slows AV nodal conduction, and prolongs AV refractoriness by blocking both K^+ channels and β adrenergic receptors, but it exerts no effect on conduction velocity in fast-response tissue. Sotalol causes EADs and triggered activity *in vitro* and can cause torsades de pointes, especially when the serum K^+ concentration is low. Unlike the situation with quinidine, the incidence of torsades de pointes (1.5-2% incidence) seems to depend on the dose of sotalol; indeed, torsades de pointes is the major toxicity with sotalol overdose. Occasional cases occur at low dosages, often in patients with renal dysfunction, because sotalol is eliminated by renal excretion of unchanged drug. The other adverse effects of sotalol therapy are those associated with β receptor blockade (see earlier in this chapter and Chapter 12).

Vernakalant. Vernakalant (RSD1235, proposed trade-name KYNAPID) is an investigational inhibitor of several ion channels that are preferentially expressed in the atria, in particular the ultra-rapidly activating delayed-rectifier K^+ current (I_{Kur} encoded by $Kv1.5$).

To a lesser extent, it also blocks the rapidly activating delayed-rectifier K^+ current (I_{Kr}), the transient outward K^+ current (I_{to}), the Na^+ current, and the L-type Ca^{2+} current. Vernakalant selectively prolongs the atrial refractory period without significantly affecting ventricular refractoriness.

Vernakalant is effective for converting atrial fibrillation of short duration to sinus rhythm (Roy et al., 2008). Vernakalant (3 mg/kg) is administered as a 10-minute infusion, followed by a second infusion of 2 mg/kg 15 minutes later if AF is not terminated. Vernakalant is not effective in converting long-duration AF (>7 days) or atrial flutter. The intravenous formulation of vernakalant was recommended for approval by an FDA advisory committee in 2008, but the drug has not received FDA approval at the time of this printing. An oral formulation is currently in clinical trials for the maintenance of sinus rhythm in patients with chronic atrial fibrillation. Vernakalant seems to have little or no proarrhythmic effects, with no reported cases of torsades de pointes in phase II and III studies.

Vernakalant is metabolized rapidly by CYP2D6 to one major and inactive metabolite (RSD1385) via 4-O-demethylation (Mao et al., 2009). There appears to be little difference in C_{max} between extensive and poor 2D6 metabolizers after single-dose IV administration. However, average $t_{1/2}$ of vernakalant was much longer in two poor metabolizers (8.5 hours) than in 10 extensive metabolizers (2.7 hours). This profound difference in $t_{1/2}$ will be important if vernakalant is used chronically to prevent atrial fibrillation.

30 chapter

Blood Coagulation and Anticoagulant, Fibrinolytic, and Antiplatelet Drugs

Jeffrey I. Weitz

The physiological systems that control the fluidity of blood are both complex and elegant. Blood must remain fluid within the vasculature and yet clot quickly when exposed to subendothelial surfaces at sites of vascular injury. When intravascular thrombi form, rapid activation of the fibrinolytic system restores fluidity. Under normal circumstances, a delicate balance between coagulation and fibrinolysis prevents both thrombosis and hemorrhages. Alteration of this balance in favor of coagulation results in thrombosis.

Composed of platelet aggregates, fibrin, and trapped red blood cells, thrombi can form in arteries or veins. Because of the predominance of platelets and fibrin in thrombi, anti-thrombotic drugs used to treat thrombosis include antiplatelet drugs, which inhibit platelet activation or aggregation, anticoagulants, which attenuate fibrin formation, and fibrinolytic agents, which degrade fibrin. These agents have very different mechanisms of action, but because they target key steps in clot formation, all anti-thrombotic drugs increase the risk of bleeding. With these drugs, toxicity typically represents an extension of the therapeutic effects. The more potent the agent, the greater the risk of bleeding.

This chapter reviews the agents commonly used for controlling blood fluidity, including:

- The parenteral anticoagulant heparin and its derivatives, which activate a natural inhibitor of coagulant proteases
- The coumarin anticoagulants, which block multiple steps in the coagulation cascade
- Fibrinolytic agents, which degrade thrombi
- Antiplatelet agents, including aspirin, thienopyridines, and glycoprotein (GP) IIb/IIIa inhibitors

In addition, some of the newer anti-thrombotic drugs in advanced stages of development also are described.

OVERVIEW OF HEMOSTASIS: PLATELET FUNCTION, BLOOD COAGULATION, AND FIBRINOLYSIS

Hemostasis is the cessation of blood loss from a damaged vessel. Platelets first adhere to macromolecules in the subendothelial regions of the injured blood vessel, where they become activated. Adherent platelets release substances that activate nearby platelets, thereby recruiting them to the site of injury. Activated platelets then aggregate to form the primary hemostatic plug.

In addition to triggering platelet adhesion and activation, vessel wall injury also exposes tissue factor (TF), which initiates the coagulation system. Platelets support and enhance activation of the coagulation system by providing a surface onto which clotting factors assemble and by releasing stored clotting factors. This results in a burst of thrombin (factor IIa) generation. Thrombin then converts fibrinogen to fibrin, which reinforces the platelet aggregate and anchors it to the vessel wall. In addition, because it serves as a potent platelet agonist, thrombin also amplifies platelet activation and aggregation.

Later, as wound healing occurs, the platelet aggregates and fibrin clots are degraded. The processes of platelet aggregation and blood coagulation are summarized in Figures 30–1 and 30–2 (see also the animation on this book's website). The pathway of clot removal, fibrinolysis, is shown in Figure 30–3, along with sites of action of fibrinolytic agents.

Figure 30–1. Platelet adhesion and aggregation. GPIa/IIa and GPIb are platelet receptors that bind to collagen and von Willebrand factor (vWF), causing platelets to adhere to the subendothelium of a damaged blood vessel. PAR1 and PAR4 are protease-activated receptors that respond to thrombin (IIa); P2Y₁ and P2Y₁₂ are receptors for ADP; when stimulated by agonists, these receptors activate the fibrinogen-binding protein GPIIb/IIIa and cyclooxygenase-1 (COX-1) to promote platelet aggregation and secretion. Thromboxane A₂ (TxA₂) is the major product of COX-1 involved in platelet activation. Prostaglandin I₂ (prostacyclin, PGI₂), synthesized by endothelial cells, inhibits platelet activation.

Figure 30–2. Major reactions of blood coagulation. Shown are interactions among proteins of the “extrinsic” (tissue factor and factor VII), “intrinsic” (factors IX and VIII), and “common” (factors X, V, and II) coagulation pathways that are important *in vivo*. Boxes enclose the coagulation factor zymogens (indicated by Roman numerals); the rounded boxes represent the active proteases. TF, tissue factor. Activated coagulation factors are followed by the letter “a”: II, prothrombin; IIa, thrombin.

Figure 30–3. Fibrinolysis. Endothelial cells secrete tissue plasminogen activator (t-PA) at sites of injury. t-PA binds to fibrin and converts plasminogen to plasmin, which digests fibrin. Plasminogen activator inhibitors-1 and -2 (PAI-1, PAI-2) inactivate t-PA; α_2 -antiplasmin (α_2 -AP) inactivates plasmin

Coagulation involves a series of zymogen activation reactions, as shown in Figure 30–2 (Mann et al., 2003). At each stage, a precursor protein, or *zymogen*, is converted to an active protease by cleavage of one or more peptide bonds in the precursor molecule. The components at each stage include a protease from the preceding stage, a zymogen, a non-enzymatic protein cofactor, Ca^{2+} , and an organizing surface that is provided by a phospholipid emulsion *in vitro* or by activated platelets *in vivo*. The final protease generated is thrombin.

Conversion of Fibrinogen to Fibrin. Fibrinogen, a 340,000-Da protein, is a dimer, each half of which consists of three pairs of polypeptide chains (designated $\text{A}\alpha$, $\text{B}\beta$, and γ). Disulfide bonds covalently link the chains and the two halves of the molecule together. Thrombin converts fibrinogen to fibrin monomers by releasing fibrinopeptide A (a 16-amino acid fragment) and fibrinopeptide B (a 14-amino acid fragment) from the amino termini of the $\text{A}\alpha$ and $\text{B}\beta$ chains, respectively. Removal of the fibrinopeptides creates new amino termini, which fit into pre-formed holes on other fibrin monomers to form a fibrin gel, which is the end point of *in vitro* tests of coagulation (see “Coagulation *in vitro*”). Initially, the fibrin monomers are bound to each other non-covalently. Subsequently, factor XIII, a transglutaminase that is activated by thrombin, catalyzes interchain covalent cross-links between adjacent fibrin monomers, which enhance the strength of the clot.

Structure of Coagulation Factors. In addition to factor XIII, the coagulation factors include factors II (prothrombin), VII, IX, X, XI,

XII, and prekallikrein. A stretch of about 200 amino acid residues at the carboxyl-termini of each of these zymogens exhibits homology to trypsin and contains the active site of the proteases. In addition, 9–12 glutamate residues near the amino termini of factors II, VII, IX, and X are converted to γ -carboxyglutamate (Gla) residues during their biosynthesis in the liver. The Gla residues bind Ca^{2+} and are necessary for the coagulant activities of these proteins.

Nonenzymatic Protein Cofactors. Factors V and VIII, which are homologous 350,000-Da proteins, serve as cofactors. Factor VIII circulates in plasma bound to von Willebrand factor, while factor V not only circulates in plasma but also is stored in platelets in a partially activated form. Platelets release this stored factor V when they are activated. Thrombin cleaves factors V and VIII to yield activated cofactors (factors Va and VIIIa) that have at least 50 times greater procoagulant activity than their nonactivated counterparts.

Factors Va and VIIIa serve as cofactors by binding to the surface of activated platelets, where they act as receptors for factors Xa and IXa, respectively. The activated cofactors also help localize prothrombin and factor X, the respective substrates for these enzymes, on the activated platelet surface. Assembly of these coagulation factor complexes increases the catalytic efficiency of factors Xa and IXa by $\sim 10^9$ -fold.

TF is a non-enzymatic lipoprotein cofactor; it initiates coagulation by enhancing the catalytic efficiency of VIIa. Not normally present on blood-contacting cells, TF is constitutively expressed on the surface of subendothelial smooth muscle cells and fibroblasts, which are exposed when the vessel wall is damaged. Lipid-rich cores of atherosclerotic plaques also are rich in TF, which explains why atherosclerotic plaque disruption often triggers the

852 formation of a superimposed thrombus that can occlude the lumen of the vessel.

When exposed to stimuli such as endotoxin, tumor necrosis factor, or interleukin-1, monocytes also express TF on their surface. Circulating TF-bearing monocytes and membrane fragments derived from them, known as microparticles, contribute to thrombosis. In response to inflammatory stimuli or products of coagulation, such as thrombin, endothelial cells express adhesion molecules, which tether these monocytes and microparticles onto their surface. This augments coagulation by delivering more TF to sites of injury. TF-bearing monocytes and microparticles also home to thrombi by binding to P-selectin expressed on the surface of activated platelets. Additional TF from these sources maintains coagulation and promotes thrombus expansion.

Another plasma protein, high-molecular-weight kininogen, also serves as a cofactor. Negatively charged surfaces, such as catheters, stents, and other blood-contacting medical devices, activate factor XII in a reaction enhanced by high-molecular-weight kininogen. Factor XIIIa then propagates coagulation by activating factor XI, a reaction also enhanced by high-molecular-weight kininogen. In the presence of activated platelets, thrombin also activates factor XI, thereby bypassing factor XIIIa.

Activation of Prothrombin. By cleaving two peptide bonds on prothrombin, factor Xa converts it to thrombin. In the presence of factor Va, a negatively charged phospholipid surface, and Ca^{2+} , factor Xa activates prothrombin with 10^9 -fold greater efficiency. The maximal rate of activation only occurs when prothrombin and factor Xa contain Gla residues, which endow them with the capacity to bind to phospholipids. Artificial mixtures of anionic phospholipids substitute for activated platelets in laboratory tests of coagulation. However, activated platelets not only provide a surface for coagulation factor assembly but also release factor Va, which may be more important than circulating factor Va for thrombin generation.

Initiation of Coagulation. Under most circumstances, TF exposed at sites of vessel wall injury initiates coagulation via the extrinsic pathway. The small amount of factor VIIa circulating in plasma binds subendothelial TF and the TF-factor VIIa complex, then activates factors X and IX (Figure 30–2). In the absence of TF, factor VIIa has minimal activity. When bound to TF in the presence of anionic phospholipids and Ca^{2+} , the activity of factor VIIa increases about 30,000-fold.

The intrinsic pathway is initiated *in vitro* when factor XII, prekallikrein, and high-molecular-weight kininogen interact with kaolin, glass, or another surface to generate small amounts of factor XIIIa. Activation of factor XI to factor XIa and factor IX to factor IXa follows. Factor IXa then activates factor X in a reaction accelerated by factor VIIIa, anionic phospholipids, and Ca^{2+} . Optimal thrombin generation depends on the formation of this factor IXa complex because it activates factor X more efficiently than the TF-factor VIIa complex. The bleeding that occurs in hemophiliacs who are deficient in

factor IX or factor VIII highlights the importance of the factor IXa–factor VIIIa complex in thrombin generation.

Activation of factor XII is not essential for hemostasis, as evidenced by the fact that patients deficient in factor XII, prekallikrein, or high-molecular-weight kininogen do not have excessive bleeding. Factor XI deficiency is associated with a variable and usually mild bleeding disorder. The mechanism responsible for factor XI activation *in vivo* is unknown. Activation may occur through feedback activation of factor XI by thrombin. Alternatively, factor XIIIa may activate factor XI after injury to the vessel wall because there is evidence that RNA released from damaged cells activates factor XII and administration of RNA-degrading enzymes to mice attenuates thrombus formation after arterial injury.

Fibrinolysis. The fibrinolytic system dissolves intravascular fibrin through the action of plasmin. To initiate fibrinolysis, plasminogen activators first convert single-chain plasminogen, an inactive precursor, into two-chain plasmin by cleavage of a specific peptide bond. There are two distinct plasminogen activators; tissue plasminogen activator (t-PA) and urokinase plasminogen activator (u-PA), or simply urokinase. Although both activators are synthesized by endothelial cells, t-PA predominates under most conditions and drives intravascular fibrinolysis. In contrast, synthesis of u-PA mainly occurs in response to inflammatory stimuli, and u-PA promotes extravascular fibrinolysis.

The fibrinolytic system is regulated such that unwanted fibrin thrombi are removed, while fibrin in wounds is preserved to maintain hemostasis (Lijnen and Collen, 2001). t-PA is released from endothelial cells in response to various stimuli, including the stasis that occurs when thrombi occlude vessels. Released t-PA is rapidly cleared from blood or inhibited by plasminogen activator inhibitor-1 (PAI-1) and, to a lesser extent, plasminogen activator inhibitor-2 (PAI-2); t-PA thus exerts little effect on circulating plasminogen in the absence of fibrin. α_2 -antiplasmin rapidly inhibits any plasmin that is generated. However, when fibrin is present, t-PA binds to it, as does plasminogen. The catalytic efficiency of t-PA activation of plasminogen increases over 300-fold in the presence of fibrin, which promotes plasmin generation on its surface. Plasmin then degrades the fibrin.

Plasminogen and plasmin bind to lysine residues on fibrin via five loop-like regions near their amino termini, which are known as kringle domains. To inactivate plasmin, α_2 -antiplasmin binds to the first of these kringle domains and then blocks the active site of plasmin. Because the kringle domains are occupied when plasmin binds to fibrin, plasmin on the fibrin surface is protected from inhibition by α_2 -antiplasmin and can digest the fibrin. Once the fibrin clot undergoes

degradation, α_2 -antiplasmin rapidly inhibits any plasmin that escapes from this local milieu. To prevent premature clot lysis, factor XIIIa mediates the covalent cross-linking of small amounts of α_2 -antiplasmin onto fibrin.

When thrombi occlude major arteries or veins, therapeutic doses of plasminogen activators sometimes are administered to degrade the fibrin and rapidly restore blood flow. In high doses, these plasminogen activators promote the generation of so much plasmin that the inhibitory controls are overwhelmed. Plasmin is a relatively nonspecific protease; it not only digests fibrin but also degrades other plasma proteins, including several coagulation factors. Reduction in the levels of these coagulation proteins impairs the capacity for thrombin generation, which can contribute to bleeding. In addition, unopposed plasmin tends to dissolve fibrin in hemostatic plugs as well as that in pathological thrombi, a phenomenon that also increases the risk of bleeding. Therefore, fibrinolytic drugs can be toxic, producing hemorrhage as their major side effect. The pathway of fibrinolysis and sites of pharmacological perturbation are summarized in Figure 30–3.

Coagulation in vitro. Whole blood normally clots in 4–8 minutes when placed in a glass tube. Clotting is prevented if a chelating agent such as ethylenediaminetetraacetic acid (EDTA) or citrate is added to bind Ca^{2+} . Recalcified plasma normally clots in 2–4 minutes. The clotting time after recalcification is shortened to 26–33 seconds by the addition of negatively-charged phospholipids and a particulate substance, such as kaolin (aluminum silicate) or celite (diatomaceous earth), which activates factor XII; the measurement of this is termed the *activated partial thromboplastin time* (aPTT). Alternatively, recalcified plasma clots in 12–14 seconds after addition of “thromboplastin” (a mixture of TF and phospholipids); the measurement of this is termed the *prothrombin time* (PT).

Two pathways of coagulation are recognized. An individual with a prolonged aPTT and a normal PT is considered to have a defect in the *intrinsic coagulation pathway* because all of the components of the aPTT test (except kaolin or celite) are intrinsic to the plasma. A patient with a prolonged PT and a normal aPTT has a defect in the *extrinsic coagulation pathway* because thromboplastin is extrinsic to the plasma. Prolongation of both the aPTT and the PT suggests a defect in a *common pathway*.

Natural Anticoagulant Mechanisms. Platelet activation and coagulation do not normally occur within an intact blood vessel (Edelberg et al., 2001). Thrombosis is prevented by several regulatory mechanisms that require a healthy vascular endothelium. Nitric oxide and prostacyclin (PGI_2) are synthesized by endothelial cells and released into the blood (Chapter 33). These substances induce vasodilation and inhibit platelet activation and subsequent aggregation.

Antithrombin is a plasma protein that inhibits coagulation enzymes of the intrinsic and common pathways (see “Mechanism of Action”). Heparan sulfate proteoglycans synthesized by endothelial cells enhance the activity of antithrombin by ~1000-fold. Another regulatory system involves protein C, a plasma zymogen that is homologous to factors II, VII, IX, and X; its activity depends on the binding of Ca^{2+} to Glu residues within its amino-terminal domain. Thrombin activates protein C, but the efficiency of this reaction increases by several orders of magnitude when thrombin binds to thrombomodulin, its receptor on the surface of endothelial cells (Esmon, 2003). Protein C binds to another endothelial cell receptor, endothelial protein C receptor (EPCR), which presents protein C to the thrombin–thrombomodulin complex for activation. Activated protein C then dissociates from EPCR and, in combination with protein S, its non-enzymatic Glu-containing cofactor, activated protein C degrades factors Va and VIIIa. Without these activated cofactors, the rates of activation of prothrombin and factor X are greatly diminished. Therefore, activated protein C downregulates thrombin generation (Esmon, 2006). Deficiency of protein C or protein S is associated with an increased risk of pathological thrombus formation and tissue necrosis associated with the use of warfarin (see the “Warfarin” section, later in the chapter).

With antithrombin requiring endogenous heparan sulfate for its full activity and protein C requiring activation by thrombomodulin-bound thrombin, the effects of both of these natural anticoagulants are localized to the vicinity of intact endothelial cells. Tissue factor pathway inhibitor (TFPI), a natural anticoagulant found in the lipoprotein fraction of plasma, also regulates thrombin generation by inhibiting TF-bound factor VIIa in a two-step fashion. TFPI first binds and inhibits factor Xa, and this binary complex then inhibits factor VIIa. Therefore, factor Xa regulates its own generation through this mechanism. TFPI also can localize on the endothelial cell surface by binding to heparan sulfate proteoglycans.

PARENTERAL ANTICOAGULANTS

Heparin and Its Derivatives

Biochemistry. Heparin, a glycosaminoglycan found in the secretory granules of mast cells, is synthesized from UDP-sugar precursors as a polymer of alternating D-glucuronic acid and N-acetyl-D-glucosamine residues (Sugahara and Kitagawa, 2002).

About 10-15 glycosaminoglycan chains, each containing 200-300 saccharide units, are attached to a core protein and yield a proteoglycan with a molecular mass of 750-1,000 kDa. The glycosaminoglycan then undergoes a series of modifications, which include the following: *N*-deacetylation and *N*-sulfation of glucosamine residues, epimerization of D-glucuronic acid to L-iduronic acid, *O*-sulfation of iduronic and glucuronic acid residues at the C2 position, and *O*-sulfation of glucosamine residues at the C3 and C6 positions. Each of these modifications is incomplete, yielding a variety of oligosaccharide structures. After transport of the heparin proteoglycan to mast cell granules, an endo- β -D-glucuronidase slowly degrades the glycosaminoglycan chains to fragments of 5-30 kDa (mean, ~15 kDa, corresponding to ~40 saccharide units).

Source. Heparin is commonly extracted from porcine intestinal mucosa, which is rich in mast cells, and preparations may contain small amounts of other glycosaminoglycans. Despite the heterogeneity in composition among different commercial preparations of heparin, their biological activities are similar (~150 USP units/mg). A USP unit reflects the quantity of heparin that prevents 1 mL of citrated sheep plasma from clotting for 1 hour after the addition of 0.2 mL of 1% CaCl₂. Although North American heparin manufacturers have traditionally quantified heparin potency in USP units, European manufacturers measure potency with an anti-factor Xa assay. This assay involves monitoring the activity of factor Xa added to human citrated plasma with a synthetic factor Xa-directed substrate that changes color when cleaved by the enzyme. The higher the heparin concentration in the sample, the less the residual factor Xa activity detected. To determine heparin potency, residual factor Xa activity in the sample is compared with that detected in controls containing known concentrations of an international heparin standard. When assessed this way, heparin potency is expressed in international units per mg.

Effective October 1, 2009, the new USP unit dose has been harmonized to the international unit dose. Contamination of heparin with oversulfated chondroitin sulfate, a non-heparin glycosaminoglycan, prompted this shift because this contaminant eludes detection with the USP assay but not with the anti-factor Xa assay. As a result, the new USP unit dose is less potent than the old USP unit dose by ~10%, and heparin doses using the new USP units will have to increase slightly to achieve the same level of anticoagulation. This

likely is of little or no clinical consequence for subcutaneous administration, due to the low and variable bioavailability of heparin when administered by this route. However, for intravenous administration, dosing adjustments and more frequent monitoring of aPTT may be necessary.

Heparin Derivatives. Derivatives of heparin in current use include low-molecular-weight heparins (LMWHs) and fondaparinux. The features that distinguish these derivatives from heparin are outlined in Table 30–1. Several LMWH preparations are marketed (e.g., dalteparin [FRAGMIN], enoxaparin [LOVENOX], tinzaparin [INNOHEP]), but all are fragments of heparin ranging in molecular weight from 1-10 kDa (mean ~5 kDa, ~17 saccharide units). LMWH preparations differ from heparin and, to a lesser extent, from each other in their pharmacokinetic properties. The potency of LMWH is assessed with anti-factor Xa assays, which use an international LMWH standard for reference purposes.

In contrast to heparin and LMWHs, which are biologicals derived from animal tissues, fondaparinux (ARIXTRA) is a synthetic five-saccharide analog of a natural pentasaccharide sequence that is found in heparin and LMWHs and mediates their interaction with antithrombin. Fondaparinux has unique pharmacokinetic properties that distinguish it from LMWH. The potency of fondaparinux also is assessed with an anti-Xa assay.

Mechanism of Action. Heparin, LMWHs, and fondaparinux have no intrinsic anticoagulant activity. Instead, these agents bind to antithrombin and accelerate the rate at which it inhibits various coagulation proteases. Antithrombin is a glycosylated, single-chain polypeptide composed of 432 amino acid residues (Olson and Chuang, 2002). Synthesized in the liver, antithrombin circulates in plasma at an approximate concentration of 2.6 μ M. Antithrombin inhibits activated coagulation factors involved in the intrinsic and common pathways but has relatively little activity against factor VIIa. Antithrombin is a “suicide substrate” for these proteases; inhibition occurs when the protease attacks a specific Arg–Ser peptide bond in the reactive center loop of antithrombin and becomes trapped as a stable 1:1 complex.

Table 30–1

Comparison of the Features of Heparin, LMWH, and Fondaparinux

FEATURES	HEPARIN	LMWH	FONDAPARINUX
Source	Biological	Biological	Synthetic
Molecular weight (Da)	15,000	5000	1500
Target	Xa and IIa	Xa and IIa	Xa
Bioavailability (%)	30	90	100
<i>t</i> _{1/2} (h)	1	4	17
Renal excretion	No	Yes	Yes
Antidote effect	Complete	Partial	None
Thrombocytopenia	<5%	<1%	<1%

Figure 30–4. The antithrombin-binding pentasaccharide structure of heparin. Sulfate groups required for binding to antithrombin are indicated in red.

Heparin binds to antithrombin via a specific pentasaccharide sequence that contains a 3-*O*-sulfated glucosamine residue (Figure 30–4). This structure occurs on ~30% of heparin molecules and is less abundant on endogenous heparan sulfate molecules. Other glycosaminoglycans (e.g., dermatan sulfate, chondroitin-4-sulfate, and chondroitin-6-sulfate) lack the antithrombin-binding structure and do not activate antithrombin.

Pentasaccharide binding to antithrombin induces a conformational change in antithrombin that renders its reactive site more accessible to the target protease (Figure 30–5).

This conformational change accelerates the rate of factor Xa inhibition by at least two orders of magnitude but has no effect on the rate of thrombin inhibition. To enhance the rate of thrombin inhibition by antithrombin, heparin serves as a catalytic template to which both the inhibitor and the protease bind. Only heparin molecules composed of 18 or more saccharide units (molecular weight >5400 Da) are of sufficient length to bridge antithrombin and thrombin together. With a mean molecular weight of 15,000 Da, most of the chains of heparin are long enough to serve this role. Consequently, by definition, heparin catalyzes the rates of factor Xa and thrombin to a similar extent, as expressed by an anti-factor Xa to anti-factor IIa (thrombin) ratio of 1:1. In contrast, at least half of LMWH molecules (mean molecular weight of 5000 Da, ~17 saccharide units) are too short to provide this bridging function and have no effect on the rate of thrombin inhibition by antithrombin. Because these shorter molecules still induce the conformational change in antithrombin that accelerates inhibition of factor Xa, LMWHs have greater anti-factor Xa activity than anti-IIa activity, and the ratio ranges from 3:1 to 2:1 depending on the preparation. Fondaparinux, an analog of the pentasaccharide sequence in heparin or LMWHs that mediates their interaction with antithrombin, has only anti-factor Xa activity because it is too short to bridge antithrombin to thrombin (Figure 30–5).

Heparin, LMWHs, and fondaparinux act in a catalytic fashion. After binding to antithrombin and promoting the formation of covalent complexes between

antithrombin and target proteases, the heparin, LMWH, or fondaparinux dissociates from the complex and can then catalyze other antithrombin molecules.

When the concentration of heparin in plasma is 0.1–1 units/mL, thrombin, factor IXa, and factor Xa are inhibited rapidly ($t_{1/2} < 0.1$ second) by antithrombin. This effect prolongs both the aPTT (discussed earlier) and the thrombin time (i.e., the time required for plasma to clot when exogenous thrombin is added); the PT is affected to a lesser degree. Factor Xa bound to platelets in the prothrombinase complex and thrombin bound to fibrin are both protected from inhibition by antithrombin in the presence of heparin or LMWH. Thus, heparin and LMWHs may promote the inhibition of factor Xa and thrombin only after they have diffused away from these binding sites.

Platelet factor 4, a cationic protein released from the α granules during platelet activation, binds heparin and prevents it from interacting with antithrombin. This phenomenon may limit the activity of heparin in the vicinity of platelet-rich thrombi. Because LMWH and fondaparinux have a lower affinity for platelet factor 4, these agents may retain their activity in the vicinity of such thrombi to a greater extent than heparin.

Miscellaneous Pharmacological Effects. High doses of heparin can interfere with platelet aggregation and thereby prolong the bleeding time. In contrast, LMWHs and fondaparinux have little effect on platelets. It is unclear to what extent the antiplatelet effect of heparin contributes to the hemorrhagic complications of treatment with the drug. Heparin “clears” lipemic plasma *in vivo* by causing the release of lipoprotein lipase into the circulation. Lipoprotein lipase hydrolyzes triglycerides to glycerol and free fatty acids. The clearing of lipemic plasma may occur at concentrations of heparin below those necessary to produce an anticoagulant effect. Rebound hyperlipemia may occur after heparin administration is stopped.

Clinical Use. Heparin, LMWH, and fondaparinux can be used to initiate treatment of venous thrombosis and pulmonary embolism because of their rapid onset of action (Hirsh et al., 2001). An oral vitamin K antagonist, such as warfarin, usually is started concurrently, and the heparin or heparin derivative is continued for at least 5 days to allow warfarin to achieve its full therapeutic

Figure 30–5. Mechanism of action of heparin, low-molecular-weight heparin (LMWH), and fondaparinux, a synthetic pentasaccharide. **A.** Heparin binds to antithrombin via its pentasaccharide sequence. This induces a conformational change in the reactive center loop of antithrombin that accelerates its interaction with factor Xa. To potentiate thrombin inhibition, heparin must simultaneously bind to antithrombin and thrombin. Only heparin chains composed of at least 18 saccharide units (molecular weight ~5,400 Da) are of sufficient length to perform this bridging function. With a mean molecular weight of 15,000 Da, virtually all of the heparin chains are long enough to do this. **B.** LMWH has greater capacity to potentiate factor Xa inhibition by antithrombin than thrombin because at least half of the LMWH chains (mean molecular weight 4,500–5,000 Da) are too short to bridge antithrombin to thrombin. **C.** The pentasaccharide accelerates only factor Xa inhibition by antithrombin; the pentasaccharide is too short to bridge antithrombin to thrombin.

effect (see the warfarin “Clinical Use” and “Monitoring Anticoagulant Therapy” sections later in the chapter). Heparin, LMWH, or fondaparinux also can be used in the initial management of patients with unstable angina or acute myocardial infarction. For most of these indications, LMWHs and fondaparinux have replaced continuous heparin infusions because of their pharmacokinetic advantages, which permit subcutaneous administration once or twice daily in fixed or weight-adjusted doses without coagulation monitoring. By contrast, full-dose heparin usually requires continuous intravenous infusion and frequent aPTT monitoring to ensure that a therapeutic level of anticoagulation has been achieved.

Because they do not require routine laboratory monitoring, LMWHs or fondaparinux can be used for out-of-hospital management of patients with venous thrombosis or pulmonary embolism, an approach that reduces healthcare expenditures. Patients who develop these disorders due to cancer often are treated with long-term LMWH instead of warfarin because nausea and vomiting from chemotherapy, involvement of the liver with cancer, and poor venous access can render therapy with warfarin problematic.

Heparin and LMWH are used during coronary balloon angioplasty with or without stent placement to prevent thrombosis. Fondaparinux is not used in this setting because of the risk of catheter thrombosis, a complication caused by catheter-induced activation of factor XII; longer heparin molecules are better than shorter ones for blocking this process. Cardiopulmonary bypass circuits also activate factor XII, which can cause clotting of the oxygenator. Heparin remains the agent of choice for surgery requiring cardiopulmonary bypass because it blocks this process and because the heparin can rapidly be neutralized with protamine sulfate after the procedure. Heparin also is used to treat selected patients with disseminated intravascular coagulation. While low-dose heparin, LMWH, or fondaparinux regimens all are effective, subcutaneous administration of low-dose heparin remains the recommended regimen for the prevention of post-operative deep venous thrombosis (DVT) and pulmonary embolism in patients undergoing major abdominothoracic surgery or who are at risk of developing thromboembolic disease. Specific recommendations for heparin use have been reviewed (Geerts et al., 2008).

In contrast to warfarin, heparin, LMWH, and fondaparinux do not cross the placenta and have not been associated with fetal malformations; therefore, these are the drugs of choice for anticoagulation during pregnancy. LMWH or fondaparinux is used most often in this setting because these agents need only be given once daily by subcutaneous injection. In addition, the risk of heparin-induced thrombocytopenia or osteoporosis is lower with LMWHs or fondaparinux than with heparin. Heparin, LMWH, and fondaparinux do not appear to increase fetal mortality or prematurity. If possible, the drugs should be discontinued 24 hours before delivery to minimize the risk of postpartum bleeding.

Absorption and Pharmacokinetics. Heparin, LMWHs, and fondaparinux are not absorbed through the GI

mucosa and therefore must be given parenterally. Heparin is given by continuous intravenous infusion, intermittent infusion every 4-6 hours, or subcutaneous injection every 8-12 hours. Heparin has an immediate onset of action when given intravenously. In contrast, there is considerable variation in the bioavailability of heparin given subcutaneously, and the onset of action is delayed 1-2 hours. LMWH and fondaparinux are absorbed more uniformly after subcutaneous injection.

The $t_{1/2}$ of heparin in plasma depends on the dose administered. When doses of 100, 400, or 800 units/kg of heparin are injected intravenously, the half-lives of the anticoagulant activities are approximately 1, 2.5, and 5 hours, respectively (see Appendix II for pharmacokinetic data). Heparin appears to be cleared and degraded primarily by the reticuloendothelial system; a small amount of undegraded heparin also appears in the urine. LMWHs and fondaparinux have longer biological half-lives than heparin, 4-6 hours and ~17 hours, respectively. Because these smaller heparin fragments are cleared almost exclusively by the kidneys, the drugs can accumulate in patients with renal impairment, which can lead to bleeding. Both LMWH and fondaparinux are contraindicated in patients with a creatinine clearance <30 mL/min. In addition, fondaparinux is contraindicated in patients with body weight <50 kg undergoing hip fracture, hip replacement, knee replacement surgery, or abdominal surgery.

Administration and Monitoring. Full-dose heparin therapy usually is administered by continuous intravenous infusion. Treatment of venous thromboembolism is initiated with a fixed-dose bolus injection of 5000 units or with a weight-adjusted bolus, followed by 800-1600 units/hour delivered by an infusion pump. Therapy routinely is monitored by measuring the aPTT. The therapeutic range for heparin is considered to be that which is equivalent to a plasma heparin level of 0.3-0.7 units/mL, as determined with an anti-factor Xa assay (Hirsh et al., 2001). The aPTT value that corresponds to this range varies depending on the reagent and instrument used to perform the assay. An aPTT two to three times the normal mean aPTT value generally is assumed to be therapeutic; however, values in this range obtained with some aPTT assays may overestimate the amount of circulating heparin and therefore be subtherapeutic. The risk of recurrence of thromboembolism is greater in patients who do not achieve a therapeutic level of anticoagulation within the first 24 hours. Initially, the aPTT should be measured and the infusion rate adjusted every 6 hours; dose adjustments may be aided by use of nomograms; weight-based nomograms appear to outperform those that used fixed doses (Hirsh et al., 2001). Once a steady dosage schedule has been established in a stable patient, daily laboratory monitoring usually is sufficient.

Very high doses of heparin are required to prevent coagulation during cardiopulmonary bypass. The aPTT is infinitely prolonged over the dosage range used. A less sensitive coagulation test, such as the activated clotting time, is employed to monitor therapy in this situation. Because the activated clotting time can be performed in a point-of-care fashion, patients undergoing coronary angioplasty also typically have their heparin therapy monitored this way.

For therapeutic purposes, heparin also can be administered subcutaneously on a twice-daily basis. A total daily dose of ~35,000 units administered as divided doses every 8-12 hours usually is sufficient to achieve an aPTT of twice the control value (measured midway between doses). Monitoring generally is unnecessary once a steady dosage schedule is established. For low-dose heparin therapy (to prevent DVT and thromboembolism in hospitalized medical or surgical patients), a subcutaneous dose of 5000 units is given two to three times daily. Laboratory monitoring of heparin administered in this way usually is unnecessary because low-dose regimens have negligible effects on the aPTT.

LMWH preparations include Enoxaparin (LOVENOX), dalteparin (FRAGMIN), tinzaparin (INNOHEP, others), ardeparin (NORMIFLO), nadroparin (FRAXIPARINE, others), and reviparin (CLIVARINE) (the latter three are not available in the U.S. currently). These agents differ considerably in composition, and one cannot assume that two preparations that have similar anti-factor Xa activity will have equivalent antithrombotic effects. The more predictable pharmacokinetic properties of LMWH, however, permit administration in a fixed or weight-adjusted dosage regimen once or twice daily by subcutaneous injection.

Because LMWHs produce a relatively predictable anticoagulant response, monitoring is not done routinely. Patients with renal impairment may require monitoring with an anti-factor Xa assay because this condition may prolong the $t_{1/2}$ and slow the elimination of LMWHs. Obese patients and children given LMWHs also may require monitoring. Specific dosage recommendations for various LMWH preparations may be obtained from the manufacturer's literature.

Fondaparinux (ARIXTRA) is administered by subcutaneous injection, reaches peak plasma levels in 2 hours, and is excreted in the urine ($t_{1/2}$ ~17 h). It should not be used in patients with renal failure. Because it does not interact significantly with blood cells or plasma proteins other than antithrombin, fondaparinux can be given once a day at a fixed dose without coagulation monitoring. Fondaparinux appears to be much less likely than heparin or LMWH to trigger the syndrome of heparin-induced thrombocytopenia (see later in the chapter). Fondaparinux is approved for thromboprophylaxis in patients undergoing hip or knee surgery or surgery for hip fracture (Buller et al., 2003) and in general medical or surgical patients. It also can be used for initial therapy in patients with pulmonary embolism or DVT.

Idraparinux, a hypermethylated version of fondaparinux, underwent phase III clinical testing. This drug has a $t_{1/2}$ of 80 hours and is given subcutaneously on a once-weekly basis. To overcome the lack of an antidote, a biotin moiety was added to idraparinux to generate idrabiotaparinux, which can be neutralized with intravenous avidin. Ongoing phase III clinical trials are comparing idrabiotaparinux with warfarin for treatment of pulmonary embolism or for stroke prevention in patients with atrial fibrillation. Idraparinux, idrabiotaparinux, and avidin are not available for routine clinical use.

Heparin Resistance. The dose of heparin required to produce a therapeutic aPTT varies due to differences in the concentrations of heparin-binding proteins in plasma, such as histidine-rich glycoprotein, vitronectin, and large multimers of von Willebrand factor and platelet factor 4; these proteins competitively inhibit binding of heparin to antithrombin. Some patients do not achieve a therapeutic aPTT unless very high doses of heparin (>50,000 units/day) are

administered. Such patients may have “therapeutic” concentrations of heparin in plasma at the usual dose when measured using an anti-factor Xa assay. This “pseudo” heparin resistance occurs because these patients have short aPTT values prior to treatment, as a result of increased concentrations of factor VIII. Other patients may require large doses of heparin because of accelerated clearance of the drug, as may occur with massive pulmonary embolism. Patients with inherited antithrombin deficiency ordinarily have 40-60% of the usual plasma concentration of this inhibitor and respond normally to intravenous heparin. However, acquired antithrombin deficiency, where concentrations may be <25% of normal, may occur in patients with hepatic cirrhosis, nephrotic syndrome, or disseminated intravascular coagulation; large doses of heparin may not prolong the aPTT in these individuals.

Because LMWHs and fondaparinux exhibit reduced binding to plasma proteins other than antithrombin, heparin resistance rarely occurs with these agents. For this reason, routine coagulation monitoring is unnecessary. Occasional patients, particularly those with underlying cancer, develop recurrent thrombosis despite therapeutic doses of a LMWH. Anti-factor Xa assays often are subtherapeutic in these patients, and higher doses of LMWH are needed to achieve a therapeutic response.

Toxicity and Adverse Events

Bleeding. Bleeding is the primary untoward effect of heparin. Major bleeding occurs in 1-5% of patients treated with intravenous heparin for venous thromboembolism (Hirsh et al., 2001). The incidence of bleeding is somewhat less in patients treated with LMWH for this indication. Although the risk of bleeding appears to increase with higher total daily doses of heparin and with the degree of prolongation of the aPTT, these correlations are weak, and patients can bleed with aPTT values that are within the therapeutic range. Often an underlying cause for bleeding is present, such as recent surgery, trauma, peptic ulcer disease, or platelet dysfunction.

The anticoagulant effect of heparin disappears within hours of discontinuation of the drug. Mild bleeding due to heparin usually can be controlled without the administration of an antagonist. If life-threatening hemorrhage occurs, the effect of heparin can be reversed quickly by the intravenous infusion of *protamine sulfate*, a mixture of basic polypeptides isolated from salmon sperm. Protamine binds tightly to heparin and thereby neutralizes its anticoagulant effect. Protamine also interacts with platelets, fibrinogen, and other plasma proteins and may cause an anticoagulant effect of its own. Therefore, one should give the minimal amount of protamine required to neutralize the heparin present in the plasma. This amount is approximately 1 mg of protamine for every 100 units of heparin remaining in the patient; protamine (up to a maximum of 50 mg) is given intravenously at a slow rate (over 10 minutes).

Protamine is used routinely to reverse the anticoagulant effect of heparin after cardiac surgery and other vascular procedures. Anaphylactic reactions occur in about 1% of patients with diabetes mellitus who have received protamine-containing insulin (*NPH insulin*

or *protamine zinc insulin*), but untoward reactions are not limited to this group. A less common reaction consisting of pulmonary vasoconstriction, right ventricular dysfunction, systemic hypotension, and transient neutropenia also may occur after protamine administration.

Protamine only binds long heparin molecules. Therefore, protamine only partially reverses the anticoagulant activity of LMWHs and has no effect on that of fondaparinux. Because the long heparin molecules account for the anti-factor IIa activity of LMWH, protamine completely reverses this activity. In contrast, protamine only partially reverses the anti-factor Xa activity of LMWH, which is mediated by shorter heparin molecules. The very short molecules of fondaparinux do not bind protamine. Therefore, fondaparinux lacks a specific antidote.

Heparin-Induced Thrombocytopenia. Heparin-induced thrombocytopenia (platelet count $<150,000/\text{mL}$ or a 50% decrease from the pretreatment value) occurs in ~0.5% of medical patients 5-10 days after initiation of therapy with heparin (Warkentin, 2007). Although the incidence may be lower, thrombocytopenia also occurs with LMWHs and fondaparinux, and platelet counts should be monitored. Thrombotic complications that can be life-threatening or lead to amputation occur in about one-half of the affected heparin-treated patients and may precede the onset of thrombocytopenia. The incidence of heparin-induced thrombocytopenia and thrombosis is higher in surgical patients than in medical patients. Women are twice as likely as men to develop this condition.

Venous thromboembolism occurs most commonly, but arterial thromboses causing limb ischemia, myocardial infarction, and stroke also occur. Bilateral adrenal hemorrhage, skin lesions at the site of subcutaneous heparin injection, and a variety of systemic reactions may accompany heparin-induced thrombocytopenia. The development of IgG antibodies against complexes of heparin with platelet factor 4 (or, rarely, other chemokines) appears to cause all of these reactions. These complexes activate platelets by binding to Fc γ IIa receptors, which results in platelet aggregation, release of more platelet factor 4, and thrombin generation. The antibodies also may trigger vascular injury by binding to platelet factor 4 attached to endogenous heparan sulfate on the endothelium.

Heparin, LMWH, and fondaparinux should be discontinued immediately if unexplained thrombocytopenia or any of the clinical manifestations mentioned above occur 5 or more days after beginning therapy, regardless of the dose or route of administration. The onset of heparin-induced thrombocytopenia may occur earlier in patients who have received heparin within the previous 3-4 months and have residual circulating antibodies. The diagnosis of heparin-induced thrombocytopenia can be confirmed by a heparin-dependent platelet activation assay or an assay for antibodies that react with heparin/platelet factor 4 complexes. Because thrombotic complications may occur after cessation of therapy, an alternative anticoagulant such as lepirudin, argatroban (see the next section), or fondaparinux should be administered to patients with heparin-induced thrombocytopenia. LMWH preparations should be avoided, because

these drugs often cross-react with heparin in heparin-dependent antibody assays. In contrast, fondaparinux does not cross-react with these heparin-dependent antibodies, and, although large clinical trials are lacking, fondaparinux has been used successfully in patients with heparin-induced thrombocytopenia. Warfarin may precipitate venous limb gangrene or multicentric skin necrosis in patients with heparin-induced thrombocytopenia and should not be used until the thrombocytopenia has resolved and the patient is adequately anticoagulated with another agent.

Other Toxicities. Abnormalities of hepatic function tests occur frequently in patients who are receiving heparin or LMWHs. Mild elevations of the activities of hepatic transaminases in plasma occur without an increase in bilirubin levels or alkaline phosphatase activity. Osteoporosis resulting in spontaneous vertebral fractures can occur, albeit infrequently, in patients who have received full therapeutic doses of heparin ($>20,000$ units/day) for extended periods (e.g., 3-6 months). The risk of osteoporosis is lower with LMWHs or fondaparinux than it is with heparin. Heparin can inhibit the synthesis of aldosterone by the adrenal glands and occasionally causes hyperkalemia, even when low doses are given. Allergic reactions to heparin (other than thrombocytopenia) are rare.

Other Parenteral Anticoagulants

Lepirudin. Lepirudin (REFLUDAN) is a recombinant derivative (Leu¹-Thr²-63-desulfohirudin) of hirudin, a direct thrombin inhibitor present in the salivary glands of the medicinal leech. Lepirudin is a 65–amino acid polypeptide that binds tightly to both the catalytic site and the extended substrate recognition site (exosite I) of thrombin. It is approved in the U.S. for treatment of patients with heparin-induced thrombocytopenia.

Lepirudin is administered intravenously at a dose adjusted to maintain the aPTT at 1.5-2.5 times the median of the laboratory's normal range for aPTT. The drug is excreted by the kidneys and has a $t_{1/2}$ of ~1.3 hours. Lepirudin should be used cautiously in patients with renal failure because it can accumulate and cause bleeding in these patients. Patients may develop antibodies against hirudin that occasionally prolong the $t_{1/2}$ and cause a paradoxical increase in the aPTT; therefore, daily monitoring of the aPTT is recommended. There is no antidote for lepirudin.

Desirudin. Desirudin (IPRIVASK) is a recombinant derivative of hirudin that differs only by the lack of a sulfate group on Tyr⁶³.

Desirudin is indicated for the prophylaxis of DVT in patients undergoing elective hip replacement surgery. The recommended dose is 15 mg every 12 hours by subcutaneous injection. It is eliminated by the kidney; the $t_{1/2}$ is ~2 hours following subcutaneous administration. Similar to lepirudin, the drug should be used cautiously in patients with decreased renal function, and serum creatinine and aPTT should be monitored daily.

Bivalirudin. Bivalirudin (ANGIOMAX) is a synthetic, 20–amino acid polypeptide that directly inhibits thrombin by a mechanism similar to that of lepirudin.

Bivalirudin contains the sequence Phe¹-Pro²-Arg³-Pro⁴, which occupies the catalytic site of thrombin, followed by a tetraglycine linker and a hirudin-like sequence that binds to exosite I. Thrombin slowly cleaves the Arg³-Pro⁴ peptide bond and thus regains activity.

Bivalirudin is administered intravenously and is used as an alternative to heparin in patients undergoing coronary angioplasty or cardiopulmonary bypass surgery. Patients with heparin-induced thrombocytopenia or a history of this disorder also can be given bivalirudin instead of heparin during coronary angioplasty. The $t_{1/2}$ of bivalirudin in patients with normal renal function is 25 minutes; dosage reductions are recommended for patients with moderate or severe renal impairment.

Argatroban. Argatroban, a synthetic compound based on the structure of l-arginine, binds reversibly to the catalytic site of thrombin.

Argatroban is administered intravenously and has an immediate onset of action. Its $t_{1/2}$ is 40-50 minutes. Argatroban is metabolized by hepatic CYPs and is excreted in the bile; therefore, dosage reduction is required for patients with hepatic insufficiency. The dosage is adjusted to maintain an aPTT of 1.5-3 times the baseline value. Argatroban can be used as an alternative to lepirudin for prophylaxis or treatment of patients with, or at risk of developing, heparin-induced thrombocytopenia. In addition to prolonging the aPTT, argatroban also prolongs the PT, which can complicate the transitioning of patients from argatroban to warfarin. A chromogenic factor X assay can be used instead of the PT to monitor warfarin in these patients.

Drotrecogin Alfa. Drotrecogin alfa (XIGRIS) is a recombinant form of human activated protein C that inhibits coagulation by proteolytic inactivation of factors Va and VIIIa. It also has anti-inflammatory effects (Esmon, 2003).

A 96-hour continuous infusion of drotrecogin alfa decreases mortality in adult patients who are at high risk for death from severe sepsis if given within 48 hours of the onset of organ dysfunction (e.g., shock, hypoxemia, oliguria). The major adverse effect is bleeding.

Antithrombin. Antithrombin (ATRYN) is a recombinant form of human antithrombin produced from the milk of genetically modified goats. It is approved as an anticoagulant for patients with hereditary antithrombin deficiency undergoing surgical procedures.

ORAL ANTICOAGULANTS

Warfarin

History. Following the report of a hemorrhagic disorder in cattle that resulted from the ingestion of spoiled sweet clover silage, Campbell and Link, in 1939, identified the hemorrhagic agent as bishydroxycoumarin (dicoumarol). In 1948, a more potent synthetic congener was introduced as an extremely effective rodenticide; the compound

was named *warfarin* as an acronym derived from the name of the patent holder, Wisconsin Alumni Research Foundation (WARF). Warfarin's potential as a therapeutic anticoagulant was recognized but not widely accepted, partly due to fear of unacceptable toxicity. However, in 1951, an army inductee uneventfully survived an attempted suicide with massive doses of a preparation of warfarin intended for rodent control. Since then, these anticoagulants have become a mainstay for prevention of thromboembolic disease.

Chemistry. Numerous anticoagulants have been synthesized as derivatives of 4-hydroxycoumarin and of the related compound, indan-1,3-dione (Figure 30-6). Only the coumarin derivatives are widely used; the 4-hydroxycoumarin residue, with a nonpolar carbon substituent at the position 3, is the minimal structural requirement for activity. This carbon is asymmetrical in warfarin (and in *phenprocoumon* and *acenocoumarol*). The R- and S-enantiomers differ in anticoagulant potency, metabolism, elimination, and interactions with other drugs. Commercial preparations of these anticoagulants are racemic mixtures. No advantage of administering a single enantiomer has been established.

Mechanism of Action. The oral anticoagulants are antagonists of vitamin K (see the section on "Vitamin K," later). Coagulation factors II, VII, IX, and X and the

Figure 30-6. Structural formulas of the vitamin K antagonists. 4-Hydroxycoumarin and indan-1,3-dione are the parent molecules from which the vitamin K antagonists are derived. The asymmetrical carbon atoms in the coumarins are shown in red.

anticoagulant proteins C and S are synthesized mainly in the liver and are biologically inactive unless 9-13 of the amino-terminal glutamate residues are carboxylated to form the Ca^{2+} -binding Gla residues. This reaction of the decarboxy precursor protein requires CO_2 , O_2 , and reduced vitamin K and is catalyzed by γ -glutamyl carboxylase (Figure 30-7). Carboxylation is directly coupled to the oxidation of vitamin K to its corresponding epoxide.

Reduced vitamin K must be regenerated from the epoxide for sustained carboxylation and synthesis of biologically competent proteins. The enzyme that catalyzes this, vitamin K epoxide reductase (VKOR), is inhibited by therapeutic doses of warfarin. Vitamin K (but not vitamin K epoxide) also can be converted to the corresponding hydroquinone by a second reductase, DT-diaphorase. This enzyme requires high concentrations of vitamin K and is less sensitive to coumarin drugs, which may explain why administration of sufficient vitamin K can counteract even large doses of oral anticoagulants.

Therapeutic doses of warfarin decrease by 30-50% the total amount of each vitamin K-dependent coagulation factor made by the liver; in addition, the secreted molecules are undercarboxylated, resulting in diminished biological activity (10-40% of normal). Congenital deficiencies of the procoagulant proteins to these levels cause mild bleeding disorders. Vitamin K antagonists have no effect on the activity of fully carboxylated molecules in the circulation. Thus, the time required for the activity of each factor in plasma to reach a new steady state after therapy is initiated or adjusted depends on its individual rate of clearance. The approximate $t_{1/2}$ (in hours) are as follows: factor VII, 6; factor IX, 24; factor X, 36; factor II, 50; protein C, 8; and protein S, 30. Because of the long $t_{1/2}$ of some of the coagulation factors, in particular factor II, the full anti-thrombotic effect of warfarin is not achieved for several days, even though the PT may be prolonged soon after administration due to the more rapid reduction of factors with a shorter $t_{1/2}$, in particular factor VII. There is no obvious selectivity of the effect of warfarin on any particular vitamin K-dependent coagulation factor, although the anti-thrombotic benefit and the hemorrhagic risk of therapy may be correlated

Figure 30-7. The vitamin K cycle and mechanism of action of warfarin. In the racemic mixture of S- and R-enantiomers, S-warfarin is more active. By blocking vitamin K epoxide reductase encoded by the *VKORC1* gene, warfarin inhibits the conversion of oxidized vitamin K epoxide into its reduced form, vitamin K hydroquinone. This inhibits vitamin K-dependent γ -carboxylation of factors II, VII, IX, and X because reduced vitamin K serves as a cofactor for a γ -glutamyl carboxylase that catalyzes the γ -carboxylation process, thereby converting prozymogens to zymogens capable of binding Ca^{2+} and interacting with anionic phospholipid surfaces. S-warfarin is metabolized by *CYP2C9*. Common genetic polymorphisms in this enzyme can influence warfarin metabolism. Polymorphisms in the C1 subunit of vitamin K reductase (*VKORC1*) also can affect the susceptibility of the enzyme to warfarin-induced inhibition, thereby influencing warfarin dosage requirements.

Dosage. The usual adult dosage of warfarin is 2-5 mg/day for 2-4 days, followed by 1-10 mg/day as indicated by measurements of the international normalized ratio (INR), a value derived from the patient's PT (see the functional definition of INR in the section on "Laboratory Monitoring"). As indicated later, common genetic polymorphisms render patients more or less sensitive to warfarin. A lower initial dose should be given to patients with an increased risk of bleeding, including the elderly. Warfarin usually is administered orally; age correlates with increased sensitivity to the drug. Warfarin also can be given intravenously without modification of the dose. Intramuscular injection is not recommended because of the risk of hematoma formation.

Absorption. The bioavailability of warfarin is nearly complete when the drug is administered orally, intravenously, or rectally. Bleeding has occurred from repeated skin contact with solutions of warfarin used as a rodenticide. However, different commercial preparations of warfarin tablets vary in their rate of dissolution, and this causes some variation in the rate and extent of absorption. Food in the GI tract also can decrease the rate of absorption. Warfarin usually is detectable in plasma within 1 hour of its oral administration, and concentrations peak in 2-8 hours.

Distribution. Warfarin is almost completely (99%) bound to plasma proteins, principally albumin, and the drug distributes rapidly into a volume equivalent to the albumin space (0.14 L/kg). Concentrations in fetal plasma approach the maternal values, but active warfarin is not found in milk (unlike other coumarins and indandiones). Therefore, warfarin can safely be administered to nursing mothers.

Biotransformation and Elimination. Warfarin is administered as a racemic mixture of S- and R-warfarin. S-warfarin is 3-5 fold more potent than R-warfarin and is metabolized principally by CYP2C9. Inactive metabolites of warfarin are excreted in urine and stool. The average rate of clearance from plasma is 0.045 mL/min⁻¹·kg⁻¹. The $t_{1/2}$ varies (25-60 hours), with a mean of ~40 hours; the duration of action of warfarin is 2-5 days.

Polymorphisms in two genes, CYP2C9 and VKORC1 (vitamin K epoxide reductase complex, subunit 1) account for most of the genetic contribution to the variability in warfarin response. CYP2C9 variants affect warfarin pharmacokinetics, whereas VKORC1 variants affect warfarin pharmacodynamics. Common variations in the CYP2C9 gene (designated CYP2C9*2 and *3), encode an enzyme with

decreased activity, and thus are associated with higher drug concentrations and reduced warfarin dose requirements. At least one variant allele of CYP2C9*2 or CYP2C9*3 is present in ~25% of European-Americans, but these variants are relatively uncommon in African-American and Asian populations (Table 30-2). Heterozygosity for CYP2C9*2 or *3 decreases the dose of warfarin required for anticoagulation by approximately 20-30% compared with "wild type" individuals (CYP2C9*1/*1). Homozygosity for CYP2C9*2 or *3 can decrease the warfarin dose requirement by approximately 50-70%. Generally, the *3 allele has a greater effect than the *2 allele.

Consistent with decreased warfarin dose requirements, subjects who carry at least one copy of a CYP2C9 variant allele appear to have an increased risk of bleeding. Thus, compared with individuals with no variant alleles, carriers of CYP2C9*2 and CYP2C9*3 have relative risks of bleeding of 1.91 and 1.77, respectively.

VKORC1 reduces vitamin K epoxide to vitamin K hydroquinone (see Figure 30-7) and is the target of coumarin anticoagulants, such as warfarin. Several genetic variations in VKORC1 are in strong linkage disequilibrium and have been designated haplotypes A and B (or non-A). VKORC1 variants are more prevalent than those of CYP2C9. The prevalence of VKORC1 genetic variants is higher in Asians, followed by European-Americans and African-Americans. Polymorphism in VKORC1 explains ~30% of the variability in warfarin dose requirements. Compared with VKORC1 non-A/non-A homozygotes, the warfarin dose requirement is decreased by ~25% in heterozygotes and ~50% in A/A homozygotes.

The clinical relevance of these genetic polymorphisms remains uncertain. The goal of warfarin therapy is to maintain a patient within a target INR range, most often an INR value between 2 and 3. The risk of serious bleeding increases with INR values >4 and is highest during initiation of warfarin therapy. Variations in VKORC1 have a greater effect than CYP2C9 variants on warfarin responses early in therapy. Patients with VKORC1 haplotype A have significantly higher INR values in the first week of warfarin therapy than non-A homozygotes; those with one or two VKORC1 haplotype A alleles achieve a therapeutic INR more rapidly and are more likely to have an INR >4 than patients with two non-A alleles. Both the VKORC1 haplotype and CYP2C9 genotype have a significant effect on the warfarin dose after the first 2 weeks of therapy.

Based on evidence that genetic variations affect warfarin dose requirements and responses to therapy, the FDA amended the prescribing information for warfarin in 2007 to indicate that lower warfarin initiation doses be considered for patients with CYP2C9 and VKORC1 genetic variations. Efforts to facilitate the rational incorporation of genetic information into patient care have included the development of a warfarin dosing algorithm and point-of-care methods for CYP2C9 and VKORC1 genotyping. In a study of more than 4000 patients, the International Warfarin Pharmacogenetics Consortium (2009) compared the accuracy of a pharmacogenetic algorithm that included VKORC1 and CYP2C9 genotypes with two conventional clinical approaches: one based on clinical information to adjust the initial dose, and the other using a fixed-dose approach. The pharmacogenetic algorithm predicted the warfarin dose significantly better than the other two approaches. Moreover, the pharmacogenetic algorithm significantly improved the dose prediction for patients who required either high or low doses of warfarin (<21 mg/week or >49 mg/week).

Genetic variation clearly affects warfarin dose requirements and predilection to toxicity. Table 30-2 summarizes the effect of

Table 30–2

Frequencies of *CYP2C9* Genotypes and *VKORC1* Haplotypes in Different Populations and Their Effect on Warfarin Dose Requirements

currently known genetic factors on warfarin dose requirements. However, it is not clear whether genotyping patients and modifying warfarin therapy accordingly will improve the quality of anticoagulation as determined by such clinically important outcomes as time to therapeutic INR, time spent within the target INR range, and rates of serious bleeding. Large randomized controlled trials comparing genotype-based therapy with standard care are under way to define the clinical impact of incorporating genetic information into clinical practice.

Drug and Other Interactions. The list of drugs and other factors that may affect the action of oral anticoagulants is prodigious and expanding (Hirsh et al., 2003). Any substance or condition is potentially dangerous if it alters:

- The uptake or metabolism of the oral anticoagulant or vitamin K
- The synthesis, function, or clearance of any factor or cell involved in hemostasis or fibrinolysis
- The integrity of any epithelial surface

Patients must be educated to report the addition or deletion of any medication, including nonprescription drugs and food supplements.

Some of the more commonly described factors that cause a decreased effect of oral anticoagulants include:

- Reduced absorption of drug caused by binding to cholestyramine in the GI tract
- Increased volume of distribution and a short $t_{1/2}$ secondary to hypoproteinemia, as in nephrotic syndrome

- Increased metabolic clearance of drug secondary to induction of hepatic enzymes, especially *CYP2C9*, by barbiturates, carbamazepine, or rifampin
- Ingestion of large amounts of vitamin K-rich foods or supplements
- Increased levels of coagulation factors during pregnancy

The PT can be shortened in any of these cases.

Frequently cited interactions that enhance the risk of hemorrhage in patients taking oral anticoagulants include decreased metabolism due to *CYP2C9* inhibition by amiodarone, azole antifungals, cimetidine, clopidogrel, cotrimoxazole, disulfiram, fluoxetine, isoniazid, metronidazole, sulfapyrazone, tolcapone, or zafirlukast, and displacement from protein binding sites caused by loop diuretics or valproate. Relative deficiency of vitamin K may result from inadequate diet (e.g., postoperative patients on parenteral fluids), especially when coupled with the elimination of intestinal flora by antimicrobial agents. Gut bacteria synthesize vitamin K and are an important source of this vitamin. Consequently, antibiotics can cause excessive PT prolongation in patients adequately controlled on warfarin. In addition to an effect on reducing intestinal flora, cephalosporins containing heterocyclic side chains also inhibit steps in the vitamin K cycle. Low concentrations of coagulation factors may result from impaired hepatic function, congestive heart failure, or hypermetabolic states, such as hyperthyroidism; generally, these conditions increase the prolongation of the PT. Serious interactions that do not alter the PT include inhibition of platelet function by agents such as *aspirin* and gastritis or frank ulceration induced by anti-inflammatory drugs. Agents may have more than one effect; e.g., clofibrate increases the rate of turnover of coagulation factors and

864 inhibits platelet function. Elderly patients are more sensitive to oral anticoagulants.

Resistance to Warfarin. Some patients require >20 mg/day of warfarin to achieve a therapeutic INR. These patients often have excessive vitamin K intake from the diet or parenteral supplementation. Noncompliance and laboratory error are other causes of apparent warfarin resistance. There have been reported a few patients with hereditary warfarin resistance, in whom very high plasma concentrations of warfarin are associated with minimal depression of vitamin K-dependent coagulation factor biosynthesis; mutations in the *VKORC1* gene have been identified in some of these patients (Rost et al., 2004).

Sensitivity to Warfarin. Approximately 10% of patients require <1.5 mg/day of warfarin to achieve an INR of 2-3. As indicated earlier, these patients often possess variant alleles of *CYP2C9* or variant *VKORC1* haplotypes, which affect the pharmacokinetics or pharmacodynamics of warfarin, respectively (Daly and King, 2003).

Toxicities

Bleeding. Bleeding is the major toxicity of warfarin (Hirsh et al., 2003). The risk of bleeding increases with the intensity and duration of anticoagulant therapy, the use of other medications that interfere with hemostasis, and the presence of a potential anatomical source of bleeding. Especially serious episodes involve sites where irreversible damage may result from compression of vital structures (e.g., intracranial, pericardial, nerve sheath, spinal cord) or from massive internal blood loss that may not be diagnosed rapidly (e.g., gastrointestinal, intraperitoneal, retroperitoneal).

Although the reported incidence of major bleeding episodes varies considerably, it is generally <3% per year in patients treated with a target INR of 2-3. The risk of intracranial hemorrhage increases dramatically with an INR >4, especially in older patients. In a large outpatient anticoagulation clinic, the most common factors associated with a transient elevation of the INR to a value >6 were use of a new medication known to potentiate warfarin (e.g., acetaminophen), advanced malignancy, recent diarrheal illness, decreased oral intake, and taking more warfarin than prescribed (Hylek et al., 1998). Patients must be informed of the signs and symptoms of bleeding, and laboratory monitoring should be done at frequent intervals during intercurrent illnesses or any changes of medication or diet.

If the INR is above the therapeutic range but <5 and the patient is not bleeding or in need of a surgical procedure, warfarin can be discontinued temporarily and restarted at a lower dose once the INR is within the therapeutic range (Hirsh et al., 2003). If the INR is ≥ 5 , vitamin K₁ (phytonadione, MEPHYTON, AQUAMEPHYTON) can be given orally at a dose of 1-2.5 mg (for $5 \leq \text{INR} \leq 9$) or 3-5 mg (for $\text{INR} > 9$). These doses of oral vitamin K₁ generally cause the INR to fall substantially within 24-48 hours without rendering the patient resistant to further warfarin therapy. Higher doses or parenteral administration may be required if more rapid correction of the INR is necessary. The effect of vitamin K₁ is delayed for at least several hours because reversal of anticoagulation requires synthesis of fully carboxylated coagulation factors. If immediate hemostatic competence is

necessary because of serious bleeding or profound warfarin overdosage (INR >20), adequate concentrations of vitamin K-dependent coagulation factors can be restored by transfusion of fresh frozen plasma (10-20 mL/kg), supplemented with 10 mg of vitamin K₁, given by slow intravenous infusion. Transfusion of plasma may need to be repeated because the transfused factors (particularly factor VII) are cleared from the circulation more rapidly than the residual oral anticoagulant. Concentrates containing three or four of the vitamin K-dependent clotting factors are available in some countries; these rapidly restore the INR to normal. Vitamin K₁ administered intravenously carries the risk of anaphylactoid reactions and therefore should be used cautiously and administered slowly. Patients who receive high doses of vitamin K₁ may become unresponsive to warfarin for several days, but heparin can be used if continued anticoagulation is required.

Birth Defects. Administration of warfarin during pregnancy causes birth defects and abortion. A syndrome characterized by nasal hypoplasia and stippled epiphyseal calcifications that resemble chondrodysplasia punctata may result from maternal ingestion of warfarin during the first trimester. Central nervous system abnormalities have been reported following exposure during the second and third trimesters. Fetal or neonatal hemorrhage and intrauterine death may occur, even when maternal PT values are in the therapeutic range. Vitamin K antagonists should not be used during pregnancy, but as indicated in the previous section, heparin, LMWH, or fondaparinux can be used safely in this circumstance.

Skin Necrosis. Warfarin-induced skin necrosis is a rare complication characterized by the appearance of skin lesions 3-10 days after treatment is initiated. The lesions typically are on the extremities, but adipose tissue, the penis, and the female breast also may be involved. Lesions are characterized by widespread thrombosis of the microvasculature and can spread rapidly, sometimes becoming necrotic and requiring disfiguring débridement or occasionally amputation. Because protein C has a shorter $t_{1/2}$ than do the other vitamin K-dependent coagulation factors (except factor VII), its functional activity falls more rapidly in response to the initial dose of vitamin K antagonist. It has been proposed that the dermal necrosis is a manifestation of a temporal imbalance between the anticoagulant protein C and one or more of the procoagulant factors and is exaggerated in patients who are partially deficient in protein C or protein S. However, not all patients with heterozygous deficiency of protein C or protein S develop skin necrosis when treated with warfarin, and patients with normal activities of these proteins also can be affected. Morphologically similar lesions can occur in patients with vitamin K deficiency.

Other Toxicities. A reversible, sometimes painful, blue-tinged discoloration of the plantar surfaces and sides of the toes that blanches with pressure and fades with elevation of the legs (purple toe syndrome) may develop 3-8 weeks after initiation of therapy with warfarin; cholesterol emboli released from atheromatous plaques have been implicated as the cause. Other infrequent reactions include alopecia, urticaria, dermatitis, fever, nausea, diarrhea, abdominal cramps, and anorexia.

Warfarin can precipitate the syndromes of venous limb gangrene and multicentric skin necrosis when given to patients with heparin-induced thrombocytopenia who are not receiving a parenteral anticoagulant (Warkentin, 2003). Other anticoagulant agents, such as lepirudin, argatroban, or fondaparinux should be continued

until the heparin-induced thrombocytopenia has resolved (see “Heparin toxicities,” earlier in the chapter).

Clinical Use. Vitamin K antagonists are used to prevent the progression or recurrence of acute DVT or pulmonary embolism following an initial course of heparin. They also are effective in preventing venous thromboembolism in patients undergoing orthopedic or gynecological surgery, recurrent coronary ischemia in patients with acute myocardial infarction, and systemic embolization in patients with prosthetic heart valves or chronic atrial fibrillation. Specific recommendations for oral anticoagulant use for these and other indications have been reviewed (Geerts et al., 2008).

Prior to initiation of therapy, laboratory tests are used in conjunction with the history and physical examination to uncover hemostatic defects that might make the use of vitamin K antagonists more dangerous (e.g., congenital coagulation factor deficiency, thrombocytopenia, hepatic or renal insufficiency, vascular abnormalities). Thereafter, the INR calculated from the patient's PT is used to monitor the extent of anticoagulation and compliance. Therapeutic INR ranges for various clinical indications have been established empirically and reflect dosages that reduce the morbidity from thromboembolic disease while minimally increasing the risk of serious hemorrhage. For most indications, the target INR is 2-3. A higher target INR (e.g., 2.5-3.5) generally is recommended for patients with high-risk mechanical prosthetic heart valves (Hirsh et al., 2003).

For treatment of acute venous thromboembolism, heparin, LMWH, or fondaparinux usually is continued for at least 5 days after warfarin therapy is begun and until the INR is in the therapeutic range on 2 consecutive days. This overlap allows for adequate depletion of the vitamin K-dependent coagulation factors with long $t_{1/2}$, especially factor II. Frequent INR measurements are indicated at the onset of therapy to guard against excessive anticoagulation in the unusually sensitive patient. The testing interval can be lengthened gradually to weekly and then monthly for patients on long-term therapy whose test results have been stable.

Monitoring Anticoagulant Therapy: The INR (International Normalized Ratio). To monitor therapy, a blood sample is obtained, and the PT is determined along with that of a sample of normal pooled plasma. Formerly, the results were reported as a simple ratio of the two PT values. However, this ratio can vary widely depending on the thromboplastin reagent and the instrument used to initiate and detect clot formation. The PT is prolonged when the functional levels of fibrinogen, factor V, or the vitamin K-dependent factors II, VII, or X are decreased. Reduced levels of factor IX or proteins C or S have no effect on the PT. PT measurements are converted to INR measurements by the following equation:

$$\text{INR} = \left(\frac{\text{PT}_{\text{pt}}}{\text{PT}_{\text{ref}}} \right)^{\text{ISI}}$$

where INR = international normalized ratio

ISI = international sensitivity index

The ISI value, supplied by the manufacturer of the test reagent, indicates the relative sensitivity of the PT (determined from a given batch of thromboplastin) to decreases in the vitamin K-dependent coagulation factors in comparison with a World Health Organization human thromboplastin standard. Reagents with lower ISI values are more sensitive to the effects of vitamin K antagonists (i.e., the PT is prolonged to a greater extent in comparison with that obtained with a less-sensitive reagent having a higher ISI). Ideally, the ISI value of each batch of thromboplastin should be confirmed in each clinical laboratory using a set of reference plasmas to control for local variables of sample handling and instrumentation.

The INR does not provide a reliable indication of the degree of anticoagulation in patients with the lupus anticoagulant, in whom the PT and other phospholipid-dependent coagulation tests are prolonged at baseline. In these patients, a chromogenic factor X assay or the prothrombin-proconvertin time assay may be used to monitor therapy (Moll and Ortel, 1997).

Other Vitamin K Antagonists

Phenprocoumon and Acenocoumarol. These agents generally are not available in the U.S. but are prescribed in the E.U. and elsewhere.

Phenprocoumon (MARCUMAR) has a longer plasma $t_{1/2}$ (5 days) than warfarin, as well as a somewhat slower onset of action and a longer duration of action (7-14 days). It is administered in daily maintenance doses of 0.75-6 mg. By contrast, acenocoumarol (SINTHROME) has a shorter $t_{1/2}$ (10-24 hours), a more rapid effect on the PT, and a shorter duration of action (2 days). The maintenance dose is 1-8 mg daily.

Indandione Derivatives. Anisindione (MIRADON) is available for clinical use in some countries. It is similar to warfarin in its kinetics of action but offers no clear advantages and may have a higher frequency of untoward effects. Phenindione (DINDEVAN) still is available in some countries. Serious hypersensitivity reactions, occasionally fatal, can occur within a few weeks of starting therapy with this drug, and its use can no longer be recommended.

Rodenticides. Bromadiolone, brodifacoum, diphenadione, chlorophacinone, and pindone are long-acting agents (prolongation of the PT may persist for weeks). They are of interest because they sometimes are agents of accidental or intentional poisoning. In this setting, reversal of the coagulopathy can require very large doses of vitamin K (i.e., >100 mg/day) for weeks or months.

NEW ORAL ANTICOAGULANTS

Dabigatran Etexilate (PRADAXA, PRADAX). A novel oral anticoagulant, dabigatran etexilate is a prodrug that is rapidly converted to dabigatran, which reversibly blocks the active site of thrombin.

The drug has oral bioavailability of ~6%, a peak onset of action in 2 hours, and a plasma $t_{1/2}$ of 12-14 hours. When given in fixed doses, dabigatran etexilate produces such a predictable anticoagulant response that routine coagulation monitoring is unnecessary.

Dabigatran etexilate is approved in the E.U. and Canada for prevention of venous thromboembolism after elective hip or knee replacement surgery. It is not yet available in the U.S. In phase III trials, dabigatran etexilate was non-inferior to warfarin for treatment of patients with venous thromboembolism (Schulman et al., 2009) and superior to warfarin for stroke prevention in patients with atrial fibrillation (Connolly et al., 2009). Therefore, this drug represents a promising alternative to warfarin for patients who require long-term anticoagulation.

Rivaroxaban (XARELTO). An oral factor Xa inhibitor, rivaroxaban has 80% oral bioavailability, a peak onset of action in 3 hours, and a plasma $t_{1/2}$ of 7-11 hours.

About one-third of the drug is excreted unchanged in the urine, the remainder is metabolized by the liver, and inactive metabolites are excreted in the urine or feces. This drug is given in fixed doses and does not require coagulation monitoring. Like dabigatran etexilate, rivaroxaban also is approved in the E.U. and Canada for thromboprophylaxis after hip or knee replacement surgery. Rivaroxaban is not available in the U.S. Ongoing trials are comparing rivaroxaban with warfarin for treatment of venous thromboembolism and stroke prevention in patients with atrial fibrillation.

Other New Agents. Other new oral anticoagulants include apixaban, edoxaban, betrixaban, YM150, and TAK-442, which are oral factor Xa inhibitors, and AZD0837, which is an oral thrombin inhibitor. Apixaban and edoxaban are currently undergoing phase III clinical evaluation.

FIBRINOLYTIC DRUGS

The fibrinolytic pathway is summarized by Figure 30–3. The action of fibrinolytic agents is best understood in conjunction with an understanding of the characteristics of the physiological components.

Plasminogen. Plasminogen is a single-chain glycoprotein of 791 amino acids; it is converted to an active protease by cleavage at Arg⁵⁶⁰.

Plasminogen's five kringle domains mediate the binding of plasminogen (or plasmin) to carboxyl-terminal lysine residues in partially degraded fibrin; this enhances fibrinolysis. A plasma carboxypeptidase termed *thrombin-activatable fibrinolysis inhibitor* (TAFI) can remove these lysine residues and thereby attenuate fibrinolysis. The lysine binding kringle domains of plasminogen are located between amino acids 80 and 165, and they also promote formation of complexes of plasmin with α_2 -antiplasmin, the major physiological plasmin inhibitor. Plasminogen concentrations in human plasma average 2 μ M. A plasmin-degraded form of plasminogen termed *lys-plasminogen* binds to fibrin with higher affinity than intact plasminogen.

α_2 -Antiplasmin. α_2 -Antiplasmin, a glycoprotein of 452 amino acid residues, forms a stable complex with plasmin, thereby inactivating it.

Plasma concentrations of α_2 -antiplasmin (1 μ M) are sufficient to inhibit about 50% of potential plasmin. When massive activation of plasminogen occurs, the inhibitor is depleted, and free plasmin causes a "systemic lytic state" in which hemostasis is impaired. In this state, fibrinogen is degraded and fibrinogen degradation products impair fibrin polymerization and therefore increase bleeding from wounds. α_2 -Antiplasmin inactivates plasmin nearly instantaneously, as long as the first kringle domain on plasmin is unoccupied by fibrin or other antagonists, such as *aminocaproic acid* (see "Inhibitors of Fibrinolysis" section).

Streptokinase. Streptokinase (STREPTASE) is a 47,000-Da protein produced by β -hemolytic streptococci. It has no intrinsic enzymatic activity but forms a stable, noncovalent 1:1 complex with plasminogen. This produces a conformational change that exposes the active site on plasminogen that cleaves Arg⁵⁶⁰ on free plasminogen to form plasmin.

Since the advent of newer agents, streptokinase is rarely used clinically for fibrinolysis. It currently is not marketed in the U.S.

Tissue Plasminogen Activator. t-PA is a serine protease of 527 amino acid residues. It is a poor plasminogen activator in the absence of fibrin (Lijnen and Collen, 2001). t-PA binds to fibrin via its finger domain and second lysine-binding kringle domain and activates fibrin-bound plasminogen several hundredfold more rapidly than it activates plasminogen in the circulation. The finger domain is homologous to a similar site on fibronectin, whereas the lysine binding kringle domain is homologous to the kringle domains on plasminogen.

Because it has little activity except in the presence of fibrin, physiological t-PA concentrations of 5-10 ng/mL do not induce systemic plasmin generation. During therapeutic infusions of t-PA, however, when concentrations rise to 300-3000 ng/mL, a systemic lytic state can occur. Clearance of t-PA primarily occurs by hepatic metabolism, and its $t_{1/2}$ is ~5 min. t-PA is effective in lysing thrombi during treatment of acute myocardial infarction or acute ischemic stroke.

t-PA (alteplase, ACTIVASE) is produced by recombinant DNA technology. The currently recommended ("accelerated") regimen for coronary thrombolysis is a 15-mg intravenous bolus, followed by 0.75 mg/kg of body weight over 30 minutes (not to exceed 50 mg) and 0.5 mg/kg (up to 35 mg accumulated dose) over the following hour. Recombinant variants of t-PA now are available (reteplase, RETAVASE and tenecteplase, TNKASE). They differ from native t-PA by having longer plasma half-lives that allow convenient bolus dosing; reteplase is administered in two bolus doses given 30 minutes apart, while tenecteplase requires only a single bolus. In contrast to t-PA and reteplase, tenecteplase is relatively resistant to inhibition by PAI-1. Despite these apparent advantages, these agents are similar to t-PA in efficacy and toxicity (GUSTO III Investigators, 1997).

Hemorrhagic Toxicity of Thrombolytic Therapy. The major toxicity of all thrombolytic agents is hemorrhage,

which results from two factors: 1) the lysis of fibrin in hemostatic plugs at sites of vascular injury, and 2) the systemic lytic state that results from systemic plasmin generation, which produces fibrinogenolysis and degradation of other coagulation factors (especially factors V and VIII).

The contraindications to fibrinolytic therapy are listed in Table 30–3. Patients with these conditions should not receive such treatment.

If heparin is used concurrently with t-PA, serious hemorrhage will occur in 2-4% of patients. Intracranial hemorrhage is by far the most serious problem. Hemorrhagic stroke occurs with all regimens and is more common when heparin is used. In several large studies, t-PA was associated with an excess of hemorrhagic strokes of about 0.3% of treated patients. Based on the data of three large trials involving almost 100,000 patients, the efficacies of t-PA and streptokinase in treating myocardial infarction are essentially identical. Both agents reduce death and reinfarction by ~30% in regimens containing aspirin. With good evidence that primary coronary angioplasty with or without stent placement, when feasible, is superior to thrombolytic therapy, the use of fibrinolytic therapy has decreased. Fibrinolytic therapy remains the treatment of choice for patients with acute ischemic stroke who present within 3 hours of symptom onset.

Inhibitors of Fibrinolysis

Aminocaproic Acid. Aminocaproic acid (AMICAR, generic) is a lysine analog that competes for lysine

binding sites on plasminogen and plasmin, blocking the interaction of plasmin with fibrin. Aminocaproic acid is thereby a potent inhibitor of fibrinolysis and can reverse states that are associated with excessive fibrinolysis. The main problem with its use is that thrombi that form during treatment with the drug are not lysed. For example, in patients with hematuria, ureteral obstruction by clots may lead to renal failure after treatment with aminocaproic acid. Aminocaproic acid has been used to reduce bleeding after prostatic surgery or after tooth extractions in hemophiliacs. Use of aminocaproic acid to treat a variety of other bleeding disorders has been unsuccessful, either because of limited benefit or because of thrombosis (e.g., after subarachnoid hemorrhage).

Aminocaproic acid is absorbed rapidly after oral administration, and 50% is excreted unchanged in the urine within 12 hours. For intravenous use, a loading dose of 4-5 g is given over 1 hour, followed by an infusion of 1-1.25 g/hour until bleeding is controlled. No more than 30 g should be given in a 24-hour period. Rarely, the drug causes myopathy and muscle necrosis.

Tranexamic Acid. Tranexamic acid (CYKLOKAPRON, LYSTEDA) is a lysine analog that, like aminocaproic acid, competes for lysine binding sites on plasminogen and plasmin, thus blocking their interaction with fibrin. Tranexamic acid can be used for the same

Table 30–3

Absolute and Relative Contraindications to Fibrinolytic Therapy

Absolute Contraindications

- Prior intracranial hemorrhage
- Known structural cerebral vascular lesion
- Known malignant intracranial neoplasm
- Ischemic stroke within 3 months
- Suspected aortic dissection
- Active bleeding or bleeding diathesis (excluding menses)
- Significant closed-head trauma or facial trauma within 3 months

Relative Contraindications

- Uncontrolled hypertension (systolic blood pressure >180 mm Hg or diastolic blood pressure >110 mm Hg)
- Traumatic or prolonged CPR or major surgery within 3 weeks
- Recent (within 2-4 weeks) internal bleeding
- Noncompressible vascular punctures
- For streptokinase: prior exposure (more than 5 days ago) or prior allergic reaction to streptokinase
- Pregnancy
- Active peptic ulcer
- Current use of warfarin and INR >1.7

CPR, cardiopulmonary resuscitation; INR, international normalized ratio.

868 indications as aminocaproic acid and can be given intravenously or orally.

Like aminocaproic acid, tranexamic acid is excreted in the urine and dose reductions are necessary in patients with renal impairment. The FDA approved oral tranexamic acid tablets for treatment of heavy menstrual bleeding in 2009. When used for this indication, tranexamic acid usually is given at a dose of 1 g four times a day for 4 days.

ANTIPLATELET DRUGS

Platelets provide the initial hemostatic plug at sites of vascular injury. They also participate in pathological thromboses that lead to myocardial infarction, stroke, and peripheral vascular thromboses. Potent inhibitors of platelet function have been developed in recent years. These drugs act by discrete mechanisms; thus, in combination, their effects are additive or even synergistic. Their availability has led to a revolution in cardiovascular medicine, whereby angioplasty and vascular stenting of lesions now are feasible with low rates of restenosis and thrombosis when effective platelet inhibition is employed. The sites of pharmacological intervention by the various antiplatelet drugs are highlighted in Figure 30–8.

Aspirin. Processes including thrombosis, inflammation, wound healing, and allergy are modulated by oxygenated metabolites of arachidonate and related polyunsaturated fatty acids that are collectively termed *eicosanoids*. Interference with the synthesis of eicosanoids is the basis for the effects of many therapeutic agents, including analgesics, anti-inflammatory drugs, and anti-thrombotic agents (see Chapters 33 and 34).

In platelets, the major cyclooxygenase product is TxA_2 (thromboxane A_2), a labile inducer of platelet aggregation and a potent vasoconstrictor. Aspirin blocks production of TxA_2 by acetylating a serine residue near the active site of platelet cyclooxygenase-1 (COX-1), the enzyme that produces the cyclic endoperoxide precursor of TxA_2 . Because platelets do not synthesize new proteins, the action of aspirin on platelet COX-1 is permanent, lasting for the life of the platelet (7–10 days). Thus, repeated doses of aspirin produce a cumulative effect on platelet function.

Complete inactivation of platelet COX-1 is achieved with a daily aspirin dose of 75 mg. Therefore, aspirin is maximally effective as an anti-thrombotic agent at doses much lower than those required for other actions of the drug. Numerous trials indicate that aspirin, when used as an anti-thrombotic drug, is maximally effective at doses of 50–320 mg/day (Antithrombotic Trialists' Collaboration, 2002; Patrono et al., 2004). Higher doses do not improve efficacy; moreover,

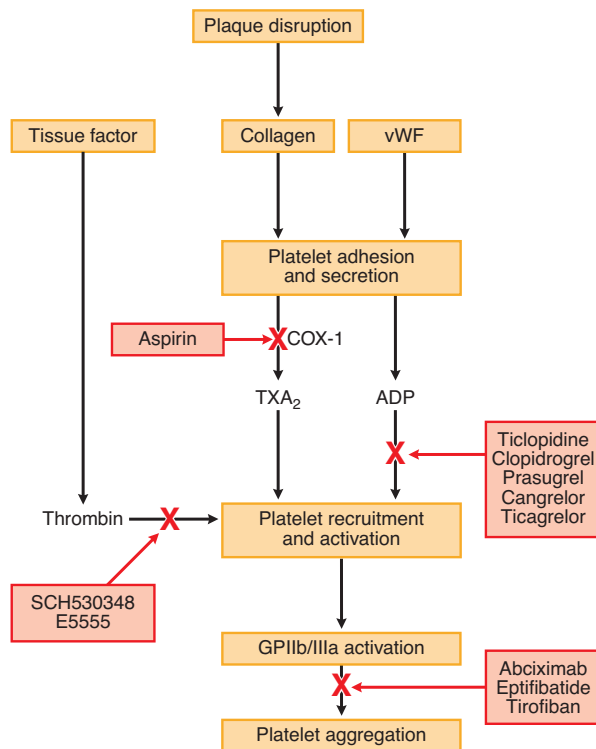

Figure 30–8. Sites of action of antiplatelet drugs. Aspirin inhibits thromboxane A_2 (TxA_2) synthesis by irreversibly acetylating cyclooxygenase-1 (COX-1). Reduced TxA_2 release attenuates platelet activation and recruitment to the site of vascular injury. Ticlopidine, clopidogrel, and prasugrel irreversibly block P2Y_{12} , a key ADP receptor on the platelet surface; cangrelor and ticagrelor are reversible inhibitors of P2Y_{12} . Abciximab, eptifibatid, and tirofiban inhibit the final common pathway of platelet aggregation by blocking fibrinogen and von Willebrand factor (vWF) from binding to activated glycoprotein (GP) IIB/IIIa. SCH530348 and E5555 inhibit thrombin-mediated platelet activation by targeting protease-activated receptor-1 (PAR-1), the major thrombin receptor on platelets.

they potentially are less efficacious because of inhibition of prostacyclin production, which can be largely spared by using lower doses of aspirin. Higher doses also increase toxicity, especially bleeding.

Other NSAIDs that are reversible inhibitors of COX-1 have not been shown to have anti-thrombotic efficacy and in fact may even interfere with low-dose aspirin regimens (see Chapters 33 and 34 for details).

Dipyridamole. Dipyridamole (PERSANTINE, others) interferes with platelet function by increasing the cellular concentration of cyclic AMP. This effect is mediated by inhibition of cyclic nucleotide phosphodiesterases and/or by blockade of uptake of adenosine, which acts at adenosine A_2 receptors to stimulate platelet adenylyl cyclase and thence cellular cyclic AMP. Dipyridamole

is a vasodilator that, in combination with warfarin, inhibits embolization from prosthetic heart valves. The drug has little or no benefit as an anti-thrombotic agent.

In trials in which a regimen of dipyridamole plus aspirin was compared with aspirin alone, dipyridamole provided no additional beneficial effect (Antithrombotic Trialists' Collaboration, 2002). Two studies suggest that dipyridamole plus aspirin reduces strokes in patients with prior strokes or transient ischemic attacks (Diener et al., 1996). A formulation containing 200 mg of dipyridamole, in an extended-release form, and 25 mg of aspirin (AGGRENOX) is available. A recent study comparing this combination with clopidogrel for secondary prevention in patients with stroke or transient ischemic attacks showed no advantage of dipyridamole plus aspirin.

Ticlopidine (TICLID, others). Platelets contain two purinergic receptors, P2Y₁ and P2Y₁₂; both are GPCRs for ADP. The ADP-activated platelet P2Y₁ receptor couples to the G_q-PLC-IP₃-Ca²⁺ pathway and induces a shape change and aggregation. The P2Y₁₂ receptor couples to G_i and, when activated by ADP, inhibits adenylyl cyclase, resulting in lower levels of cyclic AMP and thereby less cyclic AMP-dependent inhibition of platelet activation. Based on pharmacological studies, it appears that both receptors must be stimulated to result in platelet activation (Jin and Kunapuli, 1998), and inhibition of either receptor is sufficient to block platelet activation. Ticlopidine is a thienopyridine prodrug (Figure 30–9) that inhibits the P2Y₁₂ receptor.

Ticlopidine is converted to the active thiol metabolite by a hepatic CYP (Savi et al., 2000). It is rapidly absorbed and highly bioavailable. It permanently inhibits the P2Y₁₂ receptor by forming a disulfide bridge between the thiol on the drug and a free cysteine residue in the extracellular region of the receptor, and thus has a prolonged effect. Like aspirin, it has a short t_{1/2} but a long duration of action, which has been termed “hit-and-run pharmacology” (Hollopeter et al., 2001). Maximal inhibition of platelet aggregation is not seen until 8–11 days after starting therapy. The usual dose is 250 mg twice daily. Loading doses of 500 mg sometimes are given to achieve a more rapid onset of action. Inhibition of platelet aggregation persists for a few days after the drug is stopped.

Adverse Effects. The most common side effects are nausea, vomiting, and diarrhea. The most serious is severe neutropenia (absolute neutrophil count <500/μL), which occurred in 2.4% of stroke patients given the drug during premarketing clinical trials. Fatal agranulocytosis with thrombopenia has occurred within the first 3 months of therapy; therefore, frequent blood counts should be obtained during the first few months of therapy, with immediate discontinuation of therapy should cell counts decline. Platelet counts also should be monitored, as thrombocytopenia has been reported. Rare cases of thrombotic thrombocytopenic purpura-hemolytic uremic syndrome (TTP-HUS) have been associated with ticlopidine, with a reported incidence of 1 in 1600–4800 patients when the drug is used after cardiac stenting; the mortality associated

Figure 30–9. Structures of ticlopidine, clopidogrel, and prasugrel.

with these cases is reported to be as high as 18–57% (Bennett et al., 2000). Remission of TTP has been reported when the drug is stopped (Quinn and Fitzgerald, 1999).

Therapeutic Uses. Ticlopidine has been shown to prevent cerebrovascular events in secondary prevention of stroke and is at least as good as aspirin in this regard (Patrono et al., 1998). Because ticlopidine is associated with life-threatening blood dyscrasias and a relatively high rate of TTP, it has largely been replaced by clopidogrel.

Clopidogrel (PLAVIX). Clopidogrel is closely related to ticlopidine (Figure 30–9). Clopidogrel also is an irreversible inhibitor of platelet P2Y₁₂ receptors but is more potent and has a more favorable toxicity profile than ticlopidine, with thrombocytopenia and leukopenia occurring only rarely (Bennett et al., 2000). Clopidogrel is a prodrug with a slow onset of action.

The usual dose is 75 mg/day with or without an initial loading dose of 300 or 600 mg. The drug is somewhat better than aspirin in the secondary prevention of stroke, and the combination of clopidogrel plus aspirin is superior to aspirin alone for prevention of recurrent ischemia in patients with unstable angina. The superiority of the combination suggests that the actions of the two drugs are synergistic, as might be expected from their distinct mechanisms of action. Clopidogrel is used with aspirin after angioplasty and coronary stent implantation, and this combination should be continued for at least 4–6 weeks in patients with a bare metal stent and for at least 1 year in those with a drug-eluting stent. The FDA-approved indications

for clopidogrel are to reduce the rate of stroke, myocardial infarction, and death in patients with recent myocardial infarction or stroke, established peripheral arterial disease, or acute coronary syndrome.

There is wide inter-individual variability in the capacity of clopidogrel to inhibit ADP-induced platelet aggregation, and some patients are designated resistant to the antiplatelet effects of the drug. This variability reflects, at least in part, genetic polymorphisms in the CYPs involved in the metabolic activation of clopidogrel, most importantly *CYP2C19*. Clopidogrel-treated patients with the loss-of-function *CYP2C19*2* allele exhibit reduced platelet inhibition compared with those with the wild-type *CYP2C19*1* allele and experience a higher rate of cardiovascular events (see Table 30–2). Even patients with the reduced-function *CYP2C19*3*, **4*, or **5* alleles may derive less benefit from clopidogrel than those with the full-function *CYP2C19*1* allele. Concomitant administration of proton pump inhibitors, which are inhibitors of *CYP2C19*, with clopidogrel, produces a small reduction in the inhibitory effects of clopidogrel on ADP-induced platelet aggregation. The extent to which this interaction increases the risk of cardiovascular events remains controversial. Although *CYP3A4* also contributes to the metabolic activation of clopidogrel, polymorphisms in this enzyme do not appear to influence clopidogrel responsiveness. However, a small study in patients undergoing percutaneous coronary interventions revealed that atorvastatin, a competitive inhibitor of *CYP3A4*, reduced the inhibitory effect of clopidogrel on ADP-induced platelet aggregation. The impact of this interaction on clinical outcomes is unknown.

The observation that genetic polymorphisms that affect clopidogrel metabolism influence clinical outcomes raises the possibilities that pharmacogenetic profiling may be useful to identify clopidogrel-resistant patients and that point-of-care assessment of the extent of clopidogrel-induced platelet inhibition may help detect patients at higher risk for subsequent cardiovascular events. It is unknown whether administration of higher doses of clopidogrel to such patients will overcome this resistance.

Prasugrel (EFFIENT or EFIENT). The newest member of the thienopyridine class, prasugrel (Figure 30–9) also is a prodrug that requires metabolic activation. However, its onset of action is more rapid than that of ticlopidine or clopidogrel, and prasugrel produces greater and more predictable inhibition of ADP-induced platelet aggregation.

These characteristics reflect the rapid and complete absorption of prasugrel from the gut and its more efficient activation pathways. Virtually all of the absorbed prasugrel undergoes activation; by comparison, only 15% of absorbed clopidogrel undergoes metabolic activation, with the remainder inactivated by esterases.

Because the active metabolites of prasugrel and the other thienopyridines bind irreversibly to the P2Y₁₂ receptor, these drugs have a prolonged effect after discontinuation. This can be problematic if patients require urgent surgery. Such patients are at increased risk for bleeding unless the thienopyridine is stopped at least 5 days prior to the procedure.

Prasugrel was compared with clopidogrel in patients with acute coronary syndromes scheduled to undergo a coronary intervention. The incidence of cardiovascular death, myocardial infarction, and stroke was significantly lower with prasugrel than with

clopidogrel mainly reflecting a reduction in the incidence of nonfatal myocardial infarction. The incidence of stent thrombosis also was lower with prasugrel than with clopidogrel. However, these advantages were at the expense of significantly higher rates of fatal and life-threatening bleeding. Because patients with a history of a prior stroke or transient ischemic attack are at particularly high risk of bleeding, the drug is contraindicated in those with a history of cerebrovascular disease. Caution is required if prasugrel is used in patients weighing <60 kg or in those with renal impairment. After a loading dose of 60 mg, prasugrel is given once daily at a dose of 10 mg. Patients >75 years of age or weighing <60 kg may do better with a daily prasugrel dose of 5 mg.

In contrast to their effect on the bioactivation of clopidogrel, *CYP2C19* polymorphisms appear to be less important determinants of the activation of prasugrel. There is no association between the loss-of-function allele and decreased platelet inhibition or increased rates of cardiovascular events with prasugrel. Therefore, prasugrel may be a reasonable alternative to clopidogrel in patients with the loss-of-function *CYP2C19* allele.

Glycoprotein IIb/IIIa Inhibitors. Glycoprotein IIb/IIIa is a platelet-surface integrin, which is designated $\alpha_{IIb}\beta_3$ by the integrin nomenclature. There are about 80,000 copies of this dimeric glycoprotein on the platelet surface. Glycoprotein IIb/IIIa is inactive on resting platelets but undergoes a conformational transformation when platelets are activated by platelet agonists such as thrombin, collagen, or TxA₂. This transformation endows glycoprotein IIb/IIIa with the capacity to serve as a receptor for fibrinogen and von Willebrand factor, which anchor platelets to foreign surfaces and to each other, thereby mediating aggregation. Inhibition of binding to this receptor blocks platelet aggregation induced by any agonist. Thus, inhibitors of this receptor are potent antiplatelet agents that act by a mechanism distinct from that of aspirin or the thienopyridine platelet inhibitors. Three agents are approved for use at present, and their features are highlighted in Table 30–4.

Abciximab. Abciximab (REOPRO) is the Fab fragment of a humanized monoclonal antibody directed against the $\alpha_{IIb}\beta_3$ receptor. It also binds to the vitronectin receptor on platelets, vascular endothelial cells, and smooth muscle cells.

The antibody is administered to patients undergoing percutaneous angioplasty for coronary thromboses, and when used in conjunction with aspirin and heparin, has been shown to prevent restenosis, recurrent myocardial infarction, and death. The unbound antibody is cleared from the circulation with a $t_{1/2}$ of about 30 minutes, but antibody remains bound to the $\alpha_{IIb}\beta_3$ receptor and inhibits platelet aggregation as measured *in vitro* for 18–24 hours after infusion is stopped. It is given as a 0.25-mg/kg bolus followed by 0.125 μ g/kg/min for 12 hours or longer.

Adverse Effects. The major side effect of abciximab is bleeding, and the contraindications to its use are similar to those for the fibrinolytic

Table 30–4

Features of GPIIb/IIIa Antagonists

FEATURE	ABCIXIMAB	EPTIFIBATIDE	TIROFIBAN
<i>Description</i>	Fab fragment of humanized mouse monoclonal antibody	Cyclical KGD-containing heptapeptide	Nonpeptidic RGD-mimetic
<i>Specific for GPIIb/IIIa</i>	No	Yes	Yes
<i>Plasma $t_{1/2}$</i>	Short (min)	Long (2.5 h)	Long (2.0 h)
<i>Platelet-bound $t_{1/2}$</i>	Long (days)	Short (sec)	Short (sec)
<i>Renal clearance</i>	No	Yes	Yes

KGD, Lysine - Glycine - Aspartate; RGD, Arginine - Glycine - Aspartate.

agents listed in Table 30–3. The frequency of major hemorrhage in clinical trials varies from 1-10%, depending on the intensity of anticoagulation with heparin. Thrombocytopenia with a platelet count <50,000 occurs in about 2% of patients and may be due to development of neo-epitopes induced by bound antibody. Since the duration of action is long, if major bleeding or emergent surgery occurs, platelet transfusions can reverse the aggregation defect because free antibody concentrations fall rapidly after cessation of infusion. Readministration of antibody has been performed in a small number of patients without evidence of decreased efficacy or allergic reactions. The expense of the antibody limits its use.

Eptifibatide. Eptifibatide (INTEGRILIN) is a cyclic peptide inhibitor of the fibrinogen binding site on $\alpha_{IIb}\beta_3$. It is administered intravenously and blocks platelet aggregation.

Eptifibatide is given as a bolus of 180 $\mu\text{g}/\text{kg}$ followed by 2 $\mu\text{g}/\text{kg}/\text{min}$ for up to 96 hours. It is used to treat acute coronary syndrome and for angioplastic coronary interventions. In the latter case, myocardial infarction and death have been reduced by ~20%. Although the drug has not been compared directly to abciximab, it appears that its benefit is somewhat less than that obtained with the antibody, perhaps because eptifibatide is specific for $\alpha_{IIb}\beta_3$ and does not react with the vitronectin receptor. The duration of action of the drug is relatively short, and platelet aggregation is restored within 6-12 hours after cessation of infusion. Eptifibatide generally is administered in conjunction with aspirin and heparin.

Adverse Effects. The major side effect is bleeding, as is the case with abciximab. The frequency of major bleeding in trials was about 10%, compared with ~9% in a placebo group, which included heparin. Thrombocytopenia has been seen in 0.5-1% of patients.

Tirofiban. Tirofiban (AGGRASTAT) is a nonpeptide, small-molecule inhibitor of $\alpha_{IIb}\beta_3$ that appears to have a mechanism of action similar to eptifibatide. Tirofiban has a short duration of action and has efficacy in non-Q-wave myocardial infarction and unstable angina. Reductions in death and myocardial infarction have

been ~20% compared to placebo, results similar to those with eptifibatide.

Side effects also are similar to those of eptifibatide. The agent is specific to $\alpha_{IIb}\beta_3$ and does not react with the vitronectin receptor. Meta-analysis of trials using $\alpha_{IIb}\beta_3$ inhibitors suggests that their value in antiplatelet therapy after acute myocardial infarction is limited (Boersma et al., 2002). Tirofiban is administered intravenously at an initial rate of 0.4 $\mu\text{g}/\text{kg}/\text{min}$ for 30 minutes, and then continued at 0.1 $\text{mg}/\text{kg}/\text{min}$ for 12-24 hours after angioplasty or atherectomy. It is used in conjunction with heparin.

Newer Antiplatelet Agents

New agents in advanced stages of development include cangrelor and ticagrelor (BRILINTA), direct-acting reversible P2Y₁₂ antagonists, and SCH530348 and E5555, orally active inhibitors of the protease-activated receptor-1 (PAR-1), the major thrombin receptor on platelets.

Cangrelor. Cangrelor is an adenosine analog that binds reversibly to P2Y₁₂ and inhibits its activity. The drug has a $t_{1/2}$ of 3-6 minutes and is given intravenously as a bolus followed by an infusion. When stopped, platelet function recovers within 60 minutes. Recent trials comparing cangrelor with placebo during coronary interventions or comparing cangrelor with clopidogrel after such procedures revealed little or no advantages of cangrelor.

Ticagrelor. Ticagrelor is an orally active, reversible inhibitor of P2Y₁₂. The drug is given twice daily and not only has a more rapid onset and offset of action than clopidogrel, but also produces greater and more predictable inhibition of ADP-induced platelet aggregation. When compared with clopidogrel in patients with acute coronary syndromes (Wallentin et al., 2009), ticagrelor produced a greater reduction in cardiovascular death, myocardial infarction, and stroke at 1 year than clopidogrel did. This difference reflected a significant reduction in both cardiovascular death and myocardial infarction with ticagrelor. Rates of stroke were similar with ticagrelor and clopidogrel, and there were no differences in rates of major bleeding. When minor bleeding was added to the major bleeding results, however, ticagrelor showed an increase relative to clopidogrel. Although not yet

872 approved, ticagrelor is the first new antiplatelet drug to demonstrate a reduction in cardiovascular death compared with clopidogrel in patients with acute coronary syndromes.

SCH530348. SCH530348 an orally active inhibitor of PAR-1, is under investigation as an adjunct to aspirin or aspirin plus clopidogrel. Two large phase III trials are under way. E5555, a second oral PAR-1 antagonist, is earlier in development.

THE ROLE OF VITAMIN K

Vitamin K is essential in both mammals and photosynthetic organisms. In certain photosynthetic bacteria, vitamin K is a cofactor in the photosynthetic electron-transport system; in green plants, vitamin K_1 is a component of photosystem I, the membrane-bound, macromolecular light-sensitive complex. Green plants are a nutritional source of vitamin K for humans, in whom vitamin K is an essential cofactor in the γ -carboxylation of multiple glutamate residues of several clotting factors and anticoagulant proteins. The vitamin K-dependent formation of Gla residues permits the appropriate interactions of clotting factors, Ca^{2+} , and membrane phospholipids and modulator proteins (Figures 30–1, 30–2, and 30–3). Vitamin K antagonists (coumarin derivatives; Figure 30–6) block Gla (γ -carboxyglutamate) formation and thereby inhibit clotting; excess vitamin K_1 can reverse the effects of these oral anticoagulants.

History. In 1929, Dam observed that chickens fed inadequate diets developed a deficiency disease characterized by spontaneous bleeding and reduced prothrombin in the blood. Subsequently, Dam and coworkers (1935, 1936) found that the condition could be alleviated rapidly by feeding an unidentified fat-soluble substance, named *vitamin K* (*Koagulation* vitamin) by Dam. Independently, Almquist and Stokstad (1935) performed similar work. Quick and coworkers (1935) observed a coagulation defect in jaundiced individuals that was due to a decrease in the plasma concentration of prothrombin. In the same year, Hawkins and Whipple reported that animals with biliary fistulas were likely to develop excessive bleeding. Subsequently, Hawkins and Brinkhous (1936) showed that this, too, was due to a deficiency in prothrombin and that the condition could be relieved by the feeding of bile salts. The culmination of these studies came with the demonstration by Butt and coworkers (1938) and Warner and associates (1938) that combination therapy with vitamin K and bile salts was effective in the treatment of the hemorrhagic diathesis of jaundice. Thus, the relationship between vitamin K, adequate hepatic function, and the physiological mechanisms operating in the normal clotting of blood was established.

Chemistry and Occurrence. Vitamin K activity is associated with at least two distinct natural substances, designated as vitamin K_1 and vitamin K_2 . Vitamin K_1 , or *phytonadione* (also referred to as *phylloquinone*), is 2-methyl-3-phytyl-1,4-naphthoquinone; it is found in plants and is the only natural vitamin K available for therapeutic use. Vitamin K_2 actually is a series of compounds (the *menaquinones*) in

which the phytyl side chain of phytonadione has been replaced by a side chain built up of 2–13 prenyl units. Considerable synthesis of menaquinones occurs in Gram-positive bacteria; indeed, intestinal flora synthesize the large amounts of vitamin K contained in human and animal feces (Bentley and Meganathan, 1982). Depending on the bioassay system used, menadione is at least as active on a molar basis as phytonadione.

Physiological Functions and Pharmacological Actions.

In animals and humans, phytonadione and menaquinones promote the biosynthesis of: the Gla forms of factors II (prothrombin), VII, IX, and X; anticoagulant proteins C and S; protein Z (a cofactor to the inhibitor of Xa); the bone Gla protein osteocalcin; the matrix Gla protein; the growth arrest-specific protein 6 (Gas6); and four transmembrane monospans of unknown function (Brown et al., 2000; Broze, 2001; Kulman et al., 2001).

Figure 30–7 summarizes the coupling of the vitamin K cycle with glutamate carboxylation. Vitamin K, as KH_2 , the reduced vitamin K hydroquinone, is an essential cofactor for γ -glutamyl carboxylase (Rishavy et al., 2004). Using KH_2 , O_2 , CO_2 , and the glutamate-containing substrate, the enzyme forms a Gla protein and concomitantly, the 2,3-epoxide of vitamin K. A coumarin-sensitive 2,3-epoxide reductase regenerates KH_2 . The γ -glutamyl carboxylase and epoxide reductase are integral membrane proteins of the endoplasmic reticulum and seem to function as a multicomponent system that may include the chaperone protein, calumenin, which reportedly inhibits γ -carboxylation (Wajih et al., 2004). Two natural mutations in γ -glutamyl carboxylase lead to bleeding disorders (Mutucumarana et al., 2003). With respect to proteins affecting blood coagulation, these reactions occur in the liver, but γ -carboxylation of glutamate also occurs in lung, bone, and other cell types. Vitamin K epoxide reductase recently has been cloned (Rost et al., 2004; Li et al., 2004).

The γ -carboxylation reaction is aided by the grouping of glutamate residues in a *Gla domain* (~45 residues in clotting factors) near the amino terminus of the nascent substrate protein; the reaction is guided by an adjacent propeptide (18–28 amino acids) that interacts with the carboxylase. In the case of the vitamin K-dependent clotting proteins, the Gla domain is ~45 residues long, and 9–13 glutamates

are γ -carboxylated in the primary sequence of the Gla domain, C-terminal to the propeptide. The Glu \rightarrow Gla conversion enables the factors to interact well with Ca^{2+} and thence with phospholipids of platelet membranes, positioning the factors in the proper conformations for interacting with their substrates and modulators. In the absence of vitamin K (or in the presence of a coumarin derivative), newly synthesized vitamin K-dependent clotting factors lack Gla residues and are inactive because the molecular conformations needed for their interactions are not achieved.

Human Requirements. The human requirement for vitamin K has not been defined precisely. In patients made vitamin K deficient by a starvation diet and antibiotic therapy for 3-4 weeks, the minimum daily requirement is estimated to be 0.03 $\mu\text{g}/\text{kg}$ of body weight (Frick, 1967) and possibly as high as 1 $\mu\text{g}/\text{kg}$, which is approximately the recommended intake for adults (70 $\mu\text{g}/\text{day}$).

Symptoms of Deficiency. The chief clinical manifestation of vitamin K deficiency is an increased tendency to bleed (see the discussion of hypoprothrombinemia in the section on “Oral Anticoagulants,” earlier in the chapter). Ecchymoses, epistaxis, hematuria, GI bleeding, and postoperative hemorrhage are common; intracranial hemorrhage may occur. Hemoptysis is uncommon. The discovery of a vitamin K-dependent protein in bone suggests that the fetal bone abnormalities associated with the administration of oral anticoagulants during the first trimester of pregnancy (“fetal warfarin syndrome”) may be related to a deficiency of the vitamin.

Considerable evidence indicates a role for vitamin K in adult skeletal maintenance and the prevention of osteoporosis. Low concentrations of the vitamin are associated with deficits in bone mineral density and fractures; vitamin K supplementation increases the carboxylation state of osteocalcin and also improves bone mineral density, but the relationship of these two effects is unclear (Feskanich et al., 1999). Bone mineral density in adults is not changed by therapeutic use of vitamin K antagonists (Rosen et al., 1993), but new bone formation may be affected.

Toxicity. Phytonadione and the menaquinones are nontoxic to animals, even when given at 500 times the recommended daily allowance. However, menadione and its derivatives (synthetic forms of vitamin K) have been implicated in producing hemolytic anemia and kernicterus in neonates, especially in premature infants (Diploma and Ritchie, 1997). For this reason, menadione should not be used as a therapeutic form of vitamin K.

Absorption, Fate, and Excretion. The mechanism of intestinal absorption of compounds with vitamin K activity varies with their solubility. In the presence of bile salts, phytonadione and the menaquinones are adequately absorbed from the intestine, almost entirely by way of the lymph. Phytonadione is absorbed by an energy-dependent, saturable process in proximal portions of the small intestine; menaquinones are absorbed by diffusion in the distal portions of the small intestine and in the colon. Following absorption, phytonadione is incorporated into chylomicrons in close association with triglycerides and lipoproteins. In a large survey, plasma phytonadione and triglyceride concentration were well correlated (Sadowski et al., 1989). The extremely low phytonadione levels in newborns may be partly related to very low plasma lipoprotein concentrations at birth and may lead to an underestimation of vitamin K tissue stores. After absorption, phytonadione and menaquinones are concentrated in the liver, but the concentration of phytonadione declines rapidly. Menaquinones, produced in the lower

bowel, are less biologically active than phytonadione due to their long side chain. Very little vitamin K accumulates in other tissues.

Phytonadione is metabolized rapidly to more polar metabolites, which are excreted in the bile and urine. The major urinary metabolites result from shortening of the side chain to five or seven carbon atoms, yielding carboxylic acids that are conjugated with glucuronate prior to excretion.

Apparently, there is only modest storage of vitamin K in the body. Under circumstances in which lack of bile interferes with absorption of vitamin K, hypoprothrombinemia develops slowly over several weeks.

Therapeutic Uses. Vitamin K is used therapeutically to correct the bleeding tendency or hemorrhage associated with its deficiency. Vitamin K deficiency can result from inadequate intake, absorption, or utilization of the vitamin, or as a consequence of the action of a vitamin K antagonist.

Phytonadione (AQUAMEPHYTON, KONAKION, MEPHYTON, generic) is available as tablets and in a dispersion with buffered polysorbate and propylene glycol (KONAKION) or polyoxyethylated fatty acid derivatives and dextrose (AQUAMEPHYTON). KONAKION is administered only intramuscularly. AQUAMEPHYTON may be given by any route; however, oral or subcutaneous injection is preferred because severe reactions resembling anaphylaxis have followed its intravenous administration.

Inadequate Intake. After infancy, hypoprothrombinemia due to dietary deficiency of vitamin K is extremely rare: The vitamin is present in many foods and also is synthesized by intestinal bacteria. Occasionally, the use of a broad-spectrum antibiotic may itself produce a hypoprothrombinemia that responds readily to small doses of vitamin K and reestablishment of normal bowel flora. Hypoprothrombinemia can occur in patients receiving prolonged intravenous alimentation. It is recommended to give 1 mg of phytonadione per week (the equivalent of about 150 $\mu\text{g}/\text{day}$) to patients on total parenteral nutrition.

Hypoprothrombinemia of the Newborn. Healthy newborn infants show decreased plasma concentrations of vitamin K-dependent clotting factors for a few days after birth, the time required to obtain an adequate dietary intake of the vitamin and to establish a normal intestinal flora. In premature infants and in infants with hemorrhagic disease of the newborn, the concentrations of clotting factors are particularly depressed. The degree to which these changes reflect true vitamin K deficiency is controversial. Measurements of non- γ -carboxylated prothrombin suggest that vitamin K deficiency occurs in about 3% of live births (Shapiro et al., 1986).

Hemorrhagic disease of the newborn has been associated with breast-feeding; human milk has low concentrations of vitamin K (Haroon et al., 1982). In addition, the intestinal flora of breast-fed infants may lack microorganisms that synthesize the vitamin (Keenan et al., 1971). Commercial infant formulas are supplemented with vitamin K.

In the neonate with hemorrhagic disease of the newborn, the administration of vitamin K raises the concentration of these clotting factors to the level normal for the newborn infant and controls the bleeding tendency within about 6 hours. The routine administration of 1 mg phytonadione intramuscularly at birth is required by law in the U.S. This dose may have to be increased or repeated if the mother

has received anticoagulant or anticonvulsant drug therapy or if the infant develops bleeding tendencies. Alternatively, some clinicians treat mothers who are receiving anticonvulsants with oral vitamin K prior to delivery (20 mg/day for 2 weeks) (Vert and Deblay, 1982).

Inadequate Absorption. Vitamin K is poorly absorbed in the absence of bile. Thus, hypoprothrombinemia may be associated with either intrahepatic or extrahepatic biliary obstruction or a severe defect in the intestinal absorption of fat from other causes.

Biliary Obstruction or Fistula. Bleeding that accompanies obstructive jaundice or biliary fistula responds promptly to the administration of vitamin K. Oral phytonadione administered with bile salts is both safe and effective and should be used in the care of the jaundiced patient, both preoperatively and postoperatively. In the absence of significant hepatocellular disease, the prothrombin activity of the blood rapidly returns to normal. If oral administration is not feasible, a parenteral preparation should be used. The usual dose is 10 mg/day of vitamin K.

The treatment of a patient during hemorrhage requires transfusion of fresh blood or reconstituted fresh plasma. Vitamin K also should be given. If biliary obstruction has caused hepatic injury, the response to vitamin K may be poor.

Malabsorption Syndromes. Among the disorders that result in inadequate absorption of vitamin K from the intestinal tract are cystic fibrosis, sprue, Crohn's disease and enterocolitis, ulcerative colitis, dysentery, and extensive resection of bowel. Because drugs that greatly reduce the bacterial population of the bowel are used frequently in many of these disorders, the availability of the vitamin may be further reduced. Moreover, dietary restrictions also may limit the availability of the vitamin. For immediate correction of the deficiency, parenteral therapy should be used.

Inadequate Utilization. Hepatocellular disease may be accompanied or followed by hypoprothrombinemia. Hepatocellular damage also may be secondary to long-lasting biliary obstruction. In these conditions, the damaged parenchymal cells may not be able to produce the vitamin K-dependent clotting factors, even if excess vitamin is available. However, if an inadequate secretion of bile salts is contributing to the syndrome, some benefit may be obtained from the parenteral administration of 10 mg of phytonadione daily. Paradoxically, the administration of large doses of vitamin K or its analogs in an attempt to correct the hypoprothrombinemia associated with severe hepatitis or cirrhosis actually may result in a further depression of the concentration of prothrombin. The mechanism for this action is unknown.

Drug- and Venom-Induced Hypoprothrombinemia. Anticoagulant drugs such as warfarin and its congeners act as competitive antagonists of vitamin K and interfere with the hepatic biosynthesis of Gla-containing clotting factors. The treatment of bleeding caused by oral anticoagulants is discussed earlier in this chapter. Vitamin K may be of help in combating the bleeding and hypoprothrombinemia that follow the bite of the tropical American pit viper or other species whose venom destroys or inactivates prothrombin.

CLINICAL SUMMARY

A variety of anticoagulant, fibrinolytic, and antiplatelet agents are available and are among the most widely

used drugs. Heparin and LMWHs are commonly used to treat venous thromboembolism, unstable angina, and acute myocardial infarction; these agents also are used to prevent thrombosis during coronary angioplasty and for certain other high-risk indications. The major toxicities of heparin are bleeding and the syndrome of heparin-induced thrombocytopenia, which often precipitates venous or arterial thrombosis. Direct thrombin inhibitors, such as lepirudin, bivalirudin, and argatroban, are indicated for patients with heparin-induced thrombocytopenia.

Warfarin and other vitamin K antagonists are used to prevent the progression or recurrence of acute venous thromboembolism following an initial course of heparin. They also decrease the incidence of systemic embolization in patients with atrial fibrillation or prosthetic heart valves. Warfarin has a narrow therapeutic index drug and is associated with more than 200 drug-drug and drug-food interactions. Over- and under-dosing are associated with serious consequences, including thrombosis or major bleeding in a significant number of patients. Warfarin also produces fetal abnormalities when given during pregnancy. New oral anticoagulants that target thrombin or factor Xa hopefully will replace warfarin in the future. These drugs have the potential to streamline care because they can be given in fixed doses without coagulation monitoring.

Fibrinolytic agents, such as t-PA or its derivatives, reduce the mortality of acute myocardial infarction and are used in situations in which angioplasty is not readily available. Fibrinolytic therapy also is used for patients with acute ischemic stroke.

Antiplatelet agents, including aspirin, clopidogrel, prasugrel, and glycoprotein IIb/IIIa inhibitors, are used to prevent thrombosis after coronary angioplasty and in the secondary prevention of myocardial infarction and stroke. Bleeding is the major toxicity of the antiplatelet agents. Newer antiplatelet drugs that directly target the ADP or thrombin receptor on platelets are in advanced stages of development. These more potent antiplatelet drugs may produce more bleeding, highlighting the inevitable link between the efficacy and toxicity of anti-thrombotic drugs.

31 chapter

Drug Therapy for Hypercholesterolemia and Dyslipidemia

Thomas P. Bersot

Hyperlipidemia is a major cause of atherosclerosis and atherosclerosis-induced conditions, such as coronary heart disease (CHD), ischemic cerebrovascular disease, and peripheral vascular disease. Although the incidence of these atherosclerosis-related cardiovascular disease (CVD) events has declined in the U.S., these conditions cause morbidity or mortality in a majority of middle-aged or older adults and account for about one-third of all deaths of persons in this age range. The incidence and absolute number of annual events will likely increase over the next decade because of the epidemic of obesity and the aging of the U.S. population. Dyslipidemias, including hyperlipidemia (hypercholesterolemia) and low levels of high-density-lipoprotein cholesterol (HDL-C), are major causes of increased atherogenic risk; both genetic disorders and lifestyle (sedentary behavior and diets high in calories, saturated fat, and cholesterol) contribute to the dyslipidemias seen in countries around the world. For many individuals, alterations in lifestyle have a far greater potential for reducing vascular disease risk and at a lower cost than drug therapy. When pharmacotherapy is indicated, providers can choose from multiple agents with proven efficacy.

Recognition that dyslipidemia is a risk factor has led to the development of drugs that modify cholesterol levels. This chapter focuses on the following classes of drugs:

- 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors—the statins
- Bile acid-binding resins
- Nicotinic acid (*niacin*)
- Fibric acid derivatives
- The cholesterol absorption inhibitor *ezetimibe*

These drugs provide benefit in patients across the entire spectrum of cholesterol levels, primarily by reducing levels of low-density-lipoprotein cholesterol (LDL-C).

In early well-controlled clinical trials employing drug regimens that reduce LDL-C levels moderately (30-40%), fatal and nonfatal CHD events and strokes were reduced by as much as 30-40% (Grundy et al., 2004b). Clinical trial data support extending lipid-modifying therapy to high-risk patients whose major lipid risk factor is a reduced plasma level of HDL-C, even if their LDL-C level does not meet the existing threshold values for initiating hypolipidemic drug therapy (Grundy et al., 2004b). In patients with low HDL-C and average LDL-C levels, appropriate drug therapy reduced CHD endpoint events by 20-35% (Heart Protection Study Collaborative Group, 2002). Because two-thirds of patients with CHD in the U.S. have low HDL-C levels (<40 mg/dL in men, <50 mg/dL in women), it is important to include low-HDL-C patients in management guidelines for dyslipidemia, even if their LDL-C levels are in the normal range (Bersot et al., 2003).

Severe hypertriglyceridemia (i.e., triglyceride levels of >1000 mg/dL) requires therapy to prevent pancreatitis. It is unclear whether hypertriglyceridemia is an independent risk factor for developing atherothrombotic CVD (Sarwar et al., 2007). Moderately elevated triglyceride levels (150-400 mg/dL) are of concern because they often occur as part of the metabolic syndrome, which includes insulin resistance, obesity, hypertension, low HDL-C levels, a procoagulant state, and substantially increased risk of CVD. The atherogenic dyslipidemia in patients with the metabolic syndrome also is characterized by lipid-depleted LDL (sometimes referred

878 to as “small, dense LDL”) (Grundy et al., 2004a). The metabolic syndrome affects ~25% of adults and is common in CVD patients; hence, identification of moderate hypertriglyceridemia in a patient, even if the total cholesterol level is normal, should trigger an evaluation to identify insulin-resistant patients with this disorder.

PLASMA LIPOPROTEIN METABOLISM

Lipoproteins are macromolecular assemblies that contain lipids and proteins. The lipid constituents include free and esterified cholesterol, triglycerides, and phospholipids. The protein components, known as apolipoproteins or apoproteins, provide structural stability to the lipoproteins and also may function as ligands in lipoprotein–receptor interactions or as cofactors in enzymatic processes that regulate lipoprotein metabolism. In all spherical lipoproteins, the most water-insoluble lipids (cholesteryl esters and triglycerides) are core components, and the more polar, water-soluble components (apoproteins, phospholipids, and unesterified cholesterol) are located on the surface. The major classes of lipoproteins and a number of their properties are summarized in Table 31–1.

Table 31–2 describes apoproteins that have well-defined roles in plasma lipoprotein metabolism. These apolipoproteins include apolipoprotein (apo) A-I, apoA-II, apoA-IV, apoA-V, apoB-100, apoB-48, apoC-I, apoC-II, apoC-III, apoE, and apo(a). Except for apo(a), the lipid-binding regions of all apoproteins contain amphipathic helices that interact with the polar, hydrophilic lipids (such as surface phospholipids) and with the aqueous plasma environment in which the lipoproteins circulate. Differences in the non-lipid-binding regions determine the functional specificities of the apolipoproteins.

Chylomicrons. Chylomicrons are synthesized from the fatty acids of dietary triglycerides and cholesterol absorbed from the small intestine by epithelial cells. Fat-soluble vitamins also are incorporated into chylomicrons after absorption.

Chylomicrons, the largest plasma lipoproteins, are the only lipoproteins that float to the top of a tube of plasma that has been allowed to stand undisturbed for 12 hours. The buoyancy of chylomicrons reflects their high fat content (98–99%), of which 85% is from fatty acids of dietary triglycerides. In chylomicrons, the ratio of triglycerides to cholesterol is ~10 or greater. In normolipidemic individuals, chylomicrons are present in plasma for 3–6 hours after a fat-containing meal has been ingested. After a fast of 10–12 hours, no chylomicrons remain.

Intestinal cholesterol and plant sterol absorption is mediated by Niemann-Pick C1–Like 1 protein (NPC1L1), which appears to be the target of ezetimibe, a cholesterol absorption inhibitor (Davis and Altmann, 2009). Plant sterols, unlike cholesterol, are not normally esterified and incorporated into chylomicrons. Two ATP-binding cassette (ABC) half-transporters, ABCG5 and ABCG8, which reside on the apical plasma membrane of enterocytes, channel plant sterols back into the intestinal lumen, preventing their assimilation into the body. Patients with the autosomal recessive disorder sitosterolemia have mutations in either of the genes that encode ABCG5 and ABCG8. As a result, they absorb unusually large amounts of plant sterols, fail to excrete dietary sterols into the bile, and thus accumulate plant sterols in the blood and tissues; this accumulation is associated with tendon and subcutaneous xanthomas and a markedly increased risk of premature CHD.

Triglyceride synthesis is regulated by diacylglycerol transferase in many tissues. After their synthesis in the endoplasmic reticulum, triglycerides are transferred by *microsomal triglyceride transfer protein* (MTP) to the site where newly synthesized apoB-48 is available to form chylomicrons.

The apolipoproteins of chylomicrons include some that are synthesized by intestinal epithelial cells (apoB-48, apoA-I, and apoA-IV), and others acquired from HDL (apoE and apoC-I, C-II, and C-III) after chylomicrons have been secreted into the lymph and enter the plasma (Table 31–2). The apoB-48 of chylomicrons is one of two forms of apoB present in lipoproteins. ApoB-48, synthesized only by intestinal epithelial cells, is unique to chylomicrons. ApoB-100 is synthesized by the liver and incorporated into VLDL and intermediate-density lipoproteins (IDL) and LDL, which are products of VLDL catabolism. The apparent molecular weight of apoB-48 is 48% that of apoB-100, which accounts for the name “apoB-48.” The amino acid sequence of apoB-48 is identical to the first 2152 of the 4536 residues of apoB-100. An RNA-editing mechanism unique to the intestine accounts for the premature termination of the translation of the apoB-100 mRNA. ApoB-48 lacks the portion of the sequence of apoB-100 that allows apoB-100 to bind to the LDL receptor, so apoB-48 functions primarily as a structural component of chylomicrons.

Dietary cholesterol is esterified by the type 2 isozyme of acyl coenzyme A:cholesterol acyltransferase (ACAT-2). ACAT-2 is found in the intestine and in the liver, where cellular free cholesterol is esterified before triglyceride-rich lipoproteins [chylomicrons and very-low-density lipoproteins (VLDL)] are assembled. In the intestine, ACAT-2 regulates the absorption of dietary cholesterol and thus may be a potential pharmacological target for reducing blood cholesterol levels.

Table 31-1

Characteristics of Plasma Lipoproteins

LIPOPROTEIN CLASS	DENSITY (g/mL)	MAJOR LIPID CONSTITUENT	TG:CHOL RATIO	SIGNIFICANT APOPROTEINS	SITE OF SYNTHESIS	MECHANISM(S) OF CATABOLISM
Chylomicrons and remnants	<<1.006	Dietary triglycerides and cholesterol	10:1	B-48, E, A-I, A-IV, C-I, C-II, C-III	Intestine	Triglyceride hydrolysis by LPL, apoE-mediated remnant uptake by liver
VLDL	<1.006	“Endogenous” or hepatic triglycerides	5:1	B-100, E, C-I, C-II, C-III	Liver	Triglyceride hydrolysis by LPL
IDL	1.006-1.019	Cholesteryl esters and “endogenous” triglycerides	1:1	B-100, E, C-II, C-III	Product of VLDL catabolism	50% converted to LDL mediated by HL; 50% apoE-mediated uptake by liver
LDL	1.019-1.063	Cholesteryl esters	NS	B-100	Product of VLDL catabolism	ApoB-100-mediated uptake by LDL receptor (~75% in liver)
HDL	1.063-1.21	Phospholipids, cholesteryl esters	NS	A-I, A-II, E, C-I, C-II, C-III	Intestine, liver, plasma	Complex: transfer of cholesteryl ester to VLDL and LDL; uptake of HDL cholesterol by hepatocytes
Lp(a)	1.05-1.09	Cholesteryl esters	NS	B-100, apo(a)	Liver	Unknown

apo, apolipoprotein; CHOL, cholesterol; HDL, high-density lipoproteins; IDL, intermediate-density lipoproteins; Lp(a), lipoprotein(a); LDL, low-density lipoproteins; NS, not significant (triglyceride is <5% of LDL and HDL); TG, triglyceride; VLDL, very-low-density lipoproteins; HL, hepatic lipase; LPL, lipoprotein lipase.

Table 31-2

Apolipoproteins

APOLIPOPROTEIN	AVERAGE CONCENTRATION (mg/dL)	CHROMOSOME	MOLECULAR MASS (kDa)	SITES OF SYNTHESIS	FUNCTIONS
ApoA-I	130	11	~29	Liver, intestine	Structural in HDL; LCAT cofactor; ligand of ABCA1 receptor; reverse cholesterol transport
ApoA-II	40	1	~17	Liver	Forms $-S-S-$ complex with apoE-2 and E-3, which inhibits E-2 and E-3 binding to lipoprotein receptors
ApoA-V	<1	11	~40	Liver	Modulates triglyceride incorporation into hepatic VLDL; activates LPL
ApoB-100	85	2	~513	Liver	Structural protein of VLDL, IDL, LDL; LDL receptor ligand
ApoB-48	Fluctuates according to dietary fat intake	2	~241	Intestine	Structural protein of chylomicrons
ApoC-I	6	19	~6.6	Liver	LCAT activator; modulates receptor binding of remnants
ApoC-II	3	19	8.9	Liver	Lipoprotein lipase cofactor
ApoC-III	12	11	8.8	Liver	Modulates receptor binding of remnants
ApoE	5	19	34	Liver, brain, skin, gonads, spleen	Ligand for LDL receptor and receptors binding remnants; reverse cholesterol transport (HDL with apoE)
Apo(a)	Variable (under genetic control)	6	Variable	Liver	Modulator of fibrinolysis

apo, apolipoprotein; HDL, high-density lipoproteins; IDL, intermediate-density lipoproteins; LCAT, lecithin:cholesterol acyltransferase; LDL, low-density lipoproteins; LPL, lipoprotein lipase; VLDL, very-low-density lipoproteins.

Another ACAT enzyme, ACAT-1, is expressed in macrophages, including foam cells, adrenocortical cells, and skin sebaceous glands. Although ACAT-1 esterifies cholesterol and promotes foam-cell development, ACAT-1 knockout mice do not have reduced susceptibility to atherosclerosis.

After gaining entry to the circulation via the thoracic duct, chylomicrons are metabolized initially at the capillary luminal surface of tissues that synthesize *lipoprotein lipase* (LPL), a triglyceride hydrolase (Figure 31–1). These tissues include adipose tissue, skeletal and cardiac muscle, and breast tissue of lactating women. As the triglycerides are hydrolyzed by LPL, the resulting free fatty acids are taken up and utilized by the adjacent tissues. The interaction of chylomicrons and LPL requires apoC-II as an absolute cofactor. The absence of functional LPL or functional apoC-II prevents the hydrolysis of triglycerides in chylomicrons and results in severe hypertriglyceridemia and pancreatitis during childhood or even infancy (chylomicronemia syndrome). Potentially atherogenic roles for LPL have been identified that affect the metabolism and uptake of atherogenic lipoproteins by the liver and the arterial wall and that impact the dyslipidemia of insulin resistance (Brown and Rader, 2007).

The plasma concentration of chylomicrons is primarily controlled by reducing dietary fat consumption. Drugs that affect

chylomicron metabolism include *orlistat*, which inhibits hydrolysis of dietary triglycerides, *insulin replacement* in patients with type I diabetes mellitus (insulin has a “permissive effect” on LPL-mediated triglyceride hydrolysis), and *fibrates*, which enhance LPL gene expression.

Chylomicron Remnants. After LPL-mediated removal of much of the dietary triglycerides, the chylomicron remnants, which still contain all of the dietary cholesterol, detach from the capillary surface and within minutes are removed from the circulation by the liver (Figure 31–1). First, the remnants are sequestered by the interaction of apoE with heparan sulfate proteoglycans on the surface of hepatocytes and are processed by hepatic lipase (HL), further reducing the remnant triglyceride content. Next, apoE mediates remnant uptake by interacting with the hepatic LDL receptor or the *LDL receptor–related protein* (LRP) (Lillis et al., 2008). The multifunctional LRP recognizes a variety of ligands, including apoE, and several ligands unrelated to lipid metabolism.

In plasma lipid metabolism, the LRP is important because it is the backup receptor responsible for the uptake of apoE-enriched remnants of chylomicrons and VLDL. Cell-surface heparan sulfate proteoglycans facilitate the interaction of apoE-containing remnant lipoproteins with the LRP, which mediates uptake by hepatocytes. Inherited absence of either functional HL (very rare) or functional apoE impedes remnant clearance by the LDL receptor and the LRP,

Figure 31–1. The major pathways involved in the metabolism of chylomicrons synthesized by the intestine and VLDL synthesized by the liver. Chylomicrons are converted to chylomicron remnants by the hydrolysis of their triglycerides by LPL. Chylomicron remnants are rapidly cleared from the plasma by the liver. “Remnant receptors” include the LDL receptor–related protein (LRP), LDL receptors, and perhaps other receptors. Free fatty acid (FFA) released by LPL is used by muscle tissue as an energy source or taken up and stored by adipose tissue. HL, hepatic lipase; IDL, intermediate-density lipoproteins; LDL, low-density lipoproteins; LPL, lipoprotein lipase; VLDL, very-low-density lipoproteins.

During the initial hydrolysis of chylomicron triglycerides by LPL, apoA-I and phospholipids are shed from the surface of chylomicrons and remain in the plasma. This is one mechanism by which nascent (precursor) HDL are generated. Chylomicron remnants are not precursors of LDL, but the dietary cholesterol delivered to the liver by remnants increases plasma LDL levels by reducing LDL receptor-mediated catabolism of LDL by the liver.

Very-Low-Density Lipoproteins. VLDL are produced in the liver when triglyceride production is stimulated by an increased flux of free fatty acids or by increased *de novo* synthesis of fatty acids by the liver. VLDL particles are 40-100 nm in diameter and are large enough to cause plasma turbidity, but unlike chylomicrons, do not float spontaneously to the top of a tube of undisturbed plasma.

ApoB-100, apoE, and apoC-I, C-II, and C-III are synthesized constitutively by the liver and incorporated into VLDL (Table 31–2). If triglycerides are not available to form VLDL, the newly synthesized apoB-100 is degraded by hepatocytes. Triglycerides are synthesized in the endoplasmic reticulum, and along with other lipid constituents, are transferred by MTP to the site in the endoplasmic reticulum where newly synthesized apoB-100 is available to form nascent (precursor) VLDL. Small amounts of apoE and the C apoproteins are incorporated into nascent particles within the liver before secretion, but most of these apoproteins are acquired from plasma HDL after the VLDL are secreted by the liver.

ApoA-V modulates plasma triglyceride levels, possibly by several mechanisms: inhibition of hepatic VLDL triglyceride production and secretion, promoting LPL-mediated hydrolysis of chylomicrons and VLDL triglycerides, and facilitating hepatic uptake of triglyceride-rich lipoproteins and their remnants (Wong and Ryan, 2007). ApoA-V is produced solely by the liver, and despite its very low plasma concentration (~0.1% of the concentration of apoA-I), profoundly affects plasma triglyceride levels in mice and humans.

Without MTP, hepatic triglycerides cannot be transferred to apoB-100. As a consequence, patients with dysfunctional MTP fail to make any of the apoB-containing lipoproteins (VLDL, IDL, or LDL). MTP also plays a key role in the synthesis of chylomicrons in the intestine, and mutations of MTP that result in the inability of triglycerides to be transferred to either apoB-100 in the liver or apoB-48 in the intestine prevent VLDL and chylomicron production and cause the genetic disorder abetalipoproteinemia. Experimental compounds that interfere with MTP function reduce triglyceride levels but cause hepatic steatosis that has precluded their use in humans. New approaches to MTP inhibition are under study (Hussain and Bakillah, 2008).

Plasma VLDL is then catabolized by LPL in the capillary beds in a process similar to the lipolytic processing of chylomicrons (Figure 31–1). When triglyceride hydrolysis is nearly complete, the VLDL remnants, usually termed IDL, are released from the capillary endothelium and reenter the circulation. ApoB-100 containing small VLDL and IDL (VLDL remnants), which have a $t_{1/2}$ <30 minutes, have two potential fates. About 40-60% are cleared from the plasma by the liver via interaction with LDL receptors and LRP, which recognize ligands (apoB-100 and apoE) on the remnants. LPL and HL convert the remainder of the IDL to LDL by removal of additional triglycerides. The C apoproteins, apoE, and apoA-V redistribute to HDL. *Virtually all LDL particles in the plasma are derived from VLDL.*

ApoE plays a major role in the metabolism of triglyceride-rich lipoproteins (chylomicrons, chylomicron remnants, VLDL, and IDL). About half of the apoE in the plasma of fasting subjects is associated with triglyceride-rich lipoproteins, and the other half is a constituent of HDL. About three-fourths of the apoE in plasma is synthesized by the liver; brain and macrophages synthesize the bulk of the remainder. In transgenic mice, overexpression of apoE by macrophages inhibits hypercholesterolemia-induced atherogenesis. Three alleles of the apoE gene (designated $\epsilon 2$, $\epsilon 3$, and $\epsilon 4$) occur with a frequency of ~8%, 77%, and 15%, respectively, and code for the three major forms of apoE: E2, E3, and E4. Consequently, there are three homozygous apoE phenotypes (E2/2, E3/3, and E4/4) and three heterozygous phenotypes (E2/3, E2/4, and E3/4). Approximately 60% of the human population is homozygous for apoE3. Single amino acid substitutions result from genetic polymorphisms in the apoE gene. ApoE2, with a cysteine at residue 158, differs from apoE3, which has arginine at this site. ApoE3, with a cysteine at residue 112, differs from apoE4, which has arginine at this site. These single amino acid differences affect both receptor binding and lipid binding of the three apoE isoforms. Both apoE3 and apoE4 can bind to the LDL receptor, but apoE2 binds much less effectively, and as a consequence causes the remnant lipoprotein dyslipidemia of type III hyperlipoproteinemia.

Low-Density Lipoproteins. Virtually all of the LDL particles in the circulation are derived from VLDL. The LDL particles have a $t_{1/2}$ of 1.5-2 days, which accounts for the higher plasma concentration of LDL than of VLDL and IDL. In subjects without hypertriglyceridemia, two-thirds of plasma cholesterol is found in the LDL.

Plasma clearance of LDL particles is mediated primarily by LDL receptors; a small component is mediated by nonreceptor clearance mechanisms. The most common cause of autosomal dominant hypercholesterolemia involves mutations of the LDL receptor gene.

More than 900 mutations of the LDL receptor gene have been identified in association with defective or absent LDL receptors that cause high levels of plasma LDL and familial hypercholesterolemia.

ApoB-100, the primary apoprotein of LDL, is the ligand that binds LDL to its receptor. Residues 3000-3700 in the carboxyl-terminal sequence are critical for binding. Mutations in this region disrupt binding and also are a cause of autosomal dominant hypercholesterolemia (familial defective apoB-100). A third disorder causing autosomal dominant hypercholesterolemia is caused by gain of function mutations in the gene encoding PCSK9, a serine protease that destroys LDL receptors in the liver (Horton et al., 2007). Autosomal recessive hypercholesterolemia closely resembles familial hypercholesterolemia but is not caused by LDL receptor mutations.

The liver expresses a large complement of LDL receptors and removes ~75% of all LDL from the plasma. Consequently, manipulation of hepatic LDL receptor gene expression is a most effective way to modulate plasma LDL-C levels. Thyroxine and estrogen enhance LDL receptor gene expression, which explains their LDL-C-lowering effects.

The most effective dietary alteration (decreased consumption of saturated fat and cholesterol) and pharmacological treatment (statins) for hypercholesterolemia act by enhancing hepatic LDL receptor expression. Regulation of LDL receptor expression is part of a complex process by which cells regulate their free cholesterol content. This regulatory process is mediated by transcription factors called *sterol regulatory element binding proteins* (SREBPs) and *SREBP cleavage activating protein* (Scap) (Radhakrishnan et al., 2008). Scap is both a sensor of cholesterol content in the endoplasmic reticulum (ER) and an escort of SREBPs from the ER to the Golgi apparatus. In the Golgi apparatus, SREBPs undergo proteolytic cleavage, and a dimer of the amino-terminal domain, transported by importin β , translocates to the nucleus, where it activates expression of the LDL receptor gene and of other genes encoding enzymes involved in cholesterol biosynthesis. Increased ER cholesterol content binds Scap, precluding Scap from escorting SREBP to the Golgi apparatus for processing and ultimately from reaching the nucleus.

LDL becomes atherogenic when modified by oxidation (Witztum and Steinberg, 2001), a required step for LDL uptake by the scavenger receptors of macrophages. This process leads to foam-cell formation in arterial lesions. At least two scavenger receptors (SRs) are involved (SR-AI/II and CD36). Knocking out either receptor in transgenic mice retards the uptake of oxidized LDL by macrophages. Expression of the two receptors is regulated differently:

SR-AI/II appears to be expressed more in early atherogenesis, and CD36 expression is greater as foam cells form during lesion progression. Despite the large body of evidence implicating oxidation of LDL as a requisite step during atherogenesis, controlled clinical trials have not unequivocally demonstrated the efficacy of antioxidant vitamins in preventing vascular disease.

High-Density Lipoproteins. The metabolism of HDL is complex because of the multiple mechanisms by which HDL particles are modified in the plasma compartment. ApoA-I is the major HDL apoprotein, and its plasma concentration is a more powerful inverse predictor of CHD risk than is the HDL-C level (Mahley et al., 2008). ApoA-I synthesis is required for normal production of HDL. Mutations in the apoA-I gene that cause HDL deficiency are variable in their clinical expression and often are associated with accelerated atherogenesis. Conversely, overexpression of apoA-I in transgenic mice protects against experimentally induced atherogenesis.

Mature HDL can be separated by ultracentrifugation into HDL₂ ($d = 1.063\text{--}1.125$ g/mL), which are larger, more cholesterol-rich lipoproteins (70-100 Å in diameter), and HDL₃ ($d = 1.125\text{--}1.21$ g/mL), which are smaller particles (50-70 Å in diameter). In addition, two major subclasses of mature HDL particles in the plasma can be differentiated by their content of the major HDL apoproteins, apoA-I and apoA-II (Movva and Rader, 2008). Epidemiologic evidence in humans suggests that apoA-II may be atheroprotective (Birjmohun et al., 2007; Movva and Rader, 2008).

Lipoprotein particles may be distinguished by their electrophoretic mobilities: mature HDL particles have α mobility; LDL particles show β mobility. The precursor of most of the α -migrating plasma HDL is a discoidal particle containing apoA-I and phospholipid, called pre- β 1 HDL because of its pre- β 1 electrophoretic mobility. Pre- β 1 HDL are synthesized by the liver and the intestine, and they also arise when surface phospholipids and apoA-I of chylomicrons and VLDL are lost as the triglycerides of these lipoproteins are hydrolyzed. Discoidal pre- β 1 HDL can then acquire free unesterified cholesterol from the cell membranes of tissues, such as arterial wall macrophages. Two macrophage membrane transporters, ABCA1 and ABCG1, promote the efflux of cholesterol from macrophages of humans studied *in vivo*. Prior studies *in vitro* suggested that another transport protein, class B, type I scavenger receptor (SR-BI) facilitates cholesterol egress from macrophages to HDL, but *in vivo* studies in humans do not support an important role for SR-BI in this process (Wang et al., 2007). However, SR-BI in the liver facilitates the uptake of cholesteryl esters from HDL without internalizing and degrading the lipoproteins.

The membrane transporter ABCA1 facilitates the transfer of free cholesterol from cells to HDL (Attie, 2007). When ABCA1 is defective, the acquisition of cholesterol by HDL is greatly diminished, and HDL levels are markedly reduced because poorly lipidated nascent HDL are metabolized rapidly. Loss-of-function mutations of ABCA1 cause the defect observed in

884 Tangier disease, a genetic disorder characterized by extremely low levels of HDL and cholesterol accumulation in the liver, spleen, tonsils, and neurons of peripheral nerves. Transgenic animals overexpressing ABCA1 in the liver and macrophages have elevated plasma levels of HDL and apoA-I and reduced susceptibility to atherosclerosis (Van Eck et al., 2006).

After free cholesterol is acquired by the pre- β 1 HDL, it is esterified by lecithin:cholesterol acyltransferase. The newly esterified and nonpolar cholesterol moves into the core of the discoidal HDL. As the cholesteryl ester content increases, the HDL particle becomes spherical and less dense. These newly formed spherical HDL particles (HDL₃) further enlarge by accepting more free cholesterol, which is in turn esterified by lecithin:cholesterol acyltransferase. In this way, HDL₃ are converted to HDL₂, which are larger and less dense than HDL₃.

As the cholesteryl ester content of the HDL₂ increases, the cholesteryl esters of these particles begin to be exchanged for triglycerides derived from any of the triglyceride-containing lipoproteins (chylomicrons, VLDL, remnant lipoproteins, and LDL). This exchange is mediated by the cholesteryl ester transfer protein (CETP), and in humans accounts for the removal of about two-thirds of the cholesterol associated with HDL. The transferred cholesterol subsequently is metabolized as part of the lipoprotein into which it was transferred. Treatments that target CETP and the ABC transporters have yielded equivocal results in humans. While CETP inhibitors effectively reduce LDL, they also appear to paradoxically increase the frequency of adverse cardiovascular events (angina, revascularization, myocardial infarction, heart failure, and death) (Tall, 2007; Tall et al, 2008).

The triglyceride that is transferred into HDL₂ is hydrolyzed in the liver by HL, a process that regenerates smaller, spherical HDL₃ particles that recirculate and acquire additional free cholesterol from tissues containing excess free cholesterol. HL activity is regulated and modulates HDL-C levels. Both androgens and estrogens affect HL gene expression, but with opposite effects. Androgens increase HL activity, which accounts for the lower HDL-C values observed in men than in women. Estrogens reduce HL activity, but their impact on HDL-C levels in women is substantially less than that of androgens on HDL-C levels in men. HL appears to have a pivotal role in regulating HDL-C levels, as HL activity is increased in many patients with low HDL-C levels.

HDL are protective lipoproteins that decrease the risk of CHD; thus, high levels of HDL are desirable. This protective effect may result from the participation

of HDL in reverse cholesterol transport, the process by which excess cholesterol is acquired from cells and transferred to the liver for excretion. HDL also may protect against atherogenesis by mechanisms not directly related to reverse cholesterol transport. These functions include putative anti-inflammatory, anti-oxidative, platelet anti-aggregatory, anticoagulant, and profibrinolytic activities (deGoma et al., 2008).

Lipoprotein(a). Lipoprotein(a) [Lp(a)] is composed of an LDL particle that has a second apoprotein in addition to apoB-100 (Mahley et al., 2008). The second apoprotein, apo(a), is attached to apoB-100 by at least one disulfide bond and does not function as a lipid-binding apoprotein. Apo(a) of Lp(a) is structurally related to plasminogen and appears to be atherogenic by interfering with fibrinolysis of thrombi on the surfaces of plaques.

HYPERLIPIDEMIA AND ATHEROSCLEROSIS

Despite a 59% decline in the death rate from CHD between 1950 and 1999, deaths from CVD accounted for 36.3% of the 2.4 million deaths in the U.S. during 2004. Most of these deaths were caused by atherosclerosis, which is responsible for more deaths than cancer, accidents, chronic lung disease, and diabetes combined. Two-thirds of atherosclerosis deaths were due to CHD. About 82% of CHD deaths occurred in individuals >65 years of age. Among the 18% dying prematurely (<65 years), 80% died during their first CHD event. Among those dying of sudden cardiac death, 50% of the men and 64% of the women had previously been asymptomatic (American Heart Association, 2003).

These statistics illustrate the importance of identifying and managing risk factors for CHD. *The major conventional risk factors are elevated LDL-C, reduced HDL-C, cigarette smoking, hypertension, type 2 diabetes mellitus, advancing age, and a family history of premature CHD events (men <55 years; women <65 years) in a first-degree relative.* Control of the modifiable risk factors is especially important in preventing premature CHD. Observational studies suggest that modifiable risk factors account for 85% of excess risk (risk over and above that of individuals with optimal risk-factor profiles) for premature CHD. The presence of one or more conventional risk factors in 90% of patients with CHD belies claims that a large percentage of CHD is not attributable to conventional risk factors. When total cholesterol levels are below 160 mg/dL, CHD risk is markedly attenuated, even in the presence of additional

risk factors. This pivotal role of hypercholesterolemia in atherogenesis gave rise to the almost universally accepted cholesterol-diet-CHD hypothesis: elevated plasma cholesterol levels cause CHD; diets rich in saturated (animal) fat and cholesterol raise cholesterol levels; and lowering cholesterol levels reduces CHD risk. Although the relationship between cholesterol, diet, and CHD was recognized nearly 50 years ago, proof that cholesterol lowering was safe and prevented CHD death required extensive epidemiological studies and clinical trials.

Epidemiological Studies. Epidemiological studies have demonstrated the importance of the relationship between excess saturated fat consumption and elevated cholesterol levels. Reducing the consumption of dietary saturated fat and cholesterol is the cornerstone of population-based approaches to the management of hypercholesterolemia. In addition, it is clearly established that the higher the cholesterol level, the higher the CHD risk. However, very high cholesterol levels (values >300 mg/dL) account for only 5-10% of CHD events. In fact, one-third of CHD events occur in persons with total cholesterol levels between 150 and 200 mg/dL (Castelli, 2001). The challenge is how to identify and treat the 20% of individuals with cholesterol levels between 150 and 200 mg/dL who will develop CHD.

Clinical Trials. Studies of the efficacy of cholesterol lowering began in the 1960s, and the results of the earliest trials showed that modest reductions in total cholesterol and LDL-C were associated with reductions in fatal and nonfatal CHD events but not total mortality. It was not until the advent of a more efficacious class of cholesterol-lowering drugs, the statins, that cholesterol-reduction therapy was finally proven to prevent CHD events and reduce total mortality. Patients benefit regardless of gender, age (above or below 75 years of age), baseline lipid values, or whether they have a prior history of vascular disease or type 2 diabetes mellitus (Cholesterol Treatment Trialists' Collaborators, 2008; Cholesterol Treatment Trialists' Collaborators, 2005). Stroke risk is reduced by statin therapy, too, despite the rather weak relationship between total cholesterol and LDL-C levels. Statin therapy is effective in preventing first and subsequent atherothrombotic strokes. Evidence of a benefit or harm of statin therapy in patients with a prior hemorrhagic stroke is sparse and requires additional studies. Available studies suggest caution when considering statin therapy for a patient with hemorrhagic stroke (Amarenco and Labreuche, 2009).

Results of the clinical trials employing statins demonstrate benefit without offsetting adverse effects, and the benefit is proportionate to the extent of the reduction of LDL-C level. Moderate doses of statins that lower LDL-C levels by about 40% reduce cardiovascular events by about one-third (Cholesterol Treatment Trialists' Collaborators, 2005). More intensive regimens that lower LDL-C by 45-50% reduce CVD events by as much as 50% (Cannon et al., 2006).

National Cholesterol Education Program (NCEP) Guidelines for Assessing Risk

The existing NCEP Adult Treatment Panel (ATP) III guidelines were formulated in 2001 and updated in 2004 (Grundy et al., 2004b). The key features of the

update include abandoning the concept of a threshold LDL-C level that must be exceeded before initiating cholesterol-lowering drug therapy in CHD or CHD equivalent patients; adopting a new target LDL-C level (<70 mg/dL) for very high-risk patients; and employing a "standard statin dose" (a dosage sufficient to lower LDL-C by 30-40%) as a minimum therapy when initiating cholesterol-lowering therapy with statins (Grundy et al., 2004b) (Table 31-3). Subsequently, new information from clinical trials and new information about risk assessment has led to a need for a new revision, ATP IV, which is currently in progress. The new ATP IV guidelines are expected to be published in 2010. Revisions that are likely to be included in the ATP IV guidelines are described in the following discussion.

Risk Assessment. The intensity of treatment of dyslipidemia is based on the severity of a patient's risk. The risk of sustaining a heart attack or stroke or of developing heart failure in the U.S. is striking. Before death, two-thirds of men and one-half of all women will be affected (Lloyd-Jones et al., 2009). Because of this very high prevalence, it is important that all adults ≥ 20 years and high-risk children undergo an assessment of their risk of developing CVD (Daniels et al., 2008; The Expert Panel, 2002).

Patients at greatest risk of developing an atherothrombotic CVD event are those who have had a prior event (myocardial infarction, acute coronary syndrome, transient ischemic attack, stroke, or claudication) or who are at high risk because of type 2 diabetes mellitus. These subjects are at very high risk and require intensive management of plasma lipids (Table 31-3). Other subjects who have not had a prior CVD event require assessment of plasma lipid levels and the other major CVD risk factors to determine if treatment to reduce lipid-related risk is necessary.

Lipid levels (total cholesterol, triglycerides, LDL-C, HDL-C, and non-HDL-C) and glucose concentration should be measured following a fasting period of 10-12 hours. The LDL-C should be calculated [total cholesterol - (HDL-C) - (triglycerides/5) = LDL-C] and not measured by any of the "direct" techniques (Mora et al., 2009). Non-HDL-C is derived as follows: total cholesterol - HDL-C = non-HDL-C. The classification of plasma lipid values is shown in Table 31-4.

Measurement of apoA-I and apoB afford better risk prediction of lipid-related risk than LDL-C and HDL-C. However, lack of an established national reference laboratory for quality control of these apolipoprotein assays has precluded formal adoption of apoA-I and apoB measurements by the NCEP thus far (Contois et al., 2009; Sniderman, 2009; Sniderman and Marcovina, 2006). Despite this, targets for apoB levels have been established by the American Diabetes Association for the management of patients with type 2 diabetes mellitus (Brunzell et al., 2008).

Measurements of lipoprotein fraction concentrations, their subfractions, and lipoprotein particle diameters also are widely available, but it is not clear that these tests add to the ability to predict risk

Table 31-3

Treatment Based on LDL-C Levels (2004 Revision of NCEP Adult Treatment Panel III Guidelines)

RISK CATEGORY	LDL-C GOAL (mg/dL)	NON-HDL-C GOAL (mg/dL)	THERAPEUTIC LIFESTYLE CHANGE	THRESHOLD FOR DRUG THERAPY (mg/dL)
Very high risk Atherosclerosis-induced CHD plus one of: • multiple risk factors • diabetes mellitus • a poorly controlled single factor • acute coronary syndrome • metabolic syndrome	<70 ^a	<100	No threshold (initiate change)	No threshold (initiate therapy)
High risk CHD or CHD equivalent	<100 ^a	<130	No threshold	No threshold
Moderately high risk 2+ risk factors 10-year risk: <10–20%	<130 (optional <100)	<160	No threshold	≥130 (100–129) ^b
Moderate risk 2+ risk factors 10-year risk <10%	<130	<160	No threshold	>160
0–1 risk factor	<160	<160	No threshold	≥190 (optional: 160–189) ^c

^aIf pretreatment LDL-C is near or below LDL-C goal value, then a statin dose sufficient to lower LDL-C by 30–40% should be prescribed.

^bPatients in this category include those with a 10-year risk of 10–20% and one of the following: age >60 years, three or more risk factors, a severe risk factor, triglycerides >200 mg/dL and HDL-C <40 mg/dL, metabolic syndrome, highly sensitive C-reactive protein (CRP) >3 mg/L, and coronary calcium score (age/gender adjusted) >75th percentile.

^cPatients include those with any severe single risk factor, multiple major risk factors, 10-year risk >8%.

After attaining the LDL-C goal, additional therapy may be necessary to reach the non-HDL-C goal. CHD, coronary heart disease; CHD equivalent, peripheral vascular disease, abdominal aortic aneurysm, symptomatic carotid artery disease, >20% 10-year CHD risk, or diabetes mellitus; HDL-C, high-density-lipoprotein cholesterol; LDL-C, low-density-lipoprotein cholesterol; NCEP, National Cholesterol Education Program.

based on measurements of levels of cholesterol or apoA-I and apoB (Mora, 2009).

In addition to plasma lipid levels and a fasting glucose level, each subject requires an evaluation to assess the presence or absence of the other major CVD risk factors: age, a family history of premature CVD event, smoking, hypertension, type 2 diabetes mellitus, and obesity (Table 31-5). There are a host of additional novel risk factors that are being evaluated to determine if they will improve current risk prediction assessment schemes based on lipid levels and the established major CVD risk factors (Table 31-5). Thus far, routine use of any of these novel risk factors has not been shown to improve risk prediction (Folsom et al., 2006; Lloyd-Jones and Tian, 2006). However, in certain primary prevention patients, two of the recently described risk factors, C-reactive protein (CRP) and assessment of the extent of coronary calcification, may improve risk assessment beyond that based on the traditional major risk factors (Tables 31-3 and 31-5).

Using the values for levels of total cholesterol and HDL-C and the results of the assessment for the other major CHD risk factors, the next step is to calculate a person's risk of having a CHD event over the next 10 years. Risk prediction tables based on observational

studies conducted by the Framingham Heart Study are used to calculate this 10-year risk. This approach to risk assessment was adopted by the NCEP, but in the 2001 ATP III guidelines, the risk prediction model predicted only the 10-year risk of having a fatal or nonfatal myocardial infarction. However, the same risk factors that are associated with development of myocardial infarction also promote other CVD events, including stroke, transient ischemic attack, peripheral vascular disease, and heart failure. Furthermore, many patients who develop acute coronary syndrome do not sustain a myocardial infarction because of thrombolytic therapy and revascularization procedures (angioplasty and bypass graft surgery). Because cholesterol-lowering therapy is beneficial to prevent CVD events in patients with any of these manifestations of CVD, it became apparent that it would be useful for primary care physicians to be able to predict a patient's risk of developing any one of these manifestations of CVD, not just CHD. New general CVD 10-year risk prediction tables are now available from the Framingham Heart Study (D'Agostino et al., 2008; Wickramasinghe et al., 2009) (Table 31-6). Ten-year risk calculated with the general CVD tables will exceed 10-year risk calculated using the CHD tables from the ATP III guidelines.

Table 31-4

Classification of Plasma Lipid Levels (mg/dL)^a

Total cholesterol	
<200	Desirable
200-239	Borderline high
≥240	High
HDL-C	
<40	Low (consider <50 mg/dL as low for women)
>60	High
LDL-C	
<70	Optimal for very high risk (minimal goal for CHD equivalent patients)
<100	Optimal
100-129	Near optimal
130-159	Borderline high
160-189	High
≥190	Very high
Triglycerides	
<150	Normal
150-199	Borderline high
200-499	High
≥500	Very high

^a2001 National Cholesterol Education Program guidelines. HDL-C, high-density-lipoprotein cholesterol; LDL-C, low-density-lipoprotein cholesterol. From The Expert Panel, 2002.

Once the 10-year risk has been calculated, the patient's category of risk can be assigned using Table 31-3. This establishes treatment goals for LDL-C and non-HDL-C as well as thresholds for initiating drug therapy. Because CVD, diabetes mellitus, and obesity are so prevalent, diet and exercise assessment and advice are appropriate for everyone and should not depend on an arbitrary threshold value for LDL-C for implementation. Ten-year risk assessment is recognized as the guideline-mandated method for managing dyslipidemia. Unfortunately, only about 50% of physicians correctly assess their patient's risk, and 30% of adults nationwide are not being screened (Christian et al., 2006; Kuklina et al., 2009). Many high-risk patients are not being recognized and treated prior to developing clinical CHD. Among the nearly 75,000 patients admitted to 541 U.S. hospitals between 2000 and 2006 with first-ever episodes of acute coronary syndrome, only 14% were taking a cholesterol-lowering drug (Sachdeva et al., 2009).

NCEP Guidelines for Treatment: Managing Patients with Dyslipidemia

Current NCEP guidelines focus on identifying levels of risk factors associated with increased risk of a CHD

Table 31-5

Risk Factors for Coronary Heart Disease^a

Age	Male >45 years of age or female >55 years of age
Family history of premature CHD	A first-degree relative (male <55 years of age or female <65 years of age when the first CHD clinical event occurs)
Current cigarette smoking	Defined as smoking within the preceding 30 days
Hypertension	Blood pressure ≥140/90 or use of antihypertensive medication, irrespective of blood pressure
Low HDL-C	<40 mg/dL (consider <50 mg/dL as "low" for women)
Obesity^b	Body mass index >25 kg/m ² and waist circumference >40 inches (men) or >35 inches (women)
Type 2 diabetes mellitus	

^aDiabetes mellitus is considered to be a CHD-equivalent disorder; therefore, the lipid management of diabetes patients is the same as that for patients with established vascular disease (American Diabetes Association, 1999).

^bObesity was returned to the list of CHD risk factors in 1998, although it was not included as a risk factor in the 2001 NCEP guidelines (Pi-Sunyer et al., 1998). CHD, coronary heart disease; HDL-C, high-density-lipoprotein cholesterol. From The Expert Panel, 2002.

event. Primary prevention involves management of risk factors to prevent a first-ever CHD event. Secondary prevention patients are those who have had a prior CHD event and whose risk factors are treated most aggressively. Recently, the concept of primordial prevention has been applied to CHD prevention (Lloyd-Jones et al., 2010). The strategy is to prevent the development of risk factors rather than treating already established risk factors. Primordial prevention is a population-based approach that targets smoking, weight management, physical activity, healthy eating habits, cholesterol and glucose levels, and blood pressure. Goals for each of these risk factors have been set for adults and children. Including children is important because adverse health behaviors are learned in childhood (Lloyd-Jones et al., 2010).

The primordial prevention guidelines include 150 minutes/week of moderate-intensity exercise (walking 20-30 minutes/day). Dietary recommendations

include reducing total calories from fat to <30% and saturated fat to <7% to avoid trans fat; consuming <300 mg of cholesterol/day, a variety of oily fish twice a week or more often, and oils/foods rich in α -linolenic acid (canola, flaxseed, and soybean oils; flaxseed; and walnuts); and restricting sugary beverages to <36 oz/week for a person consuming 2000 Kcal daily.

The patient-based approach to manage dyslipidemia is designed for primary and secondary prevention, requires a risk assessment as described earlier (Table 31-6), and focuses on lowering LDL-C and

non-HDL-C (Grundy et al., 2004b). Non-lipid risk factors, if present, should be treated appropriately (Table 31-5). For patients with elevated levels of total cholesterol, non-HDL-C, LDL-C, or triglycerides, or reduced HDL-C values, further treatment is based on the patient's risk-factor status (Table 31-5), LDL-C and non-HDL-C levels (Table 31-3), and calculation of the general CHD Framingham risk score (Table 31-6) of primary prevention patients with two or more risk factors.

All patients who meet the criteria for lipid-lowering therapy should receive instruction about therapeutic lifestyle change. Dietary

Reproduced, with permission, from D'Agostino RB Sr, Vasan RS, Pencina MJ *et al.* General cardiovascular risk profile for use in primary care: The Framingham Heart Study. *Circulation*, 2008, 117:743–753.

restrictions include <7% of calories from saturated and trans fatty acids, <200 mg of cholesterol daily, up to 20% of calories from monounsaturated fatty acids, up to 10% of calories from polyunsaturated fat, and total fat calories ranging between 25% and 35% of all calories. Two oily fish meals/week are especially important for post–myocardial infarction patients to provide a substantial reduction in the risk of sudden cardiac death. Patients with CHD or a CHD equivalent (symptomatic peripheral or carotid vascular disease, abdominal aortic aneurysm, >20% 10-year CHD risk, or diabetes mellitus) should immediately start appropriate lipid-lowering drug therapy irrespective of their baseline LDL-C level. Patients without CHD or CHD equivalent should be managed with lifestyle advice (diet, exercise, weight management) for 3-6 months before drug therapy is implemented.

Before drug therapy is initiated, secondary causes of hyperlipidemia should be excluded. Most secondary causes (Table 31–7) can be excluded by ascertaining the patient's medication history and by measuring serum creatinine, liver function tests, fasting glucose, and thyroid-stimulating hormone levels. Treatment of the disorder causing secondary dyslipidemia may preclude the necessity of treatment with hypolipidemic drugs.

Arterial Wall Biology and Plaque Stability

More effective lipid-lowering agents and a better understanding of atherogenesis have helped to prove that

Table 31–7

Secondary Causes of Dyslipidemia

DISORDER	MAJOR LIPID EFFECT
Diabetes mellitus	Triglycerides > cholesterol; low HDL-C
Nephrotic syndrome	Triglycerides usually > cholesterol
Alcohol use	Triglycerides > cholesterol
Contraceptive use	Triglycerides > cholesterol
Estrogen use	Triglycerides > cholesterol
Glucocorticoid excess	Triglycerides > cholesterol
Hypothyroidism	Cholesterol > triglycerides
Obstructive liver disease	Cholesterol > triglycerides
HDL-C, high-density-lipoprotein cholesterol.	

aggressive lipid-lowering therapy has beneficial effects beyond those obtained by simply decreasing lipid deposition in the arterial wall. Aggressive lipid lowering results only in very small increases in lumen diameter but promptly decreases acute coronary events (Cannon et al., 2004). Lesions causing <60% occlusion are responsible for more than two-thirds of the acute events. Aggressive lipid-lowering therapy may prevent acute events through positive effects on the arterial wall; it corrects endothelial dysfunction, corrects abnormal vascular reactivity (spasm), and increases plaque stability.

Atherosclerotic lesions containing a large lipid core, large numbers of macrophages, and a poorly formed fibrous cap are prone to plaque rupture and acute thrombosis. Aggressive lipid lowering appears to alter plaque architecture, resulting in less lipid, fewer macrophages, and a larger collagen and smooth muscle cell–rich fibrous cap. Stabilization of plaque susceptibility to thrombosis appears to be a direct result of LDL-C lowering or an indirect result of changes in cholesterol and lipoprotein metabolism or arterial wall biology (see “Potential Cardioprotective Effects Other Than LDL Lowering,” later in the chapter).

Whom and When to Treat?

Large-scale trials with statins have provided new insights into which patients with dyslipidemia should be treated and when treatment should be initiated.

Gender. Both men and women with or without a prior vascular disease event benefit from lipid-lowering

therapy (Heart Protection Study Collaborative Group, 2002; Ridker et al., 2008). Statins, rather than hormone-replacement therapy, now are the recommended first-line drug therapy for lowering lipids and preventing CHD events in postmenopausal women. This recommendation reflects the increased CHD morbidity in older women with established CHD who were treated with hormone-replacement therapy (see Chapter 40).

Age. Age >45 years in men and >55 years in women is considered to be a CHD risk factor. The statin trials have shown that patients >65 years of age benefit from therapy as much as do younger patients. In fact, in those >70 years, the reduction of absolute mortality is stunning compared with individuals 55 years of age (Afilalo et al., 2008; Diamond and Kaul, 2008). Old age *per se* is not a reason to refrain from initiating drug therapy in an otherwise healthy person.

Cerebrovascular Disease Patients. In most observational studies, plasma cholesterol levels correlate positively with the risk of ischemic stroke. In clinical trials, statins reduced stroke and transient ischemic attacks in patients with and without CHD (Amarenco and Labreuche, 2009).

Peripheral Vascular Disease Patients. Statins prevent CHD events and may improve walking distance in patients with peripheral vascular disease (Aung et al., 2007).

Hypertensive Patients and Smokers. The relative risk reduction for coronary events in statin trials of hypertensive patients is similar to that in subjects without hypertension (Franz et al., 2008). Relative risk is reduced more in smokers in statin clinical trials than in nonsmokers (Cheung et al., 2004).

Type 2 Diabetes Mellitus. Patients with type 2 diabetes benefit very significantly from aggressive lipid lowering (see “Treatment of Type 2 Diabetes Patients,” later in the chapter) (Cholesterol Treatment Trialists’ Collaborators, 2008; Heart Protection Study Collaborative Group, 2003).

Post-Myocardial Infarction or Revascularization Patients. As soon as CHD is diagnosed, it is essential to begin lipid-lowering therapy (NCEP guidelines: LDL-C goal <70 mg/dL for very high-risk patients) (Grundy et al., 2004b). Compliance with drug therapy is greatly enhanced if treatment is initiated in the hospital. Statin therapy administered prior to angioplasty reduces the requirement for procedures related to myocardial infarction risk and the need for repeat revascularization (Ebrahimi et al., 2008; Zhang et al. 2010). Statin therapy also improves the long-term outcome after bypass surgery.

Can Cholesterol Levels Be Lowered Too Much? Are there total and LDL cholesterol levels below which adverse health consequences begin to increase? Observational studies initially were confusing. In the U.S. and western Europe, low cholesterol levels were associated with an increase in noncardiac mortality from chronic pulmonary disease, chronic liver disease, cancer (many primary sites), and hemorrhagic stroke; subsequent data indicate that it is the noncardiac diseases that cause the low plasma cholesterol levels and not the reverse. One exception may be hemorrhagic stroke. In the Multiple Risk Factor Intervention Trial (MRFIT), hemorrhagic stroke occurred more frequently in hypertensive patients with total cholesterol levels <160 mg/dL; however, the increased incidence of hemorrhagic stroke was more than offset by reduced CHD risk due to the low cholesterol levels. A recent meta-analysis of statin efficacy in preventing recurrent stroke found an increase in the risk of subsequent hemorrhagic stroke among patients with a prior hemorrhagic stroke who also received a statin. However, the risk of atherothrombotic stroke was reduced in proportion to the degree of cholesterol lowering by statin therapy (Amarenco and Labreuche, 2009).

Abetalipoproteinemia and hypobetalipoproteinemia, two rare disorders associated with extremely low total cholesterol levels, are instructive because affected individuals have reduced CHD risk and no increase in noncardiac mortality. Patients who are homozygous for the mutations that cause these disorders have total cholesterol levels <50 mg/dL and triglyceride levels <25 mg/dL. With the advent of more efficacious cholesterol-lowering agents, it has been possible to test the benefits and risks of lowering LDL-C levels <50 mg/dL (Ridker et al., 2008). Lower LDL-C levels translate into greater reductions in clinical events without any increase in adverse events.

Treatment of Type 2 Diabetes Patients

Diabetes mellitus is an independent predictor of high risk for CHD. CHD morbidity is two to four times higher in patients with diabetes than in nondiabetics. Glucose control is essential but provides only minimal benefit with respect to CHD prevention. Aggressive treatment of diabetic dyslipidemia through diet, weight control, and drugs is critical in reducing risk.

Diabetic dyslipidemia usually is characterized by high triglycerides, low HDL-C, and moderate elevations of total cholesterol and LDL-C. In fact, diabetics without diagnosed CHD have the same level of risk as nondiabetics with established CHD. Thus, the dyslipidemia treatment guidelines for diabetic patients are the same as for patients with CHD, irrespective of whether the diabetic patient has had a CHD event (The Expert Panel, 2002). The American Diabetes Association recommends new lipid therapy targets for diabetics. In addition to targets for LDL-C and non-HDL-C, two targets for total plasma apoB were established based on the level of CVD risk (Brunzell et al., 2008).

Clinical trials with statins have clearly established that total and vascular disease mortality are reduced in diabetics as a consequence of prevention of CVD events (Cholesterol Treatment Trialists' Collaborators, 2008). A recently completed trial comparing statin therapy to statin plus fenofibrate therapy will provide the first

outcome data for statin plus fibrate combination therapy in type 2 diabetes patients (Ginsberg et al., 2007).

Metabolic Syndrome

There is an increased CHD risk associated with the insulin-resistant, prediabetic state described under the rubric of "metabolic syndrome." This syndrome consists of a constellation of five CHD risk factors (Table 31–8).

Of the five risk factors, abdominal obesity is defined by ethnic-specific values of abdominal waist circumference (Alberti et al., 2009). An alternative to assessing the five criteria that identify the metabolic syndrome is to determine the ratio of the concentrations of fasting triglycerides divided by the HDL-C. Values >3.5 predict insulin resistance as effectively as meeting the criteria for diagnosing metabolic syndrome (McLaughlin et al., 2005). The prevalence of metabolic syndrome among patients with premature vascular disease may be as high as 50%. Treatment should focus on weight loss and increased physical activity, because being overweight or obese usually precludes optimal risk factor reduction. Specific treatment of increased LDL-C, non-HDL-C, and triglyceride levels and low HDL-C levels also should be undertaken.

Table 31–8

Clinical Identification of the Metabolic Syndrome

RISK FACTOR	DEFINING LEVEL
Abdominal obesity ^a	Waist circumference ^b
Men	>102 cm (>40 in)
Women	>88 cm (>35 in)
Triglycerides	≥150 mg/dL
HDL-C	
Men	<40 mg/dL
Women	<50 mg/dL
Blood pressure	≥130/≥85 mm Hg
Fasting glucose	>100 mg/dL ^b

The 2001 National Cholesterol Education Program (NCEP) guidelines define the metabolic syndrome as the presence of three or more of these risk factors.

^aOverweight and obesity are associated with insulin resistance and the metabolic syndrome. However, the presence of abdominal obesity is more highly correlated with the metabolic risk factors than is an elevated body mass index. Therefore, the simple measurement of waist circumference is recommended to identify the body weight component of the metabolic syndrome.

^bSome male patients can develop multiple metabolic risk factors when the waist circumference is only marginally increased (e.g., 94–102 cm [37–39 inches]). Such patients may have a strong genetic contribution to insulin resistance, and like men with categorical increases in waist circumference, they should benefit from changes in life habits. There is ethnic variation in the values of waist circumference that define abdominal obesity (Alberti et al., 2009). HDL-C, high-density-lipoprotein cholesterol. From The Expert Panel, 2002.

Treatment of Hypertriglyceridemia

There is increased CHD risk associated with the presence of triglyceride levels >150 mg/dL. Three categories of hypertriglyceridemia are recognized (Table 31–4), and treatment is recommended based on the degree of elevation. Weight loss, increased exercise, and alcohol restriction are important for all hypertriglyceridemic patients. The LDL-C goal should be ascertained based on each patient’s risk factors or CHD status (Table 31–3). If triglycerides remain >200 mg/dL after the LDL-C goal is reached, further reduction in triglycerides may be achieved by increasing the dose of a statin or of niacin. Combination therapy (statin plus niacin or statin plus fibrate) may be required, but caution is necessary with these combinations to avoid myopathy (see “Statins in Combination with Other Lipid-Lowering Drugs,” later in the chapter).

Treatment of Low HDL-C. The most frequent risk factor for premature CHD is low HDL-C. In men with angiographically documented CHD, ~60% have HDL-C levels of <35 mg/dL and only 25% have LDL-C >160 mg/dL. In older men with CHD, 38% have HDL-C levels <35 mg/dL and two-thirds have HDL-C <40 mg/dL. Subjects with “normal” cholesterol levels of <200 mg/dL but with low HDL-C (<40 mg/dL) have as much CHD risk as subjects with higher total cholesterol levels (230-260 mg/dL) and more normal HDL-C (40-49 mg/dL). In a recent study of CHD patients admitted to hospitals with acute coronary syndrome between 2000 and 2006, low HDL-C levels were clearly documented as the most prevalent lipid-related risk factor (Sachdeva et al., 2009). In clinical trials employing statins to lower LDL-C, the level of HDL-C has been documented to substantially moderate risk (Jafri et al., 2009).

In patients with low HDL-C, the total cholesterol:HDL-C ratio is a particularly useful predictor of CHD risk (Bersot, 2003). Observational studies suggest that a favorable ratio is ≤ 3.5 and a ratio of >4.5 is associated with increased risk (Table 31–9). However, results of a *post hoc* analysis of the relationship between HDL-C levels and treatment benefit of statin therapy suggest that there is substantial additional benefit associated with a total cholesterol:HDL-C ratio <3 (Barter et al., 2007). American men, who are a high-risk group, have a typical ratio of ~4.5. Patients with low HDL-C may have what are considered to be “normal” total and LDL cholesterol levels; however, because of their low HDL-C levels, such patients may be at high risk based on the total cholesterol:HDL-C ratio (e.g., a total cholesterol, 180 mg/dL; HDL-C, 30 mg/dL; ratio, 6). A desirable total cholesterol level in low-HDL-C patients may be considerably lower than 200 mg/dL, especially because low-HDL-C patients also may have moderately elevated triglycerides, which may reflect increased levels of atherogenic remnant lipoproteins. Patients with average or low LDL-C, low HDL-C, and high total cholesterol:HDL-C ratios have benefited from treatment (Barter et al., 2007).

The treatment of low HDL-C patients focuses on lowering LDL-C to the target level based on the patient’s risk factor or CHD status (Table 31–3) and a reduction of VLDL cholesterol (estimated by dividing the plasma triglyceride level by 5) to <30 mg/dL to reach the target for non-HDL-C. Satisfactory treatment results are a ratio of total cholesterol:HDL-C ≤ 3.5 (Table 3–9). Patients with total cholesterol:HDL-C ratios >4.5 are at risk even if their “non-HDL-C” levels (LDL-C and VLDL cholesterol) are at the goal values recommended by the 2001 NCEP guidelines. Consequently, it is useful to base treatment of patients with low HDL-C levels on both LDL-C and non-HDL-C levels plus the total cholesterol:HDL-C ratio (Tables 31–3 and 31–8) (Bersot et al., 2003).

DRUG THERAPY OF DYSLIPIDEMIA

Statins

The statins are the most effective and best-tolerated agents for treating dyslipidemia. These drugs are competitive inhibitors of HMG-CoA reductase, which

Table 31–9

Guidelines Based on LDL-C and Total Cholesterol:HDL-C Ratio for Treatment of Low HDL-C Patients^a

^aUnits for LDL-C: mg/dL

catalyzes an early, rate-limiting step in cholesterol biosynthesis. Higher doses of the more potent statins (e.g., atorvastatin, simvastatin, and rosuvastatin) also can reduce triglyceride levels caused by elevated VLDL levels. Some statins also are indicated for raising HDL-C levels, although the clinical significance of these effects on HDL-C remains to be proven.

Multiple well-controlled clinical trials have documented the efficacy and safety of simvastatin, pravastatin, lovastatin, atorvastatin, and rosuvastatin in reducing fatal and nonfatal CHD events, strokes, and total mortality (Cholesterol Treatment Trialists' Collaborators, 2005; Ridker et al., 2008). Rates of adverse events in statin trials were the same in the placebo groups and in the groups receiving the drug.

History. Statins were isolated from a mold, *Penicillium citrinum*, and identified as inhibitors of cholesterol biosynthesis in 1976 by

Endo and colleagues. Subsequent studies by Brown and Goldstein established that statins act by inhibiting HMG-CoA reductase. The first statin studied in humans was *compactin*, renamed *mevastatin*, which demonstrated the therapeutic potential of this class of drugs. Alberts and colleagues at Merck developed the first statin approved for use in humans, lovastatin (formerly known as mevinolin), which was isolated from *Aspergillus terreus*. Six other statins are also available. Pravastatin and simvastatin are chemically modified derivatives of lovastatin (Figure 31–2). Atorvastatin, fluvastatin, rosuvastatin, and pitavastatin are structurally distinct synthetic compounds.

A yeast that grows on rice, *monascus purpureus*, produces a series of compounds, one of which, monacolin K, is an inhibitor of HMG-CoA reductase and is chemically identical to lovastatin. OTC preparations, known as red yeast rice, contain monacolin K. As with many nutraceuticals, content of the active principle may vary, and such preparations should be used with great caution.

Chemistry. The structural formulas of the original statin (mevastatin) and the seven statins currently available in the U.S. are shown in

Figure 31–2. Chemical structures of the statins and the reaction catalyzed by HMG-CoA reductase.

Figure 31–2 along with the reaction (conversion of HMG-CoA to mevalonate) catalyzed by HMG-CoA reductase, the enzyme they competitively inhibit. The statins possess a side group that is structurally similar to HMG-CoA. Mevastatin, lovastatin, simvastatin, and pravastatin are fungal metabolites, and each contains a hexahydronaphthalene ring. Lovastatin differs from mevastatin in having a methyl group at carbon 3. There are two major side chains. One is a methylbutyrate ester (lovastatin and pravastatin) or a dimethylbutyrate ester (simvastatin). The other contains a hydroxy acid that forms a six-membered analog of the intermediate compound in the HMG-CoA reductase reaction. Fluvastatin, atorvastatin, rosuvastatin, and pitavastatin are entirely synthetic compounds containing a heptanoic acid side chain that forms a structural analog of the HMG-CoA intermediate. As a result of their structural similarity to HMG-CoA, statins are reversible competitive inhibitors of the enzyme's natural substrate, HMG-CoA. The inhibition constant (K_i) of the statins is ~ 1 nM; the dissociation constant of HMG-CoA is three orders of magnitude higher.

Lovastatin and simvastatin are lactone prodrugs that are modified in the liver to active hydroxy acid forms. Because they are lactones, they are less soluble in water than are the other statins, a difference that appears to have little if any clinical significance. Pravastatin (an acid in the active form), fluvastatin (sodium salt), and atorvastatin, rosuvastatin, and pitavastatin (calcium salts), are all administered in the active, open-ring form.

Mechanism of Action. Statins exert their major effect—reduction of LDL levels—through a mevalonic acid–like moiety that competitively inhibits HMG-CoA reductase. By reducing the conversion of HMG-CoA to mevalonate, statins inhibit an early and rate-limiting step in cholesterol biosynthesis.

Statins affect blood cholesterol levels by inhibiting hepatic cholesterol synthesis, which results in increased expression of the LDL receptor gene. In response to the reduced free cholesterol content within hepatocytes, membrane-bound SREBPs are cleaved by a protease and translocated to the nucleus. The transcription factors then bind the sterol-responsive element of the LDL receptor gene, enhancing transcription and increasing the synthesis of LDL receptors (Horton et al., 2002). Degradation of LDL receptors also is reduced. The greater number of LDL receptors on the surface of hepatocytes results in increased removal of LDL from the blood, thereby lowering LDL-C levels.

Some studies suggest that statins also can reduce LDL levels by enhancing the removal of LDL precursors (VLDL and IDL) and by decreasing hepatic VLDL production. Because VLDL remnants and IDL are enriched in apoE, a statin-induced increase in the number of LDL receptors, which recognize both apoB-100 and apoE, enhances the clearance of these LDL precursors. The reduction in hepatic VLDL production induced by statins is thought to be mediated by reduced synthesis of cholesterol, a required component of VLDL. This mechanism also likely accounts for the triglyceride-lowering effect of statins and may account for the reduction ($\sim 25\%$)

of LDL-C levels in patients with homozygous familial hypercholesterolemia treated with 80 mg of atorvastatin or simvastatin.

Triglyceride Reduction by Statins. Triglyceride levels >250 mg/dL are reduced substantially by statins, and the percent reduction achieved is similar to the percent reduction in LDL-C. Accordingly, hypertriglyceridemic patients taking the highest doses of the most potent statins experience a 35–45% reduction in LDL-C and a similar reduction in fasting triglyceride levels (Hunninghake et al., 2004). The efficacy of triglyceride lowering by pitavastatin in patients with baseline triglyceride levels >250 mg/dL is currently unknown.

Effect of Statins on HDL-C Levels. Most studies of patients treated with statins have systematically excluded patients with low HDL-C levels. In studies of patients with elevated LDL-C levels and gender-appropriate HDL-C levels (40–50 mg/dL for men; 50–60 mg/dL for women), an increase in HDL-C of 5–10% was observed, irrespective of the dose or statin employed. However, in patients with reduced HDL-C levels (<35 mg/dL), statins may differ in their effects on HDL-C levels. Simvastatin, at its highest dose of 80 mg, increases HDL-C and apoA-I levels more than a comparable dose of atorvastatin (Crouse et al., 2000). In preliminary studies of patients with hypertriglyceridemia and low HDL-C, rosuvastatin appears to raise HDL-C levels by as much as 15–20% (Hunninghake et al., 2004). More studies are needed to ascertain whether the effects of statins on HDL-C in patients with low HDL-C levels are clinically significant.

Effects of Statins on LDL-C Levels. Statins lower LDL-C by 20–55%, depending on the dose and statin used. In large trials comparing the effects of the various statins, equivalent doses appear to be 5 mg of simvastatin = ~ 15 mg of lovastatin = ~ 15 mg of pravastatin = ~ 40 mg of fluvastatin (Pedersen and Tobert, 1996), 20 mg of simvastatin = ~ 10 mg of atorvastatin (Jones et al., 1998) (Crouse III et al., 1999), and 20 mg of atorvastatin = 10 mg of rosuvastatin (Jones et al., 2003). Analysis of dose-response relationships for all statins demonstrates that the efficacy of LDL-C lowering is log-linear; LDL-C is reduced by $\sim 6\%$ (from baseline) with each doubling of the dose (Jones et al., 1998; Pedersen and Tobert, 1996). Maximal effects on plasma cholesterol levels are achieved within 7–10 days.

Table 31–10 provides information on the statin doses required to reduce LDL-C by 20–55%. *The fractional reductions achieved with the various doses are the same regardless of the absolute value of the baseline LDL-C level.* The statins are effective in almost all patients with high LDL-C levels. The exception is patients with homozygous familial hypercholesterolemia, who have very attenuated responses to the usual doses of statins because both alleles of the LDL receptor gene code for dysfunctional LDL receptors; the partial response in these patients is due to a reduction in hepatic VLDL synthesis associated with the inhibition of HMG-CoA reductase–mediated cholesterol synthesis. Statin therapy does not reduce Lp(a) levels.

Potential Cardioprotective Effects Other Than LDL Lowering. Although the statins clearly exert their major effects on CHD by lowering LDL-C and improving the lipid profile as reflected in plasma cholesterol levels, a multitude of potentially cardioprotective effects are being ascribed to these drugs (Liao, 2005). However,

Table 31–10

Dose (mg) of Statins Required to Achieve Various Reductions in Low-Density-Lipoprotein Cholesterol from Baseline

	20-25%	26-30%	31-35%	36-40%	41-50%	51-55%
Atorvastatin	—	—	10	20	40	80
Fluvastatin	20	40	80			
Lovastatin	10	20	40	80		
Pitavastatin		1	2	4		
Pravastatin	10	20	40			
Rosuvastatin	—	—	—	5	10	20, 40
Simvastatin	—	10	20	40	80	

the mechanisms of action for non-lipid-lowering roles of statins have not been established, and it is not known whether these potential pleiotropic effects represent a class-action effect, differ among statins, or are biologically or clinically relevant. Until these questions are resolved, selection of a specific statin should not be based on any one of these effects. Nevertheless, the potential importance of the non-lipid roles of statins merits discussion.

Statins and Endothelial Function. A variety of studies have established that the vascular endothelium plays a dynamic role in vasoconstriction/relaxation. Hypercholesterolemia adversely affects the processes by which the endothelium modulates arterial tone. Statin therapy enhances endothelial production of the vasodilator nitric oxide, leading to improved endothelial function. Statin therapy improves endothelial function independent of changes in plasma cholesterol levels.

Statins and Plaque Stability. The vulnerability of plaques to rupture and thrombosis is of greater clinical relevance than the degree of stenosis they cause (Corti et al., 2003). Statins affect plaque stability in a variety of ways. They inhibit monocyte infiltration into the artery wall and inhibit macrophage secretion of matrix metalloproteinases *in vitro*. The metalloproteinases degrade extracellular matrix components and thus weaken the fibrous cap of atherosclerotic plaques.

Statins also appear to modulate the cellularity of the artery wall by inhibiting proliferation of smooth muscle cells and enhancing apoptosis. It is debatable whether these effects would be beneficial or harmful if they occurred *in vivo*. Reduced proliferation of smooth muscle cells and enhanced apoptosis could retard initial hyperplasia and restenosis, but they also could weaken the fibrous cap and destabilize the lesion. Interestingly, statin-induced suppression of cell proliferation and the induction of apoptosis have been extended to tumor biology. The effects of statins on isoprenoid biosynthesis and protein phenylation associated with reduced synthesis of the cholesterol precursor mevalonate may alter the development of malignancies (Li et al., 2003; Wong et al., 2002).

Statins and Inflammation. Appreciation of the importance of inflammatory processes in atherogenesis is growing, and statins may have

an anti-inflammatory role. Statins decreased the risk of CHD and levels of CRP (an independent marker for inflammation and high CHD risk) independently of cholesterol lowering (Libby and Aikawa, 2003; Libby and Ridker, 2004). Body weight and the metabolic syndrome are associated with elevated levels of highly sensitive CRP, leading some to suggest that the CRP may simply be a marker of obesity and insulin resistance (Pearson et al., 2003). It remains to be determined whether the CRP is simply a marker of inflammation or if it contributes to the pathogenesis of atherosclerosis. The clinical utility of measuring CRP with “highly sensitive” assays appears to be limited to those primary prevention subjects with a moderate (10-20%) 10-year risk of sustaining a CHD event. Values of highly sensitive CRP >3 mg/L suggest that such patients should be managed as secondary prevention patients (Pearson et al., 2003).

Statins and Lipoprotein Oxidation. Oxidative modification of LDL appears to play a key role in mediating the uptake of lipoprotein cholesterol by macrophages and in other processes, including cytotoxicity within lesions. Statins reduce the susceptibility of lipoproteins to oxidation both *in vitro* and *ex vivo*.

Statins and Coagulation. The most compelling evidence of a non-lipid-lowering effect of a statin is the rosuvastatin-mediated reduction in venous thromboembolic events, a prespecified endpoint, in JUPITER. This trial demonstrated a 43% reduction in venous thromboembolic events in patients treated with rosuvastatin, 20 mg daily, compared with placebo during a median follow-up period of 1.9 years (Glynn et al., 2009). Statins reduce platelet aggregation and reduce the deposition of platelet thrombi. In addition, the different statins have variable effects on fibrinogen levels. Elevated plasma fibrinogen levels are associated with an increase in the incidence of CHD.

Absorption, Metabolism, and Excretion

Absorption from the Small Intestine. After oral administration, intestinal absorption of the statins is variable (30-85%). All the statins, except simvastatin and lovastatin, are administered in the β -hydroxy acid form, which is the form that inhibits HMG-CoA reductase. Simvastatin and lovastatin are administered as inactive lactones that must be transformed in the liver to their respective β -hydroxy acids, simvastatin acid (SVA) and lovastatin acid (LVA). There is extensive first-pass hepatic uptake of all statins, mediated primarily by the organic anion transporter OATP1B1 (see Chapter 5).

Due to extensive first-pass hepatic uptake, systemic bioavailability of the statins and their hepatic metabolites varies between 5% and 30% of administered doses. The metabolites of all statins, except fluvastatin and pravastatin, have some HMG-CoA reductase inhibitory activity (Bellosta et al., 2004). Under steady-state conditions, small amounts of the parent drug and its metabolites produced in the liver can be found in the systemic circulation. After the lactones of simvastatin and lovastatin are transformed in the liver to SVA and LVA, small amounts of these active inhibitors of HMG-CoA reductase, as well as small amounts of the lactone forms, can be found in the systemic circulation. In the plasma, >95% of statins and their metabolites are protein bound, with the exception of pravastatin and its metabolites, which are only 50% bound (Schachter, 2005).

After an oral dose, plasma concentrations of statins peak in 1-4 hours. The $t_{1/2}$ of the parent compounds are 1-4 hours, except in the case of atorvastatin and rosuvastatin, which have half-lives of ~20 hours, and simvastatin with a $t_{1/2}$ ~12 hours (Ieiri et al., 2007). The longer $t_{1/2}$ of atorvastatin and rosuvastatin may contribute to their greater cholesterol-lowering efficacy (Corsini et al., 1999). The liver biotransforms all statins, and more than 70% of statin metabolites are excreted by the liver, with subsequent elimination in the feces (Bellosta et al., 2004). Inhibition by other drugs of OATP1B1, which transports several statins into hepatocytes, and inhibition or induction of CYP3A4 by a variety of pharmacological agents provide rationales for drug-drug interactions involving statins (Shitara and Sugiyama, 2006).

Adverse Effects and Drug Interactions

Hepatotoxicity. Initial post-marketing surveillance studies of the statins revealed an elevation in hepatic transaminase to values greater than three times the upper limit of normal, with an incidence as great as 1%. The incidence appeared to be dose related. However, in the placebo-controlled outcome trials in which 10- to 40-mg doses of simvastatin, lovastatin, fluvastatin, atorvastatin, pravastatin, or rosuvastatin were used, the incidence of 3-fold elevations in hepatic transaminases was 1-3% in the active drug treatment groups and 1.1% in placebo patients (Law et al., 2006; Ridker et al., 2008). No cases of liver failure occurred in these trials. Although serious hepatotoxicity is rare, 30 cases of liver failure associated with statin use were reported to the FDA between 1987 and 2000, a rate of about one case per million person-years of use (Law et al., 2006). It is therefore reasonable to measure alanine aminotransferase (ALT) at baseline and thereafter when clinically indicated.

Observational studies and a prospective trial suggest that transaminase elevations in patients with nonalcoholic fatty liver disease and hepatitis C are not at risk of statin-induced liver toxicity (Alqahtani and Sanchez, 2008; Chalasani et al., 2004; Lewis et al., 2007; Norris et al., 2008). This is important, as many insulin-resistant patients are affected by nonalcoholic fatty liver disease and have elevated transaminases. As insulin resistance is associated with increased CVD risk, insulin-resistant patients, especially those with type 2 diabetes mellitus, benefit from lipid-lowering therapy with statins (Cholesterol Treatment Trialists' Collaborators, 2008). It is reassuring that these patients with elevated transaminases can safely take statins.

Myopathy. The major adverse effect associated with statin use is myopathy (Wilke et al., 2007). Between 1987 and 2001, the FDA

recorded 42 deaths from rhabdomyolysis induced by statins (excluding *cerivastatin*, which has been withdrawn from the market worldwide). This is a rate of one death per million prescriptions (30-day supply). In the statin trials described earlier (under "Hepatotoxicity"), rhabdomyolysis occurred in eight active drug recipients versus five placebo subjects. Among active drug recipients, 0.17% had CK values exceeding 10 times the upper limit of normal; among placebo-treated subjects, the incidence was 0.13%. Only 13 out of 55 drug-treated subjects and 4 out of 43 placebo subjects with greater than 10-fold elevations of CK reported any muscle symptoms (Law et al., 2006).

The risk of myopathy and rhabdomyolysis increases in proportion to statin dose and plasma concentrations. Consequently, factors inhibiting statin catabolism are associated with increased myopathy risk, including advanced age (especially >80 years of age), hepatic or renal dysfunction, perioperative periods, multi-system disease (especially in association with diabetes mellitus), small body size, and untreated hypothyroidism (Pasternak et al., 2002; Thompson et al., 2003). Concomitant use of drugs that diminish statin catabolism or interfere with hepatic uptake is associated with myopathy and rhabdomyolysis in 50-60% of all cases (Law and Rudnicka, 2006; Thompson et al., 2003). Thus, avoiding these drug interactions should reduce myopathy and rhabdomyolysis by about one-half (Law and Rudnicka, 2006). The most common statin interactions occurred with fibrates, especially *gemfibrozil* (38%), *cyclosporine* (4%), *digoxin* (5%), *warfarin* (4%), macrolide antibiotics (3%), *mibefradil* (2%), and azole antifungals (1%) (Thompson et al., 2003). Other drugs that increase the risk of statin-induced myopathy include niacin (rare), HIV protease inhibitors, *amiodarone*, and *nefazodone* (Pasternak et al., 2002).

There are a variety of pharmacokinetic mechanisms by which these drugs increase myopathy risk when administered concomitantly with statins. Gemfibrozil, the drug most commonly associated with statin-induced myopathy, inhibits both uptake of the active hydroxy acid forms of statins into hepatocytes by OATP1B1 and interferes with the transformation of most statins by glucuronidases (Prueksaritanont et al., 2002a; Prueksaritanont et al., 2002b; Prueksaritanont et al., 2002c). Primarily due to inhibition of OATP1B1-mediated hepatic uptake, co-administration of gemfibrozil nearly doubles the plasma concentration of the statin hydroxy acids (Neuvonen et al., 2006). Other fibrates, especially fenofibrate, do not interfere with the glucuronidation of statins and pose less risk of myopathy when used in combination with statin therapy. (For reviews of statin interactions with other drugs, see Bellosta et al., 2004 and Neuvonen et al., 2006). Concomitant therapy with simvastatin, 80 mg daily, and fenofibrate, 160 mg daily, results in no clinically significant pharmacokinetic interaction (Bergman et al., 2004). Similar results were obtained in a study of low-dose rosuvastatin, 10 mg daily, plus fenofibrate, 67 mg three times a day. When statins are administered with niacin, the myopathy probably is caused by an enhanced inhibition of skeletal muscle cholesterol synthesis (a pharmacodynamic interaction).

Drugs that interfere with statin oxidation are those metabolized primarily by CYP3A4 and include certain macrolide antibiotics (e.g., *erythromycin*); azole antifungals (e.g., *itraconazole*); cyclosporine; nefazodone, a phenylpiperazine antidepressant; HIV protease inhibitors; and amiodarone (Alsheikh-Ali and Karas, 2005; Bellosta et al., 2004; Corsini, 2003). These pharmacokinetic interactions are associated with increased plasma concentrations of statins

and their active metabolites. Atorvastatin, lovastatin, and simvastatin are primarily metabolized by CYPs 3A4 and 3A5. Fluvastatin is mostly (50-80%) metabolized by CYP2C9 to inactive metabolites, but CYP3A4 and CYP2C8 also contribute to its metabolism. Pravastatin, however, is not metabolized to any appreciable extent by the CYP system and is excreted unchanged in the urine. Pravastatin, fluvastatin, and rosuvastatin are not extensively metabolized by CYP3A4. Pravastatin and fluvastatin may be less likely to cause myopathy when used with one of the predisposing drugs. However, because cases of myopathy have been reported with both drugs, the benefits of combined therapy with any statin should be carefully weighed against the risk of myopathy. Although rosuvastatin is not transformed to any appreciable extent by oxidation, cases of myopathy have been reported, particularly in association with concomitant use of gemfibrozil (Schneck et al., 2004). Experience with pitavastatin is limited. There are no data regarding myopathy and rhabdomyolysis that might be associated with its use.

Despite the rarity of 10-fold elevations of CK, many patients complain of muscle aches (myalgias) while taking statins. It is unclear if such myalgias are caused by taking a statin. In one clinical trial involving 20,000 subjects randomized to simvastatin (40 mg daily) or placebo, it was observed over the 5 years of the study that one-third of patients complained of myalgia at least once, whether the active drug or the placebo was being taken (Heart Protection Study Collaborative Group, 2002).

Replacing vitamin D in patients with a vitamin D deficiency reportedly reduces statin-associated myalgias and improves statin tolerance (Ahmed et al., 2009). The observation needs to be confirmed, but it is potentially significant because vitamin D deficiency is associated with myopathy, insulin resistance, and increased incidence of CVD (Lee et al., 2008).

Pregnancy. *The safety of statins during pregnancy has not been established.* Women wishing to conceive should not take statins. During their childbearing years, women taking statins should use highly effective contraception (see Chapter 40). Nursing mothers also are advised to avoid taking statins.

Therapeutic Uses. Each statin has a low recommended starting dose that reduces LDL-C by 20-30%. Dyslipidemic patients frequently remain on their initial dose, are not titrated to achieve their target LDL-C level, and thus remain undertreated. For this reason, it is advisable to start each patient on a dose that will achieve the patient's target goal for LDL-C lowering. For example, a patient with a baseline LDL-C of 150 mg/dL and a goal of 100 mg/dL requires a 33% reduction in LDL-C and should be started on a dose expected to provide it (Table 31-10).

Hepatic cholesterol synthesis is maximal between midnight and 2:00 A.M. Thus, statins with $t_{1/2} \leq 4$ hours (all but atorvastatin and rosuvastatin) should be taken in the evening.

The initial recommended dose of lovastatin (MEVACOR) is 20 mg and is slightly more effective if taken with the evening meal than if it is taken at bedtime, although bedtime dosing is preferable

to missing doses. The dose of lovastatin may be increased every 3-6 weeks up to a maximum of 80 mg/day. The 80-mg dose is slightly (2-3%) more effective if given as 40 mg twice daily. Lovastatin, at 20 mg, is marketed in combination with 500, 750, or 1000 mg of extended-release niacin (ADVICOR). Few patients are appropriate candidates for this fixed-dose combination (see the section on "Nicotinic Acid," later in the chapter).

The approved starting dose of simvastatin (ZOCOR) for most patients is 20 mg at bedtime unless the required LDL-C reduction exceeds 45% or the patient is a high-risk secondary prevention patient, in which case a 40-mg starting dose is indicated. The maximal dose is 80 mg, and the drug should be taken at bedtime. In patients taking cyclosporine, fibrates, or niacin, the daily dose should not exceed 20 mg. Simvastatin, 20 mg, is marketed in combination with 500, 750, or 1000 mg of extended-release niacin (SIMCOR). See the section on "Nicotinic Acid."

Pravastatin (PRAVACHOL) therapy is initiated with a 20- or 40-mg dose that may be increased to 80 mg. This drug should be taken at bedtime. Because pravastatin is a hydroxy acid, bile-acid sequestrants will bind it and reduce its absorption. Practically, this is rarely a problem because the resins should be taken before meals and pravastatin should be taken at bedtime. Pravastatin also is marketed in combination with buffered aspirin (PRAVIGARD). The small advantage of combining these two drugs should be weighed against the disadvantages inherent in fixed-dose combinations.

The starting dose of fluvastatin (LESCOL) is 20 or 40 mg, and the maximum is 80 mg/day. Like pravastatin, it is administered as a hydroxy acid and should be taken at bedtime, several hours after ingesting a bile-acid sequestrant (if the combination is used).

Atorvastatin (LIPITOR) has a long $t_{1/2}$, which allows administration of this statin at any time of the day. The starting dose is 10 mg, and the maximum is 80 mg/day. Atorvastatin is marketed in combination with the Ca^{2+} -channel blocker amlodipine (CADUET) for patients with hypertension or angina as well as hypercholesterolemia. The physician should weigh any advantage of combination against the associated risks and disadvantages.

Rosuvastatin (CRESTOR) is available in doses ranging between 5 and 40 mg. It has a $t_{1/2}$ of 20-30 hours and may be taken at any time of day. Because experience with rosuvastatin is limited, treatment should be initiated with 5-10 mg daily, increasing stepwise, if needed, until the incidence of myopathy is better defined. If the combination of gemfibrozil with rosuvastatin is used, the dose of rosuvastatin should not exceed 10 mg.

Pitavastatin (LIVALO) is available in doses of 1, 2, and 4 mg. There is very limited post-marketing experience with this drug. Gemfibrozil reduces clearance of pitavastatin and raises blood concentrations; consequently, gemfibrozil should be used cautiously, if at all, in combination with pitavastatin.

The choice of statins should be based on efficacy (reduction of LDL-C) and cost. Three drugs (lovastatin, simvastatin, and pravastatin) have been used safely in clinical trials involving thousands of subjects for 5 or more years. The documented safety records of these statins should be considered, especially when initiating therapy in younger patients. Once drug treatment is initiated, it is almost always lifelong. Baseline determinations of ALT and repeat testing at 3-6 months are recommended. If ALT is normal after the initial 3-6 months, then it need not be repeated more than once every 6-12 months. Measurements of CK are not routinely necessary

unless the patient also is taking a drug that enhances the risk of myopathy. Because myopathy may develop months to years after the start of combined therapy, it is unlikely that routine monitoring for the accompanying rise in CK will consistently herald the onset, even if monitoring is performed every 3-4 months.

Statin Use by Children. Some statins have been approved for use in children with heterozygous familial hypercholesterolemia. Atorvastatin, lovastatin, and simvastatin are indicated for children ≥ 11 years. Pravastatin is approved for children ≥ 8 years.

Statins in Combination with Other Lipid-Lowering Drugs. Statins, in combination with the bile acid-binding resins *cholestyramine* and *colestipol*, produce 20-30% greater reductions in LDL-C than can be achieved with statins alone. Preliminary data indicate that *colesevelam hydrochloride* plus a statin lowers LDL-C by 8-16% more than statins alone. Niacin also can enhance the effect of statins, but the occurrence of myopathy increases when statin doses $>25\%$ of maximum (e.g., 20 mg of simvastatin or atorvastatin) are used with niacin. The combination of a fibrate (*clofibrate*, *gemfibrozil*, or *fenofibrate*) with a statin is particularly useful in patients with hypertriglyceridemia and high LDL-C levels. This combination increases the risk of myopathy but usually is safe with a fibrate at its usual maximal dose and a statin at no more than 25% of its maximal dose. Fenofibrate, which is least likely to interfere with statin metabolism, appears to be the safest fibrate to use with statins (Prueksaritanont et al., 2002b). Triple therapy with resins, niacin, and statins can reduce LDL-C by up to 70%. Vytorin, a fixed combination of simvastatin (10, 20, 40, or 80 mg) and ezetimibe (10 mg), decreased LDL-C levels by up to 60% at 24 weeks.

Bile-Acid Sequestrants

The two established bile-acid sequestrants or resins (*cholestyramine* and *colestipol*) are among the oldest of the hypolipidemic drugs, and they are probably the safest, because they are not absorbed from the intestine. These resins also are recommended for patients 11-20 years of age. Because statins are so effective as monotherapy, the resins are most often used as second agents if statin therapy does not lower LDL-C levels sufficiently. When used with a statin, *cholestyramine* and *colestipol* usually are prescribed at submaximal doses. Maximal doses can reduce LDL-C by up to 25% but are associated with unacceptable gastrointestinal side effects (bloating and constipation) that limit compliance. *Colesevelam* is a newer bile-acid sequestrant that is prepared as an anhydrous gel and taken as a tablet or as a powder that is mixed with water and taken as an oral suspension. It lowers LDL-C by 18% at its maximum dose. The safety and efficacy of *colesevelam* have not been studied in pediatric patients or pregnant women.

Chemistry. *Cholestyramine* and *colestipol* (Figure 31-3) are anion-exchange resins. *Cholestyramine*, a polymer of styrene and

divinylbenzene with active sites formed from trimethylbenzylammonium groups, is a quaternary amine. *Colestipol*, a copolymer of diethylenetriamine and 1-chloro-2,3-epoxypropane, is a mixture of tertiary and quaternary diamines. *Cholestyramine* and *colestipol* are hygroscopic powders administered as chloride salts and are insoluble in water. *Colesevelam* is a polymer, poly(allylamine hydrochloride), cross-linked with epichlorohydrin and alkylated with 1-bromodecane and (6-bromoethyl)-trimethylammonium bromide; it is a hydrophilic gel and insoluble in water.

Mechanism of Action. The bile-acid sequestrants are highly positively charged and bind negatively charged bile acids. Because of their large size, the resins are not absorbed, and the bound bile acids are excreted in the stool. Because more than 95% of bile acids are normally reabsorbed, interruption of this process depletes the pool of bile acids, and hepatic bile-acid synthesis increases. As a result, hepatic cholesterol content declines, stimulating the production of LDL receptors, an effect similar to that of statins. The increase in hepatic LDL receptors increases LDL clearance and lowers LDL-C levels, but this effect is partially offset by the enhanced cholesterol synthesis caused by upregulation of HMG-CoA reductase. Inhibition of reductase activity by a statin substantially increases the effectiveness of the resins.

The resin-induced increase in bile-acid production is accompanied by an increase in hepatic triglyceride synthesis, which is of consequence in patients with significant hypertriglyceridemia (baseline triglyceride level >250 mg/dL). In such patients, bile-acid sequestrant therapy may cause striking increases in triglyceride levels. Use of colestevlam to lower LDL-C levels in hypertriglyceridemic patients should be accompanied by frequent (every 1-2 weeks) monitoring of fasting triglyceride levels until the triglyceride level is stable, or the use of colestevlam in these patients should be avoided.

Effects on Lipoprotein Levels. The reduction in LDL-C by resins is dose dependent. Doses of 8-12 g of cholestyramine or 10-15 g of colestipol are associated with 12-18% reductions in LDL-C. Maximal doses (24 g of cholestyramine, 30 g of colestipol) may reduce LDL-C by as much as 25% but will cause gastrointestinal side effects that are poorly tolerated by most patients. One to two weeks is sufficient to attain maximal LDL-C reduction by a given resin dose. In patients with normal triglyceride levels, triglycerides may increase transiently and then return to baseline. HDL-C levels increase 4-5%. Statins plus resins or niacin plus resins can reduce LDL-C by as much as 40-60%. Colesevelam, in doses of 3-3.75 g, reduces LDL-C levels by 9-19%.

Adverse Effects and Drug Interactions. The resins are generally safe, as they are not systemically absorbed. Because they are administered as chloride salts, rare instances of hyperchloremic acidosis have been reported. Severe hypertriglyceridemia is a contraindication to the use of cholestyramine and colestipol because these resins increase triglyceride levels. At present, there are insufficient data on the effect of colestevlam on triglyceride levels.

Cholestyramine and colestipol both are available as a powder that must be mixed with water and drunk as a slurry. The gritty sensation is unpleasant to patients initially but can be tolerated. Colestipol is available in a tablet form that reduces the complaint of grittiness but not the gastrointestinal symptoms. Colesevelam is available as a hard capsule that absorbs water and creates a soft, gelatinous material that allegedly minimizes the potential for gastrointestinal irritation.

Patients taking cholestyramine and colestipol complain of bloating and dyspepsia. These symptoms can be substantially

reduced if the drug is completely suspended in liquid several hours before ingestion (e.g., evening doses can be mixed in the morning and refrigerated; morning doses can be mixed the previous evening and refrigerated). Constipation may occur but sometimes can be prevented by adequate daily water intake and psyllium, if necessary. Colesevelam may be less likely to cause the dyspepsia, bloating, and constipation observed in patients treated with cholestyramine or colestipol.

Cholestyramine and colestipol bind and interfere with the absorption of many drugs, including some thiazides, *furosemide*, *propranolol*, *L-thyroxine*, digoxin, warfarin, and some of the statins. The effect of cholestyramine and colestipol on the absorption of most drugs has not been studied. For this reason, it is wise to administer all drugs either 1 hour before or 3-4 hours after a dose of cholestyramine or colestipol. Colesevelam does not appear to interfere with the absorption of fat-soluble vitamins or of drugs such as digoxin, lovastatin, warfarin, *metoprolol*, *quinidine*, and *valproic acid*. The maximum concentration and the AUC of sustained-release *verapamil* are reduced by 31% and 11%, respectively, when the drug is co-administered with colestevlam. The effect of colestevlam on the absorption of other drugs has not been tested, but it seems prudent to recommend that patients take other medications 1 hour before or 3-4 hours after a dose of colestevlam.

Preparations and Use. Cholestyramine resin (QUESTRAN, others) is available in bulk (with scoops that measure a 4-g dose) or in individual packets of 4 g. Additional flavorings are added to increase palatability. The “light” preparations contain artificial sweeteners rather than sucrose. Colestipol hydrochloride (COLESTID, others) is available in bulk, in individual packets containing 5 g of colestipol, or as 1-g tablets.

Resins should never be taken in the dry form. The powdered forms of cholestyramine (4 g/dose) and colestipol (5 g/dose) are either mixed with a fluid (water or juice) and drunk as a slurry or mixed with crushed ice in a blender. Ideally, patients should take the resins before breakfast and before supper, starting with one scoop or packet twice daily, and increasing the dosage after several weeks or longer as needed and as tolerated. Patients generally will not take more than two doses (scoops or packets) twice a day.

Colesevelam hydrochloride (WELCHOL) is available as a solid tablet containing 0.625 g of colestevlam and as a powder in packets of 3.75 g or 1.875 g. The starting dose is either three tablets taken twice daily with meals or all six tablets taken with a meal. The tablets should be taken with a liquid. The maximum daily dose is seven tablets (4.375 g). The powder in the packets is first suspended in 4-8 oz of water and should be taken with meals. Dosing of the packet containing 3.75 g is once daily; the packet containing 1.875 g is taken twice daily.

Niacin (Nicotinic Acid)

Niacin, *nicotinic acid* (pyridine-3-carboxylic acid), one of the oldest drugs used to treat dyslipidemia, favorably affects virtually all lipid parameters.

Niacin is a water-soluble B-complex vitamin that functions as a vitamin only after its conversion to NAD or NADP, in which it occurs as an amide. Both niacin and its amide may be given orally as a source of niacin for its functions as a vitamin, but only niacin affects lipid levels. The hypolipidemic effects of niacin require larger doses than are required for its vitamin effects. Niacin is the best agent available for increasing HDL-C (30-40%); it also lowers triglycerides by 35-45% (as effectively as fibrates and the more effective statins) and reduces LDL-C levels by 20-30%. Niacin also is the only lipid-lowering drug that reduces Lp(a) levels significantly. Despite its salutary effect on lipids, niacin has side effects that limit its use (see “Adverse Effects,” later in the chapter).

Mechanism of Action. In adipose tissue, niacin inhibits the lipolysis of triglycerides by hormone-sensitive lipase, which reduces transport of free fatty acids to the liver and decreases hepatic triglyceride synthesis. Niacin and related compounds (e.g., 5-methylpyrazine-2-carboxylic-4-oxide, *acipimox*) may exert their effects on lipolysis by inhibiting adipocyte adenylyl cyclase. A GPCR for niacin has been identified and designated as GPR109A; it couples to G_i (Wise et al., 2003); its mRNA is highly expressed in the adipose tissue and spleen, sites of high-affinity nicotinic acid binding (Lorenzen et al., 2001). Acting on this receptor, niacin stimulates the G_i -adenylyl cyclase pathway in adipocytes, inhibiting cyclic AMP production and decreasing hormone-sensitive lipase activity, triglyceride lipolysis, and release of free fatty acids. Niacin also may inhibit a rate-limiting enzyme of triglyceride synthesis, diacylglycerol acyltransferase-2 (Ganji et al., 2004).

In the liver, niacin reduces triglyceride synthesis by inhibiting both the synthesis and esterification of fatty acids, effects that increase apoB degradation. Reduction of triglyceride synthesis reduces hepatic VLDL production, which accounts for the reduced LDL levels. Niacin also enhances LPL activity, which promotes the clearance of chylomicrons and VLDL triglycerides. Niacin raises HDL-C levels by decreasing the fractional clearance of apoA-I in HDL rather than by enhancing HDL synthesis. This effect is due to a reduction in the hepatic clearance of HDL-apoA-I, but not of cholesteryl esters, thereby increasing the apoA-I content of plasma and augmenting reverse cholesterol transport. In macrophages, niacin stimulates expression of the scavenger receptor CD36 and the cholesterol exporter ABCA1. The net effect of niacin on monocytic cells (“foam cells”) is HDL-mediated reduction of cellular cholesterol content (Rubic et al., 2004).

Effects on Plasma Lipoprotein Levels. Regular or crystalline niacin in doses of 2-6 g/day reduces triglycerides by 35-50%; the maximal effect occurs within 4-7 days. Reductions of 25% in LDL-C levels

are possible with doses of 4.5-6 g/day, but 3-6 weeks are required for maximal effect. HDL-C increases less in patients with low HDL-C levels (<35 mg/dL) than in those with higher levels.

Absorption, Fate, and Excretion. The pharmacological doses of regular (crystalline) niacin used to treat dyslipidemia are almost completely absorbed, and peak plasma concentrations (up to 0.24 mmol) are achieved within 30-60 minutes. The $t_{1/2}$ is about 60 minutes, which accounts for the necessity of dosing two to three times daily. At lower doses, most niacin is taken up by the liver; only the major metabolite, nicotinuric acid, is found in the urine. At higher doses, a greater proportion of the drug is excreted in the urine as unchanged nicotinic acid.

Adverse Effects. Two of niacin’s side effects, flushing and dyspepsia, limit patient compliance. The cutaneous effects include flushing and pruritus of the face and upper trunk, skin rashes, and acanthosis nigricans. Flushing and associated pruritus are prostaglandin mediated. Flushing is worse when therapy is initiated or the dosage is increased but ceases in most patients after 1-2 weeks of a stable dose. Taking an aspirin each day alleviates the flushing in many patients. Flushing recurs if only one or two doses are missed, and the flushing is more likely to occur when niacin is consumed with hot beverages (coffee, tea) or with ethanol-containing beverages. Flushing is minimized if therapy is initiated with low doses (100-250 mg twice daily) and if the drug is taken after breakfast or supper. Dry skin, a frequent complaint, can be dealt with by using skin moisturizers, and acanthosis nigricans can be dealt with by using lotions or creams containing *salicylic acid*. Dyspepsia and rarer episodes of nausea, vomiting, and diarrhea are less likely to occur if the drug is taken after a meal. Patients with any history of peptic ulcer disease should not take niacin because it can reactivate ulcer disease.

The most common, medically serious side effects are hepatotoxicity, manifested as elevated serum transaminases, and hyperglycemia. Both regular (crystalline) niacin and sustained-release niacin, which was developed to reduce flushing and itching, have been reported to cause severe liver toxicity. An extended-release niacin (NIASPAN) appears to be less likely to cause severe hepatotoxicity, perhaps simply because it is administered once daily instead of more frequently. The incidence of flushing and pruritus with this preparation is not substantially different from that with regular niacin. Severe hepatotoxicity is more likely to occur when patients take more than 2 g of sustained-release, over-the-counter preparations. Affected patients experience flu-like fatigue and weakness. Usually, aspartate transaminase and ALT are elevated, serum albumin levels decline, and total cholesterol and LDL-C levels decline substantially. In fact, reductions in LDL-C of 50% or more in a patient taking niacin should be viewed as a sign of niacin toxicity.

In patients with diabetes mellitus, niacin should be used cautiously because niacin-induced insulin resistance can cause severe hyperglycemia. Niacin use in patients with diabetes mellitus often mandates a change to insulin therapy. In a study of patients with type 2 diabetes taking niaspan, 4% stopped taking the drug because of inadequate glycemic control (Grundy et al., 2002). If niacin is prescribed for patients with known or suspected diabetes, blood glucose levels should be monitored at least weekly until proven to be stable. Niacin also elevates uric acid levels and may reactivate gout. A history of gout is a relative contraindication for niacin use. Rarer

reversible side effects include toxic amblyopia and toxic maculopathy. Atrial tachyarrhythmias and atrial fibrillation have been reported, more commonly in elderly patients. *Niacin, at doses used in humans, has been associated with birth defects in experimental animals and should not be taken by pregnant women.*

Therapeutic Use. Niacin is indicated for hypertriglyceridemia and elevated LDL-C; it is especially useful in patients with both hypertriglyceridemia and low HDL-C levels. There are two commonly available forms of niacin. Crystalline niacin (immediate-release or regular) refers to niacin tablets that dissolve quickly after ingestion. Sustained-release niacin refers to preparations that continuously release niacin for 6-8 hours after ingestion. NIASPAN is the only preparation of niacin that is FDA-approved for treating dyslipidemia and that requires a prescription.

Crystalline niacin tablets are available over the counter in a variety of strengths from 50- to 500-mg tablets. To minimize the flushing and pruritus, it is best to start with a low dose (e.g., 100 mg twice daily taken after breakfast and supper). The dose may be increased stepwise every 7 days by 100-200 mg to a total daily dose of 1.5-2 g. After 2-4 weeks at this dose, transaminases, serum albumin, fasting glucose, and uric acid levels should be measured. Lipid levels should be checked and the dose increased further until the desired effect on plasma lipids is achieved. After a stable dose is attained, blood should be drawn every 3-6 months to monitor for the various toxicities.

Because concurrent use of niacin and a statin can cause myopathy, the statin should be administered at no more than 25% of its maximal dose. Patients also should be instructed to discontinue therapy if flu-like muscle aches occur. Routine measurement of CK in patients taking niacin and statins does not assure that severe myopathy will be detected before onset of symptoms, as patients have developed myopathy after several years of concomitant use of niacin with a statin.

Over-the-counter, sustained-release niacin preparations and NIASPAN are effective up to a total daily dose of 2 g. All doses of sustained-release niacin, but particularly doses above 2 g/day, have been reported to cause hepatotoxicity, which may occur soon after beginning therapy or after several years of use (Knopp et al., 2009). The potential for severe liver damage should preclude use of OTC preparations in most patients, including those who have taken an equivalent dose of crystalline niacin safely for many years and are considering switching to a sustained-release preparation. NIASPAN may be less likely to cause hepatotoxicity.

Fibric Acid Derivatives: PPAR Activators

History. In 1962, Thorp and Waring reported that ethyl chlorophenoxyisobutyrate lowered lipid levels in rats. In 1967, the ester form (clofibrate) was approved for use in the U.S. and became the most widely prescribed hypolipidemic drug. Its use declined dramatically, however, after the World Health Organization (WHO) reported that, despite a 9% reduction in cholesterol levels, clofibrate treatment did not reduce fatal cardiovascular events, although nonfatal infarcts were reduced. Total mortality was significantly greater in the clofibrate group. The increased mortality was due to multiple causes, including cholelithiasis. Interpretation of these negative results was clouded by failure to analyze the data according to the intention-to-treat principle. A later analysis demonstrated that the apparent

increase in noncardiac mortality did not persist in the clofibrate-treated patients after discontinuation of the drug (Heady et al., 1992). Clofibrate use was virtually abandoned after publication of the results of the 1978 WHO trial. Clofibrate as well as two other fibrates, gemfibrozil and fenofibrate, remain available in the U.S.

Two subsequent trials involving only men have reported favorable effects of gemfibrozil therapy on fatal and nonfatal cardiac events without an increase in morbidity or mortality (Frick et al., 1987; Rubins et al., 1999). A third trial of men and women reported fewer events in a subgroup characterized by high triglyceride and low HDL-C levels (Haim et al., 1999).

Chemistry. Clofibrate, the prototype of the fibric acid derivatives, is the ethyl ester of *p*-chlorophenoxyisobutyrate. Gemfibrozil is a nonhalogenated phenoxyisobutyrate and thus is distinct from the halogenated fibrates. A number of fibric acid analogs (e.g., fenofibrate, *bezafibrate*, *ciprofibrate*) have been developed and are used in Europe and elsewhere (see Figure 31-4 for their structural formulas).

902 Mechanism of Action. Despite extensive studies in humans, the mechanisms by which fibrates lower lipoprotein levels, or raise HDL levels, remain unclear. Recent studies suggest that many of the effects of these compounds on blood lipids are mediated by their interaction with peroxisome proliferator-activated receptors (PPARs) (Kersten et al., 2000), which regulate gene transcription. Three PPAR isotypes (α , β , and γ) have been identified. Fibrates bind to PPAR α , which is expressed primarily in the liver and brown adipose tissue and to a lesser extent in kidney, heart, and skeletal muscle. Fibrates reduce triglycerides through PPAR α -mediated stimulation of fatty acid oxidation, increased LPL synthesis, and reduced expression of apoC-III. An increase in LPL would enhance the clearance of triglyceride-rich lipoproteins. A reduction in hepatic production of apoC-III, which serves as an inhibitor of lipolytic processing and receptor-mediated clearance, would enhance the clearance of VLDL. Fibrate-mediated increases in HDL-C are due to PPAR α stimulation of apoA-I and apoA-II expression, which increases HDL levels. Fenofibrate is more effective than gemfibrozil at increasing HDL levels.

LDL levels rise in many patients treated with gemfibrozil, especially those with hypertriglyceridemia. However, LDL levels are unchanged or fall in others, especially those whose triglyceride levels are not elevated or who are taking a second-generation agent, such as fenofibrate, bezafibrate, or ciprofibrate. The decrease in LDL levels may be due in part to changes in the cholesterol and triglyceride contents of LDL that are mediated by CETP; such changes can alter the affinity of LDL for the LDL receptor. There also is evidence that a PPAR α -mediated increase in hepatic SREBP-1 production enhances hepatic expression of LDL receptors (Kersten et al., 2000). Lastly, fibrates reduce the plasma concentration of small, dense, more easily oxidized LDL particles (Vakkilainen et al., 2003).

Most of the fibric acid agents have potential antithrombotic effects, including inhibition of coagulation and enhancement of fibrinolysis. These salutary effects also could alter cardiovascular outcomes by mechanisms unrelated to any hypolipidemic activity.

Effects on Lipoprotein Levels. The effects of the fibric acid agents on lipoprotein levels differ widely, depending on the starting lipoprotein profile, the presence or absence of a genetic hyperlipoproteinemia, the associated environmental influences, and the specific fibrate used.

Patients with type III hyperlipoproteinemia (dysbetalipoproteinemia) are among the most sensitive responders to fibrates (Mahley and Rall, 2008). Elevated triglyceride and cholesterol levels are dramatically lowered, and tuberoeruptive and palmar xanthomas may regress completely. Angina and intermittent claudication also improve.

In patients with mild hypertriglyceridemia (e.g., triglycerides <400 mg/dL), fibrate treatment decreases triglyceride levels by up to

50% and increases HDL-C concentrations by about 15%; LDL-C levels may be unchanged or increase. The second-generation agents, such as fenofibrate, bezafibrate, and ciprofibrate, lower VLDL levels to a degree similar to that produced by gemfibrozil, but they also are more likely to decrease LDL levels by 15-20%. In patients with more marked hypertriglyceridemia (e.g., 400-1000 mg/dL), a similar fall in triglycerides occurs, but LDL increases of 10-30% are seen frequently. Normotriglyceridemic patients with heterozygous familial hypercholesterolemia usually experience little change in LDL levels with gemfibrozil; with the other fibric acid agents, reductions as great as 20% may occur in some patients.

Fibrates usually are the drugs of choice for treating severe hypertriglyceridemia and the chylomicronemia syndrome. While the primary therapy is to remove alcohol and as much fat from the diet as possible, fibrates help both by increasing triglyceride clearance and decreasing hepatic triglyceride synthesis. In patients with chylomicronemia syndrome, fibrate maintenance therapy and a low-fat diet keep triglyceride levels well below 1000 mg/dL and thus prevent episodes of pancreatitis.

In a 5-year study of hyperlipidemic men, gemfibrozil reduced total cholesterol by 10% and LDL-C by 11%, raised HDL-C levels by 11%, and decreased triglycerides by 35% (Frick et al., 1987). Overall, there was a 34% decrease in the sum of fatal plus nonfatal cardiovascular events without any effect on total mortality. No increased incidence of gallstones or cancers was observed. Subgroup analysis suggested that the greatest benefit occurred in the subjects with the highest levels of VLDL or combined VLDL and LDL and in those with the lowest HDL-C levels (<35 mg/dL). Gemfibrozil may have affected the outcome by influencing platelet function, coagulation factor synthesis, or LDL size. In a recent secondary prevention trial, gemfibrozil reduced fatal and nonfatal CHD events by 22% despite a lack of effect on LDL-C levels. HDL-C levels increased by 6%, which may have contributed to the favorable outcome.

Absorption, Fate, and Excretion. All of the fibrate drugs are absorbed rapidly and efficiently (>90%) when given with a meal but less efficiently when taken on an empty stomach. The ester bond is hydrolyzed rapidly, and peak plasma concentrations are attained within 1-4 hours. More than 95% of these drugs in plasma are bound to protein, nearly exclusively to albumin. The $t_{1/2}$ of fibrates differ significantly, ranging from 1.1 hours (gemfibrozil) to 20 hours (fenofibrate). The drugs are widely distributed throughout the body, and concentrations in liver, kidney, and intestine exceed the plasma level. Gemfibrozil is transferred across the placenta. The fibrate drugs are excreted predominantly as glucuronide conjugates; 60-90% of an oral dose is excreted in the urine, with smaller amounts appearing in the feces. Excretion of these drugs is impaired in renal failure, although excretion of gemfibrozil is less severely compromised in renal insufficiency than is excretion of other fibrates. The use of fibrates is contraindicated in patients with renal failure.

Adverse Effects and Drug Interactions. Fibric acid compounds usually are well tolerated. Side effects may occur in 5-10% of patients but most often are not sufficient to cause discontinuation of the drug. Gastrointestinal side effects occur in up to 5% of patients. Other side effects are reported infrequently and include rash, urticaria, hair loss, myalgias, fatigue, headache, impotence, and anemia. Minor increases in liver transaminases and alkaline phosphatase have been reported. Clofibrate, bezafibrate, and fenofibrate have

been reported to potentiate the action of oral anticoagulants, in part by displacing them from their binding sites on albumin. Careful monitoring of the prothrombin time and reduction in dosage of the anticoagulant may be appropriate when treatment with a fibrate is begun.

A myopathy syndrome occasionally occurs in subjects taking clofibrate, gemfibrozil, or fenofibrate and may occur in up to 5% of patients treated with a combination of gemfibrozil and higher doses of statins. To diminish the risk of myopathy, statin doses should be reduced when combination therapy of a statin plus a fibrate is employed. Several drug interactions may contribute to this adverse response. Gemfibrozil inhibits hepatic uptake of statins by OATP1B1. Gemfibrozil also competes for the same glucuronosyl transferases that metabolize most statins. As a consequence, levels of both drugs may be increased when they are co-administered (Prueksaranont et al., 2002b; Prueksaranont et al., 2002c). Patients taking this combination should be instructed to be aware of the potential symptoms and should be followed at 3-month intervals with careful history and determination of CK values until a stable pattern is established. Patients taking fibrates with rosuvasatin should be followed especially closely even if low doses (5-10 mg) of rosuvasatin are employed until there is more experience with and knowledge of the safety of this specific combination. Fenofibrate is glucuronidated by enzymes that are not involved in statin glucuronidation. Thus, fenofibrate-statin combinations are less likely to cause myopathy than combination therapy with gemfibrozil and statins.

All of the fibrates increase the lithogenicity of bile. Clofibrate use has been associated with increased risk of gallstone formation.

Renal failure is a relative contraindication to the use of fibric acid agents, as is hepatic dysfunction. Combined statin-fibrate therapy should be avoided in patients with compromised renal function. Gemfibrozil should be used with caution and at a reduced dosage to treat the hyperlipidemia of renal failure. *Fibrates should not be used by children or pregnant women.*

Therapeutic Use. Clofibrate is available for oral administration. The usual dose is 2 g/day in divided doses. This compound is little used but may be useful in patients who do not tolerate gemfibrozil or fenofibrate. Gemfibrozil (LOPID) usually is administered as a 600-mg dose taken twice a day, 30 minutes before the morning and evening meals. Fenofibrate is available in two different formulations. The first preparation developed is the dimethylethyl ester of fenofibric acid, which is poorly water soluble and poorly absorbed. After uptake by the liver, this compound is hydrolyzed to produce fenofibric acid, which is the active moiety. Recently, a choline salt of fenofibric acid that is highly soluble in water and readily absorbed was developed. The effects of both formulations, however, are similar with respect to changes in plasma lipid concentrations (Grundy et al., 2005; Jones et al., 2009). The dimethylethyl ester preparations of fenofibric acid include TRICOR and LOFIBRA. The tricor brand of fenofibrate is available in tablets of 48 and 145 mg. The usual daily dose is 145 mg. Generic fenofibrate (LOFIBRA) is available in capsules containing 67, 134, and 200 mg. TRICOR, 145 mg, and LOFIBRA, 200 mg, are equivalent doses. The choline salt of fenofibric acid (TRILIPIX) is available in capsules of 135 and 45 mg. TRILIPIX, 135 mg, is equivalent to TRICOR, 145 mg, and LOFIBRA, 200 mg. Choline fenofibrate is indicated for combination therapy with statins (Jones et al., 2009). Fibrates are the drugs of choice for

treating hyperlipidemic subjects with type III hyperlipoproteinemia as well as subjects with severe hypertriglyceridemia (triglycerides >1000 mg/dL) who are at risk for pancreatitis. Fibrates appear to have an important role in subjects with high triglycerides and low HDL-C levels associated with the metabolic syndrome or type 2 diabetes mellitus (Robins, 2001). When fibrates are used in such patients, the LDL levels need to be monitored; if LDL levels rise, the addition of a low dose of a statin may be needed. Many experts now treat such patients first with a statin (Heart Protection Study Collaborative Group, 2003) and then add a fibrate, based on the reported benefit of gemfibrozil therapy. However, statin-fibrate combination therapy has not been evaluated in outcome studies (American Diabetes Association, 2004). If this combination is used, there should be careful monitoring for myopathy.

Ezetimibe and the Inhibition of Dietary Cholesterol Uptake

Ezetimibe is the first compound approved for lowering total and LDL-C levels that inhibits cholesterol absorption by enterocytes in the small intestine. It lowers LDL-C levels by ~20% and is used primarily as adjunctive therapy with statins.

History. Ezetimibe (SCH58235) was developed by pharmaceutical chemists studying inhibition of intestinal ACAT. Several compounds were found to inhibit cholesterol absorption, but by inhibiting intestinal cholesterol transport rather than ACAT.

Mechanism of Action. Ezetimibe inhibits luminal cholesterol uptake by jejunal enterocytes, by inhibiting the transport protein NPC1L1 (Altmann et al., 2004; Davis et al., 2004).

In wild-type mice, ezetimibe inhibits cholesterol absorption by about 70%; in NPC1L1 knockout mice, cholesterol absorption is 86% lower than in wild-type mice, and ezetimibe has no effect on cholesterol absorption (Altmann et al., 2004). Ezetimibe does not affect intestinal triglyceride absorption. In human subjects, ezetimibe reduced cholesterol absorption by 54%, precipitating a compensatory increase in cholesterol synthesis that can be inhibited with a cholesterol synthesis inhibitor such as a statin (Sudhop et al., 2002). There also is a substantial reduction of plasma levels of plant sterols (campesterol and sitosterol concentrations are reduced by 48% and 41%, respectively), indicating that ezetimibe also inhibits intestinal absorption of plant sterols.

The consequence of inhibiting intestinal cholesterol absorption is a reduction in the incorporation of cholesterol into chylomicrons. The reduced cholesterol content of chylomicrons diminishes the delivery of cholesterol to the liver by chylomicron remnants. The

diminished remnant cholesterol content may decrease atherogenesis directly, as chylomicron remnants are very atherogenic lipoproteins. In experimental animal models of remnant dyslipidemia, ezetimibe profoundly diminished diet-induced atherosclerosis (Davis et al., 2001a).

Reduced delivery of intestinal cholesterol to the liver by chylomicron remnants stimulates expression of the hepatic genes regulating LDL receptor expression and cholesterol biosynthesis. The greater expression of hepatic LDL receptors enhances LDL-C clearance from the plasma. Indeed, ezetimibe reduces LDL-C levels by 15-20% (Gagné et al., 2002; Knopp et al., 2003).

Combination Therapy (Ezetimibe plus Statins). The maximal efficacy of ezetimibe for lowering LDL-C is 15-20% when used as monotherapy (Knopp et al., 2003). This reduction is equivalent to, or less than, that attained with 10- to 20-mg doses of most statins. Consequently, the role of ezetimibe as monotherapy of patients with elevated LDL-C levels appears to be limited to the small group of statin-intolerant patients.

The actions of ezetimibe are complementary to those of statins. Statins, which inhibit cholesterol biosynthesis, increase intestinal cholesterol absorption (Miettinen and Gylling, 2003). Ezetimibe, which inhibits intestinal cholesterol absorption, enhances cholesterol biosynthesis by as much as 3.5 times in experimental animals (Davis et al., 2001b). Dual therapy with these two classes of drugs prevents both the enhanced cholesterol synthesis induced by ezetimibe and the increase in cholesterol absorption induced by statins. This combination provides additive reductions in LDL-C levels irrespective of the statin employed (Ballantyne et al., 2004; Ballantyne et al., 2003; Melani et al., 2003).

A combination tablet containing ezetimibe, 10 mg, and various doses of simvastatin (10, 20, 40, and 80 mg) has been approved (VYTORIN). At the highest simvastatin dose (80 mg), plus ezetimibe (10 mg), average LDL-C reduction was 60%, which is greater than can be attained with any statin as monotherapy (Feldman et al., 2004). Despite the robust laboratory-based efficacy of this combination, the clinical cardiovascular benefits remain controversial when the combination is compared to effects of statins alone (Kastelein et al., 2008; Mitka, 2009).

Absorption, Fate, and Excretion. Ezetimibe is highly water insoluble, precluding studies of its bioavailability. After ingestion, it is glucuronidated in the intestinal epithelium and absorbed and then enters an enterohepatic recirculation (Patrick et al., 2002). Pharmacokinetic studies indicate that about 70% is excreted in the feces and about 10% in the urine (as a glucuronide conjugate) (Patrick et al., 2002). Bile-acid sequestrants inhibit absorption of ezetimibe, and the two agents should not be administered together. Otherwise, no significant drug interactions have been reported.

Adverse Effects and Drug Interactions. Other than rare allergic reactions, specific adverse effects have not been observed in patients taking ezetimibe. The safety of ezetimibe during pregnancy has not been established. With doses of ezetimibe sufficient to increase exposure 10-150 times compared with a 10-mg dose in humans, fetal skeletal abnormalities were noted in rats and rabbits. *Since all statins are contraindicated in pregnant and nursing women, combination products containing ezetimibe and a statin should not be used by women in childbearing years in the absence of contraception.*

Therapeutic Use. Ezetimibe (ZETIA) is available as a 10-mg tablet that may be taken at any time during the day, with or without food. Ezetimibe may be taken with any medication other than bile-acid sequestrants, which inhibit its absorption.

CLINICAL SUMMARY

Patients with any type of dyslipidemia (e.g., elevated levels of cholesterol, low levels of HDL-C with or without hypercholesterolemia, or moderately elevated triglyceride levels with low HDL-C levels) are at risk of developing atherosclerosis-induced vascular disease. Maintaining ideal body weight, eating a diet low in saturated fat and cholesterol, and regular exercise are the cornerstones of managing dyslipidemia. In the absence of vascular disease, type 2 diabetes mellitus, or metabolic syndrome, adoption of these behaviors will alleviate the need for cholesterol-lowering medications in many subjects. Following assessment of their future risk for a vascular disease event, patients should be treated to achieve target lipid values. In virtually every type of dyslipidemic patient, statins have been proven to reduce the risk of subsequent CHD events and nonhemorrhagic stroke. For this reason, statin therapy should be the first-line choice when choosing between classes of lipid-lowering agents.

A second principle is to treat with statin doses adequate to reduce the patient's lipid values to goal levels. Most patients are not adequately treated and do not reach goal values. Safety is greatly enhanced if doctors discuss with their patients the rare but serious side effects of hepatotoxicity and rhabdomyolysis with associated renal failure.

Finally, patients with low HDL-C levels may not receive the maximum benefit of lipid-lowering therapy as prescribed by the ATP III guidelines based on levels of LDL-C or non-HDL-C. For this reason, treatment of patients with low HDL-C levels should be based on both LDL-C levels and the ratio of total cholesterol:HDL-C (Table 31-9).

Histamine, Bradykinin, and Their Antagonists

Randal A. Skidgel, Allen P. Kaplan,
and Ervin G. Erdős

The biogenic amine, histamine, is a major mediator of inflammation, anaphylaxis, and gastric acid secretion; in addition, histamine plays a role in neurotransmission. Our understanding of the physiological and pathophysiological roles of histamine has been enhanced by the development of subtype-specific receptor antagonists and by the cloning of four receptors for histamine. Competitive antagonists of H_1 receptors have diverse actions and are used therapeutically in treating allergies, urticaria, anaphylactic reactions, nausea, motion sickness, insomnia, and some symptoms of asthma. Antagonists of the H_2 receptor are effective in reducing gastric acid secretion. The peptide, bradykinin, has cardiovascular effects similar to those of histamine and plays prominent roles in inflammation and nociception.

This chapter presents the physiology and pathophysiology of histamine and kinins and the pharmacology of the antagonists that inhibit responses to these mediators.

HISTAMINE

History. The history of histamine (β -aminoethylimidazole) parallels that of acetylcholine (ACh). Both were chemically synthesized before their biological significance was recognized; they were first detected as uterine stimulants in, and isolated from, extracts of ergot, where they proved to be contaminants derived from bacterial action (Dale, 1953).

Dale and Laidlaw subjected histamine to intensive pharmacological study (Dale, 1953), discovering that it stimulated a host of smooth muscles and had an intense vasodepressor action. Importantly, they observed that when a sensitized animal was injected with a normally inert protein, the immediate responses closely resembled those of poisoning by histamine. These observations anticipated by many years the finding that endogenous histamine contributes to immediate hypersensitivity reactions and to responses to cellular injury. Best and colleagues (1927) isolated

histamine from fresh samples of liver and lung, thereby establishing it as a natural constituent of mammalian tissues, hence the name *histamine* after the Greek word for tissue, *histos*. The presence of histamine in tissue extracts delayed the acceptance of the discovery of some peptide and protein hormones (e.g., gastrin) until the technology for separating the naturally occurring substances was sufficiently advanced (Grossman, 1966).

Lewis and colleagues (Lewis, 1927) proposed that a substance with the properties of histamine (“H substance”) was liberated from the cells of the skin by injurious stimuli, including the reaction of antigen with antibody. We now know that endogenous histamine plays a role in the immediate allergic response and is an important regulator of gastric acid secretion. More recently, a role for histamine as a modulator of neurotransmitter release in the central and peripheral nervous systems has emerged.

Early suspicions that histamine acts through more than one receptor have been borne out by the elucidation of four classes of receptors, designated H_1 (Ash and Schild, 1966), H_2 (Black et al., 1972), H_3 (Arrang et al., 1987), and H_4 (Leurs et al., 2009). H_1 receptors are blocked selectively by the classical “antihistamines.” Second-generation H_1 antagonists are collectively referred to as *nonsedating antihistamines*. The term *third generation* has been applied to some recently developed antihistamines, such as active metabolites of first- or second-generation antihistamines that are not further metabolized (e.g., cetirizine derived from hydroxyzine or fexofenadine from terfenadine) or to antihistamines that have additional therapeutic effects. However, the Consensus Group on New-Generation Antihistamines concluded that none of the currently available antihistamines can be classified as true third-generation drugs, defined as lacking in cardiotoxicity, drug-drug interactions, and CNS effects or with possible additional beneficial effects (e.g., anti-inflammatory) (Holgate et al., 2003). The discovery of H_2 antagonists and their ability to inhibit gastric secretion has contributed greatly to the resurgence of interest in histamine in biology and clinical medicine (Chapter 45). H_3 receptors were discovered as presynaptic autoreceptors on histamine-containing neurons that mediate feedback inhibition of the release and synthesis of histamine. The development of selective H_3 receptor agonists and antagonists has led to an increased understanding of the importance of H_3 receptors in histaminergic neurons *in vivo*. None of these H_3 agonists or

antagonists has yet emerged as a therapeutic agent (Sander et al., 2008). The H_4 receptor is most similar to the H_3 receptor but is expressed in cells of hematopoietic lineage; the availability of H_4 -specific antagonists with anti-inflammatory properties should help to define the biological roles of the H_4 receptor (Thurmond et al., 2008).

Chemistry. Histamine is a hydrophilic molecule consisting of an imidazole ring and an amino group connected by two methylene groups. The pharmacologically active form is the monocationic $N\gamma$ -H tautomer, which is the charged form of the species depicted in Figure 32-1 (Ganellin and Parsons, 1982). H_3 and H_4 receptors have a much higher affinity for histamine than H_1 and H_2 receptors, and the four histamine receptors can be activated differently by analogs of histamine (Venable and Thurmond, 2006) (Figure 32-1 and Table 32-1). The specificities of histamine analogs were re-evaluated after the discovery of the H_4 receptor. Thus, 4-methylhistamine and dimaprit, originally classified as H_2 receptors (Black et al., 1972), are full H_4 agonists with a ~100-fold higher affinity for the H_4 receptor. A number of H_3 agonists also are weaker agonists of the H_4 receptor (Lim et al., 2005; Venable and Thurmond, 2006).

Distribution and Biosynthesis of Histamine

Distribution. Histamine is widely, if unevenly, distributed throughout the animal kingdom and is present in many venoms, bacteria, and plants. Almost all

mammalian tissues contain histamine in amounts ranging from <1 to >100 $\mu\text{g/g}$. Concentrations in plasma and other body fluids generally are very low, but human cerebrospinal fluid (CSF) contains significant amounts. The mast cell is the predominant storage site for histamine in most tissues; the concentration of histamine is particularly high in tissues that contain large numbers of mast cells, such as skin, bronchial mucosa, and intestinal mucosa.

Synthesis, Storage, and Metabolism. Histamine is formed by the decarboxylation of the amino acid histidine by the enzyme L-histidine decarboxylase (Figure 32-2), found in every mammalian tissue that contains histamine. The chief site of histamine storage in most tissues is the mast cell; in the blood, it is the basophil. These cells synthesize histamine and store it in secretory granules.

At the secretory granule pH of ~5.5, histamine is positively charged and ionically complexed with negatively charged acidic groups on other granule constituents, primarily proteases and heparin or chondroitin sulfate proteoglycans. The turnover rate of

Figure 32-1. Structure of histamine and some H_1 , H_2 , H_3 , and H_4 agonists- Dimaprit and 4-methylhistamine, originally identified as specific H_2 agonists, have a much higher affinity for the H_4 receptor; 4-methylhistamine is the most specific available H_4 agonist, with ~10-fold higher affinity than dimaprit, a partial H_4 agonist. Impromidine is among the most potent H_2 agonists but also is an antagonist at H_1 and H_3 receptors and a partial agonist at H_4 receptors. (*R*)- α -Methylhistamine and imetit are high-affinity agonists of H_3 receptors and lower-affinity full agonists at H_4 receptors.

Table 32-1

Characteristics of Histamine Receptors

	H ₁	H ₂	H ₃ *	H ₄
Size (amino acids)	487	359	329-445	390
G protein coupling (second messengers)	G _{q/11} (↑ Ca ²⁺ ; ↑ NO and ↑ cGMP)	G _s (↑ cAMP)	G _{i/o} (↓ cAMP; ↑ MAP kinase)	G _{i/o} (↓ cAMP; ↑ Ca ²⁺)
Distribution	Smooth muscle, endothelial cells, CNS	Gastric parietal cells, cardiac muscle, mast cells, CNS	CNS: presynaptic	Cells of hematopoietic origin
Representative agonist	2-CH ₃ -histamine	Amthamine	(<i>R</i>)-α-CH ₃ -histamine	4-CH ₃ -histamine
Representative antagonist	Chlorpheniramine	Ranitidine	Tiprolisant	JNJ7777120

cAMP, cyclic AMP; cGMP, cyclic GMP; CNS, central nervous system; NO, nitric oxide.

*At least 20 alternately spliced H₃ isoforms have been detected at the mRNA level. Eight of these isoforms, ranging in size from 329-445 residues, were found to be functionally competent by binding or signaling assays (see Esbenshade et al., 2008)

histamine in secretory granules is slow, and when tissues rich in mast cells are depleted of their histamine stores, it may take weeks before concentrations return to normal levels. Non-mast cell sites of histamine formation include the epidermis, the gastric mucosa, neurons within the CNS, and cells in regenerating or rapidly growing tissues. Turnover is rapid at these non-mast cell sites because the histamine is released continuously rather than stored. Non-mast cell sites of histamine production contribute significantly to the daily excretion of histamine metabolites in the urine. Because L-histidine decarboxylase is an inducible enzyme, the histamine-forming capacity at such sites is subject to regulation. Histamine that is ingested or formed by bacteria in the gastrointestinal (GI) tract does not contribute to the body's stores; rather, it is rapidly metabolized, and the metabolites are eliminated in the urine.

There are two major paths of histamine metabolism in humans (Figure 32-2). The more important is ring methylation to form *N*-methylhistamine, catalyzed by histamine-*N*-methyltransferase, which is distributed widely. Most of the *N*-methylhistamine formed is then converted to *N*-methylimidazole acetic acid by monoamine oxidase (MAO), and this reaction can be blocked by MAO inhibitors (Chapters 8, 15, and 22). Alternatively, histamine may undergo oxidative deamination catalyzed mainly by the non-specific enzyme diamine oxidase, yielding imidazole acetic acid, which is then converted to imidazole acetic acid riboside. These metabolites have little or no activity and are excreted in the urine. Measurement of *N*-methylhistamine in urine affords a more reliable index of histamine production than assessment of histamine itself. Artificially elevated levels of histamine in urine arise from genitourinary tract bacteria that can decarboxylate histidine. In addition, the metabolism of histamine appears to be altered in patients with mastocytosis such that determination of histamine metabolites is a more sensitive diagnostic indicator of the disease than histamine.

Figure 32-2. Pathways of histamine synthesis and metabolism in humans. Histamine is synthesized from histidine by decarboxylation. Histamine is metabolized via two pathways, predominantly by methylation of the ring followed by oxidative deamination (left side of figure), and secondarily by oxidative deamination and then conjugation with ribose.

Release and Functions of Endogenous Histamine

Histamine has important physiological roles. After its release from storage granules as a result of the interaction of antigen with immunoglobulin E (IgE) antibodies on the mast cell surface, histamine plays a central role in immediate hypersensitivity and allergic responses. The actions of histamine on bronchial smooth muscle and blood vessels account for many of the symptoms of the allergic response. In addition, some drugs act directly on mast cells to release histamine, causing untoward effects. Histamine has a major role in regulating gastric acid secretion and also modulates neurotransmitter release.

Role in Allergic Responses. The principal target cells of immediate hypersensitivity reactions are mast cells and basophils (Schwartz, 1994). As part of the allergic response to an antigen, IgE antibodies are generated and bind to the surfaces of mast cells and basophils via specific high-affinity F_c receptors. This receptor, $Fc\epsilon RI$, consists of α , β , and two γ chains (Chapter 35). Atopic individuals develop IgE antibodies to commonly inhaled antigens. This is a heritable trait, conferring a predilection to rhinitis, asthma, and atopic dermatitis.

Antigen bridges the IgE molecules and via $Fc\epsilon RI$ activates signaling pathways in mast cells or basophils involving tyrosine kinases and subsequent phosphorylation of multiple protein substrates within 5-15 seconds of contact with antigen. Protein kinases implicated include the *Src*-related kinases Lyn and Syk. Prominent among the phosphorylated proteins are the β and γ subunits of $Fc\epsilon RI$, itself, and phospholipase C (PLC) γ_1 and PLC γ_2 , with consequent production of inositol trisphosphate (IP_3) and mobilization of intracellular Ca^{2+} (Chapter 3). These events trigger the exocytosis of the contents of secretory granules.

Release of Other Autacoids. The release of histamine only partially explains the biological effects that ensue from immediate hypersensitivity reactions because a broad spectrum of other inflammatory mediators is released on mast cell activation.

Stimulation of IgE receptors also activates phospholipase A_2 (PLA_2), leading to the production of a host of mediators, including platelet-activating factor (PAF) and metabolites of arachidonic acid such as leukotrienes C_4 and D_4 , which contract the smooth muscles of the bronchial tree (Chapters 33 and 36). Kinins also are generated during some allergic responses. Thus, the mast cell secretes a variety of inflammatory mediators in addition to histamine, each contributing to the major symptoms of the allergic response (see below).

Regulation of Mediator Release. The wide variety of mediators released during the allergic response can explain the ineffectiveness of drug therapy focused on a single mediator. Agents that act at muscarinic or α -adrenergic receptors increase the release of mediators, an effect of little clinical significance. Epinephrine and related drugs that act through β_2 adrenergic receptors increase cellular cyclic AMP and thereby inhibit the secretory activities of mast cells. However, the beneficial effects of β adrenergic agonists in allergic states such as asthma are due mainly to relaxing bronchial smooth muscle (Chapters 12 and 36).

Histamine Release by Drugs, Peptides, Venoms, and Other Agents. Many compounds, including a large number of therapeutic agents, stimulate the release of histamine from mast cells directly and without prior sensitization. Responses of this sort are most likely to occur following intravenous injections of certain categories of substances, particularly organic bases such as amides, amidines, quaternary ammonium compounds, pyridinium compounds, piperidines, and alkaloids (Rothschild, 1966). Tubocurarine, succinylcholine, morphine, some antibiotics, radiocontrast media, and certain carbohydrate plasma expanders also may elicit the response. The phenomenon is one of clinical concern, and may account for unexpected anaphylactoid reactions. For example, vancomycin-induced *red-man syndrome*, involving hypotension and flushing in the upper body and face, may be mediated through histamine release.

In addition to therapeutic agents, certain experimental compounds stimulate the release of histamine as their dominant pharmacological characteristic. The archetype is the polybasic substance known as *compound 48/80*. This is a mixture of low-molecular-weight polymers of *p*-methoxy-*N*-methylphenethylamine, of which the hexamer is most active.

Basic polypeptides often are effective histamine releasers, and over a limited range, their potency generally increases with the number of basic groups. For example, bradykinin is a poor histamine releaser, whereas kallidin (*Lys*-bradykinin) and substance P, with more positively charged amino acids, are more active. Some venoms, such as that of the wasp, contain potent histamine-releasing peptides (Johnson and Erdös, 1973). Polymyxin B also is very active. Basic polypeptides released upon tissue injury constitute pathophysiological stimuli to secretion for mast cells and basophils.

Within seconds of the intravenous injection of a histamine liberator, human subjects experience a burning, itching sensation. This effect, most marked in the palms of the hand and in the face, scalp, and ears, is soon followed by a feeling of intense warmth. The skin reddens, and the color rapidly spreads over the trunk. Blood pressure falls, the heart rate accelerates, and the subject usually complains of headache. After a few minutes, blood pressure recovers, and crops of hives usually appear on the skin. Colic, nausea, hypersecretion

of acid, and moderate bronchospasm also frequently occur. The effect becomes less intense with successive injections as the mast cell stores of histamine are depleted. Histamine liberators do not deplete tissues of non-mast cell histamine.

Mechanism of Histamine-Releasing Agents. Histamine-releasing substances activate the secretory responses of mast cells and basophils by causing a rise in intracellular Ca^{2+} . Some are ionophores and directly facilitate the entry of Ca^{2+} into the cell; others, such as neurotensin, act on specific G protein-coupled receptors (GPCRs). In contrast, the precise mechanism by which basic secretagogues (e.g., substance P, mastoparan, kallidin, compound 48/80, and polymyxin B) release histamine still is unclear. These agents can directly activate G_i proteins after being taken up by the cell (Ferry et al., 2002), but more recent evidence indicates the involvement of a cell-surface GPCR in the *Mas*-related gene family or integrin-associated protein CD47 coupled to G_i (Sick et al., 2009). The downstream effectors appear to be $\beta\gamma$ subunits released from $G\alpha_i$, which activate the $\text{PLC}\beta\text{-IP}_3\text{-Ca}^{2+}$ pathway. Antigen-IgE complexes lead to mobilization of stored Ca^{2+} and activation of isoforms of $\text{PLC}\gamma$, as described in “Role in Allergic Responses.”

Histamine Release by Other Means. Clinical conditions related to histamine release include cold, cholinergic, and solar urticaria. Some of these involve specific secretory responses of the mast cells and cell-fixed IgE. However, nonspecific cellular damage from any cause can release histamine. The redness and urticaria that follow scratching of the skin is a familiar example.

Increased Proliferation of Mast Cells and Basophils and Gastric Carcinoid Tumors. In urticaria pigmentosa (cutaneous mastocytosis), mast cells aggregate in the upper corium and give rise to pigmented cutaneous lesions that sting when stroked. In systemic mastocytosis, overproliferation of mast cells also is found in other organs. Patients with these syndromes suffer a constellation of signs and symptoms attributable to excessive histamine release, including urticaria, dermatographism, pruritus, headache, weakness, hypotension, flushing of the face, and a variety of GI effects, such as diarrhea or peptic ulceration. Episodes of mast cell activation with attendant systemic histamine release are precipitated by a variety of stimuli, including exertion, insect stings, exposure to heat, and exposure to drugs that release histamine directly or to which patients are allergic. In myelogenous leukemia, excessive numbers of basophils are present in the blood, raising its histamine content to high levels that may contribute to chronic pruritus. Gastric carcinoid tumors secrete histamine, which is responsible for episodes of vasodilation as part of the patchy “geographical” flush.

Gastric Acid Secretion. Histamine acting at H_2 receptors is a powerful gastric secretagogue, evoking a copious secretion of acid from parietal cells (see Figure 45-1); it also increases the output of pepsin and intrinsic factor. The secretion of gastric acid from parietal cells also is caused by stimulation of the vagus nerve and by the enteric hormone gastrin. However, histamine undoubtedly is the dominant

physiological mediator of acid secretion; blockade of H_2 receptors not only antagonizes acid secretion in response to histamine but also inhibits responses to gastrin and vagal stimulation. (For regulation of gastric acid secretion and the clinical utility of H_2 antagonists, see Chapter 45.)

Central Nervous System. There is substantial evidence that histamine functions as a neurotransmitter in the CNS. Histamine-containing neurons control both homeostatic and higher brain functions, including regulation of the sleep-wake cycle, circadian and feeding rhythms, immunity, learning, memory, drinking, and body temperature (see Haas et al., 2008). However, knockout animals lacking histamine or its receptors exhibit only subtle defects unless challenged, and no human disease has yet been directly linked to dysfunction of the brain histamine system. Histamine, histidine decarboxylase, enzymes that metabolize histamine, and H_1 , H_2 , and H_3 receptors are distributed widely but non-uniformly in the CNS (see Haas et al., 2008). H_1 receptors are associated with both neuronal and non-neuronal elements (e.g., glia, blood cells, vessels) and are concentrated in regions that control neuroendocrine function, behavior, and nutritional state. Distribution of H_2 receptors is more consistent with histaminergic projections than H_1 receptors, suggesting that they mediate many of the postsynaptic actions of histamine. H_3 receptors also are heterogeneously concentrated in areas known to receive histaminergic projections, consistent with their function as presynaptic autoreceptors. Histamine inhibits appetite and increases wakefulness via H_1 receptors, explaining sedation by classical antihistamines (Haas et al., 2008).

Pharmacological Effects

Receptor-Effector Coupling and Mechanisms of Action. Histamine receptors are GPCRs (Leurs et al., 2009; Haas et al., 2008; Thurmond et al., 2008) (Table 32-1). H_1 receptors couple to $G_{q/11}$ and activate the $\text{PLC-IP}_3\text{-Ca}^{2+}$ pathway and its many possible sequelae, including activation of PKC, Ca^{2+} -calmodulin-dependent enzymes (eNOS and various protein kinases), and PLA_2 . H_2 receptors link to G_s to activate the adenylyl cyclase-cyclic AMP-PKA pathway, whereas H_3 and H_4 receptors couple to $G_{i/o}$ to inhibit adenylyl cyclase and decrease cellular cyclic AMP. Activation of H_3 receptors also can activate MAP kinase and inhibit the Na^+/H^+ exchanger, and activation of H_4 receptors mobilizes stored Ca^{2+} in some cells (Leurs et al., 2009; Haas et al., 2008; Thurmond et al., 2008; Esbenshade et al., 2008). Armed with this information, knowledge of the cellular expression of H receptor subtypes, and an understanding of the differentiated functions of a particular cell type, one can predict a cell's response to histamine. Of course, in a physiological setting, a cell is exposed to a myriad of hormones simultaneously, and significant interactions may occur between signaling pathways, such as the $G_i \rightarrow G_s$ cross-talk described in a number of systems (Meszaros et al., 2000). Furthermore, the differential expression

of H receptor subtypes on neighboring cells and the unequal sensitivities of H receptor–effector response pathways can cause parallel and opposing cellular responses to occur together, complicating interpretation of the overall response of a tissue. For example, activation of H₁ receptors on vascular endothelium stimulates the Ca²⁺-mobilizing pathway (G_q–PLC–IP₃) and activates eNOS to produce nitric oxide (NO), which diffuses to nearby smooth muscle cells to increase cyclic GMP and cause relaxation. Stimulation of H₁ receptors on smooth muscle also will mobilize Ca²⁺ but cause contraction, whereas activation of H₂ receptors on the same smooth muscle cell will link via G_s to enhanced cyclic AMP accumulation, activation of PKA, and thence to relaxation.

The existence of multiple histamine receptors was predicted by the studies of Ash and Schild (1966) and Black and colleagues (1972) a generation before the cloning of histamine receptors. Similarly, heterogeneity of H₃ receptors, predicted by kinetic and radioligand-binding studies, has been confirmed by cloning, which revealed H₃ isoforms differing in the third intracellular loop, transmembrane helices 6 and 7, and C-terminal tail, and in their capacity to couple G_i, inhibit adenylyl cyclase, and activate MAP kinase. Molecular cloning studies also identified the H₄ receptor.

As Figure 32–1 and Table 32–1 indicate, the pharmacological definition of H₁, H₂, and H₃ receptors is clear because relatively specific agonists and antagonists are available. However, the H₄ receptor exhibits 35–40% homology to isoforms of the H₃ receptor, and the two were harder to distinguish pharmacologically because many high-affinity H₃ ligands also interact with H₄ receptors. Several non-imidazole compounds that are more selective H₃ antagonists have been developed (Sander et al., 2008), and there are now several selective H₄ antagonists (Leurs et al., 2009; Venable and Thurmond, 2006). 4-Methylhistamine and dimaprit, previously identified as specific H₂ agonists (Black et al., 1972), are actually more potent H₄ agonists (Venable and Thurmond, 2006).

H₁ and H₂ Receptors. H₁ and H₂ receptors are distributed widely in the periphery and in the CNS. Histamine can exert local or widespread effects on smooth muscles and glands. It causes itching and stimulates secretion from nasal mucosa. It contracts many smooth muscles, such as those of the bronchi and gut, but markedly relaxes others, including those in small blood vessels. Histamine also is a potent stimulus of gastric acid secretion (see “Gastric Acid Secretion”). Other, less prominent effects include formation of edema and stimulation of sensory nerve endings. Bronchoconstriction and contraction of the gut are mediated by H₁ receptors. Gastric secretion results from the activation of H₂ receptors and, accordingly, can be inhibited by H₂ receptor antagonists. Some responses, such as vascular dilation, are mediated by both H₁ and H₂ receptor stimulation.

H₃ and H₄ Receptors. H₃ receptors are expressed mainly in the CNS (Arrang et al., 1987), especially in the basal ganglia, hippocampus, and cortex. H₃ receptors function as autoreceptors on histaminergic neurons, much like presynaptic α₂ receptors, inhibiting histamine release and modulating the release of other neurotransmitters. Because H₃ receptors have high constitutive activity, histamine release is tonically inhibited, and inverse agonists will thus reduce receptor activation and increase histamine release from histaminergic neurons. H₃ agonists promote sleep; thus, H₃ antagonists promote wakefulness. H₄ receptors primarily are found in cells of hematopoietic origin such as eosinophils, dendritic cells, mast cells, monocytes, basophils, and T cells but has also been detected in the GI tract, dermal fibroblasts, CNS, and primary sensory afferent neurons (Leurs et al., 2009). Activation of H₄ receptors in some of these cell types has been associated with induction of cellular shape change, chemotaxis, secretion of cytokines and upregulation of adhesion molecules, suggesting that H₄ antagonists may be useful inhibitors of allergic and inflammatory responses (Thurmond et al., 2008).

Effects on Histamine Release. H₂ receptor stimulation increases cyclic AMP and leads to feedback inhibition of histamine release from mast cells and basophils, whereas activation of H₃ and H₄ receptors has the opposite effect by decreasing cellular cyclic AMP (Oda et al., 2000). Activation of presynaptic H₃ receptors also inhibits histamine release from histaminergic neurons.

Histamine Toxicity from Ingestion. Histamine is the toxin in food poisoning from spoiled scombroid fish such as tuna (Morrow et al., 1991). The high histidine content combines with a large bacterial capacity to decarboxylate histidine, generating a lot of histamine. Ingestion of the fish causes severe nausea, vomiting, headache, flushing, and sweating. Histamine toxicity, manifested by headache and other symptoms, also can follow red wine consumption in persons with a diminished ability to degrade histamine. The symptoms of histamine poisoning can be suppressed by H₁ antagonists.

Cardiovascular System. Histamine characteristically dilates resistance vessels, increases capillary permeability, and lowers systemic blood pressure. In some vascular beds, histamine constricts veins, contributing to the extravasation of fluid and edema formation upstream in capillaries and postcapillary venules.

Vasodilation. This is the most important vascular effect of histamine in humans. Vasodilation involves both H₁ and H₂ receptors distributed throughout the resistance vessels in most vascular beds; however, quantitative differences are apparent in the degree of dilation that occurs in various beds. Activation of either the H₁ or H₂

receptor can elicit maximal vasodilation, but the responses differ. H_1 receptors have a higher affinity for histamine and cause Ca^{2+} -dependent activation of eNOS in endothelial cells; NO diffuses to vascular smooth muscle, increasing cyclic GMP (Table 32–1) and causing relaxation that results in a relatively rapid and short-lived vasodilation. By contrast, activation of H_2 receptors on vascular smooth muscle stimulates the cyclic AMP–PKA pathway, causing dilation that develops more slowly and is more sustained. As a result, H_1 antagonists effectively counter small dilator responses to low concentrations of histamine but only blunt the initial phase of larger responses to higher concentrations of the amine. In addition, there is a variable distribution of H_1 receptors on vascular smooth muscle, resulting in direct vasoconstrictor responses in vein, skin, and skeletal muscle and in larger coronary arteries.

Increased “Capillary” Permeability. Histamine’s effect on small vessels results in efflux of plasma protein and fluid into the extracellular spaces and an increase lymph flow, causing edema. H_1 receptors on endothelial cells are the major mediators of this response; the role of H_2 receptors is uncertain.

Increased permeability results from histamine activation of H_1 receptors on postcapillary venules. This contracts the endothelial cells, disrupts interendothelial junctions, and exposes the basement membrane, which is freely permeable to plasma proteins and fluid. The gaps between endothelial cells also may permit passage of circulating cells recruited to tissues during the mast cell response. Recruitment of circulating leukocytes is enhanced by H_1 receptor–mediated expression of adhesion molecules (e.g., P-selectin) on endothelial cells (Thurmond et al., 2008).

Triple Response of Lewis. If histamine is injected intradermally, it elicits a characteristic phenomenon known as the *triple response* (Lewis, 1927). This consists of:

- a localized red spot extending for a few millimeters around the site of injection that appears within a few seconds and reaches a maximum in ~1 minute
- a brighter red flush, or “flare,” extending ~1 cm beyond the original red spot and developing more slowly
- a wheal that is discernible in 1–2 minutes and occupies the same area as the original small red spot at the injection site.

The initial red spot results from the direct vasodilating effect of histamine (H_1 receptor–mediated NO production), the flare is due to histamine-induced

stimulation of axon reflexes that cause vasodilation indirectly, and the wheal reflects histamine’s capacity to increase capillary permeability (edema formation).

Constriction of Larger Vessels. Histamine tends to constrict larger blood vessels, in some species more than in others. In rodents, the effect extends to the arterioles and may overshadow dilation of the finer blood vessels, leading to an elevation in blood pressure. As noted earlier, H_1 receptor–mediated constriction may occur in some veins and in conduit coronary arteries.

Heart. Histamine affects both cardiac contractility and electrical events directly. It increases the force of contraction of both atrial and ventricular muscle by promoting the influx of Ca^{2+} , and it speeds heart rate by hastening diastolic depolarization in the sinoatrial (SA) node. It also directly slows atrioventricular (AV) conduction to increase automaticity and, in high doses, can elicit arrhythmias. The slowed AV conduction involves mainly H_1 receptors, while the other effects are largely attributable to H_2 receptors and cyclic AMP accumulation. The direct cardiac effects of histamine given intravenously are overshadowed by baroreceptor reflexes due to reduced blood pressure.

Histamine Shock. Histamine given in large doses or released during systemic anaphylaxis causes a profound and progressive fall in blood pressure. As the small blood vessels dilate, they trap large amounts of blood, their permeability increases, and plasma escapes from the circulation. Resembling surgical or traumatic shock, these effects diminish effective blood volume, reduce venous return, and greatly lower cardiac output.

Extravascular Smooth Muscle. Histamine directly contracts or, more rarely, relaxes various extravascular smooth muscles. Contraction is due to activation of H_1 receptors on smooth muscle to increase intracellular Ca^{2+} (in contrast to intact vessels, where endothelium-derived NO causes vasodilation; see “Vasodilation”), and relaxation is mainly due to activation of H_2 receptors. Responses vary widely among species and even among humans. Bronchial smooth muscle of guinea pigs is exquisitely sensitive. Minute doses of histamine also will evoke intense bronchoconstriction in patients with bronchial asthma and certain other pulmonary diseases, but in normal humans, the effect is much less. Although the spasmogenic influence of H_1 receptors is dominant in human bronchial muscle, H_2 receptors with dilator function also are present. Thus, histamine-induced bronchospasm *in vitro* is potentiated slightly

by H₂ blockade. In asthmatic subjects in particular, histamine-induced bronchospasm may involve an additional reflex component that arises from irritation of afferent vagal nerve endings (Nadel and Barnes, 1984).

The uterus of some species is contracted by histamine; in the human uterus, gravid or not, the response is negligible. Responses of intestinal muscle also vary with species and region, but the classical effect is contraction. Bladder, ureter, gallbladder, iris, and many other smooth muscle preparations are affected little or inconsistently by histamine.

Peripheral Nerve Endings: Pain, Itch, and Indirect Effects. Histamine stimulates various nerve endings and sensory effects. In the epidermis, it causes itch; in the dermis, it evokes pain, sometimes accompanied by itching. Stimulant actions on nerve endings, including autonomic afferents and efferents, contribute to the “flare” component of the triple response and to indirect effects of histamine on the bronchi and other organs. In the periphery, neuronal receptors for histamine are generally of the H₁ type (see Rocha e Silva, 1978; Ganellin and Parsons, 1982).

Clinical Uses

The practical application of histamine is limited to use as a diagnostic agent, such as to assess nonspecific bronchial hyperreactivity in asthmatics or as a positive control injection during allergy skin testing.

H₁ RECEPTOR ANTAGONISTS

History. Antihistamine activity was first demonstrated by Bovet and Staub in 1937 with one of a series of amines with a phenolic ether moiety. The substance 2-isopropyl-5-methylphenoxy-ethyl-diethyl-amine protected guinea pigs against several lethal doses of histamine but was too toxic for clinical use. By 1944, Bovet and his colleagues had described *pyrilamine maleate*, an effective histamine antagonist of this category. The discovery of the highly effective diphenhydramine and *tripelennamine* soon followed (Ganellin and Parsons, 1982). In the 1980s, nonsedating H₁ histamine receptor antagonists were developed for treatment of allergic diseases. Despite success in blocking allergic responses to histamine, the H₁ antihistamines failed to inhibit a number of other responses, notably gastric acid secretion. The discovery of H₂ receptors and H₂ antagonists by Black and colleagues provided a new class of agents that antagonized histamine-induced acid secretion (Black et al., 1972). The pharmacology of these drugs (e.g., *cimetidine*, *famotidine*) is described in Chapter 45.

Pharmacological Properties

Chemistry. All the available H₁ receptor “antagonists” are actually inverse agonists (see Chapter 3) that reduce constitutive activity of the receptor and compete with histamine (Haas et al., 2008): Whereas histamine binding to the receptor induces a fully active conformation, antihistamine binding yields an inactive conformation. At the tissue level, the effect seen is proportional to receptor

occupancy by the antihistamine. Like histamine, many H₁ antagonists contain a substituted ethylamine moiety.

Unlike histamine, which has a primary amino group and a single aromatic ring, most H₁ antagonists have a tertiary amino group linked by a two- or three-atom chain to two aromatic substituents and conform to the general formula

where Ar is aryl and X is a nitrogen or carbon atom or a —C—O— ether linkage to the β-aminoethyl side chain. Sometimes the two aromatic rings are bridged, as in the tricyclic derivatives, or the ethylamine may be part of a ring structure (Figure 32–3) (Ganellin and Parsons, 1982).

Mechanism of Action. Most H₁ antagonists have similar pharmacological actions and therapeutic applications. Their effects are largely predictable from knowledge of the consequences of the activation of H₁ receptors by histamine.

Effects on Physiological Systems.

Smooth Muscle. H₁ antagonists inhibit most of the effects of histamine on smooth muscles, especially the constriction of respiratory smooth muscle. For example, a small dose of histamine causes death by asphyxia in guinea pigs, yet the animal may survive a hundred lethal doses of histamine if given an H₁ antagonist. In the same species, striking protection also is afforded against anaphylactic bronchospasm. This is not so in humans, where allergic bronchoconstriction appears to be caused by a variety of alternative mediators, such as leukotrienes (Chapter 33).

H₁ antagonists inhibit both the vasoconstrictor effects of histamine and, to a degree, the more rapid vasodilator effects mediated by activation of H₁ receptors on endothelial cells (synthesis/release of NO and other mediators). Residual vasodilation is due to H₂ receptors on smooth muscle; administration of an H₂ antagonist suppresses the effect. The efficacy of the histamine antagonists on histamine-induced changes in systemic blood pressure parallels these vascular effects.

Capillary Permeability. H₁ antagonists strongly block the increased capillary permeability and formation of edema and wheal caused by histamine.

Figure 32–3. Representative H₁ antagonists.

Flare and Itch. H₁ antagonists suppress the action of histamine on nerve endings, including the flare component of the triple response and the itching caused by intradermal injection.

Exocrine Glands. H₁ antagonists do not suppress gastric secretion; they do inhibit histamine-evoked salivary, lacrimal, and other exocrine secretions, but with variable success. However, the antimuscarinic properties of many H₁ antagonists may contribute to lessened secretion in cholinergically innervated glands and reduce ongoing secretion in, e.g., the respiratory tree. Nasal sprays of some H₁ antagonists can be used to treat allergic rhinitis.

Immediate Hypersensitivity Reactions: Anaphylaxis and Allergy. During hypersensitivity reactions, histamine is one of the many potent autacoids released (see “Release of Other Autacoids”), and its relative contribution to the ensuing symptoms varies widely with species and tissue. The protection afforded by H₁ antagonists thus also varies accordingly. In humans, edema formation and itch are effectively suppressed. Other effects, such as hypotension, are less well antagonized. This may be explained by the participation of other types of H receptors and by effects of other mast cell mediators, chiefly eicosanoids (Thurmond et al., 2008; Campbell and Falck, 2007) (Chapter 25). Bronchoconstriction is reduced little, if at all.

Central Nervous System. The first-generation H₁ antagonists can both stimulate and depress the CNS. Stimulation occasionally is encountered in patients given conventional doses; they become restless, nervous, and unable to sleep. Central excitation also is a striking feature of overdose, which commonly results in convulsions, particularly in infants. Central depression, on the other hand, usually accompanies therapeutic doses of the older H₁ antagonists. Diminished alertness, slowed reaction times, and somnolence are common manifestations. Patients vary in their susceptibility and responses to individual drugs. The ethanolamines (e.g., diphenhydramine; Figure 32–3) are particularly prone to causing sedation. Because of the sedation that occurs with first-generation antihistamines, these drugs cannot be tolerated or used safely by many patients except at bedtime. Even then, patients may experience an antihistamine “hangover” in the morning, resulting in sedation with or without psychomotor impairment (Simons, 2003). Whether tolerance to such adverse effects results from protracted use when administered in divided doses to patients with chronic urticarial syndromes is unclear (Richardson

et al., 2002). Thus, the development of second-generation “nonsedating” antihistamines was an important advance that allowed their general use. These newer H₁ antagonists do not cross the blood-brain barrier appreciably. Their sedative effects are similar to those of placebo.

Many antipsychotic agents are H₁ and H₂ receptor antagonists, but it is unclear whether this property plays a role in the anti-psychotic effects of these agents. The atypical anti-psychotic agent *clozapine* is an effective H₁ antagonist and a weak H₃ antagonist but an H₄ receptor agonist in the rat. The H₁ antagonist activity of typical and atypical antipsychotic drugs is responsible for the effect of these agents to cause weight gain (see Haas et al., 2008).

Anticholinergic Effects. Many of the first-generation H₁ antagonists tend to inhibit responses to ACh that are mediated by muscarinic receptors and may be manifest during clinical use (see below). Some H₁ antagonists also can be used to treat motion sickness (Chapters 9 and 46). Because *scopolamine* potently prevents motion sickness, the anticholinergic properties of H₁ antagonists may be largely responsible for this effect. Indeed, promethazine has perhaps the strongest muscarinic-blocking activity among these agents and is the most effective H₁ antagonist in combating motion sickness. The second-generation H₁ antagonists have no effect on muscarinic receptors.

Local Anesthetic Effect. Some H₁ antagonists have local anesthetic activity, and a few are more potent than procaine. Promethazine (phenergan) is especially active. However, the concentrations required for this effect are much higher than those that antagonize histamine’s interactions with its receptors.

Absorption, Distribution, and Elimination. The H₁ antagonists are well absorbed from the GI tract. Following oral administration, peak plasma concentrations are achieved in 2–3 hours, and effects usually last 4–6 hours; however, some of the drugs are much longer acting (Table 32–2).

Studies of the metabolic fate of the older H₁ antagonists are limited. Diphenhydramine, given orally, reaches a maximal concentration in the blood in ~2 hours, remains there for another 2 hours, then falls exponentially with a plasma elimination $t_{1/2}$ of ~4–8 hours. The drug is distributed widely throughout the body, including the CNS. Little, if any, is excreted unchanged in the urine; most appears there as metabolites. Other first-generation H₁ antagonists can be eliminated in much the same way (see Paton and Webster, 1985). Peak concentrations of these drugs in the skin may persist after plasma levels have declined. Thus, inhibition of “wheal and flare” responses to the intradermal injection of histamine or allergen can persist for ≥36 hours after treatment, even when the concentration in plasma is low.

Like other extensively metabolized drugs, H₁ antagonists are eliminated more rapidly by children than by adults and more slowly in those with severe liver disease. H₁-receptor antagonists also

induce hepatic CYPs and thus may facilitate their own metabolism (Paton and Webster, 1985).

The second-generation H₁ antagonist loratadine is absorbed rapidly from the GI tract and metabolized in the liver to an active metabolite by CYPs (Chapter 6). Consequently, metabolism of loratadine can be affected by other drugs that compete for the P450 enzymes. Two other second-generation H₁ antagonists that were marketed previously, *terfenadine* and *astemizole*, also were converted by CYPs to active metabolites. Both of these drugs were found in rare cases to induce a potentially fatal arrhythmia, *torsades de pointes*, when their metabolism was impaired, such as by liver disease or drugs that inhibit the CYP3A family (Chapter 29). This led to the withdrawal of terfenadine and astemizole from the market in 1998 and 1999, respectively. The active metabolite of terfenadine, fexofenadine, is its replacement. Fexofenadine lacks the toxic side effects of terfenadine, is not sedating, and retains the anti-allergic properties of the parent compound (Meeves and Appajosyula, 2003). Another antihistamine developed using this strategy is *desloratadine*, an active metabolite of loratadine. Cetirizine, loratadine, and fexofenadine are all well absorbed and are excreted mainly in the unmetabolized form. Cetirizine and loratadine are excreted primarily into the urine, whereas fexofenadine is excreted primarily in the feces. Levocetirizine represents the active enantiomer of cetirizine.

Therapeutic Uses

H₁ antagonists have an established place in the symptomatic treatment of various immediate hypersensitivity reactions. The central properties of some of the drugs also are of therapeutic value for suppressing motion sickness or for sedation.

Allergic Diseases. H₁ antagonists are most useful in acute types of allergy that present with symptoms of rhinitis, urticaria, and conjunctivitis. Their effect is confined to the suppression of symptoms attributable to the histamine released by the antigen-antibody reaction. In bronchial asthma, histamine antagonists have limited efficacy and are not used as sole therapy (Chapter 36). In the treatment of systemic anaphylaxis, where autoantibodies other than histamine are important, the mainstay of therapy is *epinephrine*; histamine antagonists have only a subordinate and adjuvant role. The same is true for severe angioedema, in which laryngeal swelling constitutes a threat to life.

Other allergies of the respiratory tract are more amenable to therapy with H₁ antagonists. The best results are obtained in seasonal rhinitis and conjunctivitis (hay fever, pollinosis), in which these drugs relieve the sneezing, rhinorrhea, and itching of eyes, nose, and throat. A gratifying response is obtained in most patients, especially at the beginning of the season when pollen counts are low; however, the drugs are less effective when the allergens are most abundant, when exposure to them is prolonged, and when nasal congestion is prominent. Nasal sprays or topical ophthalmic preparations of antihistamines such as levocabastine (discontinued in the

HCl, hydrochloride.

^aFor a discussion of phenothiazines, see Chapter 16.

^bThe duration of action of H₁ antihistamines by objective assessment of suppression of histamine- or allergen-induced symptoms is longer than might be expected from measurement of plasma concentrations or terminal elimination t_{1/2} values. For a more complete discussion, see Simons, 2003.

^cPreparations are designated as follows: O, oral solids; L, oral liquids; I, injection; S, suppository; SR, sustained release; T, topical. Many H₁ receptor antagonists also are available in preparations that contain multiple drugs.

^dHas mild sedating effects.

^eDimenhydrinate is a combination of diphenhydramine and 8-chlorotheophylline in equal molecular proportions.

^fTrade-name drug also contains other medications.

^gAlso has anti-serotonin properties.

U.S.), azelastine (ASTELIN, ASTEPRO, nasal spray; OPTIVAR, ophthalmic drops), emedastine (EMADINE, drops), epinastine (ELESTAT, drops), ketotifen (ZADITOR, drops), and olopatadine (PATANOL, drops; PATANASE, spray) are effective in allergic conjunctivitis and rhinitis. H₁ antihistamines have been investigated for potential anti-inflammatory properties because histamine releases inflammatory cytokines and eicosanoids, increases expression of endothelial adhesion molecules, and activates the pro-inflammatory transcription factor NF-κB (Holgate et al., 2003; Thurmond et al., 2008). Although H₁ antihistamines do exhibit a variety of anti-inflammatory effects *in vitro* and in animal models, in many cases the doses required are higher than those normally achieved therapeutically, and clinical effectiveness has not been proven (Holgate et al., 2003; Thurmond et al., 2008). Rupatadine is a second-generation H₁ antagonist (available in many countries outside the U.S.) that also blocks receptors for the inflammatory phospholipid, PAF (Mullol et al., 2008). Although rupatadine appears to have broader anti-inflammatory effects than other antihistamines, the clinical relevance of these properties is unclear.

Certain allergic dermatoses respond favorably to H₁ antagonists. The benefit is most striking in acute urticaria. Chronic urticaria can be less responsive but also may require higher doses than has been approved for rhinitis (Siebenhaar et al., 2009; Kaplan, 2002). Furthermore, the combined use of H₁ and H₂ antagonists sometimes is effective when therapy with an H₁ antagonist alone has failed. Angioedema also responds to treatment with H₁ antagonists, but the

paramount importance of epinephrine in the severe attack must be re-emphasized, especially in life-threatening laryngeal edema (Chapter 12). In this setting, it may be appropriate to also administer an H₁ antagonist intravenously.

H₁ antagonists have a place in the treatment of pruritus. Some relief may be obtained in many patients with atopic and contact dermatitis (although topical corticosteroids are more effective) and in such diverse conditions as insect bites and poison ivy. Pruritus without an allergic basis sometimes responds to antihistamine therapy. However, the possibility of producing allergic dermatitis with local application of H₁ antagonists must be recognized. The urticarial and edematous lesions of serum sickness respond to H₁ antagonists, but fever and arthralgia often do not.

Many drug reactions attributable to allergic phenomena respond to therapy with H₁ antagonists, particularly those characterized by itch, urticaria, and angioedema. However, explosive release of histamine generally calls for treatment with epinephrine, with H₁ antagonists being accorded a subsidiary role. Nevertheless, prophylactic treatment with an H₁ antagonist may reduce symptoms to a tolerable level when a drug known to be a histamine liberator is to be given.

Common Cold. H₁ antagonists are without value in combating the common cold. The weak anticholinergic effects of the older agents may tend to lessen rhinorrhea, but this drying effect may do more harm than good, as may their tendency to induce somnolence.

Motion Sickness, Vertigo, and Sedation. Scopolamine, the muscarinic antagonist, given orally, parenterally, or transdermally, is the most effective drug for the prophylaxis and treatment of motion sickness. Some H_1 antagonists are useful for milder cases and have fewer adverse effects. These drugs include dimenhydrinate and the piperazines (e.g., cyclizine, meclizine). Promethazine, a phenothiazine, is more potent and more effective; its additional antiemetic properties may be of value in reducing vomiting, but its pronounced sedative action usually is disadvantageous. Whenever possible, the various drugs should be administered ~1 hour before the anticipated motion. Treatment after the onset of nausea and vomiting rarely is beneficial.

Some H_1 antagonists, notably dimenhydrinate and meclizine, often are of benefit in vestibular disturbances such as Meniere's disease and in other types of true vertigo. Only promethazine is useful in treating the nausea and vomiting subsequent to chemotherapy or radiation therapy for malignancies; however, other, more effective anti-emetic drugs (e.g., 5-HT₃ antagonists) are available (Chapter 46). Diphenhydramine can reverse the extrapyramidal side effects caused by phenothiazines (Chapter 16).

The tendency of some H_1 receptor antagonists to produce somnolence has led to their use as hypnotics. H_1 antagonists, principally diphenhydramine, often are present in various proprietary over-the-counter remedies for insomnia. Although these drugs generally are ineffective in the recommended doses, some sensitive individuals may derive benefit. The sedative and mild anti-anxiety activities of hydroxyzine contribute to its use as a weak anxiolytic.

Adverse Effects. The most frequent side effect in first-generation H_1 antagonists is sedation. Although sedation may be a desirable adjunct in the treatment of some patients, it may interfere with the patient's daytime activities. Concurrent ingestion of alcohol or other CNS depressants produces an additive effect that impairs motor skills. Other untoward central actions include dizziness, tinnitus, lassitude, incoordination, fatigue, blurred vision, diplopia, euphoria, nervousness, insomnia, and tremors.

The next most frequent side effects involve the digestive tract and include loss of appetite, nausea, vomiting, epigastric distress, and constipation or diarrhea. Taking the drug with meals may reduce their incidence. H_1 antagonists such as cyproheptadine may increase appetite and cause weight gain. Other side effects, owing to the antimuscarinic actions of some first-generation H_1 antagonists, include dryness of the mouth and respiratory passages (sometimes inducing cough), urinary retention or frequency, and dysuria. These effects are not observed with second-generation H_1 antagonists.

Drug allergy may develop when H_1 antagonists are given orally but occurs more commonly after topical application. Allergic dermatitis is not uncommon; other hypersensitivity reactions include drug fever and photosensitization. Hematological complications, such as leukopenia, agranulocytosis, and hemolytic anemia, are very rare. Because H_1 antihistamines cross the placenta, caution is advised for women who are or may become pregnant. Several antihistamines (e.g., azelastine, hydroxyzine, fexofenadine) had teratogenic effects in animal studies, whereas others (e.g., chlorpheniramine,

diphenhydramine, cetirizine, loratadine) did not (see Simons, 2003). Antihistamines can be excreted in small amounts in breast milk, and first-generation antihistamines taken by lactating mothers may cause symptoms such as irritability, drowsiness, or respiratory depression in the nursing infant (Simons, 2003). Because H_1 antagonists interfere with skin tests for allergy, they must be withdrawn well before such tests are performed.

In acute poisoning with H_1 antagonists, their central excitatory effects constitute the greatest danger. The syndrome includes hallucinations, excitement, ataxia, incoordination, athetosis, and convulsions. Fixed, dilated pupils with a flushed face, together with sinus tachycardia, urinary retention, dry mouth, and fever, lend the syndrome a remarkable similarity to that of atropine poisoning. Terminally, there is deepening coma with cardiorespiratory collapse and death usually within 2-18 hours. Treatment is along general symptomatic and supportive lines.

Pediatric and Geriatric Indications and Problems. Although little clinical testing has been done, second-generation antihistamines are recommended for elderly patients (>65 years of age), especially those with impaired cognitive function, because of the sedative and anticholinergic effects of first-generation drugs. Therapy should be approached cautiously, possibly at reduced dosages, because of the greater likelihood of compromised renal and hepatic function in these patients, which can reduce drug elimination.

First-generation antihistamines are not recommended for use in children because their sedative effects can impair learning and school performance. The second-generation drugs loratadine, desloratadine, fexofenadine, cetirizine, levocetirizine, and azelastine (intranasal) have been approved by the FDA for use in children and are available in appropriate lower-dose formulations (e.g., chewable or rapidly dissolving tablets, syrup).

Use of over-the-counter cough and cold medicines (containing mixtures of antihistamines, decongestants, antitussives, expectorants) in young children has been associated with serious side effects and deaths (Kuehn, 2008). In 2008, the FDA recommended that they not be used in children <2 years of age, and drug manufacturers affiliated with the Consumer Healthcare Products Association voluntarily re-labeled products "do not use" for children <4 years of age. The FDA is reviewing the safety of these medicines in children aged 2-11 years.

Available H_1 Antagonists. Summarized below are the therapeutic side effects of a number of H_1 antagonists, grouped by their chemical structures. Representative preparations are listed in Table 32-2.

Dibenzoxepin Tricyclics (Doxepin). Doxepin, the only drug in this class, is marketed as a tricyclic antidepressant (Chapter 16). It also is one of the most potent H_1 antagonists and has significant H_2 antagonist activity, but this does not translate into greater clinical effectiveness. It can cause drowsiness and is associated with anticholinergic effects. Doxepin is better tolerated by patients with depression than those who are not depressed, where even small doses (e.g., 20 mg) may cause disorientation and confusion.

Ethanolamines (Prototype: Diphenhydramine). These drugs possess significant antimuscarinic activity and have a pronounced tendency to induce sedation. About half of those treated acutely with conventional doses experience somnolence. The incidence of GI side effects, however, is low with this group.

Ethylenediamines (Prototype: Pyrilamine). These include some of the most specific H_1 antagonists. Although their central effects are relatively feeble, somnolence occurs in a fair proportion of patients. GI side effects are quite common.

Alkylamines (Prototype: Chlorpheniramine). These are among the most potent H_1 antagonists. The drugs are less prone to produce drowsiness and are more suitable for daytime use, but a significant proportion of patients do experience sedation. Side effects involving CNS stimulation are more common than with other groups.

First-Generation Piperazines. The oldest member of this group, chlorcyclizine, has a more prolonged action and produces a comparatively low incidence of drowsiness. Hydroxyzine is a long-acting compound that is used widely for skin allergies; its considerable CNS-depressant activity may contribute to its prominent anti-pruritic action. Cyclizine and meclizine have been used primarily to counter motion sickness, although promethazine and diphenhydramine are more effective (as is the antimuscarinic scopolamine; see “ H_1 Antihistamines”).

Second-Generation Piperazines (Cetirizine). Cetirizine is the only drug in this class. It has minimal anticholinergic effects. It also has negligible penetration into the brain but is associated with a somewhat higher incidence of drowsiness than the other second-generation H_1 antagonists. The active enantiomer levocetirizine has slightly greater potency and may be used at half the dose with less resultant sedation.

Phenothiazines (Prototype: Promethazine). Most drugs of this class are H_1 antagonists and also possess considerable anticholinergic activity. Promethazine, which has prominent sedative effects, and its many congeners are used primarily for their antiemetic effects (Chapter 37).

First-Generation Piperidines (Cyproheptadine, Phenindamine). Cyproheptadine uniquely has both antihistamine and anti-serotonin activity. Cyproheptadine and phenindamine cause drowsiness and also have significant anticholinergic effects and can increase appetite.

Second-Generation Piperidines (Prototype: Terfenadine). Terfenadine and astemizole were withdrawn from the market. Current drugs in this class include loratadine, desloratadine, and fexofenadine. These agents are highly selective for H_1 receptors, lack significant anticholinergic actions, and penetrate poorly into the CNS. Taken together, these properties appear to account for the low incidence of side effects of piperidine antihistamines.

H_2 RECEPTOR ANTAGONISTS

The pharmacology and clinical utility of H_2 antagonists to inhibit gastric acid secretion are described in Chapter 45.

THE HISTAMINE H_3 RECEPTOR AND ITS ANTAGONISTS

The H_3 receptor was characterized as a novel G_i -coupled receptor using (R)- α -methylhistamine, a selective H_3 agonist, and thioperamide, an antagonist (Arrang et al.,

1987). The cloning of its cDNA revealed it to be a GPCR with low sequence identity (~20%) to H_1 and H_2 receptors (Lovenberg et al., 1999). Further studies on the H_3 receptor uncovered a variety of functional isoforms resulting from alternative splicing, many within a pseudo-intron in the third intracellular loop that may control constitutive activity (Arrang et al., 2007); this, combined with the influence of cell type, signaling pathway, and interspecies differences, yields H_3 receptors with a variety of binding and signaling properties (Esbenshade et al., 2008).

H_3 receptors are presynaptic autoreceptors on histaminergic neurons that originate in the tuberomammillary nucleus in the hypothalamus and project throughout the CNS, most prominently to the hippocampus, amygdala, nucleus accumbens, globus pallidus, striatum, hypothalamus, and cortex (Haas et al., 2008; Sander et al., 2008). The activated H_3 receptor depresses neuronal firing at the level of cell bodies/dendrites and decreases histamine release from depolarized terminals. Thus, H_3 agonists decrease histaminergic transmission, and antagonists increase it. H_3 receptors also are presynaptic heteroreceptors on a variety of neurons in brain and peripheral tissues, and their activation inhibits release from noradrenergic, serotonergic, GABA-ergic, cholinergic, and glutamatergic neurons, as well as pain-sensitive C fibers. H_3 receptors in the brain have significant constitutive activity in the absence of agonist, which varies according to splicing isoform, cell type, and signaling pathway stimulated; consequently, inverse agonists will activate these neurons.

In the enterochromaffin-like cells of the stomach, H_3 receptors inhibit gastrin-induced release of histamine and, therefore, decrease HCl secretion mediated by H_2 receptors, but the effect is not large enough to warrant development of therapeutic agents. H_3 agonists decrease tachykinin release from capsaicin-sensitive C-fiber terminals and thereby reduce capsaicin-induced plasma extravasation and are antinociceptive. H_3 agonists also depress exaggerated catecholamine release in the heart (e.g., during ischemia).

By blocking H_3 autoreceptors on histaminergic neurons and H_3 heteroreceptors on other neurons, H_3 antagonists/inverse agonists have a wide range of central effects; for example, they promote wakefulness, improve cognitive function (e.g., enhance memory, learning, and attention), and reduce food intake (Esbenshade et al., 2008; Sander et al., 2008). As a result, there is considerable interest in developing H_3 antagonists for possible treatment of sleeping disorders, attention-deficit hyperactivity disorder (ADHD), epilepsy, cognitive impairment, schizophrenia, obesity, neuropathic pain, and Alzheimer's disease (Esbenshade et al., 2008; Sander et al., 2008). However, this task is complicated by the heterogeneity in receptor isoforms and signaling pathways, varying levels of constitutive H_3 activity, species differences in ligand affinities, and the effects of H_3 antagonists/inverse agonists on the release of neurotransmitters in addition to histamine (e.g., DA, ACh, NE, GABA, glutamate, and substance P) (Sander et al., 2008; Esbenshade et al., 2008). Although drug development is focused on inverse agonists to block basal and agonist-stimulated H_3 activity, it is not yet clear that such drugs will necessarily be clinically superior to neutral antagonists.

Thioperamide was the first “specific” H₃ antagonist/inverse agonist available experimentally, but it turned out to be equally effective on the H₄ receptor. A number of other imidazole derivatives have been developed as H₃ antagonists, including clobenpropit, ciproxifan, and proxyfan. However, the imidazole group can bind to and inhibit CYPs, reduce bioavailability in and penetration into the CNS, and enhance binding to H₄ receptors, prompting efforts to develop more selective H₃-receptor antagonists using non-imidazole-based structures. This has resulted in the generation of numerous antagonists/inverse agonists representing a remarkably broad variety of structural classes (Sander et al., 2008; Esbenshade et al., 2008). Although none is approved for clinical use, several non-imidazole H₃ antagonists/inverse agonists are in phase II clinical trials for treating epilepsy, narcolepsy and other sleep disorders, cognitive impairment, Alzheimer’s disease, schizophrenia, and ADHD; these include tiprolisant (BF2.649), GSK189254, GSK239512, JNJ-17216498, and MK0249.

THE HISTAMINE H₄ RECEPTOR AND ITS ANTAGONISTS

The discovery of a fourth histamine receptor with a unique pharmacology and distribution has further expanded the search for new drugs based on histamine function in inflammation (Leurs et al., 2009; Thurmond et al., 2008). The H₄ receptor has the highest homology with the H₃ receptor and binds many H₃ ligands, especially those with imidazole rings, although sometimes with different effects. For example, thioperamide is an effective inverse agonist at both H₃ and H₄ receptors, whereas H₃ inverse agonist clobenpropit is a partial agonist of the H₄ receptor; impentamine (an H₃ agonist) and iodophenpropit (an H₃ inverse agonist) are both neutral H₄ antagonists (Lim et al., 2005).

Because the H₄ receptor is expressed on cells with inflammatory or immune functions (see the discussion earlier), there is great interest in developing H₄ antagonists to treat various inflammatory conditions (Thurmond et al., 2008). Indeed, H₄ receptors can mediate histamine-induced chemotaxis, induction of cell shape change, secretion of cytokines, and upregulation of adhesion molecules. For example, the H₄ receptor likely accounts for early reports of histamine-dependent eosinophil chemotaxis, which was independent of H₁ receptors and inhibited by H₂ receptors (Clark et al., 1977). The presence of H₄ receptors in the CNS and animal studies with H₄ agonists and antagonists also have indicated a role for this receptor in pruritus and neuropathic pain (Leurs et al., 2009). The first selective H₄ antagonist, JNJ777120, exhibits ~1000-fold selectivity over other H receptors, has acceptable oral bioavailability, and has *in vivo* activity; however, its short t_{1/2} (~0.8 hour) limits its potential clinical usefulness. In addition to derivatives of the benzimidazole JNJ777120, promising H₄ antagonists have been developed using several different scaffolds, including methylpiperazine-substituted 2-quinoxalinones, quinazolines, and aminopyrimidines (Leurs et al., 2009). Although these are high-affinity ligands, relatively high doses

are required for significant anti-inflammatory effects *in vivo*, possibly due to either their pharmacokinetic properties or competition with endogenous histamine, which also has a high affinity for the receptor (Leurs et al., 2009). No H₄ antagonists have yet been tested in clinical trials.

CLINICAL SUMMARY: ANTI-HISTAMINES

H₁ Antihistamines. These medications are used widely in the treatment of allergic disorders. H₁ antihistamines are most effective in relieving the symptoms of seasonal rhinitis and conjunctivitis (e.g., sneezing; rhinorrhea; itching of the eyes, nose, and throat). In bronchial asthma, they have limited beneficial effects and are not useful as sole therapy. H₁ antagonists are useful adjuncts to epinephrine in the treatment of systemic anaphylaxis or severe angioedema. Certain allergic dermatoses, such as acute urticaria, respond favorably to H₁ antagonists, which help to relieve the itch in atopic or contact dermatitis but have no effect on the rash. Physical and chronic urticaria may require increased dosage to counter the levels of skin histamine generated (Siebenhaar et al., 2009).

Side effects are most prominent with first-generation H₁ antihistamines (e.g., diphenhydramine, chlorpheniramine, doxepin, hydroxyzine), which cross the blood-brain barrier and cause sedation. Some of the first-generation H₁ receptor antagonists also have anticholinergic properties that can be responsible for symptoms such as dryness of the mouth and respiratory passages, urinary retention or frequency, and dysuria. The second-generation drugs (e.g., levocetirizine, cetirizine, loratadine, desloratadine, fexofenadine) are largely devoid of these side effects because they do not penetrate the CNS and do not have antimuscarinic properties. Thus, they usually are the drugs of choice for the treatment of allergic disorders.

The significant sedative effects of some first-generation antihistamines have led to their use in treating insomnia, although better drugs are available. Some first-generation H₁ antagonists (e.g., dimenhydrinate, cyclizine, meclizine, and promethazine) can prevent motion sickness, although scopolamine is more effective. Antiemetic effects of these H₁ antihistamines can be beneficial in treating vertigo or postoperative emesis.

Many H₁ antihistamines are metabolized by CYPs. Thus, inhibitors of CYP activity, such as macrolide antibiotics (e.g., erythromycin) or imidazole antifungals (e.g., ketoconazole) can increase H₁ antihistamine levels, leading to toxicity. Some newer antihistamines, such as cetirizine, fexofenadine, levocabastine, and acrivastine, are not subject to these drug interactions.

Caution should be used in treating pregnant or lactating women with certain H_1 antihistamines, especially first-generation drugs, because of their possible teratogenic effects or symptomatic effects on infants resulting from secretion of the drug into breast milk. Cetirizine and loratadine are preferred if H_1 antihistamines are required, but if they are not effective, diphenhydramine can be used safely in pregnant (but not breast-feeding) women.

H_2 Antihistamines. These drugs (e.g., cimetidine, ranitidine) primarily are used to inhibit gastric acid secretion in the treatment of GI disorders (Chapter 45).

H_3 and H_4 Antihistamines. Although specific H_3 and H_4 receptor antagonists have been developed, no drugs have been approved for clinical use. Based on the functions of H_3 receptors in the CNS, H_3 antagonists have potential in the treatment of sleeping disorders, ADHD, epilepsy, cognitive impairment, schizophrenia, obesity, neuropathic pain, and Alzheimer's disease. Because of the unique localization and function of H_4 receptors, H_4 antagonists are promising candidates to treat inflammatory conditions such as allergic rhinitis, asthma, rheumatoid arthritis, and possibly pruritus and neuropathic pain.

BRADYKININ, KALLIDIN, AND THEIR ANTAGONISTS

Tissue damage, allergic reactions, viral infections, and other inflammatory events activate a series of proteolytic reactions that generate bradykinin and kallidin in the circulation or tissues. Kinin metabolites released by basic carboxypeptidases, formerly considered inactive degradation products, are agonists of a receptor (B_1) that differs from that of intact kinins (B_2). B_1 receptor expression is induced by tissue injury or inflammation. These peptides contribute to inflammatory responses as autacoids that act locally to produce pain, vasodilation, and increased vascular permeability but can also have beneficial effects, for example in the heart, kidney, and circulation. Much of their activity is due to stimulation of the release of potent mediators such as prostaglandins, NO, or endothelium-derived hyperpolarizing factor (EDHF). Although both B_1 and B_2 receptors are referred to as “bradykinin” receptors, this term properly applies only to the B_2 receptor; the B_1 receptor binds des-Arg metabolites of the kinins (Figure 32–4). These B receptors for kinins must not be confused with β receptors for catecholamines. Current efforts to develop potent non-peptide B_1 and B_2 antagonists

may open novel avenues for therapeutic intervention in chronic inflammatory conditions.

History. In the 1920s and 1930s, Frey, Kraut, and Werle characterized a hypotensive substance in urine and found a similar material in saliva, plasma, and a variety of tissues. The pancreas also was a rich source, so they named this material *kallikrein* after a Greek synonym for that organ, *kallikréas*. By 1937, Werle, Götze, and Keppler had established that kallikreins generate a pharmacologically active substance from an inactive precursor present in plasma; the active substance, *kallidin*, proved to be a polypeptide cleaved from a plasma globulin termed *kallidinogen* (see Werle, 1970).

Interest in the field intensified when Rocha e Silva, Beraldo, and associates reported that trypsin and certain snake venoms acted on plasma globulin to produce a substance that lowered blood pressure and caused a slowly developing contraction of the gut (Rocha e Silva et al., 1949; Beraldo and Andrade, 1997). Because of this slow response, they named the substance *bradykinin*, a term derived from the Greek words *bradys*, meaning “slow,” and *kinein*, meaning “to move.” In 1960, the nonapeptide bradykinin was isolated by Elliott and coworkers and synthesized by Boissonnas and associates. Shortly thereafter, kallidin was found to be a decapeptide bradykinin with an additional lysine residue at the amino terminus. These peptides, except for Lys¹, have identical chemical structures (Table 32–3) and quite similar pharmacological properties. For the whole group, the generic term *kinins* has been adopted. The kinins have short half-lives because they are destroyed by plasma and tissue enzymes originally called *kininase I* and *kininase II*. Kininase I releases a single C-terminal amino acid; kininase II releases a dipeptide (Skidgel and Erdős, 1998). Kininase II is identical to angiotensin-converting enzyme (ACE) (Yang et al., 1970).

Ferreira and colleagues (1970) reported the isolation of a bradykinin-potentiating factor from the venom of the Brazilian snake *Bothrops jararaca*. Ondetti and colleagues (1971) subsequently determined the structure of a peptide from the venom that inhibited ACE and lowered blood pressure when given intravenously to hypertensive patients. Synthetic ACE inhibitors, administered orally (Chapter 26), now are widely used in the treatment of hypertension, diabetic nephropathy, congestive heart failure, and after myocardial infarction (Pfeffer and Frolich, 2006).

Regoli and Barabé (1980) divided the kinin receptors into B_1 and B_2 classes based on the rank order of potency of kinin analogs, and this was validated at the molecular level by cloning of the B_1 and B_2 receptors (Bhoola et al., 1992; Hess, 1997). A primary feature that distinguishes peptide ligands of the B_1 and B_2 receptors is the presence of a C-terminal Arg residue; intact kinins (bradykinin and kallidin) are agonists of the B_2 receptor, whereas their des-Arg forms ([des-Arg⁹]-bradykinin and [des-Arg¹⁰]-kallidin) are agonists for the B_1 receptor. First-generation B_2 kinin-receptor antagonists were developed in the mid-1980s (Stewart, 2004), followed by second- and third-generation blockers. These antagonists revealed the role of kinins in the therapeutic effects of ACE/kininase II inhibitors and have led to increased acceptance of the importance of kinins. Studies involving B_1 and B_2 receptor knockout mice (Hess, 1997; Pesquero and Bader, 2006; Jiang et al., 2009) have furthered our understanding of the role of bradykinin in the regulation of cardiovascular homeostasis and inflammatory processes.

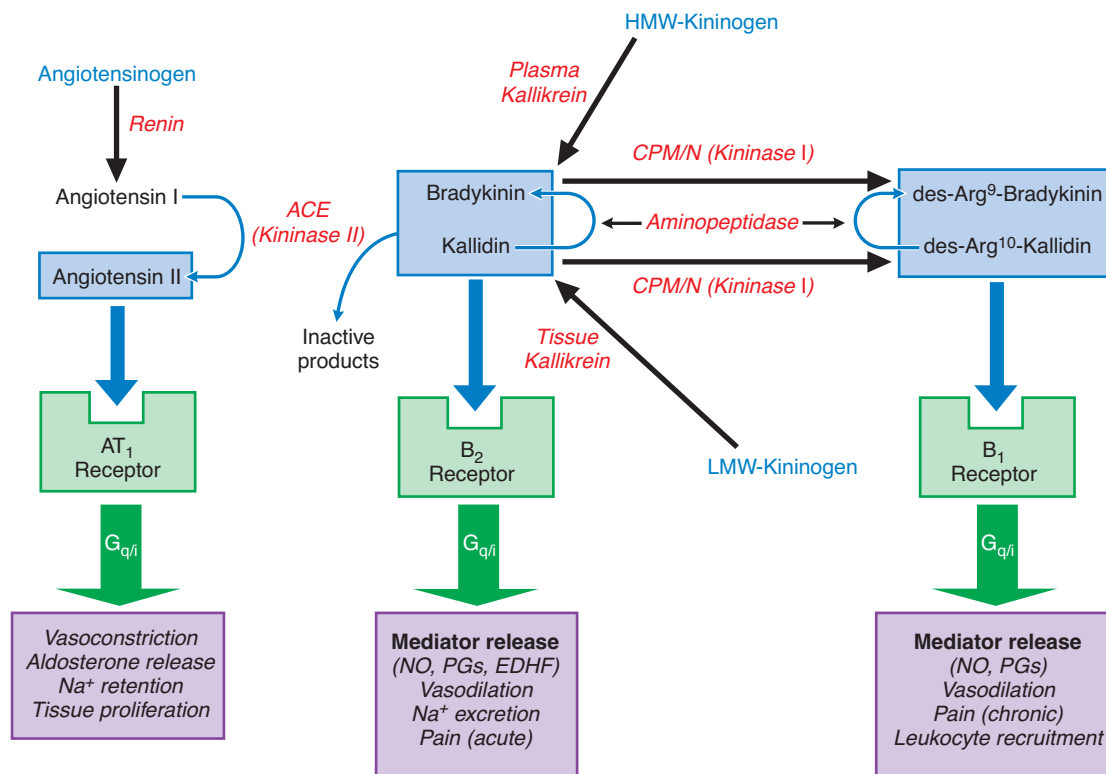

Figure 32–4. Synthesis and receptor interactions of active peptides generated by the kallikrein-kinin and renin-angiotensin systems. Bradykinin is generated by the action of *plasma* kallikrein on high-molecular-weight (HMW) kininogen, whereas kallidin (Lys¹-bradykinin) is released by the hydrolysis of low-molecular-weight (LMW) kininogen by *tissue* kallikrein. Kallidin and bradykinin are the natural ligands of the B₂ receptor but can be converted to corresponding agonists of the B₁ receptor by removal of the C-terminal Arg by kininase I-type enzymes: the plasma membrane-bound carboxypeptidase M (CPM) or soluble plasma carboxypeptidase N (CPN). Kallidin or [des-Arg¹⁰]-kallidin can be converted to the active peptides bradykinin or to [des-Arg⁹]-bradykinin by aminopeptidase cleavage of the N-terminal Lys residue. In a parallel fashion, the inactive decapeptide angiotensin I is generated by the action of renin on the plasma substrate angiotensinogen. By removal of the C-terminal His–Leu dipeptide, angiotensin-converting enzyme (ACE) generates the active peptide angiotensin II (AngII). These two systems have opposing effects. AngII is a potent vasoconstrictor that also causes aldosterone release and Na⁺ retention via activation of the AT₁ receptor; bradykinin is a vasodilator that stimulates Na⁺ excretion by activating the B₂ receptor. ACE generates active AngII and, at the same time, inactivates bradykinin and kallidin; thus, its effects are prohypertensive, and ACE inhibitors are effective antihypertensive agents. The B₂ receptor mediates most of bradykinin's effects under normal circumstances, whereas synthesis of the B₁ receptor is induced by inflammatory mediators in inflammatory conditions. Both B₁ and B₂ receptors couple through G_{q/i} to activate PLC and increase intracellular Ca²⁺; the physiological response depends on receptor distribution on particular cell types and occupancy by agonist peptides. For instance, on endothelial cells, activation of B₂ receptors results in Ca²⁺–calmodulin–dependent activation of eNOS and generation of NO, which causes cyclic GMP accumulation and relaxation in neighboring smooth muscle cells. However, in endothelial cells under inflammatory conditions, B₁ receptor stimulation results in prolonged NO production via G_i and MAP kinase-dependent activation of iNOS expression. On smooth muscle cells, activation of kinin receptors coupling through G_q results in an increased [Ca²⁺]_i and contraction. B₁ and B₂ receptors also can couple through G_i to activate PLA₂, causing the release of arachidonic acid and the local generation of prostanooids (PGs) and other metabolites such as endothelium-derived hyperpolarizing factor (EDHF). Kallikrein also plays a role in the intrinsic blood coagulation pathway (see Chapter 30).

The Endogenous Kallikrein–Kininogen–Kinin System

Synthesis of Kinins. Bradykinin is a nonapeptide; kallidin, a decapeptide containing an additional N-terminal lysine, is sometimes referred to as *lysyl-bradykinin*

(Table 32–3). The two peptides are cleaved from α₂ globulins termed *kininogens* (Figure 32–4). There are two kininogens: high-molecular-weight (HMW) kininogen and low-molecular-weight (LMW) kininogen. A number of serine proteases will generate kinins, but the highly specific proteases that release bradykinin

Table 32-3

Structure of Kinin Agonists and Antagonists

NAME	STRUCTURE	FUNCTION
Bradykinin	Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe-Arg	Agonist, B ₂
Kallidin	Lys-Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe-Arg	Agonist, B ₂
[des-Arg ⁹]-bradykinin	Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe	Agonist, B ₁
[des-Arg ¹⁰]-kallidin	Lys-Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe	Agonist, B ₁
des-Arg ¹⁰ -[Leu ⁹]-kallidin	Lys-Arg-Pro-Pro-Gly-Phe-Ser-Pro-Leu	Antagonist, B ₁
NPC-349	[D-Arg]-Arg-Pro-Hyp-Gly-Thi-Ser-D-Phe-Thi-Arg	Antagonist, B ₂
HOE-140	[D-Arg]-Arg-Pro-Hyp-Gly-Thi-Ser-Tic-Oic-Arg	Antagonist, B ₂
[des-Arg ¹⁰]-HOE-140	[D-Arg]-Arg-Pro-Hyp-Gly-Thi-Ser-Tic-Oic	Antagonist, B ₁
FR173657		Antagonist, B ₂
FR190997		Agonist, B ₂
SSR240612		Antagonist, B ₁

ABBREVIATIONS: Hyp, *trans*-4-hydroxy-Pro; Thi, β -(2-thienyl)-Ala; Tic, [D]-1,2,3,4-tetrahydroisoquinolin-3-yl-carbonyl; Oic, (3*as*,7*as*)-octahydroindol-2-yl-carbonyl.

and kallidin from the kininogens are termed *kallikreins* (see “Kallikreins”).

Kallikreins. Bradykinin and kallidin are cleaved from HMW or LMW kininogens by plasma or tissue kallikrein, respectively (Figure 32–4). Plasma kallikrein and tissue kallikrein are distinct enzymes that are activated by different mechanisms (Bhoola et al., 1992).

Plasma prekallikrein is an inactive protein of ~88,000 Da that complexes with its substrate, HMW kininogen (Mandle et al., 1976). The ensuing proteolytic cascade is restrained by the protease inhibitors present in plasma. Among the most important of these are the inhibitor of the activated first component of complement (C1-INH) and α_2 macroglobulin. Under experimental conditions, the kallikrein–kinin system is activated by the binding of factor XII, also known as *Hageman factor*, to negatively charged surfaces. Factor XII, a protease that is common to both the kinin and the intrinsic coagulation cascades (Chapter 30), undergoes autoactivation (Silverberg et al., 1980) and, in turn, activates prekallikrein. Importantly, kallikrein further activates factor XII, thereby exerting a positive feedback on the system. *In vivo*, factor XII may not undergo autoactivation on binding to endothelial cells. Instead, the binding of the HMW kininogen–prekallikrein heterodimer to a multiprotein-receptor complex on endothelial cells leads to activation of the prekallikrein–HMW kininogen complex (but not free prekallikrein) by heat shock protein 90 (Joseph et al., 2002) and by a lysosomal enzyme designated *prolylcarboxypeptidase*, which also is present on endothelial cell membranes (Schmaier, 2008). Kallikrein activates factor XII, cleaves HMW kininogen, and activates prourokinase (Schmaier, 2008; Kaplan et al., 2002; Colman, 1999). Human tissue kallikrein is a member of a large multigene family of 15 members with high sequence identity that are clustered at chromosome 19q13.4 (Emami and Diamandis, 2007). Only the classical (or “true”) tissue kallikrein, hK1, generates kinins from kininogen. Another member, hK3, better known as the prostate-specific antigen (PSA), is an important marker in diagnosing prostate cancer, and several other family members are promising tumor biomarkers (Emami and Diamandis, 2007).

Compared with plasma kallikrein, tissue kallikrein is a smaller protein (29,000 Da). It is synthesized as a preproprotein in the epithelial cells or secretory cells in several tissues, including salivary glands, pancreas, prostate, and distal nephron. Tissue kallikrein also is expressed in human neutrophils. It acts locally near its sites of origin. The synthesis of tissue prokallikrein is controlled by a number of factors, including aldosterone in the kidney and salivary gland and androgens in certain other glands. The secretion of the tissue prokallikrein also may be regulated; *for example*, its secretion from the pancreas is enhanced by stimulation of the vagus nerve. The activation of tissue prokallikrein to kallikrein requires proteolytic cleavage to remove a 7–amino acid propeptide (Takada et al., 1985).

Kininogens. The two substrates for the kallikreins, HMW kininogen and LMW kininogen, are derived from a single gene by alternative splicing. The HMW kininogen contains 626 amino acid residues: The N-terminal “heavy chain” sequence (362 amino acids) consists of domains 1–3, followed by 9 residue bradykinin sequence (domain 4), connected to a C-terminal “light chain” sequence (255 amino acids) containing domains D5 and D6. LMW kininogen is identical to domains 1–4 of HMW kininogen but is distinguished by its short C-terminal light chain (Takagaki et al., 1985). HMW kininogen

is cleaved by plasma and tissue kallikrein to yield bradykinin and kallidin, respectively. LMW kininogen is a substrate only of tissue kallikrein, and the product is kallidin. The kininogens also inhibit cysteine proteinases and thrombin binding and have anti-adhesive and profibrinolytic properties.

Metabolism of Kinins. The decapeptide kallidin is about as active as the nonapeptide bradykinin, even without conversion to bradykinin, which occurs when the N-terminal lysine residue is removed by an aminopeptidase (Skidgel and Erdös, 1998) (Figure 32–4). The nonapeptide has the minimal effective structure for standard responses on B₂ receptors (Figure 32–4 and Table 32–3).

The kinins have an evanescent existence—their $t_{1/2}$ in plasma is only ~15 seconds, and some 80–90% of the kinins may be destroyed in a single passage through the pulmonary vascular bed. Plasma concentrations of bradykinin are difficult to measure because inadequate inhibition of kininogenases or kininases in the blood can lead to artifactual formation or degradation of bradykinin during blood collection. When care is taken to inhibit these processes, the reported physiological concentrations of bradykinin in blood are in the picomolar range.

The principal catabolizing enzyme in the lung and other vascular beds is kininase II, or ACE (Figure 32–4) (Chapter 26). Removal of the C-terminal dipeptide by ACE or neutral endopeptidase 24.11 (nepilysin) inactivates kinins (Skidgel and Erdös, 1998) (Figure 32–5). A slower-acting enzyme, carboxypeptidase N (lysine carboxypeptidase, kininase I), releases the C-terminal arginine residue, producing [desArg⁹]–bradykinin or [des-Arg¹⁰]–kallidin (Table 32–3 and Figures 32–4 and 32–5), which are potent B₁ receptor agonists that no longer bind B₂ receptors (Bhoola et al., 1992; Skidgel and Erdös, 1998). Carboxypeptidase N is expressed constitutively in blood plasma, where its level is ~10⁻⁷ M (Skidgel and Erdös, 1998; Skidgel and Erdös, 2007). Carboxypeptidase M, which also cleaves basic C-terminal amino acids, is a widely distributed plasma membrane-bound enzyme (Skidgel and Erdös, 1998). The recently established crystal structures of the active subunit of carboxypeptidases N and M revealed an overall similarity with unique features consistent with their different localizations and functions (Skidgel and Erdös, 2007). A familial carboxypeptidase N deficiency, due to mutations in the active subunit, causes low plasma levels of this enzyme and is associated with angioedema or urticaria (Skidgel and Erdös, 2007; Matthews et al., 2004). Finally, aminopeptidase P can cleave the N-terminal arginine, rendering bradykinin inactive and susceptible to cleavage by dipeptidyl peptidase IV (Figure 32–5).

Kinin Receptors. The B₁ and B₂ kinin receptors are both GPCRs, sharing 36% amino acid sequence identity (Hess, 1997; Leeb-Lundberg et al., 2005).

The classical bradykinin B₂ receptor is constitutively expressed in most normal tissues, where it selectively binds intact bradykinin and kallidin (Table 32–3 and Figure 32–4) and mediates the majority of their effects. The B₁ receptor is activated by the des-Arg metabolites of bradykinin and kallidin produced by the actions of carboxypeptidases N and M (Table 32–3 and Figures 32–4 and 32–5). Interestingly, carboxypeptidase M and the B₁ receptor

Figure 32–5. Schematic diagram of the degradation of bradykinin. Arrows denote the primary cleavage sites in bradykinin. Bradykinin and kallidin are inactivated *in vivo* primarily by kininase II [angiotensin-converting enzyme (ACE)]. Neutral endopeptidase 24.11 (nepriylsin), cleaves bradykinin and kallidin at the same Pro–Phe bond as ACE and also is classified as a kininase II–type enzyme. In addition, aminopeptidase P can inactivate bradykinin by hydrolyzing the N-terminal Arg¹–Pro² bond, leaving bradykinin susceptible to further degradation by dipeptidyl peptidase IV. Bradykinin and kallidin are converted to their respective des-Arg⁹ or des-Arg¹⁰ metabolites by kininase I–type carboxypeptidases M and N. Unlike the parent peptides, these kinin metabolites are potent ligands for B₁ kinin receptors but not B₂ kinin receptors.

interact on the cell surface to form an efficient signaling complex; disruption of this interaction decreases the efficiency of generation and delivery of des-Arg-kinin agonist to the B₁ receptor and reduces subsequent B₁ signaling (Zhang et al., 2008). B₁ receptors are normally absent or expressed at low levels in most tissues. B₁ receptor expression is upregulated by tissue injury and inflammation and by cytokines, endotoxins, and growth factors (Bhoola et al., 1992; Leeb-Lundberg et al., 2005). Carboxypeptidase M expression also is increased by cytokines (Sangsree et al., 2003), to such a degree that B₁ receptor effects may predominate over B₂ effects.

The B₂ receptor activates PLA₂ and PLC via interaction with distinct G proteins. Kinin-induced PLC activation through G_q activates the IP₃–Ca²⁺ pathway, stimulating PKC activity and also enhancing NO synthesis by eNOS/NOS3. Bradykinin activates the pro-inflammatory transcription factor NF-κB through Gα_q and βγ subunits and also activates the MAP kinase pathway. Coupling of activated B₂ receptors to G_i leads to PLA₂ activation and the liberation of arachidonate from membrane-bound phospholipids, which is converted to a variety of derivatives, including inflammatory mediators and vasodilator epoxyeicosatrienoic acids (EETs) and prostacyclin (Campbell and Falck, 2007; Leeb-Lundberg et al., 2005) (Chapter 33).

B₁ receptors also couple through G_q and G_i to activate many of the same signal transduction pathways as the B₂ receptor (Leeb-Lundberg et al., 2005). However, B₁ receptor activation enhances NO production by stimulation of the inducible nitric oxide synthase (iNOS) rather than eNOS (Zhang et al., 2007). The B₁ and B₂ receptors also differ in their time courses of downregulation; the B₂ receptor response is rapidly desensitized, whereas the B₁ response is not. This likely is due to modification at a Ser/Thr-rich cluster present in the C-terminal tail of the B₂ receptor that is not conserved in the B₁ receptor sequence (Leeb-Lundberg et al., 2005).

Because B₂ receptors are distributed widely and couple to several G proteins, receptor agonists are employed frequently as tools to activate and study signal transduction pathways in a variety of cells. The antagonist icatibant (HOE-140) is commonly used to prove that cellular responses are mediated by B₂ receptors.

Nevertheless, blocking increased signaling through the B₂ receptor does not necessarily indicate enhanced kinin generation because some proteases (e.g., kallikrein) can activate the B₂ receptor directly, and this also is blocked by HOE-140 (Biyashev et al., 2006).

Activation of the angiotensin AT₂ receptor results in responses (e.g., vasodilation) that oppose those of the activated angiotensin AT₁ receptor (e.g., vasoconstriction) (Chapter 26); this can be mediated in part by cross-talk through activation of B₂ receptors (Widdop et al., 2003).

Functions and Pharmacology of Kallikreins and Kinins

The availability of specific kinin-receptor antagonists and the generation of B₁ and B₂ receptor knockout mice have advanced our understanding of the roles of the kinins (Leeb-Lundberg et al., 2005; Pesquero and Bader, 2006). Antagonists currently are being investigated in diverse areas such as pain, inflammation, chronic inflammatory diseases and the cardiovascular system. That the beneficial effects of ACE inhibitor therapy rests in part on enhancing bradykinin activity (e.g., on the heart, kidney, blood pressure; see Chapter 26) demonstrates the complexities in interpreting bradykinin's actions.

Systems Pharmacology of Kinins

Pain. The kinins are powerful algescic agents that cause an intense burning pain when applied to the exposed base of a blister. Bradykinin excites primary sensory neurons and provokes the release of neuropeptides such as substance P, neurokinin A, and calcitonin gene–related peptide. Although there is overlap, B₂ receptors generally mediate acute bradykinin algescia, whereas the pain of chronic

inflammation appears to involve increased numbers and activation of B_1 receptors.

Inflammation. Kinins participate in a variety of inflammatory conditions. Plasma kinins increase permeability in the microcirculation, acting on the small venules to cause disruption of the inter-endothelial junctions. This, together with an increased hydrostatic pressure gradient, causes edema. Edema, coupled with stimulation of nerve endings, results in a “wheal and flare” response to intradermal injection.

In hereditary angioedema, bradykinin is formed, and there is depletion of the upstream components of the kinin cascade during episodes of swelling, laryngeal edema, and abdominal pain. B_1 receptors on inflammatory cells (e.g., macrophages) can elicit production of the inflammatory mediators IL-1 and TNF- α (Bhoola et al., 1992). Kinin levels are increased in a number of chronic inflammatory diseases and may be significant in gout, disseminated intravascular coagulation, inflammatory bowel disease, rheumatoid arthritis, or asthma. Kinins also may contribute to the skeletal changes seen in chronic inflammatory states. Kinins stimulate bone resorption through B_1 and possibly B_2 receptors, perhaps by osteoblast-mediated osteoclast activation (Chapter 44).

Respiratory Disease. The kinins have been implicated in allergic airway disorders such as asthma and rhinitis (Abraham et al., 2006). Inhalation or intravenous injection of kinins causes bronchospasm in asthmatic patients but not in normal individuals. This bradykinin-induced bronchoconstriction is blocked by anticholinergic agents but not by antihistamines or cyclooxygenase inhibitors. Similarly, nasal challenge with bradykinin is followed by sneezing and glandular secretions in patients with allergic rhinitis. A B_2 receptor antagonist improved pulmonary function in patients with severe asthma and reduced nasal symptoms in allergic rhinitis (Abraham et al., 2006).

Cardiovascular System. In experimental animals and humans, infusion of bradykinin causes vasodilation and lowers blood pressure. Bradykinin causes vasodilation by activating its B_2 receptor on endothelial cells, resulting in the generation of NO, prostacyclin, and a hyperpolarizing EET that is a CYP-derived metabolite of arachidonic acid (Campbell et al., 1996). In B_2 antagonist-treated animals or B_2 receptor knockout mice, basal blood pressure is normal; however, these animals have an exaggerated blood pressure response to salt loading or activation of the renin-angiotensin system. These data suggest that the endogenous kallikrein-kinin system plays a minor role in the regulation of normal blood pressure, but it may be important in hypertensive states. Urinary kallikrein concentrations are decreased in individuals with high blood pressure (Margolius, 1995).

The kallikrein-kinin system is cardioprotective, as revealed by studies showing that many of the beneficial effects of ACE inhibitors on heart function are attributable to enhancement of bradykinin effects, such as their anti-proliferative activity or ability to increase glucose uptake in tissue (Pfeffer and Frolich, 2006; Henriksen et al., 1999; Heitsch, 2003). Bradykinin contributes to the beneficial effect of preconditioning to protect the heart against ischemia and reperfusion injury. Bradykinin also stimulates tissue plasminogen activator (tPA) release from the vascular endothelium (Leeb-Lundberg et al., 2005) and may contribute to the endogenous defense against some cardiovascular events, such as myocardial infarction and stroke. Stimulation of either B_1 or B_2 receptors produces cardioprotective effects after myocardial infarction (Leeb-Lundberg et al., 2005; Heitsch, 2003; Jiang et al., 2009).

Kidney. Renal kinins act in a paracrine manner to regulate urine volume and composition (Saitoh et al., 1995). Kallikrein is synthesized and secreted by the connecting cells of the distal nephron. Tissue kininogen and kinin receptors are present in the cells of the collecting duct. Like other vasodilators, kinins increase renal blood flow. Bradykinin also causes natriuresis by inhibiting sodium reabsorption at the cortical collecting duct. Treatment with mineralocorticoids, ACE inhibitors, and neutral endopeptidase (neprilysin) inhibitors increases renal kallikrein.

Other Effects. Many initial discoveries in the kallikrein-kinin system were made using a bioassay measuring isotonic contractions of the isolated rat uterus in estrus, which is especially sensitive to kinins. Kinins promote dilation of the fetal pulmonary artery, closure of the ductus arteriosus, and constriction of the umbilical vessels, all of which occur in the transition from fetal to neonatal circulation. The kallikrein-kinin system also functions in many other areas in the body, serving to mediate edema formation and smooth muscle contraction. Kinins also affect the CNS, disrupting the blood-brain barrier and allowing increased CNS penetration.

Potential Therapeutic Uses. Bradykinin contributes to many of the effects of the ACE inhibitors (Figure 32-4; see the history section under “Bradykinin, Kallidin, and Their Antagonists”). *Aprotinin*, a kallikrein and plasmin inhibitor, has been administered to patients undergoing coronary bypass to minimize bleeding and blood requirements (see “Kallikrein Inhibitors”, below). Based on the pro-inflammatory and algescic effects of kinins, B_1 and B_2 receptor antagonists are being tested for the treatment of inflammatory conditions and certain types of pain (Abraham et al., 2006; Campos et al., 2006).

Kallikrein Inhibitors

Aprotinin (TRASYLOL) is a natural proteinase inhibitor obtained for commercial purposes from bovine lung and is identical to Kunitz’s pancreatic trypsin inhibitor (Waxler and Rabito, 2003). *Aprotinin* inhibits mediators of the inflammatory response, fibrinolysis, and

thrombin generation following cardiopulmonary bypass surgery, including kallikrein and plasmin. Administration of aprotinin reduces requirements for blood products in patients undergoing coronary artery bypass grafting (Waxler and Rabito, 2003). Recent retrospective meta-analyses and a prospective multicenter trial linked aprotinin use with higher mortality and renal morbidity (Dietrich, 2009). Although there is controversy regarding the validity of these conclusions, the manufacturer has withdrawn the drug from the market (Dietrich, 2009); it remains available through a special investigational treatment protocol. Ecallantide (DX-88), a synthetic plasma kallikrein inhibitor, inhibits acute episodes of angioedema in patients with hereditary angioedema (Schneider et al., 2007).

Bradykinin and the Effects of ACE Inhibitors. ACE inhibitors are widely used in the treatment of hypertension, and they reduce mortality in patients with diabetic nephropathy, left ventricular dysfunction, previous myocardial infarction, or coronary artery disease (Pfeffer and Frohlich, 2006). ACE inhibitors block the conversion of Ang I to Ang II, a potent vasoconstrictor and growth promoter (Figure 32–4) (Chapter 25). Studies with the kinin B₂ antagonist HOE-140 demonstrate that bradykinin also contributes to many of the protective effects of ACE inhibitors. For example, administration of HOE-140 in animal models attenuates the favorable effects of ACE inhibitors on blood pressure, myocardial infarct size, and ischemic preconditioning. Bradykinin receptor antagonism also attenuates blood pressure lowering by acute ACE inhibition in humans (Gainer et al., 1998). These effects may result not only from decreased degradation of bradykinin by ACE but also from induction of enhanced receptor sensitivity by ACE inhibitors (Marcic et al., 1999; Biyashev et al., 2006).

A rare side effect of ACE inhibitors is angioedema, which may occur shortly after initiating therapy. This is a class effect of ACE inhibitors and may be connected to the inhibition of kinin metabolism by ACE (Slater et al., 1988). ACE inhibitor–associated angioedema is more common in blacks than in Caucasians. A common side effect of ACE inhibitors is a chronic, nonproductive cough that dissipates when the drug is stopped. The finding that angiotensin AT₁ receptor antagonists do not cause cough supports the role of bradykinin in this effect, but the mechanism has not been clearly defined.

Bradykinin also may contribute to the effects of the AT₁-receptor antagonists. During AT₁ receptor blockade, Ang II concentrations increase, which enhances signaling through the unopposed AT₂ subtype receptor, causing an increase in renal bradykinin concentrations (Widdop et al., 2003).

A new class of antihypertensive agent was developed to inhibit two major kinin-degrading enzymes, ACE and neprilysin, and the added inhibition of bradykinin metabolism was expected to enhance therapeutic effectiveness. In phase III clinical trials, the prototype drug omapatrilat was an effective antihypertensive agent but was associated with a 3-fold higher incidence of angioedema than with an ACE inhibitor alone, causing withdrawal of the drug.

Kinin Receptor Antagonists. The substitution of a D-Phe for Pro at position 7 in bradykinin conferred weak antagonist activity at the B₂ receptor and blocked the action of ACE. The addition of an N-terminal, D-Arg substitution of hydroxyproline in position 3 and thienylalanine at positions 5 and 8 resulted in the first useful and potent B₂ antagonist with *in vivo* activity (NPC-349; Table 32–3) (Stewart, 2004). However, this antagonist had a short *t*_{1/2} owing to enzymatic degradation by carboxypeptidase N *in vivo*, which converted it into a B₁ antagonist. Based on NPC-349, the longer-acting selective B₂ receptor antagonist HOE-140 (*icatibant*) was developed by substituting synthetic amino acids at positions 7 [*D*-tetrahydroisoquinoline-3-carboxylic acid (Tic)] and 8 [octahydroindole-2-carboxylic acid (Oic)] (Table 32–3). Icatibant (FIRAZYR) has been approved in the E.U. for treatment of acute episodes of swelling in patients with hereditary angioedema (Bork et al., 2008). It is administered by subcutaneous injection.

Orally active non-peptide receptor antagonists would be preferable for therapeutic use. The first of these for the B₂ receptor, WIN64338, had significant muscarinic cholinergic activity. In animals, a newer, more specific non-peptide B₂ antagonist, FR173657 (Table 32–3), decreased bradykinin-induced edema, hypotension, pain, bronchoconstriction, and inflammatory responses (Leeb-Lundberg et al., 2005; Abraham et al., 2006). This has led to increased interest by the drug industry and the generation of several new non-peptide B₂ antagonists with good oral bioavailability and *in vivo* stability and activity (Leeb-Lundberg et al., 2005; Abraham et al., 2006). On the other hand, synthetic B₂ receptor agonists (such as FR190997; Table 32–3) may be cardioprotective. Synthetic small-molecule bradykinin agonists or antagonists would not necessarily bind to the same regions of the B₂ receptor as the peptide (Heitsch, 2003).

Peptide antagonists of the B₁ receptor include des-Arg¹⁰-[Leu⁸]-kallidin and [des-Arg¹⁰]-HOE-140 (Table 32–3), among others (Campos et al., 2006). More recently, several non-peptide B₁ antagonists with *in vivo* activity have been developed (Campos et al., 2006; Feng et al., 2008); the most promising of these is SSR240612 (Table 32–3), which is orally active and inhibits inflammation and neuropathic pain in animal studies. None has yet been tested clinically.

CLINICAL SUMMARY: KININS

Aprotinin (TRASYLOL), the potent inhibitor of kallikrein and other serine proteases, has been employed clinically to reduce blood loss in patients undergoing coronary artery bypass surgery, but unfavorable survival statistics in retrospective and prospective studies have resulted in its discontinuation (Dietrich, 2009).

Because kinins and [des-Arg]-kinins enhance pain and inflammation via activation of the two kinin receptors, B₂ and B₁, antagonists may be useful in treating inflammatory diseases. A peptide-based B₂ receptor antagonist, icatibant (FIRAZYR), has been approved in the E.U. for treatment of acute episodes of swelling in patients with hereditary angioedema (Bork et al., 2008).

ACE inhibitors are widely used drugs in the treatment of hypertension, congestive heart failure, and diabetic nephropathy, and they reduce mortality in patients with a variety of cardiovascular risk factors (Chapter 26). One effect of ACE inhibitors is to prevent the degradation of bradykinin. Because bradykinin, by activating its B₂ receptor, is responsible for many of the beneficial cardioprotective effects of ACE inhibitors, the search is on to find a suitable stable B₂ agonist for clinical evaluation. A major problem for such applications is to establish a safe therapeutic window between potentially protecting the heart and avoiding pro-inflammatory stimulation (Heitsch, 2003).

Lipid-Derived Autacoids: Eicosanoids and Platelet- Activating Factor

Emer M. Smyth, Tilo Grosser,
and Garret A. FitzGerald

Membrane lipids supply the substrate for the synthesis of eicosanoids and platelet-activating factor (PAF). Eicosanoids—arachidonate metabolites, including prostaglandins (PGs), prostacyclin (PGI₂), thromboxane A₂ (TxA₂), *leukotrienes* (LTs), lipoxins, and hepxilins—are not stored but are produced, by most cells, when a variety of physical, chemical, and hormonal stimuli activate acyl hydrolases that make arachidonate available. Membrane glycerophosphocholine derivatives can be modified enzymatically to produce PAF. PAF is formed by a smaller number of cell types, principally leukocytes, platelets, and endothelial cells. Eicosanoids and PAF lipids contribute to inflammation, smooth muscle tone, hemostasis, thrombosis, parturition, and gastrointestinal secretion. Several classes of drugs, most notably aspirin, the traditional non-steroidal anti-inflammatory agents (tNSAIDs), and the specific inhibitors of cyclooxygenase-2 (COX-2), such as the coxibs, owe their principal therapeutic effects to blockade of eicosanoid formation. To understand the therapeutic potential of selective inhibitors of eicosanoid synthesis and action, we must first review the synthesis, metabolism, and mechanism of action of eicosanoids and PAF.

EICOSANOIDS

History. In 1930, Kurzrok and Lieb, two American gynecologists, observed that strips of uterine myometrium relax or contract when exposed to semen. Subsequently, Goldblatt in England and von Euler in Sweden reported independently on smooth muscle-contracting and vasodepressor activities in seminal fluid and accessory reproductive glands. In 1935, von Euler identified the active material as a lipid-soluble acid, which he named *prostaglandin*, inferring its origin in the prostatic gland. Samuelsson, Bergström, and their colleagues

elucidated the structures of prostaglandin E₁ (PGE₁) and prostaglandin F₁α (PGF₁α) in 1962. In 1964, Bergström and coworkers, and van Dorp and associates, independently achieved biosynthesis of PGE₂ from arachidonic acid (AA). Discovery of TxA₂, PGI₂, and the LTs followed. Vane, Smith, and Willis reported that aspirin and NSAIDs act by inhibiting prostaglandin biosynthesis (Vane, 1971). This remarkable period of discovery linked the Nobel Prize of von Euler in 1970 to that of Bergström, Samuelsson, and Vane in 1982.

PGs, LTs, and related compounds are called *eicosanoids*, from the Greek *eikosi* (“twenty”). Precursor essential fatty acids contain 20 carbons and three, four, or five double bonds: 8,11,14-eicosatrienoic acid (dihomo-γ-linolenic acid), 5,8,11,14-eicosatetraenoic acid [AA; Figure 33–1], and 5,8,11,14,17-eicosapentaenoic acid (EPA). In humans, AA, the most abundant precursor, is either derived from dietary linoleic acid (9,12-octadecadienoic acid) or ingested directly as a dietary constituent. EPA is a major constituent of oils from fatty fish such as salmon.

Biosynthesis. Biosynthesis of eicosanoids is limited by the availability of substrate and depends primarily on the release of AA, esterified in the *sn*-2 domain of cell membrane phospholipids, or other complex lipids, to the eicosanoid-synthesizing enzymes by acyl hydrolases, most notably phospholipase A₂ (PLA₂). Chemical and physical stimuli activate the Ca²⁺-dependent translocation of group IV_A cytosolic PLA₂ (cPLA₂), which has a high affinity for AA, to the membrane, where it hydrolyzes the *sn*-2 ester bond of membrane phospholipids (particularly phosphatidylcholine and phosphatidylethanolamine), releasing arachidonate. Multiple additional PLA₂ isoforms (secretory [s] and Ca²⁺-independent [i] forms) have been characterized. Under nonstimulated conditions, AA liberated by iPLA₂ is reincorporated into cell membranes, so there is negligible eicosanoid biosynthesis. Although cPLA₂

Figure 33–1. Metabolism of arachidonic acid (AA). The cyclooxygenase (COX) pathway is highlighted in gray. The lipoxygenase (LOX) pathways are expanded in Figure 33–2. Major degradation pathways are shown in Figure 33–3. Cyclic endoperoxides (PGG₂ and PGH₂) arise from the sequential cyclooxygenase and hydroperoxidase actions of COX-1 or COX-2 on AA released from membrane phospholipids. Subsequent products are generated by tissue-specific synthases and transduce their effects via membrane-bound receptors (blue boxes). Dashed lines indicate putative ligand–receptor interactions. Epoxyeicosatrienoic acids (EETs; shaded in blue) and isoprostanes are generated via CYP activity and non-enzymatic free radical attack, respectively. COX-2 can use modified arachidonoylglycerol, an endocannabinoid, to generate the glyceryl prostaglandins. Aspirin and tNSAIDs are nonselective inhibitors of COX-1 and COX-2 but do not affect LOX activity. Epilipoxins are generated by COX-2 following its acetylation by aspirin (see Figure 33–2). Dual 5-LOX–COX inhibitors interfere with both pathways. See the text for other abbreviations.

dominates in the acute release of AA, the inducible sPLA₂ contributes under conditions of sustained or intense stimulation of AA production. Once liberated, a portion of the AA is metabolized rapidly to oxygenated products by several distinct enzyme systems, including *cyclooxygenases* (COXs), *lipoxygenases* (LOXs), and CYPs.

Products of Prostaglandin G/H Synthases. Synthesis of the PGs, PGI₂, and thromboxane, collectively termed *prostanoids*, is accomplished in a stepwise manner by a complex of microsomal enzymes. Successive metabolism of AA by the COX and hydroperoxidase (HOX) activities of the PG endoperoxide G/H synthases, generate the cyclic endoperoxide PGs G and H (Figure 33–1). Isomerases and synthases affect the transformation of prostaglandin H₂ (PGH₂) into terminal prostanoids distinguished by substitutions on their cyclopentane rings.

PGs of the E and D series are hydroxyketones, whereas the F_α PGs are 1,3-diols (Figure 33–1). A, B, and C PGs are unsaturated ketones that arise nonenzymatically from PGE during extraction procedures; it is unlikely that they occur biologically. Prostaglandin J₂ (PGJ₂) and related compounds result from the dehydration of prostaglandin D₂ (PGD₂). Prostaglandin I₂ (PGI₂, prostacyclin) has a double-ring structure; in addition to a cyclopentane ring, a second ring is formed by an oxygen bridge between carbons 6 and 9. Thromboxanes (TXs) contain a six-member oxirane ring, instead of the cyclopentane ring of the PGs. Levuglandins are formed by non-enzymatic rearrangement of PGH₂. These γ -ketoaldehydes are highly reactive so that they are detected *in vivo* as their protein adducts (Salomon et al., 1997). The main classes are further subdivided in accord with the number of double bonds in their side chains, as indicated by numerical subscripts. Dihomo- γ -linolenic acid is the precursor of the one series, AA for the two series, and EPA for the three series. Prostanoids derived from AA carry the subscript 2 and are the major series in mammals. There is little evidence that one- or three-series prostanoids are made in adequate amounts to be important under normal circumstances. However, the health benefits of dietary supplementation with ω -3 fatty acids, like EPA or the 22-carbon-containing docosahexaenoic acid (DHA), remain a focus of investigation.

The first enzyme in the prostanoid synthetic pathway is PG endoperoxide G/H synthase, which is colloquially called *cyclooxygenase*, or COX. There are two distinct COX isoforms, COX-1 and COX-2 (Smith et al., 2000). COX-1, expressed constitutively in most cells, is considered the dominant, but not exclusive, source of prostanoids for housekeeping functions, such as cytoprotection of the gastric epithelium (see Chapter 45). COX-2, in contrast, is upregulated by cytokines, shear stress, and growth factors and is the principle source of prostanoid formation in inflammation and cancer. However, this distinction is overly simplistic; both enzymes contribute to the generation of autoregulatory and homeostatic prostanoids, and both can contribute to prostanoid formation during inflammation. Indeed, there are physiological and pathophysiological processes in which each enzyme is uniquely involved and others in which they function coordinately (Smith and Langenbach, 2001).

In addition to 61% amino acid identity, the crystal structures of COX-1 and COX-2 are remarkably similar (FitzGerald and Loll,

2001). Both isoforms are expressed as dimers homotypically inserted into the endoplasmic reticular membrane; their COX activity oxygenates and cyclizes unesterified AA to form prostaglandin G₂ (PGG₂), whereas their HOX activity converts PGG₂ to PGH₂ (Smith and Langenbach, 2001). These chemically unstable intermediates are transformed enzymatically into the prostanoids by isomerases and synthases. These enzymes are expressed in a relatively cell-specific fashion such that most cells make one or two dominant prostanoids. For example, COX-1-derived TxA₂ is the dominant product in platelets, whereas COX-2-derived PGE₂ and TxA₂ dominate in activated macrophages. Two classes of PGE synthases have been cloned. Microsomal (m) PGE synthases 1 and 2 co-localize with COX-2 in some, but not all, tissues and may be induced by cytokines and tumor promoters. Similarly, cytosolic PGE synthase often co-localizes with COX-1 and may be important in constitutive formation of PGE₂. Two forms of PGD synthase and PGF synthase have been identified. In heterologous expression systems, COX-1 couples preferentially with TxA₂ and PGF synthase, whereas COX-2 prefers PGI₂ synthase (Smyth and FitzGerald, 2009).

Prostanoids are released from cells predominantly by facilitated transport through the PG transporter and possibly other transporters (Schuster, 2002).

Products of Lipoxygenases. LOXs are a family of non-heme iron-containing enzymes that catalyze the oxygenation of polyenic fatty acids to corresponding lipid hydroperoxides (Brash, 1999). The enzymes require a fatty acid substrate with two cis double bonds separated by a methylene group. AA, which contains several double bonds in this configuration, is metabolized to hydroperoxy eicosatetraenoic acids (HPETEs), which vary in the site of insertion of the hydroperoxy group. Analogous to PGG₂ and PGH₂, these unstable intermediates, normally with *S* chirality, are further metabolized by a variety of enzymes. HPETEs are converted to their corresponding hydroxy fatty acid (HETE) either non-enzymatically or by a peroxidase.

There are five active human LOXs—5(*S*)-LOX, 12(*S*)-LOX, 12(*R*)-LOX, 15(*S*)-LOX-1, and 15(*S*)-LOX-2—classified according to the site of hydroperoxy group insertion. Human LOX products are of the *S* stereoconfiguration with the exception of 12(*R*)-LOX. Their expression is frequently cell specific (Brash, 1999); platelets have only 12(*S*)-LOX, whereas leukocytes contain both 5(*S*)- and 12(*S*)-LOX (Figure 33–2). 12(*R*)-LOX is restricted in expression mostly to the skin. The epidermal LOXs, which constitute a distinct LOX subgroup, also include 15-LOX-2 and eLOX-3, the most recently identified family member. eLOX-3 has been reported to metabolize further 12(*R*)-HETE, the product of 12(*R*)-LOX, to a specific epoxyalcohol product.

The 5-LOX pathway leads to the synthesis of the LTs, which play a major role in the development and persistence of the inflammatory response (Peters-Golden and Henderson, 2007) (Figure 33–2). A nomenclature (e.g., LTB₄, LTB₅) similar to that of prostanoids applies to the subclassification of the LTs. When eosinophils, mast cells, polymorphonuclear leukocytes, or monocytes are activated, 5-LOX translocates to the nuclear membrane and associates with 5-LOX-activating protein (FLAP), an integral membrane protein that facilitates AA to 5-LOX interaction (Evans et al., 2008). Drugs that inhibit FLAP block LT production. A two-step reaction is catalyzed by 5-LOX: oxygenation of AA at C5 to form 5-HPETE, followed by

Figure 33–2. Lipoxigenase pathways of arachidonic acid metabolism. 5-LOX-activating protein (FLAP) presents arachidonic acid to 5-LOX, leading to the generation of the LTs. CysLTs are shaded in gray. Lipoxins (shaded in orange) are products of cellular interaction via a 5-LOX–12-LOX pathway or via a 15-LOX–5-LOX pathway. Biological effects are transduced via membrane-bound receptors (blue boxes). The dashed line indicates putative ligand–receptor interactions. Zileuton inhibits 5-LOX but not the COX pathways (expanded in Figure 33–1). Dual 5-LOX–COX inhibitors interfere with both pathways. CysLT antagonists prevent activation of the CysLT1 receptor. See the text for abbreviations.

dehydration of 5-HPETE to an unstable 5,6-epoxide known as LTA_4 . LTA_4 is transformed into bioactive eicosanoids by multiple pathways depending on the cellular context: transformation by LTA_4 hydrolase to a 5,12-dihydroxyeicosatetraenoic acid known as LTB_4 ; conjugation with GSH by LTC_4 synthase, in eosinophils, monocytes, and mast cells, to form LTC_4 ; and extracellular metabolism of the peptide moiety of LTC_4 , leading to the removal of glutamic acid and subsequent cleavage of glycine, to generate LTD_4 and LTE_4 , respectively (Peters-Golden and Henderson, 2007). LTC_4 , LTD_4 , and LTE_4 , the *cysteinyl leukotrienes* (CysLTs), were known originally as the *slow-reacting substance of anaphylaxis* (SRS-A), first described >60 years ago. LTB_4 and LTC_4 are actively transported out of the cell.

At least two isoforms of 15-LOX exist, 15-LOX-1 and 15-LOX-2. The former prefers linoleic acid as a substrate and forms 15(S)-hydroxyoctadecadienoic acid, whereas the latter uses AA to generate 15(S)-HETE. Platelet-type 12(S)-LOX generates 12(S)-

HETE from AA, whereas the leukocyte isozyme can synthesize both 12- and 15-HETE and often is referred to as *12/15-LOX*. 12(S)-LOX can further metabolize LTA_4 , the primary product of the 5-LOX pathway, to form the *lipoxins* LXA_4 and LXB_4 . These mediators also can arise through 5-LOX metabolism of 15-HETE. 15(R)-HETE, derived from aspirin-acetylated COX-2, can be further transformed in leukocytes by 5-LOX to the *epilipoxins* 15-epi- LXA_4 or 15-epi- LXB_4 , the so-called aspirin-triggered lipoxins (Brink et al., 2003). 12-HETE also can undergo a catalyzed molecular rearrangement to epoxyhydroxyeicosatrienoic acids called *hepoxilins*. Two additional groups of lipid mediators, the *resolvins* and *protectins*, may be generated from EPA and DHA, through the sequential action of aspirin-acetylated COX-2 and 5- or 15-LOX (Serhan et al., 2008).

The epidermal LOXs [12(R)-LOX, 15-LOX-2, and eLOX-3] are distinct from “conventional” enzymes in their substrate preferences and products (Furstenberger et al., 2007). Although the roles

of epidermal LOXs in normal skin function are not clear, they may be relevant for skin barrier function and adipocyte differentiation. Epidermal accumulation of 12(*R*)-HETE is a feature of psoriasis and ichthyosis. Inhibitors of 12(*R*)-LOX are under investigation for the treatment of these proliferative skin disorders.

Products of CYPs. Multiple CYPs can metabolize AA (Capdevila and Falck, 2002). The epoxyeicosatrienoic acids (EETs), formed by CYP epoxygenases, primarily CYP2C and CYP2J in humans, have been a primary focus of research. Four regioisomers (14,15-; 11,12-; 8,9-; and 5,6-EETs), each containing a mixture of the (*R,S*) and (*S,R*) enantiomers, are formed in a CYP isoform-specific manner. EETs are synthesized in endothelial cells, where they function as endothelium-derived hyperpolarizing factors (EDHFs), particularly in the coronary circulation (Campbell and Falck, 2007). Their biosynthesis can be altered by pharmacological, nutritional, and genetic factors that affect CYP expression (see Chapter 6). CYP hydroxylases (primarily CYPs 4A, 4F) generate hydroxyeicosatetraenoic acids (16-, 17-, 18-, 19-, or 20-HETE), with 20-HETE being the principle product CYP-derived AA metabolite in vascular smooth muscle cells. 20-HETE is generated in response to smooth muscle cell stretch or to vasoactive agents, including angiotensin II (AngII).

EETs are metabolized by numerous pathways. The corresponding biologically less active (or inactive) dihydroxyeicosatrienoic acids (DHETs) are formed by epoxide hydrolases (EHs), whereas lysolipid acylation results in incorporation of EETs and DHETs into cellular phospholipids, where they can be stored. Inhibitors of EHs currently are under investigation. Glutathione conjugation and oxidation by COX and CYPs generate a series of glutathione conjugates, epoxyprostaglandins, diepoxides, tetrahydrofuran (THF) diols, and epoxyalcohols, whose biological relevance is not known. Similarly, 20-HETE can be converted by the COX pathway to the 20-hydroxy PGs. Intracellular fatty acid-binding proteins (FABPs) may bind EETs and DHETs differentially, thus modulating their metabolism, activities, and targeting.

Other Pathways. In addition to enzymatic formation of eicosanoids, several families of eicosanoid isomers are generated at significant concentrations *in vivo* by non-enzymatic free radical catalyzed oxidation of AA. The best characterized of these isoeicosanoids are the F₂-isoprostanes (F₂-IsoPs) (Lawson et al., 1999; Fam and Morrow, 2003; Milne et al., 2008). Unlike PGs, these compounds are initially formed esterified in phospholipids, after which they are hydrolyzed to their free form by phospholipases, including PAF acetylhydrolase (Stafforini et al., 2006), which then circulate and are metabolized and excreted into urine. Their production is not inhibited *in vivo* by inhibitors of COX-1 or COX-2, but their formation is suppressed by antioxidants. The PGF_{2 α} isomer, 8-iso-PGF_{2 α} , was the first F₂-IsoP to be identified. Measuring levels of these compounds in plasma and urine is considered the most accurate method to assess oxidative stress status *in vivo*, and increased levels are found in a large number of clinical conditions. Isoprostanes correlate with cardiovascular risk factors, but their use as predictors of coronary events remains an area of active investigation. Of particular interest is the recent finding that levels of F₂-IsoPs predict 30-day outcome in acute coronary syndrome (LeLeiko et al., 2009).

In addition to F₂-IsoPs, other PG-like isomers, including D₂/E₂-IsoPs, isothromboxanes, and isolevuglandins (alternatively termed isoketals), are also formed *in vivo* by non-enzymatic oxidation

of AA (Brame et al., 2004). Isoleukotrienes are also generated non-enzymatically. Because several isoprostanes can activate prostanoid receptors, it has been speculated that they may contribute to the pathophysiology of inflammatory responses in a manner insensitive to COX inhibitors.

In the brain, the endocannabinoids arachidonyl ethanolamide (anandamide) and 2-arachidonoylglycerol are endogenous ligands of cannabinoid receptors (Bisogno, 2008). They mimic several pharmacological effects of Δ 9-tetrahydrocannabinol, the active principle of *Cannabis sativa* preparations such as hashish and marijuana, including inhibition of adenylyl cyclase, inhibition of L-type Ca²⁺ channels, analgesia, and hypothermia. Several pathways have been proposed, but the prevalent one for biosynthesis *in vivo* remains unclarified. Conversion of anandamide and 2-arachidonoylglycerol by COX-2 generates PG-ethanolamides (prostamides) and PG-glycerol esters (Woodward et al., 2008); their biological significance remains to be clarified.

Inhibitors of Eicosanoid Biosynthesis. A number of the biosynthetic steps just described can be inhibited by drugs. Inhibition of PLA₂ decreases the release of the precursor fatty acid and thus the synthesis of all its metabolites. Because PLA₂ is activated by Ca²⁺ and calmodulin, it may be inhibited by drugs that reduce the availability of Ca²⁺. *Glucocorticoids* also inhibit PLA₂, but they appear to do so indirectly by inducing the synthesis of a group of proteins termed *annexins* (formerly *lipocortins*) that modulate PLA₂ activity (see Chapter 42). Glucocorticoids also downregulate induced expression of COX-2 but not of COX-1. Aspirin and tNSAIDs originally were found to prevent the synthesis of PGs from AA in tissue homogenates (Vane, 1971). It is now known that these drugs inhibit the COX, but not the POX, moieties of both PG G/H synthases, and thus the formation of their downstream prostanoid products. In addition, these drugs do not inhibit LOXs and may cause increased formation of LTs by shunting of substrate to the LOX pathway. LTs may contribute to the GI side effects associated with NSAIDs. Dual inhibitors of the COX and 5-LOX pathways, in particular *licofelone*, are under investigation (Kulkarni and Singh, 2007). However, the exact interplay between these enzyme families remains to be defined.

COX-1 and COX-2 differ in their sensitivity to inhibition by certain anti-inflammatory drugs (Grosser et al., 2006). This observation has led to the recent development of selective inhibitors of COX-2, including the coxibs (see Chapter 34). It was hypothesized that these drugs would have therapeutic advantages over tNSAIDs, many of which are non-selective for COX-1/2. COX-2 is the predominant COX at sites of inflammation, whereas COX-1 is the major source of

cytoprotective PGs in the GI tract. Two randomized trials of selective COX-2 inhibitors reported their superiority in GI safety over tNSAID comparators. However, there now is compelling evidence that COX-2 inhibitors confer a spectrum of cardiovascular hazards comprised of myocardial infarction, stroke, systemic and pulmonary hypertension, congestive heart failure, and sudden cardiac death (Grosser et al., 2006). Mechanistically, this hazard can be explained by suppression of cardioprotective COX-2-derived PGs, especially PGI₂, a general restraint on endogenous stimuli—including platelet COX-1-derived TxA₂—for platelet activation, vascular proliferation and remodeling, hypertension, atherogenesis, and cardiac function.

Compounds that preferentially and selectively inhibit the downstream enzymes that metabolize PGH₂ have been considered for some time. For example, agents that inhibit TxA₂ synthase might block platelet aggregation and induce vasodilation. Indeed, such drugs block TxA₂ production *in vitro* and *in vivo*; however, they have been disappointing in clinical development, perhaps owing to activation of the TxA₂ receptor by accumulated PGH₂ precursor. Given the problems associated with COX-2 inhibitors, there has been intense interest in developing drugs that might conserve the efficacy of COX-2 selectivity while shedding the cardiovascular risk. Microsomal prostaglandin E synthase-1 (mPGES-1), which catalyzes the isomerization of the COX product-PGH₂ into PGE₂, has emerged as a drug target (Samuelsson et al., 2007). The differential cardiovascular impact of mPGES-1 versus COX-2 inhibition in humans currently is unknown. However, deletion of mPGES-1 does not accelerate the response to a thrombogenic stimulus *in vivo* in rodents, in contrast to either selective inhibition of COX-2 or deletion of the IP, the I prostanoid receptor for PGI₂ (Cheng et al., 2006b). Indeed, deletion of mPGES-1 depresses systemic production of PGE₂ and augments biosynthesis of PGI₂ by redirection of the intermediate COX product PGH₂ to PGI synthase. It currently is unclear what contribution elevated PGI₂ makes to the impact on mPGES-1 inhibition and whether this shift in substrate will be seen with pharmacological inhibitors in humans.

Because LTs mediate inflammation, efforts have focused on development of LT-receptor antagonists and selective inhibitors of the LOXs. *Zileuton*, an inhibitor of 5-LOX, and selective CysLT-receptor antagonists (*zafirlukast*, *pranlukast*, and *montelukast*) have established efficacy in the treatment of mild to moderate asthma (see Chapter 36). These treatments remain, however, less effective than inhaled corticosteroids. A common polymorphism in the gene for LTC₄ synthase that correlates with increased LTC₄ generation is associated with aspirin-intolerant asthma and with the efficacy of anti-LT therapy (Kanaoka and Boyce, 2004). Interestingly, although polymorphisms in the genes encoding 5-LOX or FLAP do not appear to be linked to asthma, studies have demonstrated an association of these genes with myocardial infarction, stroke, and atherosclerosis (Peters-Golden and Henderson, 2007); thus, inhibition of LT biosynthesis may be useful in the prevention of cardiovascular disease.

Eicosanoid Catabolism. Most eicosanoids are efficiently and rapidly inactivated. About 95% of infused PGE₂ (but not PGI₂) is inactivated

during one passage through the pulmonary circulation. Broadly speaking, the enzymatic catabolic reactions are of two types: a relatively rapid initial step, catalyzed by widely distributed PG-specific enzymes, wherein PGs lose most of their biological activity, and a second step in which these metabolites are oxidized, probably by enzymes identical to those responsible for the β and ω oxidation of fatty acids (Figure 33–3). The initial step is the oxidation of the 15-OH group to the corresponding ketone by PG 15-OH dehydrogenase (PGDH) (Tai et al., 2002). Two types of 15-PGDHs have been identified. Type I, an NAD⁺-dependent enzyme, is the predominant form involved in eicosanoid catabolism. There is little circulating PGDH activity; thus, it is likely that metabolism first requires active transport to the intracellular space. The 15-keto compound then is reduced to the 13,14-dihydro derivative, a reaction catalyzed by PG Δ¹³-reductase. This enzyme is identical to the LTB₄ 12-hydroxydehydrogenase (see the discussion later). Subsequent steps consist of β and ω oxidation of the PG side chains, giving rise to polar dicarboxylic acids in the case of PGEs, which then are excreted in the urine as major metabolites (Figure 33–1); these reactions occur primarily in the liver.

Unlike PGE₂, PGD₂ initially is reduced *in vivo* to the F-ring PG, 9α,11β-PGF₂, which possesses significant biological activity. Subsequently, this compound undergoes metabolism similar to that of other eicosanoids (Figure 33–3). TxA₂ breaks down non-enzymatically (t_{1/2} = 30 seconds) into the chemically stable but biologically inactive thromboxane B₂ (TxB₂), which then is further metabolized by 11-hydroxy TxB₂ dehydrogenase to generate 11-dehydro-TxB₂ or by β oxidation to form 2,3-dinor-TxB₂ (Figure 33–3).

The degradation of PGI₂ (t_{1/2} = 3 minutes) apparently begins with its spontaneous hydrolysis in blood to 6-keto-PGF_{1α}. The metabolism of this compound in humans involves the same steps as those for PGE₂ and PGF_{2α}.

The degradation of LTC₄ occurs in the lungs, kidney, and liver. The initial steps involve its conversion to LTE₄. LTC₄ also may be inactivated by oxidation of its cysteinyl sulfur to a sulfoxide. In leukocytes, LTB₄ is inactivated principally by oxidation by members of the CYP4F subfamily. Conversion to 12-oxo-LTB₄ by LTB 12-OH dehydrogenase (see the discussion earlier) is a key pathway in tissues other than leukocytes.

Pharmacological Properties of Eicosanoids

The eicosanoids show numerous and diverse effects in biological systems. This discussion highlights those that are thought to be the most important.

Mechanism of Action. The eicosanoids function through activation of specific cell surface receptors that couple to intracellular second-messenger systems to modulate cellular activity.

Prostaglandin Receptors. PGs activate membrane receptors locally near their sites of formation. The diversity of their effects is explained to a large extent by their interaction with a diverse family of distinct receptors (Table 33–1). Eicosanoid receptors interact with G_s, G_i, and G_q to modulate the activities of adenylyl cyclase and phospholipase C (see Chapter 3). Single gene products have been identified for the receptors for PGI₂ (the IP), PGF_{2α} (the FP), and TxA₂ (the TP). Four distinct PGE₂ receptors (EP_{1–4}) and two PGD₂ receptors (DP₁ and DP₂—also known as CRTH₂) have been cloned. Additional isoforms

Figure 33–3. Major pathways of prostanoic acid degradation. Active metabolites are shaded in gray. Major urinary metabolites are shaded in orange. The red dashed lines indicate reactions that use common enzymatic processes. M, metabolite. See the text for other abbreviations.

of the TP (α and β), FP (A and B), and EP₃ (I-VI, e, f) receptors can arise through differential mRNA splicing (Narumiya et al., 1999; Smyth et al., 2009).

Cell Signaling Pathways and Expression. The prostanoid receptors appear to derive from an ancestral EP receptor and share high

homology. Phylogenetic comparison of this family reveals three subclusters: The first consists of the relaxant receptors EP₂, EP₄, IP, and DP₁, which increase cellular cyclic AMP generation; the second consists of the contractile receptors EP₁, FP, and TP, which increase cytosolic levels of Ca²⁺; and a third, consisting only of EP₃,

Table 33–1

Eicosanoid Receptors

RECEPTOR	PRIMARY LIGAND	SECONDARY LIGAND	PRIMARY COUPLING	MAJOR PHENOTYPE IN KNOCKOUT MICE
DP ₁	PGD ₂		↑ cAMP (G _s)	↓ Allergic asthma
DP ₂ /CHRT ₂	PGD ₂	15d-PGJ ₂	↓ cAMP, ↑ Ca ²⁺ _i (G _i)	↑ or ↓ Allergic airway inflammation
EP ₁	PGE ₂	PGI ₂	↑ Ca ²⁺ _i (G _q)	↓ Response of colon to carcinogens
EP ₂	PGE ₂		↑ cAMP (G _s)	Impaired ovulation and fertilization Salt-sensitive hypertension
EP ₃ I-VI, e, f	PGE ₂		↓ cAMP, ↑ Ca ²⁺ _i (G _i); ↑ cAMP (G _s); ↑ PLC, ↑ Ca ²⁺ _i (G _q)	Resistance to pyrogens ↓ Acute cutaneous inflammation
EP ₄	PGE ₂		↑ cAMP (G _s)	Patent ductus arteriosus ↓ Bone mass/density in aged mice ↑ Bowel inflammatory response ↓ Colon carcinogenesis
FP _{A,B}	PGF _{2α}	IsoPs	↑ PLC, ↑ Ca ²⁺ _i (G _q)	Failure of parturition
IP	PGI ₂	PGE ₂	↑ cAMP (G _s)	↑ Thrombotic response ↓ Response to vascular injury ↑ Atherosclerosis ↑ Cardiac fibrosis Salt-sensitive hypertension ↓ Joint inflammation
TP _{α,β}	TxA ₂	IsoPs	↑ PLC, ↑ Ca ²⁺ _i (G _q , G _i , G _{12/13} , G ₁₆); ↑ Rho, ↑ ERK activation (G _q , G _{12/13} , G ₁₆)	↑ Bleeding time ↓ Response to vascular injury ↓ Atherosclerosis ↑ Survival after cardiac allograft
BLT ₁	LTB ₄		↑ Ca ²⁺ _i , ↓ cAMP (G ₁₆ , G _i)	Some suppression of inflammatory response
BLT ₂	LTB ₄	12(S)-HETE 12(R)-HETE	↑ Ca ²⁺ _i (G _q -like, G _i -like, G _z -like)	?
CysLT ₁	LTD ₄	LTC ₄ /LTE ₄	↑ PLC, ↑ Ca ²⁺ _i (G _q)	↓ Innate and adaptive immune vascular permeability response ↑ Pulmonary inflammatory and fibrotic response
CysLT ₂	LTC ₄ /LTD ₄	LTE ₄	↑ PLC, ↑ Ca ²⁺ _i (G _q)	↓ Pulmonary inflammatory and fibrotic response

This table lists the major classes of eicosanoid receptors and their signaling characteristics. Splice variants for EP₃, TP, and FP are indicated. Major phenotypes in knockout mouse models are listed. Ca²⁺_i, cytosolic Ca²⁺; cAMP, cyclic AMP; PLC, phospholipase C (activation leads to increased cellular inositol phosphate and diacylglycerol generation and increased Ca²⁺_i); IsoPs, isoprostanes; 15d-PGJ₂, 15-deoxy- $\Delta^{12,14}$ -PGJ₂; DP₂ is a member of the fMLP-receptor superfamily; fMLP, formyl-methionyl-leucyl-phenylalanine. See the text for other abbreviations.

can couple to both elevation of intracellular calcium and a decrease in cyclic AMP. The DP₂ receptor is an exception and is unrelated to the other prostanoid receptors; rather, it is a member of the formyl-methionyl-leucyl-phenylalanine (fMLP)-receptor superfamily (Table 33-1).

TP_α and TP_β receptors couple via G_q and several other G proteins, to activate the PLC-IP₃-Ca²⁺ pathway (Figure 33-4). Activation of TP receptors also may activate or inhibit adenylyl cyclase via G_s (TP_α) or G_i (TP_β), respectively, and signal via G_q, G_{12/13}, and G₁₆, to stimulate small G protein-signaling pathways, including ERK and Rho. TP is expressed in platelets, vasculature, lung, kidney, heart, thymus, and spleen. The TP_α apparently is the sole isoform expressed in platelets (see Smyth and FitzGerald, 2009). Recognized differences between the splice variants are limited to G protein activation and receptor regulation in heterologous *in vitro* expression systems.

IP couples with G_s to stimulate adenylyl cyclase activity. It is expressed in many tissues and cells, including human kidney, lung, spine, liver, vasculature, and heart.

DP₁ also couples with adenylyl cyclase through G_s. It is the least abundant of the prostanoid receptors, with expression in mouse ileum, lung, stomach, and uterus. In humans, several subtypes of leukocytes express DP₁, including eosinophils, basophils, monocytes, dendritic cells, and T lymphocytes. DP₁ also is expressed in the central nervous system (CNS), where it appears to be limited specifically to the leptomeninges and the vasculature. DP₂ couples with the G_q-PLC-IP₃ pathway to increase intracellular Ca²⁺ (Figure 33-4). Its mRNA is found in many human tissues (brain, heart, thymus, spleen, liver, and intestine). DP₂ is expressed on mast cells, T lymphocytes (Th2 but not Th1), basophils, and eosinophils (Kim and Luster, 2007).

EP₂ and EP₄ receptors activate adenylyl cyclase via G_s. The EP₂ receptor is expressed at much lower levels in most tissues and can be induced in response to inflammatory stimuli, suggesting distinct roles for these two G_s-coupled EP receptors. The EP₁ receptor, via an unclassified G protein, can activate the PLC-IP₃-Ca²⁺ pathway. All human EP₃ isoforms can activate G_i to inhibit adenylyl cyclase; however, certain isoforms can activate G_s or G_{12/13}. EP₁ and EP₂

Figure 33-4. Prostanoid receptors and their primary signaling pathways. Prostanoid receptors are members of the heptaspanning, G protein-coupled receptor superfamily. The terms “relaxant,” “contractile,” and “inhibitory” refer to the phylogenetic characterization of their primary effects. **All EP₃ isoforms couple through G_i, but some can also activate G_s or G_{12/13} pathways. See the text for additional details.

receptors have limited distribution compared with the distribution of EP₃ and EP₄ receptors.

FP_A and FP_B receptors couple via G_q-PLC-IP₃ to mobilize cellular Ca²⁺ and activate PKC. In addition, stimulation of FP activates Rho kinase, leading to the formation of actin stress fibers, phosphorylation of p125 focal adhesion kinase, and cell rounding. The FP receptor is expressed in kidney, heart, lung, stomach, and eye; it is most abundant in the corpus luteum, where its expression pattern varies during the estrus cycle.

Leukotriene and Lipoxin Receptors. Several receptors for the LTs and lipoxins have been identified (Peters-Golden and Henderson, 2007) (Table 33–1). Two receptors exist for both LTB₄ (BLT₁ and BLT₂) and the cysteinyl leukotrienes (CysLT₁ and CysLT₂). A receptor that binds lipoxin, ALX, is identical to the fMLP-1 receptor; the nomenclature now reflects LXA₄ as a natural and potent ligand (Chiang et al., 2006).

Cell Signaling Pathways and Expression. Phylogenetic comparison reveals two clusters of LT/lipoxin receptors: the chemoattractant receptors (BLT₁, BLT₂, and ALX), which also contain the DP₂ receptor for PGD₂, and the CysLT₁ and CysLT₂ receptors. All are G protein-coupled receptors (GPCRs) and couple with G_q and other G proteins (Table 33–1), depending on the cellular context. The BLT₁ is expressed predominantly in leukocytes, thymus, and spleen, whereas BLT₂, the low-affinity receptor for LTB₄, is found in spleen, leukocytes, ovary, liver, and intestine. BLT₂ binds 12(*S*)- and 12(*R*)-HETE with reasonable affinity, although the biological relevance of this observation is not clear.

CysLT₁ binds LTD₄ with higher affinity than LTC₄, while CysLT₂ shows equal affinity for both LTs. Both receptors bind LTE₄ with low affinity. Activation of G_q, leading to increased intracellular Ca²⁺, is the primary signaling pathway reported. Studies also have placed G_i downstream of CysLT₂. CysLT₁ is expressed in lung and intestinal smooth muscle, spleen, and peripheral blood leukocytes, whereas CysLT₂ is found in heart, spleen, peripheral blood leukocytes, adrenal medulla, and brain.

Responses to ALX-receptor activation vary with cell type. In human neutrophils, AA release is stimulated, whereas Ca²⁺ mobilization is blocked; in monocytes, LXA₄ stimulates Ca²⁺ mobilization. The ALX receptor is expressed in lung, peripheral blood leukocytes, and spleen.

Other Agents. Other AA metabolites (e.g., isoprostanes, epoxy-eicosatrienoic acids, hepoxilins) have potent biological activities, and there is evidence for distinct receptors for some of these substances. Some isoprostanes appear to act as incidental ligands at the TP (Audoly et al., 2000), which may be important in the pathology of cardiovascular disease. Others activate the FP (Kunapuli et al., 1997). Certain eicosanoids, most notably 15-deoxy-Δ^{12,14}-PGJ₂ (15d-PGJ₂), a dehydration product of PGD₂, have been reported as endogenous ligands for a family of nuclear receptors called peroxisome proliferator-activated receptors (PPARs) that regulate lipid metabolism and cellular proliferation and differentiation. However, their affinities for PPARs are significantly lower than for cell surface receptors, raising doubt about the physiological relevance of the ligand-receptor interaction. *in vitro* 15d-PGJ₂ can bind PPARγ, but the quantities formed *in vivo* are orders of magnitude lower than those necessary for PPAR activation (Bell-Parikh et al., 2003). Specific receptors for the HETEs and EETs have been proposed but not yet isolated.

Endogenous Prostaglandins, Thromboxanes, and Leukotrienes: Functions in Physiological and Pathological Processes

The widespread biosynthesis and myriad of pharmacological actions of eicosanoids are reflected in their complex physiology and pathophysiology. The development of mice with targeted disruptions of genes regulating eicosanoid biosynthesis and eicosanoid receptors has revealed unexpected roles for these autacoids and has clarified hypotheses about their function (Austin and Funk, 1999; Narumiya and FitzGerald, 2001; Matsuoka and Narumiya, 2007; Smyth and FitzGerald, 2009).

Platelets. Platelet aggregation leads to activation of membrane phospholipases, with the release of AA and consequent eicosanoid biosynthesis. In human platelets, TxA₂ and 12-HETE are the two major eicosanoids formed, although eicosanoids from other sources (e.g., PGI₂ derived from vascular endothelium) also affect platelet function. A naturally occurring mutation in the first intracellular loop of the TP receptor is associated with a mild bleeding diathesis and resistance of platelet aggregability to TP agonists (Hirata et al., 1994). The importance of the TxA₂ pathway is evident from the efficacy of low-dose aspirin in the secondary prevention of myocardial infarction and ischemic stroke. The total biosynthesis of TxA₂, as determined by excretion of its urinary metabolites, is augmented in clinical syndromes of platelet activation, including unstable angina, myocardial infarction, and stroke (Smyth et al., 2009). Deletion of the TP receptor in the mouse prolongs bleeding time, renders platelets unresponsive to TP agonists, modifies their response to collagen but not to ADP, and blunts the response to vasopressors and the proliferative response to vascular injury.

PGI₂ inhibits platelet aggregation and disaggregates preformed clumps. Deficiency of the IP receptor in disease-free mice does not alter platelet aggregation significantly *ex vivo*, although increased responsiveness to thrombin was evident in a mouse model of atherosclerosis (Smyth and FitzGerald, 2009). Augmented biosynthesis of PGI₂ in syndromes of platelet activation serves to constrain the effects platelet agonists, vasoconstrictors, and stimuli to platelet activation. However, PGI₂ does limit platelet activation by TxA₂ *in vivo*, reducing the thrombotic response to vascular injury (Cheng et al., 2002). The increased incidence of myocardial infarction and stroke in patients receiving selective inhibitors of COX-2, most parsimoniously explained by inhibition of COX-2-dependent PGI₂ formation, supports this concept (Grosser et al., 2006b).

Low concentrations of PGE₂ activate the EP₃ receptor, leading to platelet aggregation (Fabre, 2001). Deletion of the EP₃ in mice leads to an increased bleeding tendency and decreased susceptibility to thromboembolism. Deletion of mPGES-1 did not affect thrombogenesis *in vivo*, probably due to substrate redirection and augmented formation of PGI₂ (Cheng et al., 2006b).

Vascular Tone. Because of their short t_{1/2}, prostanoids do not circulate and generally are considered not to impact directly on systemic vascular tone. They may, however, modulate vascular tone locally

at their sites of biosynthesis or through renal or other indirect effects. PGI₂, the major arachidonate metabolite released from the vascular endothelium, is derived primarily from COX-2 in humans (Catella-Lawson et al., 1999; McAdam et al., 1999). PGI₂ generation and release is regulated by shear stress and by both vasoconstrictor and vasodilator autacoids. Deletion of the IP in mice augments vascular proliferation, remodeling, atherogenesis, and hypertension, while PGI synthase polymorphisms have been associated with essential hypertension and myocardial infarction (Smyth and FitzGerald, 2009). PGI₂ limits pulmonary hypertension induced by hypoxia and systemic hypertension induced by AngII and lowers pulmonary resistance in patients with pulmonary hypertension.

Deficiency of EP₁ or EP₄ receptors reduces resting blood pressure in male mice; EP₁-receptor deficiency is associated with elevated renin-angiotensin activity. Both EP₂ and EP₄ receptor-deficient animals develop hypertension in response to a high-salt diet, reflecting the importance of PGE₂ in maintenance of renal blood flow and salt excretion. PGI₂ and PGE₂ are implicated in the hypotension associated with septic shock. PGs also may play a role in the maintenance of placental blood flow. Although conflicting data exist, it appears that loss of mPGES-1 in mice is less likely than loss of COX-2 to alter blood pressure (Smyth et al., 2009).

COX-2-derived PGE₂, via the EP₄ receptor, maintains the ductus arteriosus patent until birth, when reduced PGE₂ levels (a consequence of increased PGE₂ metabolism) permit closure. (Coggin et al., 2002). The tNSAIDs induce closure of a patent ductus in neonates (see Chapter 34). Contrary to expectation, animals lacking the EP₄ receptor die with a patent ductus during the perinatal period (Table 33–1) because the mechanism for control of the ductus *in utero*, and its remodeling at birth, is absent.

Endogenous biosynthesis of EETs is increased in human syndromes of hypertension. An analog of 11,12-EET abrogated the enhanced renal microvascular reactivity to AngII associated with hypertension (Imig et al., 2001), and blood pressure is lower in mice deficient in soluble EH (Sinal et al., 2000); these findings suggest that EH enzyme may be a potential pharmacological target for hypertension. Much indirect evidence suggests the existence of EET receptors, although none has been cloned.

Inflammatory Vascular Disease. Studies with knockout mice strongly implicate prostanoids in the development of atherogenesis and abdominal aortic aneurism; both inflammatory cardiovascular diseases (Smyth et al., 2009; Smyth and FitzGerald, 2009). Suppression of TxA₂ biosynthesis, as well as antagonism or deletion of the TP, retards atherogenesis in mice. Deletion of the FP receptor reduces blood pressure and retards atherogenesis, coincident with reduced renin. Conversely, PGI₂ appears atheroprotective and also limits vascular proliferative and remodeling responses. In humans, an arginine²¹² to cysteine substitution in the fifth intracellular loop of the IP, which disrupts IP signaling, co-segregated with increased cardiovascular risk in a recent study (Arehart et al., 2008), concordant with a role for this prostanoid in modifying human cardiovascular disease.

The role of PGE₂ effects on inflammatory cardiovascular disease is less clear. Deletion of mPGES-1 does not accelerate the response to a thrombogenic stimulus *in vivo* in rodents (in contrast to either selective inhibition of COX-2 or deletion of the IP (Cheng et al., 2006b) but does retard atherogenesis in fat-fed hyperlipidemic

mice (Wang et al., 2006). It is unclear, however, whether this results from loss of PGE₂ or because of concomitant elevations in PGI₂ biosynthesis. Deletion, or selective inhibition, of COX-2, but not inhibition of COX-1, decreases abdominal aortic aneurism formation in hyperlipidemic mice (King et al., 2006). Similar results were seen in mPGES-1-deficient mice (Wang et al., 2008), although, again, it is unclear to what extent redirection to biosynthesis of other prostanoids (e.g., PGI₂) contributes.

There is growing evidence for a role of the LTs in cardiovascular disease (Peters-Golden and Henderson, 2007). Although conflicting data have been reported in animal studies, human genetic studies have demonstrated a link between cardiovascular disease and polymorphisms in the LT biosynthetic enzymes and FLAP.

Lung. A complex mixture of autacoids is released when sensitized lung tissue is challenged by the appropriate antigen. COX-derived bronchodilator (PGE₂) and bronchoconstrictor (e.g., PGF_{2α}, TxA₂, PGD₂) substances are released. IP deletion in mice exaggerates features of acute and chronic experimental asthma, including increased bronchial hyperresponsiveness. Inhaled iloprost (a PGI₂ analog) suppresses the cardinal features of asthma in mice via inhibition of airway dendritic cell function.

Polymorphisms in the genes for PGD₂ synthase and the TP receptor have been associated with asthma in humans. Deletion of either DP₁ or DP₂ in mice suggests an important role of this prostanoid in asthma (and in other allergic responses), although contradictory findings in DP₂-deficient mice suggest significant complexity in the function of PGD₂ in airway inflammation (Pettipher et al., 2007).

The CysLTs probably dominate during allergic constriction of the airway (Drazen, 1999). Deficiency of 5-LOX leads to reduced influx of eosinophils in airways and attenuates bronchoconstriction. Furthermore, unlike COX inhibitors and histaminergic antagonists, CysLT-receptor antagonists and 5-LOX inhibitors are effective in the treatment of human asthma (see “Inhibitors of Eicosanoid Biosynthesis”). The relatively slow LT metabolism in lung contributes to the long-lasting bronchoconstriction that follows challenge with antigen and may be a factor in the high bronchial tone that is observed in asthmatic patients in periods between acute attacks (see Chapter 36).

Kidney. Long-term use of all COX inhibitors is limited by the development of hypertension, edema, and congestive heart failure in a significant number of patients. PGE₂, along with PGI₂, apparently derived from COX-2, plays a critical role in maintaining renal blood flow and salt excretion, whereas there is some evidence that the COX-1-derived vasoconstrictor TxA₂ may play a counterbalancing role. Biosynthesis of PGE₂ and PGI₂ is increased by factors that reduce renal blood flow (e.g., stimulation of sympathetic nerves; AngII).

Barter’s syndrome is an autosomal recessive trait that is manifested as hypokalemic metabolic alkalosis. The syndrome results from inappropriate renal salt absorption caused primarily by dysfunctional mutations in the Na⁺-K⁺-2Cl⁻ co-transporter NKCC2, a target of loop diuretics in the ascending thick limb of the loop of Henle (Simon et al., 1996) (see Chapter 25). The syndrome also can result from dysfunctional alterations in proteins whose activities can limit NKCC2 function: the K⁺ channel ROMK2 (Kir1.1) that recycles K⁺ into the tubular fluid; the basolateral membrane Cl⁻ channel, ClC-Kb; and Barttin, the integral membrane protein that forms the α-subunit of the ClC-Kb heteromer (O’Shaughnessy and Karet, 2004). The antenatal variant of Bartter’s syndrome, owing to

dysfunctional ROMK2, also is known as *hyperprostaglandin E syndrome*. The elevated PGE₂ may exacerbate the symptoms of salt and water loss. The relationship between dysfunctional ROMK2 and elevated PGE₂ synthesis is not clear. However, in patients with antenatal Bartter's syndrome, inhibition of COX-2 ameliorates many of the clinical symptoms (Nüsing et al., 2001).

Inflammatory and Immune Responses. PGs and LTs are synthesized in response to a host of stimuli that elicit inflammatory and immune responses, and contribute significantly to inflammation and immunity (Tilley et al., 2001; Brink et al., 2003; Kim and Luster, 2007). Prostanoids generally promote acute inflammation, although there are some exceptions, such as the inhibitory actions of PGE₂ on mast cell activation (see "Inflammation and Immunity"). Data from animals deficient in either COX-1 or COX-2 yield conflicting results depending on the inflammatory model used, perhaps reflecting the contribution of both isozymes to inflammation. Deletion of mPGES markedly reduced inflammation in several mouse models.

LTs are potent mediators of inflammation. Deletion of either 5-LOX or FLAP reduces inflammatory responses. Generation of BLT₁-deficient mice confirms the role of LTB₄ in chemotaxis, adhesion, and recruitment of leukocytes to inflamed tissues (Toda et al., 2002). Increased vascular permeability resulting from innate and adaptive immune challenges is offset in mice deficient in CysLT₁ or LTC₄ synthase (Kanaoka and Boyce, 2004) (Table 33–1). Deletion either of LTC₄ synthase (and thus loss of CysLT biosynthesis) or CysLT₂ reduced chronic pulmonary inflammation and fibrosis in response to bleomycin. In contrast, absence of CysLT₁ led to an exaggerated response. These findings demonstrate a role for CysLT₂ in promoting, and an unexpected role for CysLT₁ in counteracting, chronic inflammation.

Heart. Studies suggest a role for COX-2 in cardiac function (Smyth et al., 2009). PGI₂ and PGE₂, acting on the IP or the EP₃, respectively (Dowd et al., 2001; Shinmura et al., 2005), protect against oxidative injury in cardiac tissue. IP deletion augments myocardial ischemia/reperfusion injury and both mPGES-1 deletion (Degousee et al., 2008) and cardiomyocyte specific deletion of the EP₄ (Qian et al., 2008) exacerbate the decline in cardiac function after experimental myocardial infarction. COX-2-derived TxA₂ contributed to oxidant stress, isoprostane generation, and activation of the TP, and also possibly the FP, to increase cardiomyocyte apoptosis and fibrosis in a model of heart failure (Zhang et al., 2003). Selective deletion of COX-2 in cardiomyocytes results in mild heart failure and a predisposition to arrhythmogenesis.

Reproduction and Parturition. Studies with knockout mice confirm a role for PGs in reproduction and parturition (Smyth and FitzGerald, 2009). COX-1-derived PGF_{2α} appears important for luteolysis, consistent with delayed parturition in mice deficient in COX-1. Subsequent upregulation of COX-2 generates prostanoids, including PGF_{2α} and TxA₂, that are important in the final stages of parturition. Mice lacking both COX-1 and oxytocin undergo normal parturition, demonstrating the critical interplay between PGF_{2α} and oxytocin in onset of labor. EP₂ receptor-deficient mice demonstrate a preimplantation defect (Table 33–1), which likely underlies some of the breeding difficulties seen in COX-2 knockouts.

Cancer. Pharmacological inhibition or genetic deletion of COX-2 restrains tumor formation in models of colon, breast, lung, and other

cancers. Large human epidemiological studies report that the incidental use of NSAIDs is associated with significant reductions in relative risk for developing these and other cancers (Harris et al., 2005). PGE₂ has been implicated as the primary pro-oncogenic prostanoid in multiple studies. The pro- and anti-oncogenic roles of other prostanoids remain under investigation, with TxA₂ emerging as another likely COX-2-derived pro-carcinogenic mediator. Studies in mice lacking EP₁, EP₂, and EP₄ reduce disease in multiple carcinogenesis models. EP₃, in contrast, may even play a protective role in some cancers. Three randomized controlled trials of COX-2 inhibitors reported a significant reduction in the reoccurrence of adenomas in patients receiving either celecoxib or rofecoxib compared to placebo (Bertagnolli, 2007), while polymorphisms in COX-2 have been associated with an increased risk of colon and other cancers. In mouse mammary tissue, COX-2 is pro-oncogenic (Liu et al., 2001), whereas aspirin use is associated with a reduced risk of breast cancer in women, especially for hormone receptor-positive tumors (Terry et al., 2004). Despite the emphasis on COX-2, studies support a role for both COX enzymes in pro-oncogenic processes, and it remains untested whether selective COX-2 inhibitors will prove superior to nonselective NSAIDs for the prevention or treatment of human cancer. The CysLT and LTB₄ receptors also are implicated in cancer, raising interest in the use of LT inhibitors/antagonists in chemoprevention/therapy.

Pharmacological Effects

Cardiovascular System. Prostanoids do not circulate and thus do not directly impact systemic vascular tone. They may, however, modulate local vascular tone at the site of their formation and affect systemic blood pressure through their renal actions, including changes of tone of the efferent arteriole. In most vascular beds, PGE₂, PGI₂, and PGD₂ elicit vasodilation and a drop in blood pressure (Smyth and FitzGerald, 2009). PGE₂ can cause vasoconstriction through activation of the EP₁ and EP₃. Infusion of PGD₂ in humans results in flushing, nasal stuffiness, and hypotension. Local subcutaneous release of PGD₂ contributes to dilation of the vasculature in the skin, which causes facial flushing associated with niacin treatment in humans (Cheng et al., 2006a). Subsequent formation of F-ring metabolites from PGD₂ may result in hypertension. PGI₂ relaxes vascular smooth muscle, causing hypotension and reflex tachycardia on intravenous administration. Responses to PGF_{2α} vary with species and vascular bed; it is a potent constrictor of both pulmonary arteries and veins in humans. Blood pressure is increased by PGF_{2α} in some experimental animals, owing to venoconstriction; however, in humans, PGF_{2α} does not alter blood pressure. TxA₂ is a potent vasoconstrictor. It contracts vascular smooth muscle *in vitro* and is a vasoconstrictor in the whole animal and in isolated vascular beds.

Cardiac output generally is increased by infusion of PGs of the E and F series. Weak, direct inotropic effects have been noted in various isolated preparations. In the intact animal, however, increased force of contraction and increased heart rate are, in large measure, a reflex consequence of a fall in total peripheral resistance. Animal studies suggest direct cardioprotective effects of PGI₂ and PGE₂ (Smyth et al., 2009).

LTC₄ and LTD₄ can constrict or relax isolated vascular smooth muscle preparations, depending on the concentrations used and the vascular bed (Brink et al., 2003). Hypotension in humans may result partly from a decrease in intravascular volume and also from decreased cardiac contractility secondary to a marked LT-induced reduction in coronary blood flow. Although LTC₄ and LTD₄ have little effect on most large arteries or veins, coronary arteries and distal segments of the pulmonary artery are contracted by nanomolar concentrations of these agents. The renal vasculature is resistant to this constrictor action, but the mesenteric vasculature is not. LTC₄ and LTD₄ act in the microvasculature to increase permeability of postcapillary venules; they are approximately 1,000-fold more potent than histamine in this regard. At higher concentrations, LTC₄ and LTD₄ can constrict arterioles and reduce exudation of plasma. Vascular smooth muscle proliferation can be promoted by 12S-HETE and 20-HETE.

EETs cause vasodilation in a number of vascular beds by activating the large conductance Ca²⁺-activated K⁺ channels of smooth muscle cells, thereby hyperpolarizing the smooth muscle and causing relaxation. EETs likely also function as endothelium-derived hyperpolarizing factors (EDHFs), particularly in the coronary circulation (Campbell and Falck, 2007). In contrast to EETs, 20-HETE inhibits large conductance Ca²⁺-activated K⁺ channels, resulting in depolarization of the vascular smooth muscle cell, Ca²⁺ entry, and potent vasoconstriction (Kroetz and Xu, 2005). Evidence supports the role of 20-HETE in the regulation of vascular tone, particularly in renal autoregulation.

Isoprostanes usually are vasoconstrictors, although there are examples of vasodilation in precontracted vessels.

Platelets. Low concentrations of PGE₂, via the EP₃, enhance platelet aggregation. In contrast, higher concentrations of PGE₂, acting via the IP or possibly the G_s-coupled EP₂ or EP₄, inhibit platelet aggregation (Smyth et al., 2009). Both PGI₂ and PGD₂ inhibit the aggregation of human platelets *in vitro*, through cyclic AMP-dependent deactivation of myosin light-chain kinase.

Mature platelets express only COX-1. Megakaryocytes and immature platelet forms, released in clinical conditions of accelerated platelet turnover, also express COX-2 (Rocca et al., 2002), but its role in platelet development and function has yet to be elucidated. TxA₂, the major product of COX-1 in platelets, induces platelet shape change, through G₁₂/G₁₃-mediated Rho/Rho-kinase-dependent regulation of myosin light-chain phosphorylation, and aggregation through G_q-dependent activation of PKC. Perhaps more importantly, TxA₂ amplifies the signal for other, more potent platelet agonists, such as thrombin and ADP (FitzGerald, 1991). The actions of TxA₂ on platelets are restrained by its short t_{1/2} (~30 seconds), by rapid TP desensitization, and by endogenous inhibitors of platelet function,

including NO and PGI₂, which inhibits platelet aggregation by all recognized agonists. The biological importance of 12-HETE formation is poorly understood, although deletion of the platelet 12-LOX augments ADP-induced platelet aggregation and AA-induced sudden death in mice. Some isoprostanes increase the response of platelets to pro-aggregatory agonists *in vitro*.

Inflammation and Immunity. Eicosanoids play a major role in the inflammatory and immune responses, as reflected by the clinical usefulness of the NSAIDs. While LTs generally are pro-inflammatory and lipoxins anti-inflammatory, prostanoids can exert both kinds of activity. A more complete description of inflammation is outlined in Chapter 34.

COX-2 is the major source of prostanoids formed during and after an inflammatory response, although COX-1 also contributes. PGE₂ and PGI₂ are the predominant pro-inflammatory prostanoids, as a result of increased vascular permeability and blood flow in the inflamed region. TxA₂ can increase platelet-leukocyte interaction. Prostanoids, especially PGD₂, also contribute to resolution of inflammation. PGs generally inhibit lymphocyte function and proliferation, suppressing the immune response (Rocca et al., 2002). PGE₂ depresses the humoral antibody response by inhibiting the differentiation of B lymphocytes into antibody-secreting plasma cells. PGE₂ acts on T lymphocytes to inhibit mitogen-stimulated proliferation and lymphokine release by sensitized cells. PGE₂ and TxA₂ also may play a role in T lymphocyte development by regulating apoptosis of immature thymocytes (Tilley et al., 2001). PGD₂, a major product of mast cells, is a potent leukocyte chemoattractant (Pettipher et al., 2007), primarily through the DP₂. Activation of the DP₂ promotes chemotaxis and activation of T_H2 lymphocytes, eosinophils, and basophils. The PGD₂ degradation product, 15d-PGJ₂, also may activate eosinophils via the DP₂. PDG₂-mediated polarization of T cells to the T_H2 phenotype is DP₁-mediated. A counterregulatory role for DP₁ in leukocyte activation has been proposed, although complementary functions for the two receptors have been reported. The precise interplay between DP₁ and DP₂ *in vivo* remains to be clarified.

LTB₄ is a potent activator and chemotactic agent for neutrophils, T lymphocytes, eosinophils, monocytes, dendritic cells, and possibly also mast cells (Kim and Luster, 2007). These effects are primarily BLT₁ receptor-mediated and, although BLT₂ expression has been reported in eosinophils, mast cells, and dendritic cells, its contribution to LBT₄ function is unclear. LTB₄ stimulates the aggregation of eosinophils and promotes degranulation and the generation of superoxide. LTB₄ promotes adhesion of neutrophils to vascular endothelial cells and their transendothelial migration and stimulates synthesis of pro-inflammatory cytokines from macrophages and lymphocytes. Mast cell-generated LTB₄ also may contribute significantly to T lymphocyte migration.

The CysLTs are chemotaxins for eosinophils and monocytes through activation of the CysLT₁ receptor. They also induce cytokine generation in eosinophils, mast cells, and dendritic cells. A distinct set of cytokines are produced through activation of mast cell CysLT₁ and CysLT₂. At higher concentrations, these LTs also promote eosinophil adherence, degranulation, cytokine or chemokine release, and oxygen radical formation. In addition, CysLTs contribute to

inflammation by increasing endothelial permeability, thus promoting migration of inflammatory cells to the site of inflammation.

Lipoxins have diverse effects on leukocytes, including activation of monocytes and macrophages and inhibition of neutrophil, eosinophil, and lymphocyte activation (McMahon and Godson, 2004). Both lipoxin A and B inhibit natural killer cell cytotoxicity.

Smooth Muscle. PGs also contract or relax smooth muscles in tissues outside the vasculature. The LTs contract most smooth muscles.

Bronchial and Tracheal Muscle. In general, TxA_2 , $\text{PGF}_{2\alpha}$, and PGD_2 contract, and PGE_2 and PGI_2 relax, bronchial and tracheal muscle. PGD_2 appear to be the primary bronchoconstrictor prostanoid of relevance in humans. Roughly 10% of people given aspirin or tNSAIDs develop bronchospasm. This appears attributable to a shift in AA metabolism to LT formation, as reflected by an increase in urinary LTE_4 in response to aspirin challenge in such individuals. This substrate diversion appears to involve COX-1; such patients do not develop bronchospasm when treated with selective inhibitors of COX-2. The CysLTs are bronchoconstrictors in many species, including humans (Brink et al., 2003). These LTs act principally on smooth muscle in the airways and are a thousand times more potent than histamine both *in vitro* and *in vivo*. They also stimulate bronchial mucus secretion and cause mucosal edema.

PGI_2 causes bronchodilation in most species; human bronchial tissue is particularly sensitive, and PGI_2 antagonizes bronchoconstriction induced by other agents.

Uterus. Strips of nonpregnant human uterus are contracted by $\text{PGF}_{2\alpha}$ and TxA_2 but are relaxed by PGEs. Sensitivity to the contractile response is most prominent before menstruation, whereas relaxation is greatest at midcycle. Uterine strips obtained at hysterectomy from pregnant women are contracted by $\text{PGF}_{2\alpha}$ and by low concentrations of PGE_2 . PGE_2 , together with oxytocin, is essential for the onset of parturition. PGI_2 and high concentrations of PGE_2 produce relaxation. The intravenous infusion of PGE_2 or $\text{PGF}_{2\alpha}$ to pregnant women produces a dose-dependent increase in uterine tone and in the frequency and intensity of rhythmic uterine contractions. PGEs and PGFs are used to terminate pregnancy. Uterine responsiveness to PGs increases as pregnancy progresses but remains smaller than the response to oxytocin.

Gastrointestinal Muscle. PGEs and PGFs stimulate contraction of the main longitudinal muscle from stomach to colon. PG endoperoxides, TxA_2 , and PGI_2 also produce contraction but are less active. Circular muscle generally relaxes in response to PGE_2 and contracts in response to $\text{PGF}_{2\alpha}$. The LTs have potent contractile effects. PGs reduce transit time in the small intestine and colon. Diarrhea, cramps, and reflux of bile have been noted in response to oral PGE; these are common side effects (along with nausea and vomiting) in patients given PGs for abortion. PGEs and PGFs stimulate the movement of water and electrolytes into the intestinal lumen. Such effects may underlie the watery diarrhea that follows their oral or parenteral administration. By contrast, PGI_2 does not induce diarrhea; indeed, it prevents that provoked by other PGs.

PGE_2 appears to contribute to the water and electrolyte loss in cholera, a disease that is somewhat responsive to therapy with tNSAIDs.

Gastric and Intestinal Secretions. In the stomach, PGE_2 and PGI_2 contribute to increased mucus secretion (*cytoprotection*), reduced acid secretion, and reduced pepsin content. These effects result from their vasodilatory properties and probable direct effects on secretory cells. PGE_2 and its analogs also inhibit gastric damage caused by a variety of ulcerogenic agents and promote healing of duodenal and gastric ulcers (see Chapter 45). Although COX-1 may be the dominant source of such cytoprotective PGs under physiological conditions, COX-2 predominates during ulcer healing. Selective inhibitors of COX-2 and deletion of the enzyme delay ulcer healing in rodents, but the impact of COX-2 inhibitors in humans is unclear. CysLTs, by constricting gastric blood vessels and enhancing production of pro-inflammatory cytokines, may contribute to the gastric damage.

Kidney. Renal prostanoids, especially PGE_2 and PGI_2 , but also $\text{PGF}_{2\alpha}$ and TxA_2 , perform complex and intricate functions in the kidney (Hao and Breyer, 2007). Both the renal medulla and cortex synthesize prostanoids, although substantially more are generated in the medulla. COX-2-derived PGE_2 and PGI_2 increase medullary blood flow and inhibit tubular sodium reabsorption. Expression of medullary COX-2 is increased during high salt intake. COX-1-derived products promote salt excretion in the collecting ducts. Cortical COX-2-derived PGE_2 and PGI_2 increase renal blood flow and glomerular filtration through their local vasodilating effects, actions that may be particularly relevant to maintaining renal function in marginally functioning kidneys and volume-contracted states. An added layer of complexity is evident from the increased expression of cortical COX-2 expression during low dietary salt intake. Through the action of PGE_2 , and also possibly PGI_2 , this results in increased renin release, leading to sodium retention and elevated blood pressure.

TxA_2 , generated at low levels in the normal kidney, has potent vasoconstrictor effects that reduce renal blood flow and glomerular filtration rate. Infusion of $\text{PGF}_{2\alpha}$ causes both natriuresis and diuresis. Conversely, $\text{PGF}_{2\alpha}$ may activate the renin-angiotensin system, contributing to elevated blood pressure.

There is substantial evidence for a role of the CYP epoxygenase products in regulating renal function, although their exact role in the human kidney remains unclear. Both 20-HETE and the EETs are generated in renal tissue. 20-HETE constricts the renal arteries, while EETs mediate vasodilation and natriuresis.

Eye. Although $\text{PGF}_{2\alpha}$ induces constriction of the iris sphincter muscle, its overall effect in the eye is to decrease intraocular pressure (IOP) by increasing the

aqueous humor outflow of the eye via the uveoscleral and trabecular meshwork pathway. A variety of FP receptor agonists have proven effective in the treatment of open-angle glaucoma, a condition associated with the loss of COX-2 expression in the pigmented epithelium of the ciliary body (see Chapter 64).

CNS. Although effects have been reported following injection of several PGs into discrete brain areas, the best established biologically active mediators are PGE₂ and PGD₂. The induction of fever by a range of endogenous and exogenous pyrogens appears to be mediated by PGE₂ (Smyth and FitzGerald, 2009). The hypothalamus regulates the body temperature set point, which is elevated by endogenous pyrogens such as interleukin (IL)-1 β , IL-6, tumor necrosis factor- α (TNF- α), and interferons. The initial phase of the thermoregulatory response to pyrogens is thought to be mediated by ceramide release in neurons of the preoptic area in the anterior hypothalamus, while the late response is mediated by coordinate induction of COX-2 and mPGES-1 in the endothelium of blood vessels in the preoptic hypothalamic area to form PGE₂. PGE₂ can cross the blood-brain barrier and acts on EP₃, and perhaps EP₁, on thermosensitive neurons. This triggers the hypothalamus to elevate body temperature by promoting an increase in heat generation and a decrease in heat loss. Exogenous PGF_{2 α} and PGI₂ induce fever but do not contribute to the pyretic response. PGD₂ and TxA₂ do not induce fever. PGD₂ also appears to act on arachnoid trabecular cells in the basal forebrain to mediate an increase in extracellular adenosine that, in turn, facilitates induction of sleep.

COX-2-derived prostanoids also have been implicated in several CNS degenerative disorders (e.g. Alzheimer's disease, Parkinson disease; see Chapter 22), although the therapeutic efficacy of blocking their synthesis or action remains to be established.

Pain. Inflammatory mediators, including LTs and PGs, increase the sensitivity of nociceptors and potentiate pain perception. Both PGE₂, through the EP₁ and EP₄, and PGI₂, via the IP, reduce the threshold to stimulation of nociceptors, causing "peripheral sensitization". Centrally, both COX-1 and COX-2 are expressed in the spinal cord under basal conditions and release PGs in response to peripheral pain stimuli. PGE₂, and perhaps also PGD₂, PGI₂, and PGF_{2 α} , can increase excitability in pain transmission neuronal pathways in the spinal cord, causing hyperalgesia and allodynia. Hyperalgesia also is produced by LTB₄. The release of these eicosanoids during the inflammatory process thus serves as an amplification system for the pain mechanism.

The role of PGE₂ and PGI₂ in inflammatory pain is discussed in more detail in Chapter 34.

Endocrine System. A number of endocrine tissues respond to PGs. In several species, the systemic administration of PGE₂ increases circulating concentrations of adrenocorticotrophic hormone (ACTH), growth hormone, prolactin, and gonadotropins. Other effects include stimulation of steroid production by the adrenals, stimulation of insulin release, and thyrotropin-like effects on the thyroid. The critical role of PGF_{2 α} in parturition relies on its ability to induce an oxytocin-dependent decline in progesterone levels. PGE₂ works as part of a positive-feedback loop to induce oocyte maturation required for fertilization during and after ovulation.

LOX metabolites also have endocrine effects. 12-HETE stimulates the release of aldosterone from the adrenal cortex and mediates a portion of the aldosterone release stimulated by AngII, but not that which occurs in response to ACTH.

Bone. PGs are strong modulators of bone metabolism. COX-1 is expressed in normal bone, while COX-2 is upregulated in certain settings, such as inflammation and during mechanical stress. PGE₂ stimulates bone formation by increasing osteoblastogenesis. Bone resorption also is mediated via PGE₂, through activation of osteoclasts.

Therapeutic Uses

Inhibitors and Antagonists. As a consequence of the important and diverse physiological roles of eicosanoids, mimicking their effects with stable agonists, inhibiting eicosanoid formation, and antagonizing eicosanoid receptors produce therapeutically useful responses. As outlined earlier in "Inhibitors of Eicosanoid Biosynthesis" and in Chapter 34, the nonselective tNSAIDs, and those with selective COX-2 inhibition, are used widely as anti-inflammatory drugs, whereas low-dose aspirin is employed frequently for cardioprotection. LT antagonists are useful clinically in the treatment of asthma, and FP agonists are used in the treatment of open-angle glaucoma (Chapter 64). EP agonists are used to induce labor and to ameliorate gastric irritation owing to tNSAIDs.

There are as of yet no potent selective antagonists of prostanoid receptors in clinical use. TP antagonists were abandoned as antiplatelet agents when it seemed like they would confer nothing superior to aspirin. Now that the clinical implications of suppressing PGI₂ are recognized, the partial suppression by even low doses of aspirin may confer an advantage on TP antagonists, as may blockade of receptor activation by unconventional

ligands such as oxidized lipids. DP₁ antagonists may be useful in offsetting the facial flushing associated with niacin. Orally active antagonists of LTC₄ and D₄, which block the CysLT₁ receptor, are used in the treatment of mild to moderately severe asthma (see Chapter 36). Their effectiveness in patients with aspirin-induced asthma also has been shown.

The use of eicosanoids or eicosanoid derivatives themselves as therapeutic agents is limited in part because systemic administration of prostanoids frequently is associated with significant adverse effects and because of their short t_{1/2} in the circulation. Despite these limitations, however, several prostanoids are of clinical utility in the following situations.

Therapeutic Abortion. The ability of PGEs, PGFs, and their analogs, to terminate pregnancy at any stage by promoting uterine contractions has been adapted to common clinical use. When given early in pregnancy, their action as abortifacients may be variable and often incomplete and accompanied by adverse effects. PGs appear, however, to be of value in missed abortion and molar gestation, and they have been used widely for the induction of midtrimester abortion. Dinoprostone, a synthetic preparation of PGE₂, is approved for inducing abortion in the second trimester of pregnancy, for missed abortion, for cervical ripening prior to induction of labor, and for managing benign hydatidiform moles. Several studies have shown that systemic or intravaginal administration of the PGE₁ analog misoprostol in combination with mifepristone (RU486) or methotrexate is highly effective in the termination of early pregnancy. An analog of PGF_{2α}, carboprost tromethamine, is used to induce second-trimester abortions and to control postpartum hemorrhage that is not responding to conventional methods.

PGE₂ or PGF_{2α} can induce labor at term. However, they may have more value when used to facilitate labor by promoting ripening and dilation of the cervix.

Gastric Cytoprotection. The capacity of several PG analogs to suppress gastric ulceration is a property of therapeutic importance. Misoprostol (CYTOTEC), a PGE₁ analog, is approved for prevention of NSAID-induced gastric ulcers. It is about as effective as the proton pump inhibitor omeprazole (Chapter 45).

Impotence. PGE₁ (alprostadil), given as an intracavernous injection (CAVERJECT, EDEX) or urethral suppository (MUSE) is a second-line treatment of erectile dysfunction. The erection lasts for 1-3 hours and is sufficient for sexual intercourse. PGE₁ has been superseded largely by the use of phosphodiesterase 5 (PDE5) inhibitors, such as sildenafil, tadalafil, and vardenafil (see Chapters 27 and 28).

Maintenance of Patent Ductus Arteriosus. The ductus arteriosus in neonates is highly sensitive to vasodilation by PGE₁. Maintenance of a patent ductus may be important hemodynamically in some neonates with congenital heart disease. PGE₁ (alprostadil, PROSTIN VR PEDIATRIC) is highly effective for palliative, but not definitive, therapy to maintain temporary patency until surgery can be performed. Apnea is observed in ~10% of neonates treated, particularly those who weigh <2 kg at birth.

Pulmonary Hypertension. Primary pulmonary hypertension is a rare idiopathic disease that mainly affects young adults. It leads to right-sided heart failure and frequently is fatal. Long-term therapy with PGI₂ (prostacyclin; epoprostenol, FLOLAN), via continuous intravenous infusion, improves symptoms and can delay or preclude the need for lung or heart-lung transplantation in a number of patients. Epoprostenol also has been used successfully to treat portopulmonary hypertension that arises secondary to liver disease, again with a goal of facilitating ultimate transplantation (Krowka et al., 1999). Several PGI₂ analogs with longer t_{1/2} have been developed and used clinically. Iloprost can be inhaled (VENTAVIS) or delivered by intravenous administration (not available in the U.S.). Treprostinil (REMODULN) (t_{1/2} ~4 hours) may be delivered by continuous subcutaneous or intravenous infusion.

Glaucoma. Latanoprost, a stable, long-acting PGF_{2α} derivative, was the first prostanoid used for glaucoma. The success of latanoprost has stimulated development of similar prostanoids with ocular hypotensive effects, and bimatoprost and travoprost are now available. These drugs act as agonists at the FP receptor and are administered as ophthalmic drops (Chapter 64).

PLATELET-ACTIVATING FACTOR

History. In 1971, Henson demonstrated that a soluble factor released from leukocytes caused platelets to aggregate. Benveniste and his coworkers characterized the factor as a polar lipid and named it *platelet-activating factor*. During this period, Muirhead described an antihypertensive polar renal lipid (APRL) produced by interstitial cells of the renal medulla that proved to be identical to PAF. Hanahan and coworkers then synthesized acetyl glyceryl ether phosphorylcholine (AGEPC) and determined that this phospholipid had chemical and biological properties identical to those of PAF. Independent determination of the structures of PAF and APRL showed them to be structurally identical to AGEPC. The commonly accepted name for this substance is platelet-activating factor; however, its actions extend far beyond platelets.

Chemistry and Biosynthesis. PAF is 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine.

PAF contains a long-chain alkyl group joined to the glycerol backbone in an ether linkage at position 1 and an acetyl group at position 2. PAF actually represents a family of phospholipids because the alkyl group at position 1 can vary in length from 12-18 carbon atoms. In human neutrophils, PAF consists predominantly of a mixture of the 16- and 18-carbon ethers, but its composition may change when cells are stimulated. The family is expanded by unregulated oxidative production to PAF-like lipids whose mode of action is analogous to PAF (Stafforini et al., 2003).

Analogous to the eicosanoids, PAF is not stored in cells but is synthesized in response to stimulation. The major pathway, termed the remodeling pathway, of PAF generation involves the precursor 1-*O*-alkyl-2-acyl-glycerophosphocholine, a lipid found in high concentrations in the membranes of many types of cells. The 2-acyl substituents include AA. PAF is synthesized from this substrate in two steps (Figure 33–5). The first involves the action of PLA₂, the initiating enzyme for eicosanoid biosynthesis, with the formation of 1-*O*-alkyl-2-lyso-glycerophosphocholine (lyso-PAF) and a free fatty acid (usually AA) (Prescott et al., 2000; Honda et al., 2002; Stafforini et al., 2003). Eicosanoid and PAF biosynthesis thus is closely coupled, and deletion of cPLA₂ in mice leads to an almost complete loss of both eicosanoid and PAF generation. The second, rate-limiting step is performed by the acetyl-coenzyme-A-lyso-PAF acetyltransferase. PAF synthesis also can occur *de novo*; a phosphocholine substituent is transferred to alkyl acetyl glycerol by a distinct lyso-glycerophosphate acetyl-coenzyme-A transferase. This pathway may contribute to physiological levels of PAF for normal cellular functions. The synthesis of PAF may be stimulated during antigen–antibody reactions or by a variety of agents, including chemotactic peptides, thrombin, collagen, and other autacoids; PAF also can stimulate its own formation. Both the phospholipase and acetyltransferase are Ca²⁺-dependent enzymes; thus, PAF synthesis is regulated by the availability of Ca²⁺.

The inactivation of PAF is catalyzed by PAF acetylhydrolases (PAF-AHs) (McIntyre et al., 2009) (Figure 33–5). This is a family of

Figure 33–5. Synthesis and degradation of platelet-activating factor (PAF). RCOO⁻ is a mixture of fatty acids but is enriched in arachidonic acid that may be metabolized to eicosanoids. CoA, coenzyme A.

four related Ca²⁺-independent phospholipases A₂ that show marked specificity for phospholipids with short acyl chains at the *sn*-2 position. Two PAF-AHs, which are group VII enzymes, are commonly known as plasma PAF-AH (or lipoprotein-associated PLA₂) and liver type II PAF-AH. The remaining two are known as type I and II intracellular PAF-AH. PAF is inactivated by PAF-AH-catalyzed hydrolysis of the acetyl group, generating Lyso-PAF, which is then converted to a 1-*O*-alkyl-2-acyl-glycerophosphocholine by an acyltransferase.

PAF is synthesized by platelets, neutrophils, monocytes, mast cells, eosinophils, renal mesangial cells, renal medullary cells, and vascular endothelial cells. Depending on cell type, PAF can either remain cell associated or be secreted. For example, PAF is released from monocytes but retained by leukocytes and endothelial cells. In endothelial cells, PAF is displayed on the surface for juxtacrine signaling and stimulates adherent leukocytes (Honda et al., 2002).

In addition to these enzymatic routes, PAF-like molecules can be formed from the oxidative fragmentation of membrane phospholipids (oxPLs) (Stafforini et al., 2003). These compounds are increased in settings of oxidant stress, such as cigarette smoking, and differ structurally from PAF in that they contain a fatty acid at the *sn*-1 position of glycerol joined through an ester bond and various short-chain acyl groups at the *sn*-2 position. oxPLs mimic the structure of PAF closely enough to bind to its receptor (see “Mechanism of Action of PAF”) and elicit the same responses. Unlike the synthesis of PAF, which is highly controlled, oxPL production is unregulated; degradation by PAF-AH, therefore, is necessary to suppress the toxicity of oxPLs. Levels of plasma PAF-AH are increased in colon cancer, cardiovascular disease, and stroke (Prescott et al., 2002), and polymorphisms have been associated with altered risk of cardiovascular events (Ninio et al., 2004). A common missense mutation in Japanese people is associated disproportionately with more severe asthma.

Mechanism of Action of PAF. Extracellular PAF exerts its actions by stimulating a specific GPCR (Honda et al., 2002). The PAF receptor’s strict recognition requirements, including a specific head group and specific atypical *sn*-2 residue, also are met by oxPLs. The PAF receptor couples to activation of the PLC-IP₃-Ca²⁺ pathway and to inhibition of adenylyl cyclase, via G_q and G_i, respectively. Activation of phospholipases A₂, C, and D give rise to second messengers. These include AA-derived PGs, TxA₂, or LTs, which may function as extracellular mediators of the effects of PAF. In addition, p38 MAP kinase is activated downstream of PAF-receptor coupling to G_q, while ERK activation can occur through a number of pathways, including coupling to G_q, G_o, or G_{βγ} or via transactivation of the epidermal growth factor receptor, leading to NF-κB activation (Stafforini et al., 2003). Thus, the PAF receptor couples to a variety of downstream signaling cascades in a cell-dependent manner.

PAF exerts many of its important pro-inflammatory actions without leaving its cell of origin. For example, PAF is synthesized in a regulated fashion by endothelial cells stimulated by inflammatory mediators. This PAF is presented on the surface of the endothelium, where it activates the PAF receptor on juxtaposed cells, including platelets, polymorphonuclear leukocytes, and monocytes, and acts cooperatively with P selectin to promote adhesion (Prescott et al., 2000). This function of PAF is important for orchestrating the interaction of platelets and circulating inflammatory cells with the inflamed endothelium.

Physiological and Pathological Functions of PAF. PAF generally is viewed as a mediator of pathological events and has been implicated in allergic asthma, endotoxic shock, acute pancreatitis, certain cancers, dermal inflammation, and inflammatory cardiovascular diseases such as atherosclerosis. Dysregulation of PAF signaling or degradation has been associated with some human diseases, aided by data from genetically modified animals.

Reproduction and Parturition. A role for PAF in ovulation, implantation, and parturition has been suggested by numerous studies. However, PAF receptor-deficient mice are normal reproductively, indicating that PAF may not be essential for reproduction.

Inflammatory and Allergic Responses. The pro-inflammatory actions of PAF, and its elaboration by endothelial cells, leukocytes, and mast cells under inflammatory conditions, are well characterized. The plasma concentration of PAF is increased in experimental anaphylactic shock, and the administration of PAF reproduces many of its signs and symptoms, suggesting a role for the autacoid in anaphylactic shock. Indeed, studies with PAF receptor-deficient mice confirm the actions of PAF, and PAF-like molecules, as dominant anaphylactic mediators. In addition, mice overexpressing the PAF receptor exhibit bronchial hyperreactivity and increased lethality when treated with endotoxin (Ishii et al., 2002). PAF-receptor knockout mice display milder anaphylactic responses to exogenous antigen challenge, including less cardiac instability, airway constriction, and alveolar edema; they are, however, still susceptible to endotoxic shock. Deletion of the PAF receptor augments the lethality of infection with gram-negative bacteria while improving host defense against gram-positive pneumococcal pneumonia. PAF receptor-overexpressing mice show increased airway responsiveness when challenged, an effect likely mediated through generation of TxA_2 and CysLTs (Ishii and Shimizu, 2000). PAF-AH deficiency is associated with asthma in some populations (Stafforini, 2009).

Despite the broad implications of these observations, the effects of PAF antagonists in the treatment of inflammatory and allergic disorders have been disappointing. Although PAF antagonists reverse the bronchoconstriction of anaphylactic shock and improve survival in animal models, the impact of these agents on animal models of asthma and inflammation is marginal. Similarly, in patients with asthma, PAF antagonists partially inhibit the bronchoconstriction induced by antigen challenge but not by challenges by methacholine, exercise, or inhalation of cold air. These results may reflect the complexity of these pathological conditions and the likelihood that other mediators contribute to the inflammation associated with these disorders.

Cardiovascular System. PAF is a potent vasodilator in most vascular beds; when administered intravenously, it causes hypotension in all species studied. PAF-induced vasodilation is independent of effects on sympathetic innervation, the renin-angiotensin system, or arachidonate metabolism and likely results from a combination of direct and indirect actions. PAF may, alternatively, induce vasoconstriction depending on the concentration, vascular bed, and involvement of platelets or leukocytes. For example, the intracoronary administration of very low concentrations of PAF increases coronary blood flow by a mechanism that involves the release of a platelet-derived vasodilator. Coronary blood flow is decreased at

higher doses by the formation of intravascular aggregates of platelets and/or the formation of TxA_2 . The pulmonary vasculature also is constricted by PAF, and a similar mechanism is thought to be involved.

Intradermal injection of PAF causes an initial vasoconstriction followed by a typical wheal and flare. PAF increases vascular permeability and edema in the same manner as histamine and bradykinin. The increase in permeability is due to contraction of venular endothelial cells, but PAF is more potent than histamine or bradykinin by three orders of magnitude.

Platelets. The PAF receptor is constitutively expressed on the surface of platelets. PAF potently stimulates platelet aggregation *in vitro* and *in vivo*. Although this is accompanied by the release of TxA_2 and the granular contents of the platelet, PAF does not require the presence of TxA_2 or other aggregating agents to produce this effect. The intravenous injection of PAF causes formation of intravascular platelet aggregates and thrombocytopenia.

Because PAF is synthesized by platelets and promotes aggregation, it was proposed as the mediator of COX-inhibitor-resistant, thrombin-induced aggregation. However, no bleeding or thrombotic phenotypes have been associated with deletion of the PAF receptor. In addition, PAF antagonists fail to block thrombin-induced aggregation, even though they prolong bleeding time and prevent thrombus formation in some experimental models. Thus, PAF may contribute to thrombus formation, but it does not function as an independent mediator of platelet aggregation.

Leukocytes. PAF is a potent and common activator of inflammatory cells, providing a point of convergence between the hemostatic and innate immune systems (Zimmerman et al., 2002). PAF stimulates a variety of responses in polymorphonuclear leukocytes (eosinophils, neutrophils, and basophils) when it is generated in both physiological and pathological situations. PAF stimulates PMNs to aggregate, degranulate, and generate free radicals and LTs. Because LTB_4 is more potent in inducing leukocyte aggregation, it may mediate the aggregatory effects of PAF. PAF is a potent chemotactic for eosinophils, neutrophils, and monocytes and promotes PMN-endothelial adhesion contributing, along with other adhesion molecular systems, to leukocyte rolling, tight adhesion, and migration through the endothelial monolayer. PAF also stimulates basophils to release histamine, activates mast cells, and induces cytokine release from monocytes. In addition, PAF promotes aggregation of monocytes and degranulation of eosinophils. When given systemically, PAF causes leukocytopenia, with neutrophils showing the greatest decline. Intradermal injection causes the accumulation of neutrophils and mononuclear cells at the site of injection. Inhaled PAF increases the infiltration of eosinophils into the airways.

Smooth Muscle. PAF generally contracts GI, uterine, and pulmonary smooth muscle. PAF enhances the amplitude of spontaneous uterine contractions; quiescent muscle contracts rapidly in a phasic fashion. These contractions are inhibited by inhibitors of PG synthesis. PAF does not affect tracheal smooth muscle but contracts airway smooth muscle. Most evidence suggests that another autacoid (e.g., LTC_4 or TxA_2) mediates this effect of PAF. When given by aerosol, PAF increases airway resistance as well as the responsiveness to other bronchoconstrictors. PAF also increases mucus secretion and the permeability of pulmonary microvessels; this results in fluid accumulation in the mucosal and submucosal regions of the bronchi and trachea.

Stomach. In addition to contracting the fundus of the stomach, PAF is the most potent known ulcerogen. When given intravenously, it causes hemorrhagic erosions of the gastric mucosa that extend into the submucosa.

Kidney. When infused intrarenally in animals, PAF decreases renal blood flow, glomerular filtration rate, urine volume, and excretion of Na⁺ without changes in systemic hemodynamics (Lopez-Novoa, 1999). These effects are the result of a direct action on the renal circulation. PAF exerts a receptor-mediated biphasic effect on afferent arterioles, dilating them at low concentrations and constricting them at higher concentrations. The vasoconstrictor effect appears to be mediated, at least in part, by COX products, whereas vasodilation is a consequence of the stimulation of NO production by endothelium.

Other. PAF receptor-overexpressing mice spontaneously develop melanocyte tumors. PAF, a potent mediator of angiogenesis, also has been implicated in breast and prostate cancer. PAF-AH deficiency has been associated with small increases in a range of cardiovascular and thrombotic diseases in some human populations (Stafforini, 2009). Administration of PAF-AH reduces injury-induced neointima formation and atherogenesis in genetically prone mice, suggesting a role for PAF in inflammatory cardiovascular disease.

Receptor Antagonists. Several experimental PAF-receptor antagonists exist that selectively inhibit the actions of PAF *in vivo* and *in vitro*. One would expect a PAF-receptor antagonist to be a potent anti-inflammatory agent that might be useful in the therapy of disorders such as asthma, sepsis, and other diseases in which PAF is postulated to play a role. However, trials in humans have been disappointing, and the clinical efficacy of PAF antagonists has yet to be realized. Plasma PAF-AH activity modulates the acute and chronic inflammatory response in animal models, indicating that it may provide an alternative inflammatory drug target. However, humans that are homozygous for a mutant PAF-AH, leading to undetectable levels of plasma PAF-AH, do not display rampant inflammation (McIntyre et al., 2009), and thus far, PAF-AH has not been translated into a meaningful therapeutic approach.

Anti-Inflammatory, Antipyretic, and Analgesic Agents; Pharmacotherapy of Gout

Tilo Grosser, Emer Smyth,
and Garret A. FitzGerald

This chapter describes the nonsteroidal anti-inflammatory drugs (NSAIDs) used to treat inflammation, pain, and fever and the drugs used for hyperuricemia and gout.

Most currently available traditional NSAIDs (tNSAIDs) act by inhibiting the prostaglandin (PG) G/H synthase enzymes, colloquially known as the cyclooxygenases (COXs; see Chapter 33). The inhibition of cyclooxygenase-2 (COX-2) is thought to mediate, in large part, the antipyretic, analgesic, and anti-inflammatory actions of tNSAIDs, while the simultaneous inhibition of cyclooxygenase-1 (COX-1) largely but not exclusively accounts for unwanted adverse effects in the GI tract. Selective inhibitors of COX-2 (celecoxib, etoricoxib, lumiracoxib) are a subclass of NSAIDs that are also discussed. Aspirin, which irreversibly acetylates COX, is discussed, along with several structural subclasses of tNSAIDs, including propionic acid derivatives (ibuprofen, naproxen), acetic acid derivatives (indomethacin), and enolic acids (piroxicam), all of which compete in a reversible manner with the arachidonic acid (AA) substrate at the active site of COX-1 and COX-2. Acetaminophen (paracetamol) is a weak anti-inflammatory drug; it is effective as an antipyretic and analgesic agent at typical doses that partly inhibit COXs. Acetaminophen has fewer GI side effects than the tNSAIDs.

History. The history of aspirin provides an interesting example of the translation of a compound from the realm of herbal folklore to contemporary therapeutics. The use of willow bark and leaves to relieve fever has been attributed to Hippocrates but was most clearly documented by Edmund Stone in a 1763 letter to the president of The Royal Society. Similar properties were attributed to potions from meadowsweet (*Spiraea ulmaria*), from which the name aspirin is

derived. Salicin was crystallized in 1829 by Leroux, and Pina isolated salicylic acid in 1836. In 1859, Kolbe synthesized salicylic acid, and by 1874, it was being produced industrially. It soon was being used for rheumatic fever, gout, and as a general antipyretic. However, its unpleasant taste and adverse GI effects made it difficult to tolerate for more than short periods. In 1899, Hoffmann, a chemist at Bayer Laboratories, sought to improve the adverse-effect profile of salicylic acid (which his father was taking with difficulty for arthritis). Hoffmann came across the earlier work of the French chemist, Gerhardt, who had acetylated salicylic acid in 1853, apparently ameliorating its adverse-effect profile, but without improving its efficacy, and therefore abandoned the project. Hoffmann resumed the quest, and Bayer began testing acetylsalicylic acid (ASA) in animals by 1899—the first time that a drug was tested on animals in an industrial setting—and proceeded soon thereafter to human studies and the marketing of aspirin.

Acetaminophen was first used in medicine by von Mering in 1893. However, it gained popularity only after 1949, when it was recognized as the major active metabolite of both acetanilide and phenacetin. Acetanilide is the parent member of this group of drugs. It was introduced into medicine in 1886 under the name antifebrin by Cahn and Hepp, who had discovered its antipyretic action accidentally. However, acetanilide proved to be excessively toxic. A number of chemical derivatives were developed and tested. One of the more satisfactory of these was phenacetin. It was introduced into therapy in 1887 and was extensively employed in analgesic mixtures until it was implicated in analgesic-abuse nephropathy, hemolytic anemia, and bladder cancer; it was withdrawn in the 1980s. Discussion of its pharmacology can be found in earlier editions of this textbook.

Inflammation, Pain, and Fever

Inflammation. The inflammatory process is the response to an injurious stimulus. It can be evoked by a wide variety of noxious agents (e.g., infections, antibodies, physical injuries). The ability to mount an inflammatory response is essential for survival in the

face of environmental pathogens and injury; in some situations and diseases, the inflammatory response may be exaggerated and sustained without apparent benefit and even with severe adverse consequences. No matter what the initiating stimulus, the classic inflammatory symptoms include calor (warmth), dolor (pain), rubor (redness), and tumor (swelling). The inflammatory response is characterized mechanistically by a transient local vasodilation and increased capillary permeability, infiltration of leukocytes and phagocytic cells, and tissue degeneration and fibrosis.

Many molecules are involved in the promotion and resolution of the inflammatory process (Nathan, 2002). Histamine was one of the first identified mediators of the inflammatory process. Although several H_1 histamine receptor antagonists are available, they are useful only for the treatment of vascular events in the early transient phase of inflammation (see Chapter 32). Bradykinin and 5-hydroxytryptamine (serotonin, 5-HT) also may play a role, but their antagonists ameliorate only certain types of inflammatory response (see Chapter 32). Leukotrienes (LTs) exert pro-inflammatory actions and LT-receptor antagonists (montelukast and zafirlukast) and have been approved for the treatment of asthma (see Chapters 33 and 36). Another lipid autacoid, platelet-activating factor (PAF), has been implicated as an important mediator of inflammation; however, inhibitors of PAF synthesis and PAF-receptor antagonists have proven disappointing in the treatment of inflammation (see Chapter 33).

Prostanoid biosynthesis is significantly increased in inflamed tissue. Inhibitors of the COXs, which depress prostanoid formation, are effective and widely used anti-inflammatory agents, highlighting the general role of prostanoids as pro-inflammatory mediators. The rapid induction of COX-2 in inflamed tissue and infiltrating cells provided a rationale for the development of selective COX-2 inhibitors for treatment of inflammation (see Chapter 33). Although COX-2 is the major source of pro-inflammatory prostanoids, COX-1 also contributes (McAdam et al., 2000). Both COX isozymes are expressed in circulating inflammatory cells *ex vivo*, and COX-1 accounts for ~10-15% of the PG formation induced by lipopolysaccharide in volunteers. Impaired inflammatory responses have been reported in both COX-1- and COX-2-deficient mouse models, although they diverge in time course and intensity (Langenbach et al., 1999; Ballou et al., 2000; Yu et al., 2005). Human data are compatible with the concept that COX-1-derived products play a dominant role in the initial phase of an acute inflammatory response, while COX-2 is upregulated within several hours.

Prostaglandin E_2 (PGE_2) and prostacyclin (PGI_2) are the primary prostanoids that mediate inflammation. They increase local blood flow, vascular permeability,

and leukocyte infiltration through activation of their respective receptors, EP_2 and IP (see Table 33–1 and Figure 33–4). PGD_2 , a major product of mast cells, contributes to inflammation in allergic responses, particularly in the lung. Activation of its DP_1 receptor increases perfusion and vascular permeability and promotes T_H2 cell differentiation. PGD_2 also can activate mature T_H2 cells and eosinophils via its DP_2 receptor (Pettipher et al., 2007). DP_2 antagonists may prove useful in the treatment of airway inflammation.

Activation of endothelial cells plays a key role in “targeting” circulating cells to inflammatory sites. Cell adhesion occurs by recognition of cell-surface glycoproteins and carbohydrates on circulating cells due to the augmented expression of adhesion molecules on resident cells. Thus, endothelial activation results in leukocyte adhesion as the leukocytes recognize newly expressed L- and P-selectin; other important interactions include those of endothelial-expressed E-selectin with sialylated Lewis X and other glycoproteins on the leukocyte surface and endothelial intercellular adhesion molecule (ICAM)-1 with leukocyte integrins.

The recruitment of inflammatory cells to sites of injury also involves the concerted interactions of several types of soluble mediators. These include the complement factor C5a, PAF, and the eicosanoid LTB_4 (see Chapter 33). All can act as chemotactic agonists. Several cytokines also play essential roles in orchestrating the inflammatory process, especially tumor necrosis factor (TNF) (Dempsey et al., 2003) and interleukin-1 (IL-1) (O’Neill, 2008). They are secreted by monocytes, macrophages, adipocytes, and other cells. Working in concert with each other and various cytokines and growth factors (such as IL-6, IL-8, and granulocyte-macrophage colony-stimulating factor [GM-CSF]; see Chapters 32, 33, and 35), they induce gene expression and protein synthesis—including expression of COX-2, adhesion molecules, and acute-phase proteins—in a variety of cells to mediate and promote inflammation.

TNF is composed of two closely related proteins: mature TNF (TNF- α) and lymphotoxin (TNF- β), both of which are recognized by the TNF receptors, a 75-kd type 1 receptor and a 55-kd type 2 receptor (Dempsey et al., 2003). TNF- α blockers (see Chapter 35) are used to treat inflammatory conditions, including rheumatoid arthritis, juvenile idiopathic arthritis, psoriasis and psoriatic arthritis, ankylosing spondylitis, and Crohn’s disease. TNF- α blockers fall into the category of disease-modifying anti-rheumatic drugs (DMARDs) because they reduce the disease activity of rheumatoid arthritis and retard the progression of arthritic tissue destruction. NSAIDs generally are not considered DMARDs.

IL-1 comprises two distinct polypeptides (IL-1 α and IL-1 β) that bind to an 80-kd IL-1 receptor type 1 and a 68-kd IL-1 receptor type 2, which are present on different cell types (O'Neill, 2008). Plasma IL-1 levels are increased in patients with active inflammation. A naturally occurring IL-1 receptor antagonist (IL-1ra) competes with IL-1 for receptor binding and blocks IL-1 activity *in vitro* and *in vivo*. IL-1ra often is found in high levels in patients with various infections or inflammatory conditions and may act to limit the extent of an inflammatory response. Clinical studies suggest that the administration of a recombinant form of human IL-1ra (anakinra; see Chapter 35) antagonizes IL-1 action at its receptor and thereby inhibits the progression of structural damage associated with active rheumatoid arthritis and other inflammatory conditions. Canakinumab (ILARIS) is an IL-1 β monoclonal antibody recently approved for two forms of the cryopyrin-associated periodic syndrome: familial cold auto-inflammatory syndrome and Muckle-Wells syndrome (see Chapter 35).

Other cytokines and growth factors (e.g., IL-2, IL-6, IL-8, GM-CSF) contribute to manifestations of the inflammatory response. The concentrations of many of these factors are increased in the synovia of patients with inflammatory arthritis. Glucocorticoids interfere with the synthesis and actions of cytokines, such as IL-1 or TNF- α (see Chapter 35). Although some of the actions of these cytokines are accompanied by the release of PGs and thromboxane A₂ (TxA₂), COX inhibitors appear to block only their pyrogenic effects. In addition, many of the actions of the PGs are inhibitory to the immune response, including suppression of the function of helper T cells and B cells and inhibition of the production of IL-1 (see Chapter 33). Other cytokines and growth factors counter the effects and initiate resolution of inflammation. These include transforming growth factor β_1 (TGF- β_1), which increases extracellular matrix formation and acts as an immunosuppressant; IL-10, which decreases cytokine and PGE₂ formation by inhibiting monocytes; and interferon gamma (IFN- γ), which possesses myelosuppressive activity and inhibits collagen synthesis and collagenase production by macrophages.

Many cytokines, including IL-1 and TNF- α , have been found in the rheumatoid synovium. Rheumatoid arthritis appears to be an autoimmune disease driven largely by activated T cells, giving rise to T cell–derived cytokines, such as IL-1 and TNF- α . Activation of B cells and the humoral response also are evident, although most of the antibodies generated are immunoglobulins G of unknown specificity, apparently elicited by polyclonal activation of B cells rather than from a response to a specific antigen (Brennan and McInnes, 2008).

Pain. Nociceptors, peripheral terminals of primary afferent fibers that sense pain, can be activated by various stimuli, such as heat, acids, or pressure. Inflammatory mediators released from non-neuronal cells during tissue

injury increase the sensitivity of nociceptors and potentiate pain perception. Some of the main components of this inflammatory “mélange” are bradykinin, H⁺, neurotransmitters such as serotonin and ATP, neurotrophins (nerve growth factor), LTs, and PGs. Cytokines appear to liberate PGs and some of the other mediators. Neuropeptides, such as substance P and calcitonin gene-related peptide (CGRP), also may be involved in eliciting pain (see Chapter 18).

PGE₂ and PGI₂ reduce the threshold to stimulation of nociceptors, causing *peripheral sensitization* (Lopshire and Nicol, 1998; Pulichino et al., 2006). Thus, PGE₂ promotes—probably via its receptors, EP₁ and EP₄—the phosphorylation of transient receptor potential V₁ and other ion channels on nociceptors and increases their terminal membrane excitability. Reversal of peripheral sensitization is thought to represent the mechanistic basis for the peripheral component of the analgesic activity of NSAIDs. NSAIDs also have important central actions in the spinal cord and brain. Both COX-1 and COX-2 are expressed in the spinal cord under basal conditions and release PGs in response to peripheral pain stimuli (Vanegas and Schaible, 2001). Centrally active PGE₂ and perhaps also PGD₂, PGI₂, and PGF_{2 α} contribute to *central sensitization*, an increase in excitability of spinal dorsal horn neurons that causes hyperalgesia and allodynia in part by disinhibition of glycinergic pathways (Reinold et al., 2005).

Basal COX-2, expressed in both neurons and glia cells, contributes to central sensitization in the early phase of peripheral inflammation. COX-2 is upregulated widely in the spinal cord within a few hours to contribute to prolonged central sensitization (Samad et al., 2001). A role for COX-1 in nociception has been implicated by COX-1–deleted mice, which show increased tolerance to pain stimuli (Ballou et al., 2000). This isoform is predominant in neurons of dorsal root ganglia. Central sensitization reflects the plasticity of the nociceptive system that is invoked by injury. This usually is reversible within hours to days following adequate responses of the nociceptive system (e.g., in postoperative pain). However, chronic inflammatory diseases may cause persistent modification of the architecture of the nociceptive system, which may lead to long-lasting changes in its responsiveness. These mechanisms contribute to chronic pain.

Fever. Regulation of body temperature requires a delicate balance between the production and loss of heat; the hypothalamus regulates the set point at which body temperature is maintained. This set point is elevated in fever, reflecting an infection, or resulting from tissue damage, inflammation, graft rejection, or malignancy. These conditions all enhance formation of cytokines such as IL-1 β , IL-6, TNF- α , and interferons, which act as

endogenous pyrogens. The initial phase of the thermoregulatory response to such pyrogens is thought to be mediated by ceramide release in neurons of the preoptic area in the anterior hypothalamus (Sanchez-Alavez et al., 2006). The late response is mediated by coordinate induction of COX-2 and microsomal PGE synthase-1 (mPGES-1) in the endothelium of blood vessels in the preoptic hypothalamic area to form PGE₂ (Engblom et al., 2003). PGE₂ can cross the blood-brain barrier and acts on EP₃ and perhaps EP₁ receptors on thermosensitive neurons. This triggers the hypothalamus to elevate body temperature by promoting an increase in heat generation and a decrease in heat loss. NSAIDs suppress this response by inhibiting PGE₂ synthesis.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

NSAIDs traditionally are grouped by their chemical characteristics. Following the development of the

selective COX-2 inhibitors, the classification into tNSAIDs, which inhibit both COX-1 and COX-2, and COX-2-selective NSAIDs, emerged. Initially, only agents designed specifically for the purpose of COX-2-selective inhibition—colloquially termed the coxibs—were attributed to the group of COX-2-selective NSAIDs. However, some older NSAIDs (e.g., diclofenac, meloxicam, nimesulide) show a degree of selectivity for COX-2 that is similar to that of the first coxib, celecoxib. Thus, these drugs might better be classified as COX-2-selective NSAIDs, although this is not, as yet, commonplace (Figure 34–1). Other classifications of NSAIDs were developed based on $t_{1/2}$, such as those with a shorter (<6 hours) or longer (>10 hours) $t_{1/2}$ (Figure 34–1).

Most NSAIDs are competitive, reversible, active site inhibitors of the COX enzymes. However, aspirin (ASA) acetylates the isozymes and inhibits them irreversibly; thus, aspirin often is distinguished from the tNSAIDs. Similarly, acetaminophen, which is antipyretic

Figure 34–1. Classification of NSAIDs by chemical similarity (panel A), cyclooxygenase (COX) isoform selectivity (panel B), and plasma $t_{1/2}$ (panel C). The COX selectivity chart is plotted from data published in Warner et al., 1999, and FitzGerald and Patrono, 2001. tNSAIDs, traditional nonsteroidal anti-inflammatory drugs.

and analgesic but largely devoid of anti-inflammatory activity, also is conventionally segregated from the group, despite sharing many properties with tNSAIDs relevant to its clinical action *in vivo*.

Chemistry. NSAIDs are a chemically heterogeneous group of compounds, which nevertheless share certain therapeutic actions and adverse effects. The class includes derivatives of salicylic acid (e.g., aspirin, diflusalin), propionic acid (e.g., naproxen, ibuprofen, flurbiprofen, ketoprofen), acetic acid (e.g., indomethacin, etodolac, diclofenac, ketorolac), enolic acid (e.g., piroxicam, phenylbutazone), fenamic acid (e.g., mefenamic acid, meclofenamic acid), alkanones (nabumetone), and diaryl heterocyclic compounds (e.g., celecoxib, valdecoxib, rofecoxib, etoricoxib) (Figure 34–1).

The vast majority of tNSAID compounds are organic acids with relatively low pK_a values (Figure 34–1). Even the non-acidic parent drug nabumetone is converted to an active acetic acid derivative *in vivo*. As organic acids, the compounds generally are well absorbed orally, highly bound to plasma proteins, and excreted either by glomerular filtration or by tubular secretion. They also accumulate in sites of inflammation, where the pH is lower, potentially confounding the relationship between plasma concentrations and duration of drug effect. Most COX-2–selective NSAIDs are diaryl heterocyclic compounds with a relatively bulky side group, which aligns with a large side pocket in the AA binding channel of COX-2 but hinders its optimal orientation in the smaller binding channel of COX-1 (Figure 34–2) (Smith et al., 2000). Both tNSAIDs and the COX-2–selective NSAIDs generally are hydrophobic drugs, a feature that allows them to access the hydrophobic arachidonate binding channel and results in shared pharmacokinetic characteristics. Again, aspirin and acetaminophen are exceptions to this rule.

Mechanism of Action

Cyclooxygenase Inhibition. The principal therapeutic effects of NSAIDs derive from their ability to inhibit PG

production. The first enzyme in the PG synthetic pathway is COX, also known as PG G/H synthase. This enzyme converts AA to the unstable intermediates PGG₂ and PGH₂ and leads to the production of the prostanoids, TxA₂, and a variety of PGs (see Chapter 33).

There are two forms of COX, COX-1 and COX-2. COX-1, expressed constitutively in most cells, is the dominant (but not exclusive) source of prostanoids for housekeeping functions, such as gastric epithelial cytoprotection and hemostasis. Conversely, COX-2, induced by cytokines, shear stress, and tumor promoters, is the more important source of prostanoid formation in inflammation and perhaps in cancer (see Chapter 33). However, both enzymes contribute to the generation of autoregulatory and homeostatic prostanoids, and both can contribute to prostanoid formation in syndromes of human inflammation and pain (see “Inflammation and Pain” at the beginning of this chapter). Importantly, COX-1 is expressed as the dominant, constitutive isoform in gastric epithelial cells and is thought to be the major source of cytoprotective PG formation. Inhibition of COX-1 at this site is thought to account largely for the gastric adverse events that complicate therapy with tNSAIDs, thus providing the rationale for the development of NSAIDs specific for inhibition of COX-2 (FitzGerald and Patrono, 2001).

Aspirin and NSAIDs inhibit the COX enzymes and PG production; they do not inhibit the lipoygenase (LOX) pathways of AA metabolism and hence do not suppress LT formation (see Chapter 33). Glucocorticoids suppress the induced expression of

Figure 34–2. Structural basis for cyclooxygenase-2 (COX-2)-selective inhibition. The active centers of COX-1 and COX-2 are shown crystallized with the nonselective inhibitor flurbiprofen (COX-1) (Picot et al., 1994) and the experimental COX-2 inhibitor SC-558 (Kurumbail et al., 1996). The active center of COX-2 is characterized by a larger side pocket, which can accommodate molecules with bulkier side chains than COX-1. (Courtesy of Dr. Vineet Sangar.)

COX-2, and thus COX-2-mediated PG production. They also inhibit the action of PLA₂, which releases AA from the cell membrane. These effects contribute to the anti-inflammatory actions of glucocorticoids (see Chapter 35).

At higher concentrations, NSAIDs also are known to reduce production of superoxide radicals, induce apoptosis, inhibit the expression of adhesion molecules, decrease NO synthase, decrease pro-inflammatory cytokines (e.g., TNF- α , IL-1), modify lymphocyte activity, and alter cellular membrane functions *in vitro*. However, there are differing opinions as to whether any of these actions might contribute to the anti-inflammatory activity of NSAIDs (Vane and Botting, 1998) at the concentrations attained during clinical dosing. The hypothesis that their anti-inflammatory actions in humans derive solely from COX inhibition alone has not been rejected based on current evidence.

Observational studies suggest that acetaminophen, which is a very weak anti-inflammatory agent at the typical dose of 1000 mg, is associated with a reduced incidence of GI adverse effects compared to tNSAIDs. At this dose, acetaminophen inhibits both COXs by ~50%. The ability of acetaminophen to inhibit the enzyme is conditioned by the peroxide tone of the immediate environment (Boutaud et al., 2002). This may partly explain the poor anti-inflammatory activity of acetaminophen, because sites of inflammation usually contain increased concentrations of leukocyte-generated peroxides.

Irreversible Cyclooxygenase Inhibition by Aspirin.

Aspirin covalently modifies COX-1 and COX-2, irreversibly inhibiting COX activity. This is an important distinction from all the NSAIDs because the duration of aspirin's effects is related to the turnover rate of COXs in different target tissues. The duration of effect of non-aspirin NSAIDs, which inhibit the active sites of the COX enzymes competitively, relates to the time course of drug disposition. The importance of enzyme turnover in recovery from aspirin action is most notable in platelets, which, being anucleate, have a markedly limited capacity for protein synthesis. Thus, the consequences of inhibition of platelet COX-1 (COX-2 is expressed in megakaryocytes and perhaps immature platelet forms) last for the lifetime of the platelet. Inhibition of platelet COX-1-dependent TxA₂ formation therefore is cumulative with repeated doses of aspirin (at least as low as 30 mg/day) and takes ~8-12 days—the platelet turnover time—to recover fully once therapy has been stopped. Importantly, even a partially recovered platelet pool—just a few days after the last aspirin dose—may afford recovery of sufficient hemostatic integrity for some types of elective surgery to be performed. However, such a partial platelet function also may predispose noncompliant patients to thrombotic events.

COXs are configured such that the active site is accessed by the AA substrate via a hydrophobic channel. Aspirin acetylates serine 529 of COX-1, located high up in the hydrophobic channel. Interposition of the bulky acetyl residue prevents the binding of AA to the active site of the enzyme and thus impedes the ability of the enzyme to make PGs. Aspirin acetylates a homologous serine at position 516 in COX-2. Although covalent modification of COX-2 by aspirin also blocks the COX activity of this isoform, an interesting property not shared by COX-1 is that acetylated COX-2 synthesizes 15(*R*)-hydroxyeicosatetraenoic acid [15(*R*)-HETE]. This may be metabolized, at least *in vitro*, by 5-LOX to yield 15-epi-lipoxin A₄, which has potent anti-inflammatory properties (see Chapter 33). Repeated doses of aspirin that acutely do not completely inhibit platelet COX-1-derived TxA₂ can exert a cumulative effect with complete blockade. This has been shown in randomized trials for doses as low as 30 mg/day. However, most of the clinical trials demonstrating cardioprotection from low-dose aspirin have used doses in the range of 75-81 mg/day.

The unique sensitivity of platelets to inhibition by such low doses of aspirin is related to their presystemic inhibition in the portal circulation before aspirin is deacetylated to salicylate on first pass through the liver (Pedersen and FitzGerald, 1984). In contrast to aspirin, salicylic acid has no acetylating capacity. It is a weak, reversible, competitive inhibitor of COX. Salicylic acid derivatives, rather than the acid, are available for clinical use. The lack of acetylation often is used as justification to prefer trisalicylate or salsalate over aspirin in presurgical patients. High doses of salicylate inhibit the activation of NF κ B *in vitro*, but the relevance of this property to the concentrations attained *in vivo* is not clear (Yin et al., 1998). Salicylic acid also may inhibit the expression of COX-2 by interfering with the binding of CCAAT/enhancer binding protein (C/EBP) β transcription factor to the COX-2 promoter (Cieslik et al., 2002). This was observed *in vitro* at concentrations of salicylic acid that are attained in humans.

Selective Inhibition of Cyclooxygenase-2. The therapeutic use of the tNSAIDs is limited by their poor GI tolerability. Chronic users are prone to experience GI irritation in $\leq 20\%$ of cases. Following the discovery of COX-2, it was proposed that the constitutively expressed COX-1 was the predominant source of cytoprotective PGs formed by the GI epithelium. Because its expression is regulated by cytokines and mitogens, COX-2 was thought to be the dominant source of PG formation in inflammation and cancer. Thus, selective inhibitors of COX-2 were developed based on the hypothesis that they would afford efficacy similar to tNSAIDs with better GI tolerability (FitzGerald and Patrono, 2001). Six COX-2 inhibitors specifically designed for such purpose, the coxibs, were initially approved for use in the U.S. or E.U.: celecoxib, rofecoxib, valdecoxib and its prodrug parecoxib, etoricoxib, and lumiracoxib. Most coxibs have been either severely restricted in their use or withdrawn from the market in view of their adverse event profile. Celecoxib

(CELEBREX) currently is the only COX-2 inhibitor licensed for use in the U.S.

The relative degree of selectivity for COX-2 inhibition is lumiracoxib = etoricoxib > valdecoxib = rofecoxib >> celecoxib (Figure 34–1). Although there were differences in relative hierarchies, depending on whether screens were performed using recombinantly expressed enzymes, cells, or whole-blood assays, most tNSAIDs expressed similar selectivity for inhibition of the two enzymes. Some compounds, conventionally thought of as tNSAIDs—diclofenac, meloxicam, and nimesulide (not available in the U.S.)—exhibit selectivity for COX-2 that is close to that of celecoxib *in vitro* (Figure 34–1) (Warner et al., 1999; FitzGerald and Patrono, 2001). Indeed, meloxicam achieved approval in some countries as a selective inhibitor of COX-2. Thus, selectivity for COX-2 should not be viewed as an absolute category; the isoform selectivity for COX-2 (just like selectivity for β_1 adrenergic receptors) is a continuous rather than a discreet variable, as illustrated in Figure 34–1.

Absorption, Distribution, and Elimination

Absorption. Most NSAIDs are rapidly absorbed following oral ingestion, and peak plasma concentrations usually are reached within 2–3 hours. All COX-2–selective NSAIDs are well absorbed, but peak concentrations are achieved with lumiracoxib and etoricoxib in ~1 hour compared to 2–4 hours with the other agents. The poor aqueous solubility of most NSAIDs often is reflected by a less than proportional increase in area under the curve (AUC) of plasma concentration–time curves, due to incomplete dissolution, when the dose is increased. Food intake may delay absorption and sometimes decreases systemic availability (i.e., fenoprofen, sulindac). Antacids, commonly prescribed to patients on NSAID therapy, variably delay, but rarely reduce, absorption. Most interaction studies performed with proton pump inhibitors suggest that relevant changes in NSAID kinetics are unlikely. Little information exists regarding the absolute oral bioavailability of many NSAIDs, as solutions suitable for intravenous administration often are not available. Some compounds (e.g., diclofenac, nabumetone) undergo first-pass or presystemic elimination. Acetaminophen is metabolized to a small extent during absorption. Aspirin begins to acetylate platelets within minutes of reaching the presystemic circulation.

Distribution. Most NSAIDs are extensively bound to plasma proteins (95–99%), usually albumin. Plasma protein binding often is concentration dependent (i.e., naproxen, ibuprofen) and saturable at high concentrations. Conditions that alter plasma protein concentration may result in an increased free drug fraction with potential toxic effects. Highly protein bound NSAIDs have the potential to displace other drugs, if they compete for the same binding sites. Most NSAIDs are distributed widely throughout the body and readily penetrate arthritic joints, yielding synovial fluid concentrations in the range of half the plasma concentration (i.e., ibuprofen, naproxen, piroxicam). Some substances yield synovial drug concentrations similar to (i.e., indomethacin), or even exceeding (i.e., tolmetin), plasma concentrations. Most NSAIDs achieve sufficient concentrations in the CNS to have a central analgesic effect. Celecoxib is particularly lipophilic, so it accumulates in fat and is readily transported into the CNS. Lumiracoxib is more acidic than other

COX-2–selective NSAIDs, which may favor its accumulation at sites of inflammation. Multiple NSAIDs are marketed in formulations for topical application on inflamed or injured joints. However, direct transport of topically applied NSAIDs into inflamed tissues and joints appears to be minimal, and detectable concentrations in synovial fluid of some agents (i.e., diclofenac) following topical use are primarily attained via dermal absorption and systemic circulation.

Elimination. Plasma $t_{1/2}$ varies considerably among NSAIDs. For example, ibuprofen, diclofenac, and acetaminophen have relatively rapid elimination ($t_{1/2}$ of 1–4 hours), while piroxicam has a $t_{1/2}$ of ~50 hours at steady state that can increase to up to 75 hours in the elderly. Published estimates of the $t_{1/2}$ of COX-2–selective NSAIDs vary (2–6 hours for lumiracoxib, 6–12 hours for celecoxib, and 20–26 hours for etoricoxib). However, peak plasma concentrations of lumiracoxib at marketed doses considerably exceed those necessary to inhibit COX-2, suggesting an extended pharmacodynamic $t_{1/2}$. Hepatic biotransformation and renal excretion is the principal route of elimination of the majority of NSAIDs. Some have active metabolites (e.g., fenbufen, nabumetone, meclofenamic acid, sulindac). Elimination pathways frequently involve oxidation or hydroxylation (Table 34–1). Acetaminophen, at therapeutic doses, is oxidized only to a small fraction to form traces of the highly reactive metabolite, *N*-acetyl-*p*-benzoquinone imine (NAPQI). When overdosed (usually >10 g of acetaminophen), however, the principal metabolic pathways are saturated, and hepatotoxic NAPQI concentrations can be formed (see Chapters 4 and 6). Rarely, other NSAIDs also may be complicated by hepatotoxicity (e.g., diclofenac, lumiracoxib). Several NSAIDs or their metabolites are glucuronidated or otherwise conjugated. In some cases, such as the propionic acid derivatives naproxen and ketoprofen, the glucuronide metabolites can hydrolyze back to form the active parent drug when the metabolite is not removed efficiently due to renal insufficiency or competition for renal excretion with other drugs. This may prolong elimination of the NSAID significantly. NSAIDs usually are not removed by hemodialysis due to their extensive plasma protein binding; salicylic acid is an exemption to this rule. In general, NSAIDs are not recommended in the setting of advanced hepatic or renal disease due to their adverse pharmacodynamic effects.

Therapeutic Uses

All NSAIDs, including selective COX-2 inhibitors, are antipyretic, analgesic, and anti-inflammatory, with the exception of acetaminophen, which is antipyretic and analgesic but is largely devoid of anti-inflammatory activity.

Inflammation. NSAIDs find their chief clinical application as anti-inflammatory agents in the treatment of musculoskeletal disorders, such as rheumatoid arthritis and osteoarthritis. In general, NSAIDs provide mostly symptomatic relief from pain and inflammation associated with the disease and are not considered to be DMARDs. A number of NSAIDs are approved for the treatment of ankylosing spondylitis and gout. The use of NSAIDs for mild arthropathies, together with rest

Classification and Comparison of Nonsteroidal Analgesics

CLASS/DRUG (SUBSTITUTION)	PHARMACOKINETICS		DOSING ^d		COMMENTS	COMPARED TO ASPIRIN
Salicylates						
Aspirin (acetyl ester)	Peak C _p ^a Protein binding Metabolites ^b t _{1/2} ^c , therapeutic t _{1/2} , toxic dose	1 hour 80-90% Salicylic acid 2-3 hours 15-30 hours	Antiplatelet Pain/fever Rheumatic fever Children	40-80 mg/day 325-650 mg every 4-6 hours 1 g every 4-6 hours 10 mg/kg every 4-6 hours	Permanent platelet COX-1 inhibition (acetylation) Main side effects: GI, increased bleeding time, hypersensitivity Avoid in children with acute febrile illness	
Diflunisal (defluoro- phenyl)	Peak C _p Protein binding Metabolites t _{1/2}	2-3 hours 99% Glucuronide 8-12 hours		250-500 mg every 8-12 hours	Not metabolized to salicylic acid Competitive COX inhibitor Excreted into breast milk	Analgesic and anti- inflammatory effects 4-5 times more potent Antipyretic effect weaker Fewer platelet and GI side effects
Para-aminophenol derivative						
Acetaminophen	Peak C _p Protein binding Metabolites t _{1/2}	30-60 minutes 20-50% Glucuronide conjugates (60%); sulfuric acid conjugates (35%) 2 hours		10-15 mg/kg every 4 hours (maximum of 5 doses/24 hours)	Weak nonspecific inhibitor at common doses Potency may be modulated by peroxides Overdose leads to production of toxic metabolite and liver necrosis	Analgesic and antipyretic effects equivalent Anti-inflammatory, GI, and platelet effects less than aspirin at 1000 mg/day
Acetic acid derivatives						
Indomethacin (methylated indole)	Peak C _p Protein binding Metabolites t _{1/2}	1-2 hours 90% O-demethylation (50%); unchanged (20%) 2.5 hours		25 mg 2-3 times/day; 75-100 mg at night	Side effects (3-50% of patients): frontal headache, neutropenia, thrombocytopenia; 20% discontinue therapy	10-40× more potent; intolerance limits dose

Sulindac (sulfoxide prodrug)	Peak C _p	1-2 hours; 8 hours for sulfide metabolite; extensive enterohepatic circulation	150-200 mg twice/day		20% suffer GI side effects; 10% get CNS side effects	Efficacy comparable
	Metabolites	Sulfone and conjugates (30%); sulindac and conjugates (25%)				
	t _{1/2}	7 hours; 18 hours for metabolite				
Etodolac (pyranocar- boxylic acid)	Peak C _p	1 hour	200-400 mg 3-4 times/day		Some COX-2 selectivity <i>in vitro</i>	100 mg etodolac has similar efficacy to 650 mg of aspirin, but may be better tolerated
	Protein binding	99%				
	Metabolites	Hepatic metabolites				
	t _{1/2}	7 hours				
Tolmetin (heteroaryl acetate derivative)	Peak C _p	20-60	400-600 mg	20 mg/kg/day	Food delays and decreases peak absorption	Efficacy similar; 25-40% develop side effects; 5-10% discontinue drug
	Protein binding	99%	3 times/day for children (anti- inflammatory)	in 3-4 divided doses		
	Metabolites	Oxidized to carboxylic acid/other derivatives, then conjugated			May persist longer in synovial fluid to give a biological efficacy longer than its plasma t _{1/2}	
	t _{1/2}	5 hours				
Ketorolac (pyrrolizine carboxylate)	Peak C _p	30-60	<65 years: 20 mg (orally), then 10 mg every 4-6 hours (not to exceed 40 mg/24 hours); >65 years: 10 mg every 4-6 hours (not to exceed 40 mg/24 hours)		Commonly given parenterally (60 mg IM followed by 30 mg every 6 hours, or 30 mg IV every 6 hours)	Potent analgesic, poor anti- inflammatory
	Protein binding	99%				
	Metabolites	glucuronide conjugate (90%)			Available as ocular preparation (0.25%); 1 drop every 6 hours	
	t _{1/2}	4-6 hours				
Diclofenac (phenylacetate derivatives)	Peak C _p	2-3 hours	50 mg 3 times/day or 75 mg twice/day		Available as topical gel, ophthalmic solution, and oral tablets combined with misoprostol	More potent; 20% develop side effects, 2% discontinue use, 15% develop elevated liver enzymes
	Protein binding	99%				
	Metabolites	Glucuronide and sulfide (renal 65%, bile 35%)			First-pass effect; oral bioavailability, 50%	
	t _{1/2}	1-2 hours

Classification and Comparison of Nonsteroidal Analgesics (Continued)

CLASS/DRUG (SUBSTITUTION)	PHARMACOKINETICS	DOSING ^d	COMMENTS	COMPARED TO ASPIRIN		
Fenamates (N-phenyl-anthranilates)						
Mefenamic acid	Peak C _p Protein binding Metabolites	2-4 hours High Conjugates of 3-hydroxy and 3-carboxyl metabolites (20% recovered in feces)	500-mg load, then 250 mg every 6 hours	Isolated cases of hemolytic anemia May have some central action	Efficacy similar; GI side effects (25%)	
Meclofenamate	t _{1/2} Peak C _p Protein binding Metabolites	3-4 hours 0.5-2 hours 99% Hepatic metabolism; fecal and renal excretion	50-100 mg 4-6/day (maximum of 400 mg/day)		Efficacy similar; GI side effects (25%)	
Flufenamic acid	t _{1/2} <i>Not available in the U.S.</i>	2-3 hours				
Propionic acid derivatives				Intolerance of one does not preclude use of another propionate derivative	Usually better tolerated	
Ibuprofen	Peak C _p Protein binding Metabolites t _{1/2}	15-30 minutes 99% Conjugates of hydroxyl and carboxyl metabolites 2-4 hours	Analgesia Anti-inflammatory	200-400 mg every 4-6 hours 300 mg/6-8 hours or 400-800 mg 3-4 times/day	10-15% discontinue due to adverse effects Children's dosing Antipyretic: 5-10 mg/kg every 6 hours (max: 40 mg/kg/day) Anti-inflammatory: 20-40 mg/kg/day in 3-4 divided doses	Equipotent

Naproxen	Peak C _p Protein binding Metabolites t _{1/2}	1 hour 99% (less in elderly) 6-demethyl and other metabolites 14 hours	250 mg 4 times/day or 500 mg twice/day Children: anti- inflammatory	5 mg/kg twice/day	Peak anti-inflammatory effects may not be seen until 2-4 weeks of use Decreased protein binding and delayed excretion increase risk of toxicity in elderly	More potent <i>in vitro</i> ; usually better tolerated; variably prolonged t _{1/2} may afford cardioprotection in some individuals
Fenoprofen	Peak C _p Protein binding Metabolites t _{1/2}	2 hours 99% Glucuronide, 4-OH metabolite 2 hours	200 mg 4-6 times/day; 300-600 mg 3-4 times/day			15% experience side effects; few discontinue use
Ketoprofen	Peak C _p Protein binding Metabolites t _{1/2}	1-2 hours 98% Glucuronide conjugates 2 hours	Analgesia Anti- inflammatory	25 mg 3-4 times/day 50-75 mg 3-4 times/day		30% develop side effects (usually GI, usually mild)
Flurbiprofen	Peak C _p Protein binding Metabolites t _{1/2}	1-2 hours 99% Hydroxylates and conjugates 6 hours	200-300 mg/day in 2-4 divided doses		Available as a 0.03% ophthalmic solution	
Oxaprozin	Peak C _p Protein binding Major metabolites t _{1/2}	3-4 hours 99% Oxidates and glucuronide conjugates 40-60 hours	600-1800 mg/day		Long t _{1/2} allows for daily administration; slow onset of action; inappropriate for fever/acute analgesia	
Enolic acid derivatives						
Piroxicam	Peak C _p Protein binding Metabolites t _{1/2}	3-5 hours 99% Hydroxylates and then conjugated 45-50 hours	20 mg/day		May inhibit activation of neutrophils, activity of proteoglycanase, collagenases	Equipotent; perhaps better tolerated 20% develop side effects; 5% discontinue drug

CLASS/DRUG (SUBSTITUTION)	PHARMACOKINETICS	DOSING ^d	COMMENTS	COMPARED TO ASPIRIN	
Meloxicam	Peak C _p Protein binding Metabolites t _{1/2}	5-10 hours 99% Hydroxylation 15-20 hours	7.5-15 mg/day		Some COX-2 selectivity, especially at lower doses
Nabumetone (naphthyl alkanone)	Peak C _p Protein binding Major metabolites t _{1/2}	3-6 hours 99% O-demethylation, then conjugation 24 hours	500-1000 mg 1-2 times/day	A prodrug, rapidly metabolized to 6-methoxy-2-naphthyl acetic acid; pharmacokinetics reflect active compound	Shows some COX-2 selectivity (active metabolite does not) Fewer GI side effects than many NSAIDs
Diaryl heterocyclic NSAIDs (COX-2 selective)				Evidence for cardiovascular adverse events	Decrease in GI side effects and in platelet effects
Celecoxib [diaryl substituted pyrazone; (sulfonamide derivative)]	Peak C _p Protein binding Metabolites t _{1/2}	2-4 hours 97% Carboxylic acid and glucuronide conjugates 6-12 hours	100 mg 1-2 times/day	Substrate for CYP2C9; inhibitor of CYP2D6 Coadministration with inhibitors of CYP2C9 or substrates of CYP2D6 should be done with caution	See the text for an overview of COX-2 inhibitors
Parecoxib Etoricoxib Lumaricoxi	} <i>Not approved for use in the U.S.</i>				

^aTime to peak plasma drug concentration (C_p) after a single dose. In general, food delays absorption but does not decrease peak concentration. ^bThe majority of NSAIDs undergo hepatic metabolism, and the metabolites are excreted in the urine. Major metabolites or disposal pathways are listed. ^cTypical t_{1/2} is listed for therapeutic doses; if t_{1/2} is much different with the toxic dose, this is also given. ^dLimited dosing information given. For additional information, refer to the text and product information literature. Additional references can be found in earlier editions of this textbook. CNS, central nervous system; COX, cyclooxygenase; GI, gastrointestinal; IM, intramuscularly; IV, intravenously.

and physical therapy, generally is effective. When the symptoms are limited either to trouble sleeping because of pain or significant morning stiffness, a single NSAID dose given at night may suffice. Patients with more debilitating disease may not respond adequately to full therapeutic doses of NSAIDs and may require aggressive therapy with second-line agents. Substantial inter- and intraindividual differences in clinical response have been noted.

Pain. When employed as analgesics, these drugs usually are effective only against pain of low to moderate intensity, such as dental pain. Although their maximal efficacy is generally much less than the opioids, NSAIDs lack the unwanted adverse effects of opiates in the CNS, including respiratory depression and the potential for development of physical dependence. Co-administration of NSAIDs can reduce the opioid dose needed for sufficient pain control and reduce the likelihood of adverse opioid effects. NSAIDs do not change the perception of sensory modalities other than pain. They are particularly effective when inflammation has caused peripheral and/or central sensitization of pain perception. Thus, postoperative pain or pain arising from inflammation, such as arthritic pain, is controlled well by NSAIDs, whereas pain arising from the hollow viscera usually is not relieved. An exception to this is menstrual pain. The release of PGs by the endometrium during menstruation may cause severe cramps and other symptoms of primary dysmenorrhea; treatment of this condition with NSAIDs has met with considerable success (Marjoribanks et al., 2003). Not surprisingly, the selective COX-2 inhibitors such as rofecoxib and etoricoxib also are efficacious in this condition. NSAIDs are commonly used as first-line therapy to treat migraine attacks and can be combined with second-line drugs, such as the triptans (e.g., TREXIMET, which is a fixed-dose combination of naproxen and sumatriptan), or with antiemetics to aid relief of the associated nausea. NSAIDs lack efficacy in neuropathic pain.

Fever. Antipyretic therapy is reserved for patients in whom fever in itself may be deleterious and for those who experience considerable relief when fever is lowered. Little is known about the relationship between fever and the acceleration of inflammatory or immune processes; it may at times be a protective physiological mechanism. The course of the patient's illness may be obscured by the relief of symptoms and the reduction of fever by the use of antipyretic drugs. NSAIDs reduce fever in most situations, but not the circadian variation in temperature or the rise in response to exercise or

increased ambient temperature. Comparative analysis of the impact of tNSAIDs and selective COX-2 inhibitors suggests that COX-2 is the dominant source of PGs that mediate the rise in temperature evoked by bacterial lipopolysaccharide (LPS) administration (McAdam et al., 1999). This is consistent with the antipyretic clinical efficacy of both subclasses of NSAIDs. It seems logical to select an NSAID with rapid onset for the management of fever associated with minor illness in adults.

Fetal Circulatory System. PGs have long been implicated in the maintenance of patency of the ductus arteriosus, and indomethacin, ibuprofen, and other tNSAIDs have been used in neonates to close the inappropriately patent ductus. Conversely, infusion of PGE₂ maintains ductal patency after birth. Both COX-1 and COX-2 appear to participate in maintaining patency of the ductus arteriosus in fetal lambs (Clyman et al., 1999), while in mice COX-2 appears to play the dominant role (Loftin et al., 2002). It is not known which isoform or isoforms are involved in maintaining patency of the fetal ductus *in utero* in humans.

In mice, PGE₂ maintains a low ductal smooth muscle cell tone via the G_s-coupled receptor EP₄ that increases intracellular cyclic AMP. In the late gestational period, pulmonary expression of an enzyme that eliminates PGE₂ from the bloodstream, PG 15-OH dehydrogenase (PGDH), is rapidly upregulated (Coggins et al., 2002). At birth, PGE₂ blood concentrations are dramatically reduced by pulmonary PGDH and by additional exposure of circulating PGE₂ to this enzyme with the increase of pulmonary blood flow. Due to reduced EP₄ signaling, intracellular cyclic AMP concentrations in the ductus arteriosus drop, and vasodilating effects are outweighed by vasoconstrictor signals, which initiate remodeling. However, surprisingly little information about the human ductal physiology exists, and a role for PGDH remains to be established in humans.

Cardioprotection. Ingestion of aspirin prolongs bleeding time. For example, a single 325-mg dose of aspirin approximately doubles the mean bleeding time of normal persons for 4-7 days. This effect is due to irreversible acetylation of platelet COX and the consequent inhibition of platelet function until sufficient numbers of new, unmodified platelets are released from megakaryocytes. It is the permanent and complete suppression of platelet TxA₂ formation that is thought to underlie the cardioprotective effect of aspirin. Aspirin reduces the risk of serious vascular events in high-risk patients (e.g., those with previous myocardial infarction) by 20-25%. Low-dose (<100 mg/day) aspirin, which is relatively (but not exclusively) selective for COX-1, is as effective as higher doses (e.g., 325 mg/day) but is associated with a lower risk for GI adverse events.

However, low-dose aspirin is not risk free. Placebo-controlled trials reveal that aspirin increases the incidence of serious GI bleeds, reflecting suppression not just of platelet thromboxane, but also reduction of gastroepithelial PGE₂ and PGI₂. It also increases the incidence of intracranial bleeds. Although benefit from aspirin outweighs these risks in the case of secondary prevention of cardiovascular disease, the issue is much more nuanced in patients who have never had a serious atherothrombotic event (primary prevention); here, prevention of myocardial infarction by aspirin is numerically balanced by the serious GI bleeds it precipitates (Patrono et al., 2005).

Given their relatively short $t_{1/2}$ and reversible COX inhibition, most other tNSAIDs are not thought to afford cardioprotection, a view supported by most epidemiological analyses (García Rodríguez et al., 2004). Data suggest that cardioprotection is lost when combining low-dose aspirin with ibuprofen. An exception in some individuals may be naproxen. Although there is considerable between-person variation, a small study suggests that platelet inhibition might be anticipated throughout the dosing interval in some, but not all, individuals on naproxen (Capone et al., 2005). Epidemiological evidence of cardioprotection is less impressive; it suggests an ~10% reduction in myocardial infarction, compared to 20-25% with low-dose aspirin (Antithrombotic Trialists' Collaboration, 2002). This would fit with heterogeneity of response to naproxen. Reliance on prescription databases may have constrained the ability of this approach to address the question with precision. In the Alzheimer's Disease Anti-inflammatory Prevention Trial (ADAPT Research Group, 2008), naproxen was associated with a higher rate of cardiac events than celecoxib. Hence, naproxen should not be used as a substitute for aspirin for cardioprotection. COX-2-selective NSAIDs are devoid of antiplatelet activity, as mature platelets do not express COX-2.

Other Clinical Uses

Systemic Mastocytosis. Systemic mastocytosis is a condition in which there are excessive mast cells in the bone marrow, reticuloendothelial system, GI system, bones, and skin. In patients with systemic mastocytosis, PGD₂, released from mast cells in large amounts, has been found to be the major mediator of severe episodes of flushing, vasodilation, and hypotension; this PGD₂ effect is resistant to antihistamines. The addition of aspirin or ketoprofen has provided relief (Worobec, 2000). However, aspirin and tNSAIDs can cause degranulation of mast cells, so blockade with H₁ and H₂ histamine receptor antagonists should be established before NSAIDs are initiated.

Niacin Tolerability. Large doses of niacin (nicotinic acid) effectively lower serum cholesterol levels, reduce low-density lipoprotein, and raise high-density lipoprotein (see Chapter 31). However, niacin is tolerated poorly because it induces intense facial flushing. This flushing is mediated largely by release of PGD₂ from the skin, which can be inhibited by treatment with aspirin (Jungnickel et al., 1997), and would be susceptible to inhibition of PGD synthesis, or antagonism of its DP₁ receptor.

Bartter Syndrome. Bartter syndrome includes a series of rare disorders (frequency $\leq 1/100,000$ persons) characterized by hypokalemic,

hypochloremic metabolic alkalosis with normal blood pressure and hyperplasia of the juxtaglomerular apparatus. Fatigue, muscle weakness, diarrhea, and dehydration are the main symptoms. Distinct variants are caused by mutations in a Na⁺-K⁺-2Cl⁻ co-transporter, an apical ATP-regulated K⁺ channel, a basolateral Cl⁻ channel, a protein (barttin) involved in co-transporter trafficking, and the extracellular Ca²⁺-sensing receptor. Renal COX-2 is induced, and biosynthesis of PGE₂ is increased. Treatment with indomethacin, combined with potassium repletion and spironolactone, is associated with improvement in the biochemical derangements and symptoms. Selective COX-2 inhibitors also have been used (Guay-Woodford, 1998).

Cancer Chemoprevention. Chemoprevention of cancer is an area in which the potential use of aspirin and/or NSAIDs is under active investigation. Epidemiological studies suggested that frequent use of aspirin is associated with as much as a 50% decrease in the risk of colon cancer (Kune et al., 2007). Similar observations have been made with NSAID use in this and other cancers (Harris et al., 2005). NSAIDs have been used in patients with familial adenomatous polyposis (FAP), an inherited disorder characterized by multiple adenomatous colon polyps developing during adolescence and the inevitable occurrence of colon cancer by the sixth decade.

Studies in small numbers of patients over short periods of follow-up have shown a decrease in the polyp burden with the use of sulindac, celecoxib, or rofecoxib (Steinbach et al., 2000; Cruz-Correa et al., 2002; Hallak et al., 2003). Celecoxib is approved as an adjunct to endoscopic surveillance and surgery in FAP based on superiority in a short-term, placebo-controlled trial for polyp prevention/regression. However, more recently, the Adenoma Prevention with Celecoxib (APC) Trial showed a significant reduction in the incidence of adenomatous polyps in patients with a history of colorectal adenomas at high doses of celecoxib (200 mg twice a day and 400 mg twice a day versus placebo) (Bertagnolli et al., 2009). The trial was prematurely terminated because of a 2.5 times increase in cardiovascular risk for patients taking 200 mg twice a day of celecoxib and a 3.4 times increase in risk for patients taking 400 mg twice a day (Solomon et al., 2005). Similarly, the Prevention of colorectal Sporadic Adenomatous Polyps (PreSAP) trial found a reduction of polyps at a single daily dose of 400 mg of celecoxib (Arber et al., 2006), which was offset by an increase in cardiovascular risk (Solomon et al., 2006). Finally, the APPROVe trial of 25 mg of rofecoxib showed a reduction in the incidence of adenomatous polyps (Baron et al., 2006) and an increase in cardiovascular adverse events (Bresalier et al., 2005; Baron et al., 2008) that led to the termination of the trial and to rofecoxib's withdrawal from the market. Controlled evidence is not available to determine if selective COX-2 inhibitors differ from non-COX-2-selective tNSAIDs or aspirin in the extent of adenomatous colorectal polyp reduction in patients with FAP. Likewise, it is unknown whether there is even a clinical benefit from the reduction. Increased expression of COX-2 has been reported in multiple epithelial tumors, and in some cases, the degree of expression has been related to prognosis. Deletion or inhibition of COX-2 dramatically inhibits polyp formation in mouse genetic models of polyposis coli. Although the phenotypes in these models do not completely recapitulate the human disease, deletion of COX-1 had a similar effect. Speculation as to how the two COXs might interact in tumorigenesis includes the possibility that products of COX-1

might induce expression of COX-2. However, the nature of this interaction is poorly understood, as are its therapeutic consequences.

Alzheimer's Disease. Observational studies have suggested that NSAID use, in particular ibuprofen, is associated with lower risk of developing Alzheimer's disease. However, more recent prospective studies, including a randomized, controlled clinical trial comparing celecoxib, naproxen, and placebo (ADAPT Research Group, 2008), did not find a significant reduction in Alzheimer's dementia with the use of NSAIDs.

Adverse Effects of NSAID Therapy

Common adverse events that complicate therapy with aspirin and NSAIDs are outlined in Table 34–2. Age generally is correlated with an increased probability of developing serious adverse reactions to NSAIDs, and caution is warranted in choosing a lower starting dose for elderly patients. NSAIDs are labeled with a black box warning related to cardiovascular risks and are specifically contraindicated following coronary artery bypass graft (CABG) surgery.

Gastrointestinal. The most common symptoms associated with these drugs are gastrointestinal, including anorexia, nausea, dyspepsia, abdominal pain, and diarrhea. These symptoms may be related to the induction of gastric or intestinal ulcers, which is estimated to occur in 15-30% of regular users. Ulceration may range from small superficial erosions to full-thickness perforation of the muscularis mucosa. There may be single or multiple ulcers, and ulceration may be uncomplicated or complicated by bleeding, perforation, or obstruction. Blood loss can be gradual, leading to anemia over time, or acute and life-threatening. The risk is further increased in those with *Helicobacter pylori* infection, heavy alcohol consumption, or other risk factors for mucosal injury, including the concurrent use of glucocorticoids. Although there is a perception that tNSAIDs vary considerably in their tendency to cause erosions and ulcers, this is based on overview analyses of small and heterogeneous studies, often at single doses of individual tNSAIDs.

Large-scale comparative studies of tNSAIDs have not been performed, and there is no reliable information on which to assess the comparative likelihood of GI ulceration on anti-inflammatory doses of aspirin versus tNSAIDs. Thus, most information is derived from the use of surrogate markers or from epidemiological data sets and suggests that the relative risk for serious adverse GI events is elevated about 3-fold in tNSAID users compared to non-users. Epidemiological studies suggest that combining low-dose aspirin (for cardioprotection) with other NSAIDs synergistically increases the likelihood of GI adverse events (see “Drug Interactions”). Similarly, the combination of multiple tNSAIDs and high dosage of a single tNSAIDs (including inappropriately high dosage in the

Table 34–2

Common and Shared Side Effects of NSAIDs

SYSTEM	MANIFESTATIONS
GI	Abdominal pain Nausea Diarrhea Anorexia Gastric erosions/ulcers ^a Anemia ^a GI hemorrhage ^a Perforation/obstruction ^a

Hypersensitivity	Vasomotor rhinitis Angioneurotic edema Asthma Urticaria Flushing Hypotension Shock

^aSide effects decreased with COX-2-selective NSAIDs. ^bWith the exception of low-dose aspirin.

elderly) has been found to raise the risk for ulcer complications by 7- and 9-fold, respectively. Age >70 years alone increases the likelihood of complications almost 6-fold. The risk of ulcer complications is increased in patients with past uncomplicated (6-fold) or complicated ulcers (13-fold), or concurrent drug therapy including

warfarin (12-fold), glucocorticoids (4-fold), or selective serotonin reuptake inhibitors (SSRIs; 3-fold) (Gabriel et al., 1991; Dalton et al., 2003; García Rodríguez and Barreales Tolosa, 2007).

COX-2-selective NSAIDs were originally designed for a niche indication, to improve treatment safety for patients at high risk for GI complications requiring chronic tNSAIDs—a population of <5% of tNSAID users (Dai et al., 2005). Prescription behavior changed over time, however, and more than one-third of patients at the lowest risk for GI events received a COX-2 inhibitor in 2002. Paradoxically, the incidence of GI adverse events had been falling sharply in the population prior to the introduction of the coxibs—which were developed to reduce the risk of serious GI complication, perhaps reflecting a move away from use of high-dose aspirin as an anti-inflammatory drug strategy. All selective COX-2 inhibitors are less prone to induce endoscopically visualized gastric ulcers than equally efficacious doses of tNSAIDs (Deeks et al., 2002). A more detailed discussion on this topic can be found in the prior edition of this textbook.

Gastric damage by NSAIDs can be brought about by at least two distinct mechanisms (see Chapter 33). Inhibition of COX-1 in gastric epithelial cells depresses mucosal cytoprotective PGs, especially PGI₂ and PGE₂. These eicosanoids inhibit acid secretion by the stomach, enhance mucosal blood flow, and promote the secretion of cytoprotective mucus in the intestine. Inhibition of PGI₂ and PGE₂ synthesis may render the stomach more susceptible to damage and can occur with oral, parenteral, or transdermal administration of aspirin or NSAIDs. There is some evidence that COX-2 also contributes to constitutive formation of these PGs by human gastric epithelium; products of COX-2 certainly contribute to ulcer healing in rodents (Mizuno et al., 1997). This may partly reflect an impairment of angiogenesis by the inhibitors (Jones et al., 1999). Indeed, coincidental deletion or inhibition of both COX-1 and COX-2 seems necessary to replicate NSAID-induced gastropathy in mice, and there is some evidence for gastric pathology in the face of prolonged inhibition or deletion of COX-2 alone (Sighthorsson et al., 2002). Another mechanism by which NSAIDs or aspirin may cause ulceration is by local irritation from contact of orally administered drug with the gastric mucosa. Local irritation allows backdiffusion of acid into the gastric mucosa and induces tissue damage. However, the incidence of GI adverse events is not significantly reduced by formulations that reduce drug contact with the gastric mucosa, such as enteric coating or effluent solutions, suggesting that the contribution of direct irritation to the overall risk is minor. It also is possible that enhanced generation of LOX products (e.g., LTs) contributes to ulcerogenicity in patients treated with NSAIDs.

Co-administration of the PGE₁ analog, misoprostol, or proton pump inhibitors (PPIs) in conjunction with NSAIDs can be beneficial in the prevention of duodenal and gastric ulceration (Rostom et al., 2002).

Several groups have attached NO-donating moieties to NSAIDs and to aspirin in the hope of reducing the incidence of adverse events. Benefit might be attained by abrogation of the inhibition of angiogenesis by tNSAIDs during ulcer healing, as observed in rodents (Ma et al., 2002); however, the clinical benefit of this strategy remains to be established. Similarly, LTs may accumulate in the presence of COX inhibition, and there is some evidence in rodents that combined LOX-COX inhibition may be a useful strategy.

Cardiovascular. COX-2-selective NSAIDs were developed to improve the GI safety of anti-inflammatory therapy in patients at elevated risk for GI complications. However, placebo-controlled trials with three structurally distinct compounds—celecoxib, valdecoxib (withdrawn), and rofecoxib (withdrawn)—revealed an increase in the incidence of myocardial infarction, stroke, and thrombosis (Bresalier et al., 2005; Nussmeier et al., 2005; Solomon et al., 2006). The risk appears to also extend to those of the older tNSAIDs, which are quite selective for COX-2, such as diclofenac, meloxicam, and nimesulide (Grosser et al., 2006). Regulatory agencies in the U.S, E.U., and Australia have concluded that all NSAIDs have the potential to increase the risk of heart attack and stroke.

The cardiovascular hazard is plausibly explained by the depression of COX-2-dependent prostanoids formed in vasculature and kidney (Grosser et al., 2006). Vascular PGI₂ constrains the effect of prothrombotic and atherogenic stimuli, and renal PGI₂ and PGE₂ formed by COX-2 contribute to arterial pressure homeostasis (see Chapter 33). Genetic deletion of the PGI₂ receptor, IP, in mice augments the thrombotic response to endothelial injury, accelerates experimental atherogenesis, increases vascular proliferation, and adds to the effect of hypertensive stimuli (Cheng et al., 2002; Egan et al., 2004; Kobayashi et al., 2004; Cheng et al., 2006). Genetic deletion or inhibition of COX-2 accelerates the response to thrombotic stimuli and raises blood pressure. Together, these mechanisms would be expected to alter the cardiovascular risk of humans, as COX-2 inhibition in humans depresses PGI₂ synthesis (Catella-Lawson et al., 1999; McAdam et al., 1999). Indeed, a human mutation of the IP, which disrupts its signaling, is associated with increased cardiovascular risk (Arehart et al., 2008).

Patients at increased risk of cardiovascular disease or thrombosis are likely to be particularly prone to cardiovascular adverse events while on NSAIDs. This includes patients with rheumatoid arthritis, as the relative risk of myocardial infarction is increased in these patients compared to patients with osteoarthritis or no arthritis. The risk appears to be conditioned by factors influencing drug exposure, such as dose, t_{1/2}, degree of COX-2 selectivity, potency, and treatment duration. Thus, the lowest possible dose should be prescribed for the shortest possible period. NSAIDs with selectivity for COX-2 should be reserved for patients at high risk for GI complications.

Blood Pressure, Renal, and Renovascular Adverse Events. NSAIDs and COX-2 inhibitors have been associated with renal and renovascular adverse events. NSAIDs have little effect on renal function or blood pressure in normal human subjects. However, in patients with congestive heart failure, hepatic cirrhosis, chronic kidney disease, hypovolemia, and other states of activation of the sympathoadrenal or renin-angiotensin systems, PG formation becomes crucial in model systems and in humans. NSAIDs are associated with loss of the

PG-induced inhibition of both the reabsorption of Cl^- and the action of antidiuretic hormone, leading to the retention of salt and water.

Experiments in mice that attribute the generation of vasodilator PGs (PGE_2 and PGI_2) to COX-2 raise the likelihood that the incidence of hypertensive complications (either new onset or worsened control) induced by NSAIDs in patients may correlate with the degree of inhibition of COX-2 in the kidney and the selectivity with which it is attained (Qi et al., 2002). Deletion of receptors for both PGI_2 and PGE_2 elevate blood pressure in mice, mechanistically integrating hypertension with a predisposition to thrombosis. Although this hypothesis has never been addressed directly, epidemiological studies suggest hypertensive complications occur more commonly in patients treated with coxibs than with tNSAIDs.

NSAIDs promote reabsorption of K^+ as a result of decreased availability of Na^+ at distal tubular sites and suppression of the PG-induced secretion of renin. The latter effect may account in part for the usefulness of NSAIDs in the treatment of Bartter syndrome (see “Bartter Syndrome”).

Analgesic Nephropathy. Analgesic nephropathy is a condition of slowly progressive renal failure, decreased concentrating capacity of the renal tubule, and sterile pyuria. Risk factors are the chronic use of high doses of combinations of NSAIDs and frequent urinary tract infections. If recognized early, discontinuation of NSAIDs permits recovery of renal function.

Pregnancy and Lactation. In the hours before parturition, there is induction of myometrial COX-2 expression, and levels of PGE_2 and $\text{PGF}_{2\alpha}$ increase markedly in the myometrium during labor (Slater et al., 2002). Prolongation of gestation by NSAIDs has been demonstrated in model systems and in humans. Some NSAIDs, particularly indomethacin, have been used off-label to terminate preterm labor. However, this use is associated with closure of the ductus arteriosus and impaired fetal circulation *in utero*, particularly in fetuses older than 32 weeks' gestation. COX-2-selective inhibitors have been used off-label as tocolytic agents; this use has been associated with stenosis of the ductus arteriosus and oligohydramnios. Finally, the use of NSAIDs and aspirin late in pregnancy may increase the risk of postpartum hemorrhage. Therefore, pregnancy, especially close to term, is a relative contraindication to the use of all NSAIDs. In addition, their use must be weighed against potential fetal risk, even in cases of premature labor, and especially in cases of pregnancy-induced hypertension (Duley et al., 2004).

Hypersensitivity. Certain individuals display hypersensitivity to aspirin and NSAIDs, as manifested by symptoms that range from vasomotor rhinitis, generalized

urticaria, and bronchial asthma to laryngeal edema, bronchoconstriction, flushing, hypotension, and shock. Aspirin intolerance is a contraindication to therapy with any other NSAID because cross-sensitivity can provoke a life-threatening reaction reminiscent of anaphylactic shock. Despite the resemblance to anaphylaxis, this reaction does not appear to be immunological in nature.

Although less common in children, this cross-sensitivity may occur in 10–25% of patients with asthma, nasal polyps, or chronic urticaria and in 1% of apparently healthy individuals. It is provoked by even low doses (<80 mg) of aspirin and apparently involves COX inhibition. Cross-sensitivity extends to other salicylates, structurally dissimilar NSAIDs, and rarely acetaminophen (see “Adverse Effects” in the “Acetaminophen” section). Treatment of aspirin hypersensitivity is similar to that of other severe hypersensitivity reactions, with support of vital organ function and administration of epinephrine. Aspirin hypersensitivity is associated with an increase in biosynthesis of LTs, perhaps reflecting diversion of AA to LOX metabolism. Indeed, results in a small number of patients suggest that blockade of 5-LOX with the drug zileuton or off-label use of the LT-receptor antagonists may ameliorate the symptoms and signs of aspirin intolerance, albeit incompletely.

Aspirin Resistance. All forms of treatment failure with aspirin have been collectively called *aspirin resistance*. Although this has attracted much attention, there is little information concerning the prevalence of a stable, aspirin-specific resistance or the precise mechanisms that might convey this “resistance.” Genetic variants of COX-1 that co-segregate with resistance have been described, but the relation to clinical outcome is not clear.

Reye's Syndrome. Due to the possible association with Reye's syndrome, aspirin and other salicylates are contraindicated in children and young adults <20 years of age with viral illness-associated fever. Reye's syndrome, a severe and often fatal disease, is characterized by the acute onset of encephalopathy, liver dysfunction, and fatty infiltration of the liver and other viscera (Glasgow and Middleton, 2001). The etiology and pathophysiology are not clear, nor is it clear whether a causal relationship between aspirin and Reye's syndrome exists (Schorr, 2007). However, the epidemiologic evidence for an association between aspirin use and Reye's syndrome seemed sufficiently compelling that labeling of aspirin and aspirin-containing medications to indicate Reye's syndrome as a risk in children was first mandated in 1986 and extended to bismuth subsalicylate in 2004. Since then, the use of aspirin in children has declined dramatically, and Reye's syndrome has almost disappeared. Acetaminophen has not been

implicated in Reye's syndrome and is the drug of choice for antipyresis in children, teens, and young adults.

Concomitant NSAIDs and Low-Dose Aspirin. Many patients combine either tNSAIDs or COX-2 inhibitors with "cardioprotective," low-dose aspirin. Epidemiological studies suggest that this combination therapy increases significantly the likelihood of GI adverse events over either class of NSAID alone.

Prior occupancy of the active site of platelet COX-1 by the commonly consumed tNSAID ibuprofen impedes access of aspirin to its target Ser 529 and prevents irreversible inhibition of platelet function (Catella-Lawson et al., 2001). Epidemiological studies have provided conflicting data as to whether this adversely impacts clinical outcomes, but they generally are constrained by the use of prescription databases to examine an interaction between two drug groups commonly obtained without prescription. Evidence in support of this interaction has been observed in comparing ibuprofen-treated patients with and without aspirin in two coxib outcome studies (CLASS and TARGET), but the trials were not powered to address this question definitively. In theory, this interaction should not occur with selective COX-2 inhibitors, because mature human platelets lack COX-2. However, the GI safety advantage of NSAIDs selective for COX-2 is lost when they are combined with low-dose aspirin.

Drug Interactions

Angiotensin-converting enzyme (ACE) inhibitors act, at least partly, by preventing the breakdown of kinins that stimulate PG production. Thus, it is logical that NSAIDs might attenuate the effectiveness of ACE inhibitors by blocking the production of vasodilator and natriuretic PGs. Due to hyperkalemia, the combination of NSAIDs and ACE inhibitors also can produce marked bradycardia leading to syncope, especially in the elderly and in patients with hypertension, diabetes mellitus, or ischemic heart disease. Corticosteroids and SSRIs may increase the frequency or severity of GI complications when combined with NSAIDs. NSAIDs may augment the risk of bleeding in patients receiving warfarin both because almost all tNSAIDs suppress normal platelet function temporarily during the dosing interval and because some NSAIDs also increase warfarin levels by interfering with its metabolism; thus, concurrent administration should be avoided. Many NSAIDs are highly bound to plasma proteins and thus may displace other drugs from their binding sites. Such interactions can occur in patients given salicylates or other NSAIDs together with warfarin, sulfonylurea hypoglycemic agents, or methotrexate; the dosage of such agents may require adjustment to prevent toxicity. Patients taking lithium should be monitored because certain NSAIDs (e.g., piroxicam) can reduce the renal

excretion of this drug and lead to toxicity, while others can decrease lithium levels (e.g., sulindac).

Pediatric and Geriatric Indications and Problems

Therapeutic Uses in Children. Therapeutic indications for NSAID use in children include fever, mild pain, postoperative pain, and inflammatory disorders, such as juvenile arthritis and Kawasaki disease. Inflammation associated with cystic fibrosis has emerged as a potential indication for pediatric NSAID use (Konstan et al., 1995); however, concern about GI adverse effects has limited NSAID use for this indication. The choice of drugs for children is considerably restricted; only drugs that have been extensively tested in children should be used (acetaminophen, ibuprofen, and naproxen).

Kawasaki Disease. Aspirin generally is avoided in pediatric populations due to its potential association with Reye's syndrome (see "Reye's Syndrome"). However, high doses of aspirin (30-100 mg/kg/day) are used to treat children during the acute phase of Kawasaki disease, followed by low-dose antiplatelet therapy in the subacute phase. Aspirin is thought to reduce the likelihood of aneurysm formation as a consequence of the vasculitis particularly in the coronary arteries. Small randomized studies did not conclusively show whether aspirin adds benefit beyond the standard treatment of Kawasaki disease with intravenous immunoglobulin (Baumer et al., 2006).

Pharmacokinetics in Children. Despite the recognition that age-dependent differences in gastric emptying time, plasma protein binding capacity and oxidative liver metabolism affect NSAID pharmacokinetics in children, dosing recommendations frequently are based on extrapolation of pharmacokinetic data from adults. The majority of pharmacokinetic studies that were performed in children involved patients >2 years of age, which often provide insufficient data for dose selection in younger infants. For example, the pharmacokinetics of the most commonly used NSAID in children, acetaminophen, differ substantially between the neonatal period and older children or adults. The systemic bioavailability of rectal acetaminophen formulations in neonates and preterm babies is higher than in older patients. Acetaminophen clearance is reduced in preterm neonates probably due to their immature glucuronide conjugation system (sulphatation is the principal route of biotransformation at this age). Therefore, acetaminophen dosing intervals need to be extended (8-12 hours) or daily doses reduced to avoid accumulation and liver toxicity. Aspirin elimination also is delayed in neonates and young infants compared to adults bearing the risk of accumulation.

Disease also may affect NSAID disposition in children. For example, ibuprofen plasma concentrations are reduced and clearance increased (~80%) in children with cystic fibrosis. This probably

is related to the GI and hepatic pathologies associated with this disease. Aspirin's kinetics are markedly altered during the febrile phase of rheumatic fever or Kawasaki vasculitis. The reduction in serum albumin associated with these conditions causes an elevation of the free salicylate concentration, which may saturate renal excretion and result in salicylate accumulation to toxic levels. In addition to dose reduction, monitoring of the free drug may be warranted in these situations.

Pharmacokinetics in the Elderly. Physiological changes in absorption, distribution, and elimination in aging patients can be expected to affect the pharmacokinetics of most drugs, including NSAIDs. Coincident diseases may further complicate the prediction of the response to the drug. The clearance of many NSAIDs is reduced in the elderly due to changes in hepatic metabolism. Particularly NSAIDs with a long $t_{1/2}$ and primarily oxidative metabolism (i.e., piroxicam, tenoxicam, celecoxib) have elevated plasma concentrations in elderly patients. For example, plasma concentrations after the same dose of celecoxib may rise up to 2-fold higher in patients >65 years of age than in patients <50 years of age (U.S. Food and Drug Administration, 2001), warranting careful dose adjustment. The capacity of plasma albumin to bind drugs is diminished in older patients and may result in higher concentrations of unbound NSAIDs. Free naproxen concentrations, e.g., are markedly increased in older patients, although total plasma concentrations essentially are unchanged. The higher susceptibility of older patients to GI complications may be due to both a reduction in gastric mucosal defense and to elevated total and/or free NSAID concentrations. Generally, it is advisable to start most NSAIDs at a low dosage in the elderly and increase the dosage only if the therapeutic efficacy is insufficient.

SPECIFIC PROPERTIES OF INDIVIDUAL NSAIDS

General properties shared by tNSAIDs (including aspirin and acetaminophen) and COX-2-selective NSAIDs were considered in the preceding section, “Nonsteroidal Anti-Inflammatory Drugs.” In the following section, important characteristics of individual substances are discussed. NSAIDs are grouped by their chemical similarity (Figure 34–1).

ASPIRIN AND OTHER SALICYLATES

Despite the introduction of many new drugs, aspirin is still the most widely consumed analgesic, antipyretic, and anti-inflammatory agent and is the standard for the comparison and evaluation of the others. Aspirin is the most common household analgesic; yet, because the drug is so generally available, the possibility of misuse and serious toxicity probably is underappreciated, and it remains a cause of fatal poisoning in children.

Chemistry. Salicylic acid (ortho-hydroxybenzoic acid) is so irritating that it can only be used externally; therefore various derivatives

of this acid have been synthesized for systemic use. These comprise two large classes, namely esters of salicylic acid obtained from substitutions within the carboxyl group and salicylate esters of organic acids, in which the carboxyl group is retained and substitution is made in the hydroxyl group. For example, aspirin is an ester of acetic acid. In addition, there are sodium, magnesium, and choline salts of salicylic acid. The chemical relationships can be seen from the structural formulas shown in Figure 34–3. Substitutions on the carboxyl or hydroxyl groups change the potency or toxicity of salicylates. The ortho position of the hydroxyl group is an important feature for the action of the salicylates. The effects of simple substitutions on the benzene ring have been studied extensively. A difluorophenyl derivative, diflunisal, also is available for clinical use.

Mechanism of Action

Salicylates generally act by virtue of their content of salicylic acid. The effects of aspirin are largely caused by its capacity to acetylate proteins, as described in “Irreversible Cyclooxygenase Inhibition by Aspirin,” although high concentrations of aspirin result in therapeutic plasma concentrations of salicylic acid. In addition to their effect on PG biosynthesis (see the NSAIDs section and Chapter 33), the mechanism of action of the salicylates in rheumatic disease also may involve effects on other cellular and immunological processes in mesenchymal and connective tissues. Attention has been directed to the capacity of salicylates to suppress a variety of antigen–antibody reactions. These include the inhibition of antibody production, of antigen–antibody aggregation, and of antigen-induced release of histamine. Salicylates also induce a nonspecific stabilization of

Figure 34–3. Chemical structures of the salicylic acid derivatives.

capillary permeability during immunological insults. The concentrations of salicylates needed to produce these effects are high, and the relationship of these effects to the anti-rheumatic efficacy of salicylates is not clear. Salicylates also can influence the metabolism of connective tissue, and these effects may be involved in their anti-inflammatory action. For example, salicylates can affect the composition, biosynthesis, or metabolism of connective tissue mucopolysaccharides in the ground substance that provides barriers to the spread of infection and inflammation.

Absorption, Distribution, and Elimination

Absorption. Orally ingested salicylates are absorbed rapidly, partly from the stomach but mostly from the upper small intestine. Appreciable concentrations are found in plasma in <30 minutes; after a single dose, a peak value is reached in ~1 hour and then declines gradually. The rate of absorption is determined by many factors, particularly the disintegration and dissolution rates of the tablets administered, the pH at the mucosal surface, and gastric emptying time.

Salicylate absorption occurs by passive diffusion primarily of undissociated salicylic acid or ASA across GI membranes and hence is influenced by gastric pH. Even though salicylate is more ionized as the pH is increased, a rise in pH also increases the solubility of salicylate and thus dissolution of the tablets. The overall effect is to enhance absorption. As a result, there is little meaningful difference between the rates of absorption of sodium salicylate, aspirin, and the numerous buffered preparations of salicylates. The presence of food delays absorption of salicylates. Rectal absorption of salicylate usually is slower than oral absorption and is incomplete and inconsistent.

Salicylic acid is absorbed rapidly from the intact skin, especially when applied in oily liniments or ointments, and systemic poisoning has occurred from its application to large areas of skin. Methyl salicylate likewise is speedily absorbed when applied cutaneously; however, its GI absorption may be delayed many hours, making gastric lavage effective for removal even in poisonings that present late after oral ingestion.

Distribution. After absorption, salicylates are distributed throughout most body tissues and transcellular fluids, primarily by pH-dependent passive processes. Salicylates are transported actively by a low-capacity, saturable system out of the cerebrospinal fluid (CSF) across the choroid plexus. The drugs readily cross the placental barrier.

The volume of distribution of usual doses of aspirin and sodium salicylate in normal subjects averages ~170 mL/kg of body weight; at high therapeutic doses, this volume increases to ~500 mL/kg because of saturation of binding sites on plasma proteins. Ingested aspirin mainly is absorbed as such, but some enters the systemic circulation as salicylic acid after hydrolysis by esterases in the GI mucosa and liver. Aspirin can be detected in the plasma only for a short time as a result of hydrolysis in plasma, liver, and erythrocytes; for example, 30 minutes after a dose of 0.65 g, only 27% of the total plasma salicylate is in the acetylated form. Methyl salicylate also is hydrolyzed rapidly to salicylic acid, mainly in the liver.

Roughly 80-90% of the salicylate in plasma is bound to proteins, especially albumin, at concentrations encountered clinically;

the proportion of the total that is bound declines as plasma concentrations increase. Hypoalbuminemia, as may occur in rheumatoid arthritis, is associated with a proportionately higher level of free salicylate in the plasma. Salicylate competes with a variety of compounds for plasma protein binding sites; these include thyroxine, triiodothyronine, penicillin, phenytoin, sulfapyrazone, bilirubin, uric acid, and other NSAIDs such as naproxen. Aspirin is bound to a more limited extent; however, it acetylates human plasma albumin *in vivo* by reaction with the ϵ -amino group of lysine and may change the binding of other drugs to albumin. Aspirin also acetylates hormones, DNA, and hemoglobin and other proteins.

Elimination. The biotransformation of salicylates takes place in many tissues, but particularly in the hepatic endoplasmic reticulum and mitochondria. The three chief metabolic products are salicylic acid (the glycine conjugate), the ether or phenolic glucuronide, and the ester or acyl glucuronide. In addition, a small fraction is oxidized to gentisic acid (2,5-dihydroxybenzoic acid) and to 2,3-dihydroxybenzoic and 2,3,5-trihydroxybenzoic acids; gentisic acid, the glycine conjugate of gentisic acid, also is formed.

Salicylates are excreted in the urine as free salicylic acid (10%), salicylic acid (75%), salicylic phenolic (10%) and acyl glucuronides (5%), and gentisic acid (<1%). However, excretion of free salicylates is extremely variable and depends on the dose and the urinary pH. In alkaline urine, >30% of the ingested drug may be eliminated as free salicylate, whereas in acidic urine, this may be as low as 2%.

The plasma $t_{1/2}$ for aspirin is ~20 minutes, and for salicylate is 2-3 hours at antiplatelet doses, rising to 12 hours at usual anti-inflammatory doses. The $t_{1/2}$ of salicylate may be as long as 15-30 hours at high therapeutic doses or when there is intoxication. This dose-dependent elimination is the result of the limited capacity of the liver to form salicylic acid and the phenolic glucuronide, resulting in a larger proportion of unchanged drug being excreted in the urine at higher doses.

Salicylate metabolism shows high intersubject variability due to the variable contribution of different metabolic pathways. Women frequently exhibit higher plasma concentrations, perhaps due to lower intrinsic esterase activity and gender differences in hepatic metabolism. Salicylate clearance is reduced and salicylate exposure is significantly increased in the elderly (see "Pharmacokinetics in the Elderly"). The plasma concentration of salicylate is increased by conditions that decrease glomerular filtration rate or reduce proximal tubule secretion, such as renal disease or the presence of inhibitors that compete for the transport system (e.g., probenecid). Changes in urinary pH also have significant effects on salicylate excretion. For example, the clearance of salicylate is about four times as great at pH 8 as at pH 6, and it is well above the glomerular filtration rate at pH 8. High rates of urine flow decrease tubular reabsorption, whereas the opposite is true in oliguria. In case of an overdose, hemodialysis and hemofiltration techniques remove salicylic acid effectively from the circulation.

Monitoring of Plasma Salicylate Concentrations. Aspirin is one of the NSAIDs for which plasma salicylate can provide a means to monitor therapy and toxicity. Intermittent analgesic-antipyretic doses of aspirin typically produce plasma aspirin levels of <20 $\mu\text{g/mL}$ and plasma salicylate levels of <60 $\mu\text{g/mL}$. The daily

ingestion of anti-inflammatory doses of 4–5 g of aspirin produces plasma salicylate levels in the range of 120–350 $\mu\text{g/mL}$. Optimal anti-inflammatory effects for patients with rheumatic diseases require plasma salicylate concentrations of 150–300 $\mu\text{g/mL}$. Significant adverse effects can be seen at levels of $>300 \mu\text{g/mL}$. At lower concentrations, the drug clearance is nearly constant (despite the fact that saturation of metabolic capacity is approached) because the fraction of drug that is free, and thus available for metabolism or excretion, increases as binding sites on plasma proteins are saturated. The total concentration of salicylate in plasma is therefore a relatively linear function of dose at lower concentrations. At higher concentrations, however, as metabolic pathways of disposition become saturated, small increments in dose can disproportionately increase plasma salicylate concentration. Failure to anticipate this phenomenon can lead to toxicity.

Therapeutic Uses

Systemic Uses. The dose of salicylate depends on the condition being treated.

The analgesic–antipyretic dose of aspirin for adults is 324–1000 mg orally every 4–6 hours. The anti-inflammatory doses of aspirin recommended for arthritis, spondyloarthropathies, and systemic lupus erythematosus (SLE) range from 3–4 g/day in divided doses. Salicylates are contraindicated for fever associated with viral infection in children (see “Reye’s Syndrome”); for nonviral etiologies, 40–60 mg/kg/day given in six divided doses every 4 hours is recommended. The maximum recommended daily dose of aspirin for adults and children >12 years or older is 4 g. The rectal administration of aspirin suppositories may be preferred in infants or when the oral route is unavailable. Although aspirin is regarded as the standard against which other drugs should be compared for the treatment of rheumatoid arthritis, many clinicians favor the use of other NSAIDs perceived to have better GI tolerability, even though this perception remains untested by randomized clinical trials. Salicylates suppress clinical signs and improve tissue inflammation in acute rheumatic fever. Much of the possible subsequent tissue damage, such as cardiac lesions and other visceral involvement, however, is unaffected by salicylate therapy.

Other salicylates available for systemic use include salalate (salicylsalicylic acid), which is hydrolyzed to salicylic acid during and after absorption, and magnesium salicylate (tablets; DOAN’S, MOMENTUM, others). A combination of choline salicylate and magnesium salicylate (choline magnesium–trisalicylate) also is available.

Diflunisal is a difluorophenyl derivative of salicylic acid that is not converted to salicylic acid *in vivo*. Diflunisal is more potent than aspirin in anti-inflammatory tests in animals and appears to be a competitive inhibitor of COX. However, it is largely devoid of antipyretic effects, perhaps because of poor penetration into the CNS. The drug has been used primarily as an analgesic in the

treatment of osteoarthritis and musculoskeletal strains or sprains; in these circumstances, it is about three to four times more potent than aspirin. The usual initial dose is 1000 mg, followed by 500 mg every 8–12 hours. For rheumatoid arthritis or osteoarthritis, 250–1000 mg/day is administered in two divided doses; maintenance dosage should not exceed 1.5 g/day. Diflunisal produces fewer auditory side effects (see “Ototoxic Effects”) and appears to cause fewer and less intense GI and antiplatelet effects than does aspirin.

Local Uses. Mesalamine (5-aminosalicylic acid) is a salicylate that is used for its local effects in the treatment of inflammatory bowel disease (see Chapter 47, especially Figure 47–4). The drug as an immediate-release formulation would not be effective orally because it is poorly absorbed and is inactivated before reaching the lower intestine. However, oral formulations that deliver drug to the lower intestine—mesalamine formulated in a pH-sensitive, polymer-coated, delayed-release tablet (ASACOL, LIALDA); an extended-release mesalamine capsule (APRISO); and olsalazine (sodium azodisalicylate, a dimer of 5-aminosalicylate linked by an azo bond; DIPENTUM)—are efficacious in the treatment of inflammatory bowel disease (in particular, ulcerative colitis). Mesalamine is available as a rectal enema (ROWASA, others) for treatment of mild to moderate ulcerative colitis, proctitis, and proctosigmoiditis and as a rectal suppository (CANASA) for the treatment of active ulcerative proctitis. Sulfasalazine (salicylazosulfapyridine; AZULFIDINE, others) contains mesalamine linked covalently to sulfapyridine, and balsalazide (COLAZAL, others) contains mesalamine linked to the inert carrier molecule 4-aminobenzoyl- β -alanine. Both drugs are absorbed poorly after oral administration and cleaved to the active moiety by bacteria in the colon. Sulfasalazine and olsalazine have been used in the treatment of rheumatoid arthritis and ankylosing spondylitis. Some over-the-counter medications to relieve indigestion and diarrhea agents contain bismuth subsalicylate (PEPTO-BISMOL, others) and have the potential to cause salicylate intoxication, particularly in children.

The keratolytic action of free salicylic acid is employed for the local treatment of warts, corns, fungal infections, and certain types of eczematous dermatitis. After treatment with salicylic acid, tissue cells swell, soften, and desquamate. Methyl salicylate (oil of wintergreen) is a common ingredient of ointments and deep-heating liniments used in the management of musculoskeletal pain; it also is available in herbal medicines and as a flavoring agent. The cutaneous application of methyl salicylate can result in pharmacologically active, and even toxic, systemic salicylate concentrations and has been reported to increase prothrombin time in patients receiving warfarin.

Adverse Effects

Respiration. Salicylates increase O_2 consumption and CO_2 production (especially in skeletal muscle) at anti-inflammatory doses; these effects are a result of uncoupling oxidative phosphorylation. The increased production of CO_2 stimulates respiration (mainly by an increase in depth of respiration with only a slight increase in rate). The increased alveolar ventilation balances the increased CO_2 production, and thus plasma CO_2 tension (PCO_2) does not change or may decrease slightly. Salicylates also stimulate the respiratory center directly in the medulla. Respiratory rate and depth increases, the Pco_2 falls, and primary respiratory alkalosis ensues. Both mechanisms can occur in parallel, although the stimulation of ventilation

after initiation of therapy is predominantly driven by the increase in the metabolic rate, and direct effects of salicylates on the central nervous respiratory center contribute later at higher steady-state concentrations.

Acid-Base and Electrolyte Balance and Renal Effects. Therapeutic doses of salicylate produce definite changes in the acid-base balance and electrolyte pattern. Compensation for the initial event, respiratory alkalosis (see “Respiration” in the aspirin section), is achieved by increased renal excretion of bicarbonate, which is accompanied by increased Na^+ and K^+ excretion; plasma bicarbonate is thus lowered, and blood pH returns toward normal. This is the stage of compensatory renal acidosis. This stage is most often seen in adults given intensive salicylate therapy and seldom proceeds further unless toxicity ensues (see “Salicylate Intoxication”). Salicylates can cause retention of salt and water, as well as acute reduction of renal function in patients with congestive heart failure, renal disease, or hypovolemia. Although long-term use of salicylates alone rarely is associated with nephrotoxicity, the prolonged and excessive ingestion of analgesic mixtures containing salicylates in combination with other NSAIDs can produce papillary necrosis and interstitial nephritis (see “Analgesic Nephropathy”).

Cardiovascular Effects. Low doses of aspirin (≤ 100 mg daily) are used widely for their cardioprotective effects. At high therapeutic doses (≥ 3 g daily), as might be given for acute rheumatic fever, salt and water retention can lead to an increase ($\leq 20\%$) in circulating plasma volume and decreased hematocrit (via a dilutional effect). There is a tendency for the peripheral vessels to dilate because of a direct effect on vascular smooth muscle. Cardiac output and work are increased. Those with carditis or compromised cardiac function may not have sufficient cardiac reserve to meet the increased demands, and congestive cardiac failure and pulmonary edema can occur. High doses of salicylates can produce noncardiogenic pulmonary edema, particularly in older patients who ingest salicylates regularly over a prolonged period.

GI Effects. The ingestion of salicylates may result in epigastric distress, nausea, and vomiting. Salicylates also may cause gastric ulceration, exacerbation of peptic ulcer symptoms (heartburn, dyspepsia), GI hemorrhage, and erosive gastritis. These effects occur primarily with acetylated salicylates (i.e., aspirin). Because nonacetylated salicylates lack the ability to acetylate COX and thereby irreversibly inhibit its activity, they are weaker inhibitors than aspirin.

Aspirin-induced gastric bleeding sometimes is painless and, if unrecognized, may lead to iron-deficiency anemia. The daily ingestion of anti-inflammatory doses of aspirin (3-4 g) results in an average fecal blood loss of between 3 and 8 mL/day, as compared with ~ 0.6 mL/day in untreated subjects. Gastroscopic examination of aspirin-treated subjects often reveals discrete ulcerative and hemorrhagic lesions of the gastric mucosa; in many cases, multiple hemorrhagic lesions with sharply demarcated areas of focal necrosis are observed.

Hepatic Effects. Salicylates can cause hepatic injury, usually in patients treated with high doses of salicylates that result in plasma concentrations of >150 $\mu\text{g}/\text{mL}$. The injury is not an acute effect; rather, the onset characteristically occurs after several months of treatment. The majority of cases occur in patients with connective tissue disorders. There usually are no symptoms, simply an increase

in serum levels of hepatic transaminases, but some patients note right upper quadrant abdominal discomfort and tenderness. Overt jaundice is uncommon. The injury usually is reversible upon discontinuation of salicylates. However, the use of salicylates is contraindicated in patients with chronic liver disease. Considerable evidence, as discussed earlier in “Reye’s Syndrome,” implicates the use of salicylates as an important factor in the severe hepatic injury and encephalopathy observed in Reye’s syndrome. Large doses of salicylates may cause hyperglycemia and glycosuria and deplete liver and muscle glycogen.

Uricosuric Effects. The effects of salicylates on uric acid excretion are markedly dependent on dose. Low doses (1 or 2 g/day) may decrease urate excretion and elevate plasma urate concentrations; intermediate doses (2 or 3 g/day) usually do not alter urate excretion. Large doses (>5 g/day) induce uricosuria and lower plasma urate levels; however, such large doses are tolerated poorly. Even small doses of salicylate can block the effects of probenecid and other uricosuric agents that decrease tubular reabsorption of uric acid.

Effects on the Blood. Irreversible inhibition of platelet function is the mechanism underlying the cardioprotective effect of aspirin (see “Concomitant NSAIDs and Low-Dose Aspirin”). If possible, aspirin therapy should be stopped at least 1 week before surgery; however, preoperative aspirin often is recommended prior to carotid artery stenting, carotid endarterectomy, infrainguinal arterial bypass, and PCI procedures. Patients with severe hepatic damage, hypoprothrombinemia, vitamin K deficiency, or hemophilia should avoid aspirin because the inhibition of platelet hemostasis can result in hemorrhage. Care also should be exercised in the use of aspirin during long-term treatment with oral anticoagulant agents because of the combined danger of prolongation of bleeding time coupled with blood loss from the gastric mucosa. On the other hand, aspirin is used widely for the prophylaxis of thromboembolic disease, especially in the coronary and cerebral circulation, and is coupled frequently with oral anticoagulants in patients with bioprosthetic or mechanical heart valves (see Chapter 30).

Salicylates ordinarily do not alter the leukocyte or platelet count, the hematocrit, or the hemoglobin content. However, doses of 3-4 g/day markedly decrease plasma iron concentration and shorten erythrocyte survival time. Aspirin can cause a mild degree of hemolysis in individuals with a deficiency of glucose-6-phosphate dehydrogenase. As noted earlier (see “Cardiovascular Effects”), high doses (>3 g/day) can expand plasma volume and decrease hematocrit by dilution.

Endocrine Effects. Long-term administration of salicylates decreases thyroidal uptake and clearance of iodine, but increases O_2 consumption and the rate of disappearance of thyroxine and triiodothyronine from the circulation. These effects probably are caused by the competitive displacement by salicylate of thyroxine and triiodothyronine from transthyretin and the thyroxine-binding globulin in plasma (see Chapter 39).

Ototoxic Effects. Hearing impairment, alterations of perceived sounds, and tinnitus commonly occur during high-dose salicylate therapy. Tinnitus, historically used as an index of exceeding the acceptable plasma concentration in patients, is not a reliable guide; thus, surveillance for this symptom is no substitute for periodic

monitoring of serum salicylate levels. Ototoxic symptoms sometimes are observed at low doses, and no threshold plasma concentration exists. Symptoms usually resolve within 2 or 3 days after withdrawal of the drug. Ototoxic symptoms are caused by increased labyrinthine pressure or an effect on the hair cells of the cochlea, perhaps secondary to vasoconstriction in the auditory microvasculature. As most competitive COX inhibitors are not associated with hearing loss or tinnitus, a direct effect of salicylic acid rather than suppression of PG synthesis is likely.

Salicylates and Pregnancy. Infants born to women who ingest salicylates for long periods may have significantly reduced birth weights. When administered during the third trimester, there also is an increase in perinatal mortality, anemia, antepartum and postpartum hemorrhage, prolonged gestation, and complicated deliveries; thus, its use during this period should be avoided. As mentioned earlier in “Pregnancy and Lactation,” administration of NSAIDs during the third trimester of pregnancy also can cause premature closure of the ductus arteriosus. The use of aspirin has been advocated for the treatment of women at high risk of preeclampsia, but it is estimated that treatment of 90 women is required to prevent one case of preeclampsia (Villar et al., 2004).

Local Irritant Effects. Salicylic acid is irritating to skin and mucosa and destroys epithelial cells.

Drug Interactions. The plasma concentration of salicylates generally is little affected by other drugs, but concurrent administration of aspirin lowers the concentrations of indomethacin, naproxen, ketoprofen, and fenoprofen, at least in part by displacement from plasma proteins. Important adverse interactions of aspirin with warfarin, sulfonyleureas, and methotrexate are mentioned earlier in “Drug Interactions.” Other interactions of aspirin include the antagonism of spironolactone-induced natriuresis and the blockade of the active transport of penicillin from CSF to blood. Magnesium-aluminum hydroxide antacids can alkalinize the urine enough to increase salicylic acid clearance significantly and reduce steady-state concentrations. Conversely, discontinuation of antacid therapy can increase plasma concentrations to toxic levels.

Salicylate Intoxication

Salicylate poisoning or serious intoxication often occurs in children and sometimes is fatal. CNS effects, intense hyperpnea, and hyperpyrexia are prominent symptoms. Salicylate intoxication should be seriously considered in any young child with coma, convulsions, or cardiovascular collapse. The fatal dose varies with the preparation of salicylate. Death has followed use of 10–30 g of sodium salicylate or aspirin in adults, but much larger amounts (130 g of aspirin in one case) have been ingested without a fatal outcome. The lethal dose of methyl salicylate (also known as oil of wintergreen, sweet birch oil, gaultheria oil, betula oil) is considerably less than that of sodium salicylate. As little as a taste of methyl salicylate by children <6 years of age and >4 mL (4.7 g) of methyl salicylate by children ≥6 years of age may cause severe systemic toxicity and warrants referral to an emergency department. Symptoms of poisoning by methyl salicylate differ little from those described earlier for aspirin in “Adverse Effects.” The drug’s odor can be detected easily on the breath and in the urine and vomitus. Poisoning by salicylic acid differs only in the increased prominence of GI symptoms due to the marked local

irritation. Mild chronic salicylate intoxication is called *salicylism*. When fully developed, the syndrome includes headache, dizziness, tinnitus, difficulty hearing, dimness of vision, mental confusion, lassitude, drowsiness, sweating, thirst, hyperventilation, nausea, vomiting, and occasionally diarrhea.

Neurological Effects. In high doses, salicylates have toxic effects on the CNS, consisting of stimulation (including convulsions) followed by depression. Confusion, dizziness, tinnitus, high-tone deafness, delirium, psychosis, stupor, and coma may occur. Salicylates induce nausea and vomiting, which result from stimulation of sites that are accessible from the CSF, probably in the medullary chemoreceptor trigger zone. In humans, centrally induced nausea and vomiting often appear at plasma salicylate concentrations of ~270 µg/mL, but these same effects may occur at much lower plasma levels as a result of local gastric irritation.

Respiration. The respiratory effects of salicylates contribute to the serious acid–base balance disturbances that characterize poisoning by this class of compounds. Salicylates stimulate respiration indirectly by uncoupling of oxidative phosphorylation and directly by stimulation of the respiratory center in the medulla (see “Respiration” in the aspirin section). Uncoupling of oxidative phosphorylation also leads to excessive heat production, and salicylate toxicity is associated with hyperthermia, particularly in children. Marked hyperventilation occurs when the level approaches 500 µg/mL. However, should salicylate toxicity be associated with the co-administration of a barbiturate or opioid, then central respiratory depression will prevent hyperventilation, and the salicylate-induced uncoupling of oxidative phosphorylation will be associated with a marked increase in plasma P_{CO_2} and respiratory acidosis. Prolonged exposure to high doses of salicylates leads to depression of the medulla, with central respiratory depression and circulatory collapse, secondary to vasomotor depression. Because enhanced CO_2 production continues, respiratory acidosis ensues. Respiratory failure is the usual cause of death in fatal cases of salicylate poisoning. Elderly patients with chronic salicylate intoxication often develop noncardiogenic pulmonary edema, which is considered an indication for hemodialysis.

Acid–Base Balance and Electrolytes. As described earlier in “Acid–Base and Electrolyte Balance and Renal Effects” in the aspirin section, high therapeutic doses of salicylate are associated with a primary respiratory alkalosis and compensatory renal acidosis. Subsequent changes in acid–base status generally occur only when toxic doses of salicylates are ingested by infants and children or occasionally after large doses in adults. The phase of primary respiratory alkalosis rarely is recognized in children with salicylate toxicity. They usually present in a state of mixed respiratory and renal acidosis, characterized by a decrease in blood pH, a low plasma bicarbonate concentration, and normal or nearly normal plasma P_{CO_2} . Direct salicylate-induced depression of respiration prevents adequate respiratory hyperventilation to match the increased peripheral production of CO_2 . Consequently, plasma P_{CO_2} increases and blood pH decreases. Because the concentration of bicarbonate in plasma already is low due to increased renal bicarbonate excretion, the acid–base status at this stage essentially is an uncompensated respiratory acidosis. Superimposed, however, is a true metabolic acidosis caused by accumulation of acids as a

result of three processes. First, toxic concentrations of salicylates displace ~2-3 mEq/L of plasma bicarbonate. Second, vasomotor depression caused by toxic doses of salicylates impairs renal function, with consequent accumulation of sulfuric and phosphoric acids; renal failure can ensue. Third, salicylates in toxic doses may decrease aerobic metabolism as a result of inhibition of various enzymes. This derangement of carbohydrate metabolism leads to the accumulation of organic acids, especially pyruvic, lactic, and acetoacetic acids.

The same series of events also causes alterations of water and electrolyte balance. The low plasma P_{CO_2} leads to decreased renal tubular reabsorption of bicarbonate and increased renal excretion of Na^+ , K^+ , and water. Water also is lost by salicylate-induced sweating (especially in the presence of hyperthermia) and hyperventilation; dehydration, which can be profound, particularly in children, rapidly occurs. Because more water than electrolyte is lost through the lungs and by sweating, the dehydration is associated with hypernatremia. Prolonged exposure to high doses of salicylate also causes depletion of K^+ due to both renal and extrarenal factors.

Cardiovascular Effects. Toxic doses of salicylates lead to an exaggeration of the unfavorable cardiovascular responses seen at high therapeutic doses (see “Adverse Effects”), and central vasomotor paralysis occurs. Petechiae may be seen due to defective platelet function.

Metabolic Effects. Large doses of salicylates may cause hyperglycemia and glycosuria and deplete liver and muscle glycogen; these effects are partly explained by the release of epinephrine. Such doses also reduce aerobic metabolism of glucose, increase glucose-6-phosphatase activity, and promote the secretion of glucocorticoids. There is a greater risk of hypoglycemia and subsequent permanent brain injury in children. Salicylates in toxic doses cause a significant negative nitrogen balance, characterized by an aminoaciduria. Adrenocortical activation may contribute to the negative nitrogen balance by enhancing protein catabolism. Salicylates reduce lipogenesis by partially blocking incorporation of acetate into fatty acids; they also inhibit epinephrine-stimulated lipolysis in fat cells and displace long-chain fatty acids from binding sites on human plasma proteins. The combination of these effects leads to increased entry and enhanced oxidation of fatty acids in muscle, liver, and other tissues and to decreased plasma concentrations of free fatty acids, phospholipid, and cholesterol; the oxidation of ketone bodies also is increased.

Endocrine Effects. Very large doses of salicylates stimulate steroid secretion by the adrenal cortex through an effect on the hypothalamus and transiently increase plasma concentrations of free corticosteroids by their displacement from plasma proteins. The therapeutic anti-inflammatory effects of salicylate are independent of these effects.

Management of Salicylate Overdose. Salicylate poisoning represents an acute medical emergency, and death may result despite heroic efforts. Monitoring of salicylate levels is a useful guide to therapy but must be used in conjunction with an assessment of the patient’s overall clinical condition, acid–base balance, formulation of salicylate ingested, timing, and dose (O’Malley, 2007).

There is no specific antidote for salicylate poisoning. Management begins with a rapid assessment followed by the ABCD

approach to medical emergencies: “A (airway), B (breathing), C (circulation), D (decontamination)”.

PARA-AMINOPHENOL DERIVATIVES: ACETAMINOPHEN

Acetaminophen (paracetamol; *N*-acetyl-*p*-aminophenol; *TYLENOL*, others) is the active metabolite of phenacetin.

Acetaminophen raises the threshold to painful stimuli, thus exerting an analgesic effect against pain due to a variety of etiologies. It is available without a prescription and is used as a common household analgesic. The drug also is available in fixed-dose combinations containing narcotic and non-narcotic analgesics (including aspirin and other salicylates), barbiturates, caffeine, vascular headache remedies, sleep aids, toothache remedies, antihistamines, antitussives, decongestants, expectorants, cold and flu preparations, and sore throat treatments. Acetaminophen is an effective alternative to aspirin as an analgesic–antipyretic agent; however, its anti-inflammatory effects are much weaker. Although it is indicated for pain relief in patients with osteoarthritis, it is not a suitable substitute for aspirin or other NSAIDs in chronic inflammatory conditions such as rheumatoid arthritis. Acetaminophen is well tolerated and has a low incidence of GI side effects. However, acute overdose can cause severe hepatic damage, and the number of accidental or deliberate poisonings with acetaminophen continues to grow. Chronic use of <2 g/day is not typically associated with hepatic dysfunction, but overuse of acetaminophen-containing narcotic and over-the-counter combination products marketed in the U.S. has led to heightened awareness of the possibility of toxicity.

Mechanism of Action

Acetaminophen has analgesic and antipyretic effects similar to those of aspirin. However, as mentioned in the preceding section, it has only weak anti-inflammatory effects, and it has been thought to have a generally poor ability to inhibit COX in the presence of high concentrations of peroxides, as are found at sites of inflammation. This aspect of its action has not been addressed rigorously. A dose of 1000 mg results in ~50% inhibition of both COX-1 and COX-2 in whole blood assays *ex vivo* in healthy volunteers.

It has been suggested that COX inhibition might be disproportionately pronounced in the brain, explaining its antipyretic efficacy (Ouellet and Percival, 2001; Boutaud et al., 2002). A COX-1 splice variant identified in the canine brain shows some susceptibility for inhibition by acetaminophen *in vitro* (Chandrasekharan et al., 2002). However, this splice variant does not exist in humans.

Absorption, Distribution, and Elimination

Oral acetaminophen has excellent bioavailability. Peak plasma concentrations occur within 30-60 minutes, and the $t_{1/2}$ in plasma is ~2 hours after therapeutic doses. Acetaminophen is relatively uniformly distributed throughout most body fluids. Binding of the drug to plasma proteins is variable but less than with other NSAIDs; only 20-50% is bound at the concentrations encountered during acute intoxication. Some 90-100% of the drug may be recovered in the urine within the first day at therapeutic dosing, primarily after hepatic conjugation with glucuronic acid (~60%), sulfuric acid (~35%), or cysteine (~3%); small amounts of hydroxylated and deacetylated metabolites also have been detected (Table 34-1). Children have less capacity for glucuronidation of the drug than do adults. A small proportion of acetaminophen undergoes CYP-mediated *N*-hydroxylation to form NAPQI, a highly reactive intermediate. This metabolite normally reacts with sulfhydryl groups in glutathione (GSH) and thereby is rendered harmless. However, after ingestion of large doses of acetaminophen, the metabolite is formed in amounts sufficient to deplete hepatic GSH and contributes significantly to the toxic effects of overdose (see "Acetaminophen Intoxication").

Therapeutic Uses. Acetaminophen is suitable for analgesic or antipyretic uses; it is the first-line analgesic in osteoarthritis and particularly valuable for patients in whom aspirin is contraindicated (e.g., those with peptic ulcer, aspirin hypersensitivity, children with a febrile illness). The conventional oral dose of acetaminophen is 325-650 mg every 4-6 hours; total daily doses should not exceed 4000 mg (2000 mg/day for chronic alcoholics).

In 2009, an FDA advisory panel recommended a lower maximum daily dose of acetaminophen of 2600 mg and a decrease in the maximum single dose from 1000 mg to 650 mg. Single doses for children 2-11 years of age range from 160-480 mg, depending on age and weight; no more than five doses should be administered in 24 hours. A dose of 10 mg/kg also may be used. Particular attention is warranted due to the availability of a wide variety of prescription and non-prescription multi-ingredient medications that represent potentially toxic overlapping sources of acetaminophen.

Adverse Effects. Acetaminophen usually is well tolerated at recommended therapeutic doses. Single or repeated therapeutic doses of acetaminophen have no effect on the cardiovascular and respiratory systems, platelets, or coagulation. Acid-base changes and uricosuric effects do not occur. Epidemiological studies suggest that GI adverse effects are less common than with therapeutic doses of tNSAIDs (García Rodríguez et al., 2004). Rash and other allergic reactions occur occasionally. The rash usually is erythematous or urticarial,

but sometimes it is more serious and may be accompanied by drug fever and mucosal lesions. Patients who show hypersensitivity reactions to the salicylates only rarely exhibit sensitivity to acetaminophen. The use of acetaminophen has been associated anecdotally with neutropenia, thrombocytopenia, pancytopenia, hemolytic anemia, and methemoglobinemia. Kidney damage has been reported, and liver damage is a prominent feature of overdose.

Acetaminophen Intoxication

Acute ingestion of >7.5 g of acetaminophen, or repeat use of supratherapeutic doses, can result in toxicity. The most serious acute adverse effect of overdosage of acetaminophen is a potentially fatal hepatic necrosis. Renal tubular necrosis and hypoglycemic coma also may occur. The mechanism by which overdosage with acetaminophen leads to hepatocellular injury and death involves its conversion to the toxic metabolite, NAPQI. The glucuronide and sulfate conjugation pathways become saturated, and increasing amounts undergo CYP-mediated *N*-hydroxylation to form NAPQI. This is eliminated rapidly by conjugation with GSH and then further metabolized to a mercapturic acid and excreted into the urine. In the setting of acetaminophen overdose, hepatocellular levels of GSH become depleted. The highly reactive NAPQI metabolite binds covalently to cell macromolecules, leading to dysfunction of enzymatic systems and structural and metabolic disarray. Furthermore, depletion of intracellular GSH renders the hepatocytes highly susceptible to oxidative stress and apoptosis (see Figure 4-5 and Chapter 6).

Hepatotoxicity. In adults, hepatotoxicity may occur after ingestion of a single dose of 10-15 g (150-250 mg/kg) of acetaminophen; doses of 20-25 g or more are potentially fatal. Conditions of CYP induction (e.g., heavy alcohol consumption) or GSH depletion (e.g., fasting or malnutrition) increase the susceptibility to hepatic injury, which has been documented, albeit uncommonly, with doses in the therapeutic range.

Symptoms that occur during the first 2 days of acute poisoning by acetaminophen reflect gastric distress (e.g., nausea, abdominal pain, anorexia) and belie the potential seriousness of the intoxication. Plasma transaminases become elevated, sometimes markedly so, beginning ~12-36 hours after ingestion. Clinical indications of hepatic damage manifest within 2-4 days of ingestion of toxic doses, with right subcostal pain, tender hepatomegaly, jaundice, and coagulopathy. Renal impairment or frank renal failure may occur. Liver enzyme abnormalities typically peak 72-96 hours after ingestion. The onset of hepatic encephalopathy or worsening coagulopathy beyond this time indicates a poor prognosis. Biopsy of the liver reveals centrilobular necrosis with sparing of the periportal area. In nonfatal cases, the hepatic lesions are reversible over a period of weeks or months.

Management of Acetaminophen Overdose. Acetaminophen overdose constitutes a medical emergency (Heard, 2008). Severe liver damage occurs in 90% of patients with plasma concentrations of acetaminophen >300 µg/mL at 4 hours or 45 µg/mL at 15 hours after the ingestion of the drug. Minimal hepatic damage can be anticipated when the drug concentration is <120 µg/mL at 4 hours or 30 µg/mL at 12 hours after ingestion. The Rumack-Matthew nomogram relates the plasma levels of acetaminophen and time after ingestion to the predicted risk of liver injury (Rumack et al., 1981).

Early diagnosis and treatment of acetaminophen overdose is essential to optimize outcome. Perhaps 10% of poisoned patients who do not receive specific treatment develop severe liver damage; 10-20% of these eventually die of hepatic failure despite intensive supportive care. Activated charcoal, if given within 4 hours of ingestion, decreases acetaminophen absorption by 50-90% and is the preferred method of gastric decontamination. Gastric lavage generally is not recommended.

N-acetylcysteine (NAC) (MUCOMYST, ACETADOTE) is indicated for those at risk of hepatic injury. NAC therapy should be instituted in suspected cases of acetaminophen poisoning before blood levels become available, with treatment terminated if assay results subsequently indicate that the risk of hepatotoxicity is low. NAC functions by detoxifying NAPQI. It both repletes GSH stores and may conjugate directly with NAPQI by serving as a GSH substitute. There is some evidence that in cases of established acetaminophen toxicity, NAC may protect against extrahepatic injury by its anti-oxidant and anti-inflammatory properties. Even in the presence of activated charcoal, there is ample absorption of NAC, and neither should activated charcoal be avoided nor NAC administration be delayed because of concerns of a charcoal-NAC interaction. Adverse reactions to NAC include rash (including urticaria, which does not require drug discontinuation), nausea, vomiting, diarrhea, and rare anaphylactoid reactions. An oral loading dose of 140 mg/kg is given, followed by the administration of 70 mg/kg every 4 hours for 17 doses. Where available, the intravenous loading dose is 150 mg/kg by intravenous infusion in 200 mL of 5% dextrose over 60 minutes, followed by 50 mg/kg by intravenous infusion in 500 mL of 5% dextrose over 4 hours, then 100 mg/kg by intravenous infusion in 1000 mL of 5% dextrose over 16 hours.

In addition to NAC therapy, aggressive supportive care is warranted. This includes management of hepatic and renal failure if they occur and intubation if the patient becomes obtunded. Hypoglycemia can result from liver failure, and plasma glucose should be monitored closely. Fulminant hepatic failure is an indication for liver transplantation, and a liver transplant center should be contacted early in the course of treatment of patients who develop severe liver injury despite NAC therapy.

ACETIC ACID DERIVATIVES

Indomethacin

Indomethacin (INDOCIN, others), a methylated indole derivative, was introduced in 1963 and is indicated for the treatment of moderate to severe rheumatoid arthritis, osteoarthritis, and acute gouty arthritis; ankylosing

spondylitis; and acute painful shoulder. Although indomethacin is still used clinically, mainly as a steroid-sparing agent, toxicity and the availability of safer alternatives have limited its use. Indomethacin is available in an injectable form for the closure of patent ductus arteriosus.

Mechanism of Action. Indomethacin is a more potent nonselective inhibitor of the COXs than is aspirin; it also inhibits the motility of polymorphonuclear leukocytes, depresses the biosynthesis of mucopolysaccharides, and may have a direct, COX-independent vasoconstrictor effect. Indomethacin has prominent anti-inflammatory and analgesic-antipyretic properties similar to those of the salicylates.

Absorption, Distribution, and Elimination. Oral indomethacin has excellent bioavailability. Peak concentrations occur 1-2 hours after dosing (Table 34-1). The concentration of the drug in the CSF is low, but its concentration in synovial fluid is equal to that in plasma within 5 hours of administration. There is enterohepatic cycling of the indomethacin metabolites and probably of indomethacin itself. The $t_{1/2}$ in plasma is variable, perhaps because of enterohepatic cycling, but averages ~2.5 hours.

Therapeutic Uses. Indomethacin is estimated to be ~20 times more potent than aspirin. A high rate of intolerance limits the long-term analgesic use of indomethacin. Likewise, it is not commonly used as an analgesic or antipyretic unless the fever has been refractory to other agents (e.g., Hodgkin's disease). When tolerated, indomethacin often is more effective than aspirin.

Indomethacin is FDA approved for closure of persistent patent ductus arteriosus in premature infants who weigh between 500 and 1750 g, who have a hemodynamically significant patent ductus arteriosus, and in whom other supportive maneuvers have been attempted. The regimen involves intravenous administration of 0.1-0.25 mg/kg every 12 hours for three doses, with the course repeated one time if necessary. Successful closure can be expected in >70% of neonates treated. The principal limitation of treating neonates is renal toxicity, and therapy is interrupted if the output of urine falls to <0.6 mL/kg/hr. Renal failure, enterocolitis, thrombocytopenia, or hyperbilirubinemia are contraindications to the use of indomethacin. Treatment with indomethacin also may decrease the incidence and severity of intraventricular hemorrhage in low-birth-weight neonates (Ment et al., 1994).

Adverse Effects and Drug Interactions. A very high percentage (35-50%) of patients receiving usual therapeutic doses of indomethacin experience untoward symptoms, and ~20% must discontinue its use because of the side effects. GI adverse events are common and can be fatal; elderly patients are at significantly greater risk. Diarrhea may occur and sometimes is associated with ulcerative lesions of the bowel. Acute pancreatitis has been reported, as have rare, but potentially fatal, cases of hepatitis. The most frequent CNS effect (indeed, the most common side effect) is severe frontal headache, occurring in 25-50% of patients who take the drug for long periods. Dizziness, vertigo, light-headedness, and mental confusion may occur. Seizures have been reported, as have severe depression, psychosis, hallucinations, and suicide. Caution is advised when administering indomethacin to elderly patients or to those with underlying epilepsy, psychiatric disorders, or Parkinson's disease, because they are at greater risk for the development of serious CNS adverse effects. Hematopoietic reactions include neutropenia, thrombocytopenia, and rarely aplastic anemia.

The total plasma concentration of indomethacin plus its inactive metabolites is increased by concurrent administration of probenecid, but indomethacin does not interfere with the uricosuric effect of probenecid. Indomethacin antagonizes the natriuretic and antihypertensive effects of furosemide and thiazide diuretics and blunts the antihypertensive effect of β -receptor antagonists, AT_1 -receptor antagonists, and ACE inhibitors.

Sulindac

Sulindac (CLINORIL, others) is a congener of indomethacin, which was developed in an attempt to find a less toxic but effective alternative (see Haanen, 2001).

Mechanism of Action. Sulindac is a prodrug and appears to be either inactive or relatively weak *in vitro*. The active sulfide metabolite is >500 times more potent than sulindac as an inhibitor of COX but less than half as potent as indomethacin. The early notion that gastric or intestinal mucosa is not directly exposed to high concentrations of active drug after oral administration of sulindac provided an initial rationale for the claim that sulindac results in a lower incidence of GI toxicity than indomethacin. However, this notion ignores the fact that the mucosa of the GI tract is directly exposed to circulating levels of active drug and no advantage of sulindac over non-indomethacin NSAIDs has materialized in clinical practice. Similarly, early clinical studies

suggesting that sulindac, in contrast to other NSAIDs, did not alter renal PG levels and therefore might avoid the association with hypertension in susceptible individuals, have been discredited (Kulling et al., 1995). *In short, the same precautions that apply to other NSAIDs regarding patients at risk for GI toxicity, cardiovascular risk, and renal impairment also apply to sulindac.*

Absorption, Distribution, and Elimination. The metabolism and pharmacokinetics of sulindac are complex. About 90% of the drug is absorbed in humans after oral administration (Table 34-1). Peak concentrations of sulindac in plasma are attained within 1-2 hours, while those of the sulfide metabolite occur ~8 hours after oral administration. Sulindac undergoes two major biotransformations. It is oxidized to the sulfone and then reversibly reduced to the sulfide, the active metabolite. The sulfide is formed largely by the action of bowel microflora on sulindac excreted in the bile. All three compounds are found in comparable concentrations in human plasma. The $t_{1/2}$ of sulindac itself is ~7 hours, but the active sulfide has a $t_{1/2}$ as long as 18 hours. Sulindac and its metabolites undergo extensive enterohepatic circulation, and all are bound highly to plasma protein. Little of the sulfide (or of its conjugates) is found in urine. The principal components excreted in the urine are the sulfone and its conjugates, which account for nearly 30% of an administered dose; sulindac and its conjugates account for ~20%. Up to 25% of an oral dose may appear as metabolites in the feces.

Therapeutic Uses. Sulindac has been used mainly for the treatment of rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, tendonitis, bursitis, acute painful shoulder, and the pain of acute gout. Its analgesic and anti-inflammatory effects are comparable to those achieved with aspirin. The most common dosage for adults is 150-200 mg twice a day. A use proposed for sulindac is to prevent colon cancer in patients with familial adenomatous polyposis (see "Cancer Chemoprevention").

Adverse Effects. Although the incidence of toxicity is lower than with indomethacin, untoward reactions to sulindac are common. The typical NSAID GI side effects are seen in nearly 20% of patients. CNS side effects as described earlier for indomethacin in "Adverse Effects and Drug Interactions" are seen in $\leq 10\%$ of patients. Rash and pruritus occur in 5% of patients. Transient elevations of hepatic transaminases in plasma are less common.

Etodolac

Therapeutic Uses. Etodolac is an acetic acid derivative with some degree of COX-2 selectivity (Figure 34-1). Thus, at anti-inflammatory doses, the frequency of gastric irritation may be less than with other NSAIDs (Warner et al., 1999). A single oral dose (200-400 mg) of etodolac provides postoperative analgesia that typically lasts for 6-8 hours. Etodolac also is effective in the treatment of osteoarthritis, rheumatoid arthritis, and mild to moderate pain, and the drug appears to be uricosuric. Sustained-release preparations are available, allowing once-a-day administration.

Adverse Effects. Etodolac appears to be relatively well tolerated. About 5% of patients who have taken the drug for ≤ 1 year discontinue treatment because of side effects, which include GI intolerance, rashes, and CNS effects.

Tolmetin

Therapeutic Uses. Tolmetin (TOLECTIN, others), a heteroaryl acetic acid derivative, is approved in the U.S. for the treatment of osteoarthritis, rheumatoid arthritis, and juvenile rheumatoid arthritis; it also has been used in the treatment of ankylosing spondylitis. Accumulation of the drug in synovial fluid begins within 2 hours and persists for ≤ 8 hours after a single oral dose. It appears to be approximately equivalent in efficacy to moderate doses of aspirin, in recommended doses (200-600 mg three times/day). The maximum recommended dose is 1.8 g/day, typically given in divided doses with meals, milk, or antacids to lessen abdominal discomfort. However, peak plasma concentrations and bioavailability are reduced when the drug is taken with food. Tolmetin possesses typical tNSAID properties and side effects.

Adverse Effects. Side effects occur in 25-40% of patients who take tolmetin, and 5-10% discontinue use of the drug. GI side effects are the most common (15%), and gastric ulceration has been observed. CNS side effects similar to those seen with indomethacin and aspirin occur, but they are less common and less severe.

Ketorolac

Ketorolac, a heteroaryl acetic acid derivative, is a potent analgesic but only a moderately effective anti-inflammatory drug.

KETOROLAC

Therapeutic Uses. The use of ketorolac is limited to ≤ 5 days for acute pain requiring opioid-level analgesia and can be administered intramuscularly, intravenously, or orally. Like other NSAIDs, aspirin sensitivity is a contraindication to the use of ketorolac. Typical doses are 30-60 mg (intramuscular), 15-30 mg (intravenous), and 10-20 mg (oral). Ketorolac has a rapid onset of action and a short duration of action. It is widely used in postoperative patients, but it should not be used for routine obstetric analgesia. Topical (ophthalmic) ketorolac (ACULAR, others) is FDA approved for the treatment of seasonal allergic conjunctivitis and postoperative ocular inflammation after cataract extraction and after corneal refractive surgery. The pharmacology of ketorolac has been reviewed (Buckley and Brogden, 1990).

Adverse Effects. Side effects at usual oral doses include somnolence, dizziness, headache, GI pain, dyspepsia, nausea, and pain at the site of injection. The black box warning for ketorolac stresses the possibility of serious adverse GI, renal, bleeding, and hypersensitivity reactions from the use of this potent NSAID analgesic. Patients receiving greater than recommended doses or concomitant NSAID therapy and those at the extremes of age appear to be particularly at risk.

Nabumetone

Nabumetone is the prodrug of 6-methoxy-2-naphthylacetic acid; thus it is a weak inhibitor of COX *in vitro* but a potent COX inhibitor *in vivo*.

NABUMETONE

Therapeutic Uses. Nabumetone is an anti-inflammatory agent approved in 1991 for use in the U.S. It has been reviewed (Davies, 1997). Clinical trials with nabumetone have indicated substantial efficacy in the treatment of rheumatoid arthritis and osteoarthritis, with a relatively low incidence of side effects. The dose typically is 1000 mg given once daily. The drug also has off-label use in the short-term treatment of soft-tissue injuries.

Absorption, Distribution, and Elimination. Nabumetone is absorbed rapidly and is converted in the liver to one or more active metabolites, principally 6-methoxy-2-naphthylacetic acid, a potent nonselective inhibitor of COX. This metabolite, inactivated by *O*-demethylation in the liver, is then conjugated before excretion and is eliminated with a $t_{1/2}$ of ~ 24 hours.

Common Adverse Effects. Nabumetone is associated with crampy lower abdominal pain and diarrhea, but the incidence of GI ulceration appears to be lower than with other tNSAIDs, although randomized, controlled studies directly comparing tolerability and clinical outcomes have not been performed. Other side effects include rash, headache, dizziness, heartburn, tinnitus, and pruritus.

Diclofenac

Diclofenac, a phenylacetic acid derivative, is among the most commonly used NSAIDs in the E.U. (McNeely and Goa, 1999). It is marketed as a potassium salt (ZIPSOR, others) for oral administration, as an epolamine form (FLECTOR) for transdermal administration, and as a sodium salt for topical (SOLARAZE gel; VOLTAREN ophthalmic drops, others) or oral (VOLTAREN, VOLTAREN-XR, others) administration.

DICLOFENAC

Mechanism of Action. Diclofenac has analgesic, antipyretic, and anti-inflammatory activities. Its potency is substantially greater than that of indomethacin, naproxen, or several other tNSAIDs. The selectivity of diclofenac for COX-2 resembles that of celecoxib. In addition, diclofenac appears to reduce intracellular concentrations of free AA in leukocytes, perhaps by altering its release or uptake.

Absorption, Distribution, and Elimination. Diclofenac has rapid absorption, extensive protein binding, and a $t_{1/2}$ of 1-2 hours (Table 34-1). The short $t_{1/2}$ makes it necessary to dose diclofenac considerably higher than would be required to inhibit COX-2 fully at peak plasma concentrations to afford inhibition throughout the dosing interval. There is a substantial first-pass effect, such that only ~50% of diclofenac is available systemically. The drug accumulates in synovial fluid after oral administration, which may explain why its duration of therapeutic effect is considerably longer than its plasma $t_{1/2}$. Diclofenac is metabolized in the liver by a member of the CYP2C subfamily to 4-hydroxydiclofenac, the principal metabolite, and other hydroxylated forms; after glucuronidation and sulfation, the metabolites are excreted in the urine (65%) and bile (35%).

Therapeutic Uses. Diclofenac is approved in the U.S. for the long-term symptomatic treatment of rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, pain, primary dysmenorrhea, and acute migraine. Four oral formulations are available: immediate-release tablets (CATAFLAM, others) and capsules (ZIPSOR), delayed-release tablets [VOLTAREN, VOLTAROL (U.K.), others], extended-release tablets (VOLTAREN-XR, others), and a powder for oral solution (CAMBIA). The usual daily oral dosage is 100-200 mg, given in several divided doses. For migraine, one packet of powder (50 mg) dissolved in 1-2 oz of water is administered. Diclofenac for topical use is available as a gel (VOLTAREN) and as a transdermal patch (FLECTOR); systemically active concentrations released from these preparations are thought to contribute more to symptom relief than direct transport through the skin into the inflamed tissue. Diclofenac also is available in combination with misoprostol, a PGE₁ analog (ARTHROTEC). This combination retains the efficacy of diclofenac while reducing the frequency of GI ulcers and erosions. In addition, an ophthalmic solution of diclofenac (VOLTAREN, others) is available for treatment of postoperative inflammation following cataract extraction and postoperative pain and photophobia following corneal refractive surgery.

Adverse Effects. Diclofenac produces side effects (particularly GI) in ~20% of patients, and ~2% of patients discontinue therapy as a result. The incidence of serious GI adverse effects did not differ between diclofenac and the COX-2-selective inhibitors, celecoxib (Juni et al., 2002) and etoricoxib (Cannon et al., 2006), likely because diclofenac exhibits a degree of COX-2 selectivity that is similar to that of celecoxib. The drug carries the same black box warning as all other tNSAIDs regarding cardiovascular events. Hypersensitivity reactions have occurred following topical application.

Modest elevation of hepatic transaminases in plasma occurs in 5-15% of patients. Although usually moderate, transaminase values may increase more than 3-fold in a small percentage of patients. The elevations usually are reversible. Another member of this phenylacetic acid family of NSAIDs, bromfenac, was withdrawn from the market because of its association with severe, irreversible liver injury in some patients. Bromfenac was re-licensed in the U.S. in 2005 as an ophthalmic solution (XIBROM) for postoperative ocular inflammation and pain following cataract extraction. The structurally similar nepafenac (NEVANAC) was licensed as an ophthalmic in the same year for the same indication. Lumiracoxib, another diclofenac analog (see the following section), was withdrawn from the market in several countries due to liver toxicity. Transaminases should be measured

during the first 8 weeks of therapy with diclofenac, and the drug should be discontinued if abnormal values persist or if other signs or symptoms develop. Other untoward responses to diclofenac include CNS effects, rashes, allergic reactions, fluid retention, edema, and renal function impairment. The drug is not recommended for children, nursing mothers, or pregnant women. Consistent with its preference for COX-2, and unlike ibuprofen, diclofenac does not interfere with the antiplatelet effect of aspirin (Catella-Lawson et al., 2001).

Lumiracoxib

Lumiracoxib is an analog of diclofenac; it differs only by an additional methyl group and one fluorine substitution for chlorine. Lumiracoxib has greater COX-2 selectivity *in vitro* than any of the currently available coxibs. Its structural similarity to diclofenac is thought to account for their common hepatic adverse event profiles that may occur via a mechanism independent from COX inhibition. Lumiracoxib's potency is similar to that of naproxen. It is used at daily doses of 100 or 200 mg for osteoarthritis and 400 mg for acute pain. Lumiracoxib is not approved in the U.S., and marketing authorization was revoked in 2007 in many countries following reports of serious liver toxicity. Refer to earlier editions of this text for further details.

PROPRIONIC ACID DERIVATIVES

Ibuprofen, the most commonly used tNSAID in the U.S., was the first member of the propionic acid class of NSAIDs to come into general use and is available without a prescription in the U.S. Naproxen, also available without prescription, has a longer but variable $t_{1/2}$, making twice-daily administration feasible (and perhaps once daily in some individuals). Oxaprozin also has a long $t_{1/2}$ and may be given once daily. Figure 34-4 shows the chemical structures of propionic acid derivatives.

Mechanism of Action. Propionic acid derivatives are nonselective COX inhibitors with the effects and side effects common to other tNSAIDs. Although there is considerable variation in their potency as COX inhibitors, this is not of obvious clinical consequence. Some of the propionic acid derivatives, particularly naproxen, have prominent inhibitory effects on leukocyte function, and some data suggest that naproxen may have slightly better efficacy with regard to analgesia and relief of morning stiffness. This suggestion of benefit accords with the clinical pharmacology of naproxen that suggests that some but not all individuals dosed with 500 mg twice daily sustain platelet inhibition throughout the dosing interval.

Therapeutic Uses. Ibuprofen, naproxen, flurbiprofen, fenoprofen, ketoprofen, and oxaprozin, are available in the U.S. Several additional agents in this class, including fenbufen, carprofen, piroprofen, indobufen, and tiaprofenic acid, are in use or under study in other countries.

Propionic acid derivatives are approved for use in the symptomatic treatment of rheumatoid arthritis and osteoarthritis. Some also are approved for pain, ankylosing spondylitis, acute gouty arthritis, tendinitis, bursitis, and migraine and for primary dysmenorrhea. Small clinical studies suggest that the propionic acid

Figure 34–4. Chemical structures of propionic acid derivatives.

derivatives are comparable in efficacy to aspirin for the control of the signs and symptoms of rheumatoid arthritis and osteoarthritis, perhaps with improved tolerability.

Drug Interactions. Ibuprofen also has been shown to interfere with the antiplatelet effects of aspirin (see “Concomitant NSAIDs and Low-Dose Aspirin”). There also is evidence for a similar interaction between aspirin and naproxen. Propionic acid derivatives have not been shown to alter the pharmacokinetics of the oral hypoglycemic drugs or warfarin.

Ibuprofen

Absorption, Distribution, and Elimination. Ibuprofen is absorbed rapidly, bound avidly to protein, and undergoes hepatic metabolism (90% is metabolized to hydroxylate or carboxylate derivatives) and renal excretion of metabolites. The $t_{1/2}$ is ~2 hours. Slow equilibration with the synovial space means that its anti-arthritic effects may persist after plasma levels decline. In experimental animals, ibuprofen and its metabolites readily cross the placenta.

Therapeutic Uses. Ibuprofen [ADVIL, MOTRIN IB, BRUFEN (U.K.), ANADIN ULTRA (U.K.), others] is supplied as tablets, capsules, caplets, and gelcaps containing 50–800 mg; as oral drops; and as an oral suspension. Dosage forms containing ≤ 200 mg are available without a prescription. Ibuprofen is licensed for marketing in fixed-dose combinations with antihistamines, decongestants, oxycodone (COMBUNOX, others), and hydrocodone (REPREXAIN, IBUDONE, VICOPROFEN, others). An injectable formulation for closure of patent ductus (ibuprofen lysine; NEOPROFEN) has been licensed since 2006, and an injectable formulation for pain that was initially approved in 1974, CALDOLOR, was licensed by the FDA in 2009 for in-hospital use.

Doses of ≤ 800 mg four times daily can be used in the treatment of rheumatoid arthritis and osteoarthritis, but lower doses often are adequate. The usual dose for mild to moderate pain, such as that of primary dysmenorrhea, is 400 mg every 4–6 hours as needed. For pain or fever, intravenous ibuprofen is administered at a dose of 100–800 mg over 30 minutes every 4–6 hours. Ibuprofen has been reviewed (Davies, 1998a; Rainsford, 2003).

Adverse Effects. Ibuprofen is thought to be better tolerated than aspirin and indomethacin and has been used in patients with a history of GI intolerance to other NSAIDs. Nevertheless, 5–15% of patients experience GI side effects.

Epidemiological studies suggest that the relative risk of myocardial infarction is unaltered by ibuprofen or perhaps slightly increased but is considerably less than the risk from COX-2–selective inhibitors. Other adverse effects of ibuprofen have been reported less frequently. They include thrombocytopenia, rashes, headache, dizziness, blurred vision, and in a few cases, toxic amblyopia, fluid retention, and edema. Patients who develop ocular disturbances should discontinue the use of ibuprofen. Ibuprofen can be used occasionally by pregnant women; however, the concerns apply regarding third-trimester effects, including delay of parturition. Excretion into breast milk is thought to be minimal, so ibuprofen also can be used with caution by women who are breastfeeding.

Naproxen

Naproxen (ALEVE, NAPROSYN, others) is supplied as tablets, delayed-release tablets, controlled-release tablets, gelcaps, and caplets containing 200–750 mg of naproxen or naproxen sodium and as an oral suspension. Dosage forms containing ≤ 200 mg are available without a prescription. Naproxen is licensed for marketing in fixed-dose combinations with pseudoephedrine (ALEVE-D SINUS & COLD, others) and sumatriptan (TREXIMET) and is co-packaged with lansoprazole (PREVACID NAPRAPAC). Naproxen holds more FDA-approved indications than other tNSAIDs. It is indicated for juvenile and rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, pain, primary dysmenorrhea, tendonitis, bursitis, and acute gout. The pharmacological properties and therapeutic uses of naproxen have been reviewed (Davies and Anderson, 1997b).

Absorption, Distribution, and Elimination. Naproxen is absorbed fully when administered orally. Food delays the rate but not the extent of absorption. Peak concentrations in plasma occur within 2–4 hours and are somewhat more rapid after the administration of naproxen sodium. Absorption is accelerated by the concurrent administration of sodium bicarbonate but delayed by magnesium

oxide or aluminum hydroxide. Naproxen also is absorbed rectally but more slowly than after oral administration. The $t_{1/2}$ of naproxen in plasma is variable. About 14 hours in the young, it may increase about 2-fold in the elderly because of age-related decline in renal function (Table 34–1).

Metabolites of naproxen are excreted almost entirely in the urine. About 30% of the drug undergoes 6-demethylation, and most of this metabolite, as well as naproxen itself, is excreted as the glucuronide or other conjugates.

Naproxen is almost completely (99%) bound to plasma proteins after normal therapeutic doses. Naproxen crosses the placenta and appears in the milk of lactating women at ~1% of the maternal plasma concentration.

Common Adverse Effects. Epidemiological studies suggest that the relative risk of myocardial infarction may be reduced by ~10% by naproxen, compared to a reduction of 20–25% by aspirin. This is consistent with its long $t_{1/2}$, which may result in complete and persistent platelet inhibition in some patients. However, increased rates of cardiovascular events also have been reported (see the “Cardioprotection” and “Cardiovascular” sections). Typical GI adverse effects with naproxen occur at approximately the same frequency as with indomethacin and other tNSAIDs but perhaps with less severity. CNS side effects range from drowsiness, headache, dizziness, and sweating to fatigue, depression, and ototoxicity. Less common reactions include pruritus and a variety of dermatological problems. A few instances of jaundice, impairment of renal function, angioedema, thrombocytopenia, and agranulocytosis have been reported.

Other Propionic Acid Derivatives

Fenoprofen. The pharmacological properties and therapeutic uses of fenoprofen (NALFON 200, others) have been reviewed (Brogden et al., 1981). Oral doses of fenoprofen are readily but incompletely (85%) absorbed (Table 34–1). The concomitant administration of antacids does not seem to alter the concentrations that are achieved. The GI side effects of fenoprofen are similar to those of ibuprofen or naproxen and occur in ~15% of patients.

Ketoprofen. A more potent S-enantiomer is available in Europe (Barbanoj et al., 2001). In addition to COX inhibition, ketoprofen may stabilize lysosomal membranes and antagonize the actions of bradykinin. It is unknown if these actions are relevant to its efficacy in humans. Ketoprofen is conjugated with glucuronic acid in the liver, and the conjugate is excreted in the urine (Table 34–1). Patients with impaired renal function eliminate the drug more slowly. Approximately 30% of patients experience mild GI side effects with ketoprofen, which are decreased if the drug is taken with food or antacids.

Flurbiprofen. Flurbiprofen is available as tablets (ANSAID, others) and as an ophthalmic solution (OCUFEN, others) indicated for intraoperative miosis. The pharmacological properties, therapeutic indications, and adverse effects of orally administered flurbiprofen are similar to those of other anti-inflammatory derivatives of propionic acid (Table 34–1) and have been reviewed (Davies, 1995).

Oxaprozin. Oxaprozin (DAYPRO, others) has similar pharmacological properties, adverse effects, and therapeutic uses to those of other propionic acid derivatives (Davies, 1998b). However, its

pharmacokinetic properties differ considerably. Peak plasma levels are not achieved until 3–6 hours after an oral dose, while its $t_{1/2}$ of 40–60 hours allows for once-daily administration.

THE FENAMATES

Mefenamic acid and meclofenamate are *N*-substituted phenylanthranilic acids. The pharmacological properties of the fenamates are those of typical tNSAIDs, and therapeutically, they have no clear advantages over others in the class.

Available Preparations and Therapeutic Uses. The fenamates include mefenamic, meclofenamic, and flufenamic acids. Mefenamic acid [PONSTEL, PONSTAN (U.K.), DYSMAN (U.K.)] and meclofenamate sodium have mostly been used in the short-term treatment of pain in soft-tissue injuries, dysmenorrhea, and rheumatoid and osteoarthritis; flufenamic acid is not licensed for use in the U.S. These drugs are not recommended for use in children or pregnant women.

Common Adverse Effects. Approximately 25% of users develop GI side effects at therapeutic doses. Roughly 5% of patients develop a reversible elevation of hepatic transaminases. Diarrhea, which may be severe and associated with steatorrhea and inflammation of the bowel, also is relatively common. Autoimmune hemolytic anemia is a potentially serious but rare side effect.

ENOLIC ACIDS (OXICAMS)

The oxamic derivatives are enolic acids that inhibit COX-1 and COX-2 and have anti-inflammatory, analgesic, and antipyretic activity. In general, they are nonselective COX inhibitors, although one member (meloxicam) shows modest COX-2 selectivity comparable to celecoxib in human blood *in vitro* and was approved as a COX-2-selective NSAID in some countries. The oxamic derivatives are similar in efficacy to aspirin, indomethacin, or naproxen for the long-term treatment of rheumatoid arthritis or osteoarthritis. Controlled trials comparing GI tolerability with aspirin have not been performed. The main advantage suggested for these compounds is their long $t_{1/2}$, which permits once-a-day dosing.

Piroxicam

The pharmacological properties and therapeutic uses of piroxicam (FELDENE, others) have been reviewed (Guttadauria, 1986).

Mechanism of Action. Piroxicam can inhibit activation of neutrophils, apparently independently of its ability to inhibit COX; hence, additional modes of anti-inflammatory action have been proposed, including inhibition of proteoglycanase and collagenase in cartilage.

Absorption, Distribution, and Elimination. Piroxicam is absorbed completely after oral administration and undergoes enterohepatic recirculation; peak concentrations in plasma occur within 2–4 hours (Table 34–1). Food may delay absorption. Estimates of the $t_{1/2}$ in plasma have been variable; the average is ~50 hours.

After absorption, piroxicam is extensively (99%) bound to plasma proteins. Concentrations in plasma and synovial fluid are similar at steady state (e.g., after 7-12 days). Less than 5% of the drug is excreted into the urine unchanged. The major metabolic transformation in humans is hydroxylation of the pyridyl ring (predominantly by an isozyme of the CYP2C subfamily), and this inactive metabolite and its glucuronide conjugate account for ~60% of the drug excreted in the urine and feces.

Therapeutic Uses. Piroxicam is approved in the U.S. for the treatment of rheumatoid arthritis and osteoarthritis. Due to its slow onset of action and delayed attainment of steady state, it is less suited for acute analgesia but has been used to treat acute gout. The usual daily dose is 20 mg, and because of the long $t_{1/2}$, steady-state blood levels are not reached for 7-12 days.

Adverse Events. Approximately 20% of patients experience side effects with piroxicam, and ~5% of patients discontinue use because of these effects. In 2007, the European Medicines Agency reviewed the safety of orally administered piroxicam and concluded that its benefits outweigh its risks, but advised it should no longer be used first-line, nor should it be used for the treatment of acute (short-term) pain and inflammation. Piroxicam was singled out for special review because of signals that it is associated with more GI and serious skin reactions than other nonselective NSAIDs.

Meloxicam

Therapeutic Uses. Meloxicam (MOBIC, others) is FDA-approved for use in osteoarthritis. It has been reviewed (Davies and Skjodt, 1999; Fleischmann et al., 2002). The recommended dose for meloxicam is 7.5-15 mg once daily.

Adverse Events. On average, meloxicam demonstrates ~10-fold COX-2 selectivity in *ex vivo* assays. However, this is quite variable, and a clinical advantage or hazard has yet to be established for the drug. Indeed, even with surrogate markers, the relationship to dose is nonlinear. There is significantly less gastric injury compared to piroxicam (20 mg/day) in subjects treated with 7.5 mg/day of meloxicam, but the advantage is lost with a dosage of 15 mg/day.

Other Oxicams

A number of other oxicam derivatives are under study or in use outside the U.S. These include several prodrugs of piroxicam (amproxicam, droxicam, and pivoxicam), which have been designed to reduce GI irritation. However, as with sulindac, any theoretical diminution in gastric toxicity associated with administration of a prodrug is offset by gastric COX-1 inhibition from active drug circulating systemically. Other oxicams under study or in use outside the U.S. include lornoxicam, cinnoxamic, sudoxicam, and tenoxicam. The efficacy and toxicity of these drugs are similar to those of piroxicam. Lornoxicam is unique among the enolic acid derivatives in that it has a rapid onset of action and a relatively short $t_{1/2}$ (3-5 hours).

PYRAZOLON DERIVATIVES

This group of drugs includes phenylbutazone, oxyphenbutazone, antipyrine, aminopyrine, and dipyrone; currently, only antipyrine eardrops are available for human use in the U.S. These drugs were

used clinically for many years but have essentially been abandoned because of their propensity to cause irreversible agranulocytosis. Dipyrone was reintroduced in the E.U. a decade ago because epidemiological studies suggested that the risk of adverse effects was similar to that of acetaminophen and lower than that of aspirin. However, the use of dipyrone remains limited. The pyrazolone derivatives are discussed in previous editions of this book and may be accessed on the G&G website.

DIARYL HETEROCYCLIC COX-2-SELECTIVE NSAIDS

The first COX-2-selective NSAIDs were diaryl heterocyclic coxibs. Celecoxib is the only such compound still approved in the U.S. Etoricoxib is approved in several countries; rofecoxib and valdecoxib were withdrawn worldwide and have been discussed in previous editions. Parecoxib is a water soluble, injectable prodrug of valdecoxib marketed for treatment of acute pain in several countries. Lumiracoxib, a structural analog of the phenylacetic acid derivative diclofenac, also is not available in the U.S. and has been discussed earlier (see “Lumiracoxib”).

Chemistry. Most members of the diaryl heterocyclic family of selective COX-2 inhibitors consist of a central 1,2-diaryl heterocyclic moiety. Celecoxib is a diaryl substituted pyrazole compound; valdecoxib is a diaryl substituted isoxazol derivative. Valdecoxib was made water soluble for parenteral use (parecoxib) by coupling propionic acid via an amide group to its sulfonamide moiety. Etoricoxib is slightly different; it is a monoaryl substituted bipyridine, which results in a three-ring configuration that is superimposable onto the diaryl heterocyclic pharmacophore. Celecoxib, valdecoxib, and its prodrug parecoxib contain a sulfonamide moiety that bares the risk for cross-reactivity in patients with sulfonamide hypersensitivity and, thus, must be avoided in such patients. Etoricoxib has a methylsulfonyl group that is thought to be free of such risk.

Mechanism of Action. Compounds with higher affinity for COX-2 than COX-1 were identified in screens of combinatorial libraries. Subsequent crystallography revealed a hydrophobic pocket in the substrate binding channel of COX-2, which is absent in COX-1 (Figure 34-2). Thus, selective inhibitors of COX-2 are molecules with side chains—the third ring—that fit within this hydrophobic pocket but are too large to block COX-1 with equally high affinity. There is considerable difference in response to the coxibs among individuals (Fries et al., 2006), and it is not known how the degree of selectivity may relate to either efficacy or adverse effect profile, although it seems likely to be related to both. No controlled clinical trials comparing outcomes among the coxibs have been performed. Several tNSAIDs (e.g., nimesulide, diclofenac, meloxicam) exhibit relative selectivity for COX-2 inhibition in whole blood assays that resembles that of celecoxib (FitzGerald and Patrono, 2001; Brune and Hinz, 2004).

Therapeutic Uses. All COX-2-selective NSAIDs have been shown to afford relief from postextraction dental pain and to afford

dose-dependent relief from inflammation in osteoarthritis and rheumatoid arthritis. The European Medicines Agency advises that these medicines should not be used in patients with ischemic heart disease or stroke and that prescribers should exercise caution when using selective COX-2 inhibitors in patients with risk factors for heart disease such as hypertension, hyperlipidemia, diabetes, smoking, or peripheral arterial disease. As for all NSAIDs, the agency advises the lowest effective dose for the shortest possible duration of treatment.

Celecoxib

Celecoxib (CELEBREX) was approved for marketing in the U.S. in 1998. Details of its pharmacology have been reviewed (Davies et al., 2000).

Absorption, Distribution, and Elimination. The bioavailability of oral celecoxib is not known, but peak plasma levels occur at 2-4 hours after the dose is taken. The elderly (≥ 65 years of age) may have up to 2-fold higher peak concentrations and AUC values than younger patients (≤ 55 years of age). Celecoxib is bound extensively to plasma proteins. Little drug is excreted unchanged; most is excreted as carboxylic acid and glucuronide metabolites in the urine and feces. The elimination $t_{1/2}$ is ~ 11 hours. The drug commonly is given once or twice per day during chronic treatment. Renal insufficiency is associated with a modest, clinically insignificant decrease in plasma concentration. Celecoxib has not been studied in patients with severe renal insufficiency. Plasma concentrations are increased by $\sim 40\%$ and 180% in patients with mild and moderate hepatic impairment, respectively, and dosages should be reduced by at least 50% in patients with moderate hepatic impairment. Celecoxib is metabolized predominantly by CYP2C9. Although not a substrate, celecoxib is an inhibitor of CYP2D6. Clinical vigilance is necessary during co-administration of drugs that are known to inhibit CYP2C9 and drugs that are metabolized by CYP2D6. For example, celecoxib inhibits the metabolism of metoprolol and can result in its accumulation.

Therapeutic Uses. Celecoxib is approved in the U.S. for the management of acute pain in adults, for the treatment of osteoarthritis, rheumatoid arthritis, juvenile rheumatoid arthritis, ankylosing spondylitis, and primary dysmenorrhea. The recommended dose for treating osteoarthritis is 200 mg/day as a single dose or divided as two 100-mg doses. In the treatment of rheumatoid arthritis, the recommended dose is 100-200 mg twice per day. In the light of its cardiovascular hazard, physicians are advised to use the lowest possible dose for the shortest possible time. Current evidence does not support use of celecoxib as a first choice among the tNSAIDs. Celecoxib also is approved for the chemoprevention of polyposis coli; however, placebo-controlled trials revealed a dose-dependent increase in myocardial infarction and stroke (Solomon et al., 2006).

Adverse Effects. Placebo-controlled trials have established that celecoxib confers a risk of myocardial infarction and stroke and this appears to relate to dose and the underlying risk of cardiovascular disease that anteceded drug administration. Effects attributed to inhibition of PG production in the kidney—hypertension and edema—occur with nonselective COX inhibitors and also with celecoxib. Studies in mice and some epidemiological evidence suggest that the likelihood of patients' developing hypertension while on NSAIDs reflects the degree of inhibition of COX-2 and the selectivity with which it is attained. Indeed, the prevalence of hypertension is higher in patients taking etoricoxib than diclofenac, consistent with the greater selectivity for inhibition of COX-2 of the former drug (Cannon et al., 2006; Laime et al., 2007). Thus, the risk of thrombosis, hypertension, and accelerated atherogenesis are mechanistically integrated. The coxibs should be avoided in patients prone to cardiovascular or cerebrovascular disease. None of the coxibs has established superior efficacy over tNSAIDs. Celecoxib carries the same cardiovascular and GI black box warning as tNSAIDs. Although selective COX-2 inhibitors do not interact to prevent the antiplatelet effect of aspirin, it now is thought that they lose their GI advantage over a tNSAID alone when used in conjunction with aspirin. Experience with selective COX-2 inhibitors in patients who exhibit aspirin hypersensitivity is limited, and caution should be observed.

Parecoxib

Parecoxib is the only COX-2-selective NSAID administered by injection and has been shown to be an effective analgesic for the peri-operative period when patients are unable to take oral medication. It is not widely available, and clinical experience is limited.

Absorption, Distribution, and Elimination. Parecoxib is absorbed rapidly (~ 15 minutes after intramuscular injection) and converted (15-50 minutes) by deoxymethylation to valdecoxib, the active drug (Table 34-1). Valdecoxib undergoes extensive hepatic metabolism by CYPs 3A4 and 2C9 and non-CYP-dependent glucuronidation. It is a weak inhibitor of CYP2C9 and a weak to moderate inhibitor of CYP2C19. The metabolites of valdecoxib are excreted in the urine. The $t_{1/2}$ is ~ 7 -8 hours but can be significantly prolonged in the elderly or those with hepatic impairment, with subsequent drug accumulation.

Therapeutic Uses. Parecoxib (DYNASTAT) is available in Germany and Australia, but not in the U.K. or U.S., for management of acute pain, including moderate to severe postsurgical pain. It is supplied as a lyophilized powder equivalent to 20 or 40 mg parecoxib to be reconstituted with sterile saline for injection.

Adverse Effects. The cardiovascular risk of parecoxib and valdecoxib was detected in two postoperative pain management trials of high-risk patients (Grosser et al., 2006). Patients undergoing coronary bypass graft (CABG) surgery were initially treated intravenously with parecoxib or placebo and then switched to oral valdecoxib or placebo. The majority of cardiovascular events occurred within days of treatment initiation in these populations, who were subject to acute hemostatic activation after bypass surgery. Clinical studies suggest that cardiovascular complications

attributable to COX-2–selective NSAIDs is proportional to baseline cardiovascular risk and to the duration of drug exposure (Grosser et al., 2006). All NSAIDs and celecoxib carry a black box warning contraindicating their use for pain following CABG surgery.

Life-threatening skin reactions (including toxic epidermal necrolysis, Stevens-Johnson syndrome, and erythema multiforme) have been reported in association with valdecoxib, which contains a sulfonamide group. The risk of hypersensitivity or skin reactions applies also to parecoxib. The drug must be discontinued at the first sign of rash, mucosal lesion, or any other sign of hypersensitivity. This additional hazard renders valdecoxib an unlikely therapeutic choice.

Etoricoxib

Etoricoxib is a COX-2–selective inhibitor with selectivity second only to that of lumiracoxib.

Absorption, Distribution, and Elimination. Etoricoxib is incompletely (~80%) absorbed and has a long $t_{1/2}$ of ~20–26 hours (Table 34–1). It is extensively metabolized before excretion. Small studies suggest that those with moderate hepatic impairment are prone to drug accumulation, and the dosing interval should be adjusted. Renal insufficiency does not affect drug clearance.

Therapeutic Uses. Etoricoxib (ARCOXIA) is approved in some countries (not in U.S.) as a once-daily medicine for symptomatic relief in the treatment of osteoarthritis, rheumatoid arthritis, and acute gouty arthritis, as well as for the short-term treatment of musculoskeletal pain, postoperative pain, and primary dysmenorrhea (Patrignani et al., 2003).

Common Adverse Effects. In keeping with other coxibs, etoricoxib shows decreased GI injury as assessed endoscopically. The European regulatory agency concluded that etoricoxib, along with other coxibs, increased the risk of heart attack and stroke; the agency specifically restricted its use in patients with uncontrolled hypertension.

Rofecoxib

Rofecoxib (VIOXX) was introduced in 1999. Details of its pharmacodynamics, pharmacokinetics, therapeutic efficacy, and toxicity have been reviewed (Davies et al., 2003). Based on interim analysis of data from the Adenomatous Polyp Prevention on Vioxx (APPROVe) study, which showed a significant (2-fold) increase in the incidence of serious thromboembolic events in subjects receiving 25 mg of rofecoxib relative to placebo (Bresalier et al., 2005), rofecoxib was withdrawn from the market worldwide in 2004.

OTHER NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Apazone (Azapropazone)

Apazone is a tNSAID that has anti-inflammatory, analgesic, and antipyretic activity and is a potent uricosuric agent. It is available in E.U. but not in U.S. Some of its efficacy may arise from its capacity to inhibit neutrophil migration, degranulation, and superoxide production.

Apazone has been used for the treatment of rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, and gout but usually

is restricted to cases where other tNSAIDs have failed. Typical doses are 600 mg three times per day for acute gout. Once symptoms have abated, or for non-gout indications, typical dosage is 300 mg three to four times per day. Clinical experience to date suggests that apazone is well tolerated. Mild GI side effects (nausea, epigastric pain, dyspepsia) and rashes occur in ~3% of patients, while CNS effects (headache, vertigo) are reported less frequently. Precautions appropriate to other nonselective COX inhibitors also apply to apazone.

Nimesulide

Nimesulide is a sulfonanilide compound available in Europe that demonstrates COX-2 selectivity similar to celecoxib in whole-blood assays. Additional effects include inhibition of neutrophil activation, decrease in cytokine production, decrease in degradative enzyme production, and possibly activation of glucocorticoid receptors (Bennett, 1999).

Nimesulide is administered orally in doses ≤100 mg twice daily as an anti-inflammatory, analgesic, and antipyretic. Its use in the E.U. is limited to ≤15 days due to the risk of hepatotoxicity.

CLINICAL SUMMARY: NSAIDs

Both tNSAIDs and COX-2–selective NSAIDs have anti-inflammatory, analgesic, and antipyretic activity by virtue of inhibition of PG biosynthesis. Selective inhibitors of COX-2 were developed to reduce GI adverse effects but have never been shown to exhibit an efficacy advantage over tNSAIDs, and most have been eliminated from the market due to cardiovascular and hepatic toxicities. Choice and dosing of an NSAID are usually guided by multiple considerations, including the therapeutic indication, patient age, coincident diseases or allergies, the drug's safety and interaction profile, and cost considerations. Drugs with more rapid onset of action and shorter duration of action (sometimes marketed as rapid release or liquid formulations that facilitate absorption) probably are preferable for fever accompanying minor viral illnesses, pain after minor musculoskeletal injuries, or headache, whereas a longer duration of action may be preferable for management of postoperative or arthritic pain.

The choice among tNSAIDs for the treatment of chronic arthritic conditions such as rheumatoid arthritis largely is empirical. Substantial differences in response have been noted among individuals treated with the same tNSAID and within an individual treated with different tNSAIDs, even when the drugs are structurally related. It is reasonable to give a drug for a week or two as a therapeutic trial and to continue it if the response is satisfactory. Initially, all patients should be asked about previous hypersensitivity to aspirin or any member of the NSAID class. Thereafter, low doses of

the chosen agent should be prescribed to determine initial patient tolerance. Older patients may require lower doses than younger patients to reduce the risk of toxicity. Regulatory agencies stress use of the lowest effective dose for the shortest possible duration of treatment. Alterations in dosing may take several days ($>3-4 t_{1/2}$) to translate into clinically detectable changes. Delayed distribution into the synovial compartment may extend this interval. Indeed, some NSAIDs that are short lived in plasma are sustained in synovial fluid and may afford sufficient relief even when administered at intervals longer than their plasma $t_{1/2}$ time. If the patient does not achieve therapeutic benefit from one NSAID, another may be tried. For mild arthropathies, the scheme outlined earlier in this paragraph, together with rest and physical therapy, probably will be sufficiently effective. When the patient has sleeping problems because of pain or morning stiffness, a larger proportion of the daily dose may be given at night. However, patients with more debilitating disease may not respond adequately, prompting the initiation of more aggressive therapy with disease-modifying anti-rheumatic drugs (see below). The experience in children is limited to a small number of drugs, which are dosed by age and body weight.

Some adverse effects may manifest in the first weeks of therapy; however, the risk of gastric ulceration and bleeding accumulates with the duration of dosing. Combination therapy with more than one NSAID is to be avoided. A number of risk factors for GI complications have been determined in epidemiological studies. Patients at high risk for GI complications should be prescribed a gastroprotective agent. These patients also are potential candidates for a COX-2-selective NSAID.

Placebo-controlled trials have established that selective inhibition of COX-2 confers an increased risk of heart attack and stroke. The likelihood of hazard would be expected to be related to selectivity attained *in vivo*, dose, potency and duration of action, and duration of dosing, as well as the underlying cardiovascular risk profile of an individual patient. It seems likely that some of the older drugs with COX-2 selectivity (e.g., diclofenac) may closely resemble celecoxib. The cardiovascular hazard from both celecoxib and rofecoxib, the two inhibitors for which data are available from placebo-controlled trials lasting >1 year, appeared to increase with chronicity of dosing. This is consistent with a mechanism-based acceleration of atherogenesis directly via inhibition of PGI_2 and indirectly due to the rise in blood pressure consequent to inhibition of COX-

2-derived PGE_2 and PGI_2 . Similarly, the increased risk conferred by rofecoxib has been shown to dissipate slowly, if at all, in the year after drug cessation. If a COX-2-selective inhibitor is prescribed, it should be used at the lowest possible dose for the shortest period of time.

Patients at risk of cardiovascular disease or prone to thrombosis should not be treated with COX-2-selective NSAIDs. Small absolute risks of thrombosis attributable to these drugs may interact geometrically with small absolute risks from genetic variants like factor V Leiden or concomitant therapies, such as anovulant oral contraceptives. Some tNSAIDs (ibuprofen, naproxen) have been shown to interfere with the antiplatelet activity of low-dose aspirin, and aspirin's cardioprotective effect may be diminished in patients who take low-dose aspirin and a tNSAID concomitantly. The administration of immediate-release (not enteric-coated) aspirin should be separated from the dose of tNSAID to avoid the interaction. For example, ibuprofen should not be taken within 30 minutes of the ingestion of low-dose aspirin and low-dose aspirin should not be ingested within 8 hours of a dose of ibuprofen. Patients at high risk for cardiovascular events should preferentially use analgesics that do not interfere with platelet action.

DISEASE-MODIFYING ANTI-RHEUMATIC DRUGS

Rheumatoid arthritis is an autoimmune disease that affects ~1% of the population. The pharmacological management of rheumatoid arthritis includes symptomatic relief through the use of NSAIDs. However, although they have anti-inflammatory effects, NSAIDs have minimal, if any effect on progression of joint deformity. DMARDs (disease-modifying anti-rheumatic drugs), on the other hand, reduce the disease activity of rheumatoid arthritis and retard the progression of arthritic tissue destruction. DMARDs include a diverse group of small molecule non-biologicals and biological agents (mainly antibodies or binding proteins), as summarized in Table 34-3.

Treatment with single non-biological DMARDs can achieve remission or at least a state of very low disease activity in a large number of rheumatoid arthritis patients (Saag et al., 2008). Combinations of non-biological DMARDs (e.g., methotrexate + sulfasalazine, methotrexate + hydroxychloroquine, methotrexate + leflunomide, methotrexate + sulfasalazine + hydroxychloroquine) are indicated for patients with moderate or high disease activity or prolonged disease duration or for those who fail to respond to a single compound. Biological DMARDs remain reserved for patients

Table 34–3

Disease-Modifying Anti-Rheumatic Drugs

DRUG	CLASS OR ACTION	REFERENCE (CHAPTER NUMBER)
Small molecules		
Methotrexate	Anti-folate	61
Leflunomide	Pyrimidine synthase inhibitor	61
Hydroxychloroquine	Anti-malarial	49
Minocycline	5-lipoxygenase inhibitor, tetracycline antibiotic	33, 55
Sulfasalazine	Salicylate	34, 47
Azathioprine	Purine synthase inhibitor	61
Cyclosporine	Calcineurin inhibitor	35
Cyclophosphamide	Alkylating agent	61
Biologicals		
Adalimumab	Ab, TNF- α antagonist	35
Golimumab	Ab, TNF- α antagonist	35
Infliximab	IgG-TNF receptor fusion protein (anti-TNF)	35
Certolizumab	Fab fragment toward TNF- α	35
Abatacept	T-cell co-stimulation inhibitor (binds B7 protein on antigen-presenting cell)	35
Rituximab	Ab toward CD20 (cytotoxic toward B cells)	62
Anakinra	IL-1-receptor antagonist	35, 62

IL, interleukin; TNF, tumor necrosis factor.

with persistent moderate or high disease activity and indicators of poor prognosis such as functional impairment, radiographic bony erosions, extra-articular disease, and rheumatoid factor positivity. Therapy is tailored to the individual patient, and the use of these agents must be weighed against their potentially serious adverse effects. The combination of NSAIDs with these agents is common.

Short-term glucocorticoids often are used to bring the level of inflammation quickly under control. Glucocorticoids are not suitable for long-term use because of adrenal suppression. The older agents (gold, penicillamine) have unclear mechanisms of action and tend to have slight efficacy and significant side effects. Their pharmacology is described in more detail in previous editions of this book.

PHARMACOTHERAPY OF GOUT

Gout results from the precipitation of urate crystals in the tissues and the subsequent inflammatory response (Terkeltaub et al., 2006). Acute gout usually causes an exquisitely painful distal monoarthritis, but it also can cause joint destruction, subcutaneous deposits (tophi), and renal calculi and damage. Gout affects ~0.5-1% of the population of Western countries. Once considered a disease of kings and the rich, gout is no respecter of class and is found at all socioeconomic strata. Indeed,

gout is the most common form of inflammatory arthritis in the elderly.

The pathophysiology of gout is understood incompletely. Hyperuricemia, while a prerequisite, does not inevitably lead to gout. Uric acid, the end product of purine metabolism, is relatively insoluble compared to its hypoxanthine and xanthine precursors, and normal serum urate levels (~5 mg/dL, or 0.3 mM) approach the limit of solubility. In most patients with gout, hyperuricemia arises from underexcretion rather than overproduction of urate. Mutations of one of the renal urate transporters, URAT-1, are associated with hypouricemia (Enomoto et al., 2002); the uricosuric effect of benzbromarone and probenecid can be explained by inhibition of this transporter. Urate tends to crystallize as monosodium urate in colder or more acidic conditions. Monosodium urate crystals activate monocytes/macrophages via the Toll-like receptor pathway mounting an innate immune response. This results in the secretion of cytokines, including IL-1 β and TNF- α ; endothelial activation; and attraction of neutrophils to the site of inflammation (Terkeltaub et al., 2006). Neutrophils secrete

inflammatory mediators that lower the local pH and lead to further urate precipitation.

The aims of treatment are to:

- decrease the symptoms of an acute attack
- decrease the risk of recurrent attacks
- lower serum urate levels

The substances available for these purposes are:

- drugs that relieve inflammation and pain (NSAIDs, colchicine, glucocorticoids)
- drugs that prevent inflammatory responses to crystals (colchicine and NSAIDs)
- drugs that act by inhibition of urate formation (allopurinol, febuxostat) or to augment urate excretion (probenecid)

NSAIDs have been discussed earlier. Glucocorticoids are discussed in Chapter 42. This section focuses on colchicine, allopurinol, febuxostat and the uricosuric agents probenecid and benzbromarone.

Colchicine

Colchicine is one of the oldest available therapies for acute gout. Plant extracts containing colchicine were used for joint pain in the sixth century. Colchicine is considered second-line therapy because it has a narrow therapeutic window and a high rate of side effects, particularly at higher doses. There no longer is a role for colchicine in the treatment of primary biliary cirrhosis, psoriasis, or Behçet's disease.

Mechanism of Action. Colchicine exerts a variety of pharmacological effects, but how these occur or how they relate to its activity in gout is not well understood. Its structure-activity relationship has been discussed (Levy et al., 1991). It has antimitotic effects, arresting cell division in G_1 by interfering with microtubule and spindle formation (an effect shared with vinca alkaloids). This effect is greatest on cells with rapid turnover (e.g., neutrophils, GI epithelium). Colchicine may alter neutrophil motility in *ex vivo* assays (Levy et al., 1991). Experimental data suggest that colchicine decreases the crystal-induced secretion of chemotactic factors and superoxide anions by activated neutrophils. It also limits neutrophil adhesion to endothelium by modulating the expression of endothelial adhesion molecules. Higher concentrations inhibit IL-1 β processing and release from neutrophils *in vitro*.

Colchicine inhibits the release of histamine-containing granules from mast cells, the secretion of insulin from pancreatic β cells, and the movement of melanin granules in melanophores. These processes also may involve interference with the microtubular system, but whether this occurs at clinically relevant concentrations is questionable.

Colchicine also exhibits a variety of other pharmacological effects. It lowers body temperature, increases the sensitivity to central depressants, depresses the respiratory center, enhances the response to sympathomimetic agents, constricts blood vessels, and induces hypertension by central vasomotor stimulation. It enhances GI activity by neurogenic stimulation but depresses it by a direct effect, and alters neuromuscular function.

Absorption, Distribution, and Elimination. The absorption of oral colchicine is rapid but variable. Peak plasma concentrations occur 0.5-2 hours after dosing. In plasma, 50% of colchicine is protein bound. The formation of colchicine-tubulin complexes in many tissues contributes to its large volume of distribution. There is significant enterohepatic circulation. The exact metabolism of colchicine in humans is unknown, but *in vitro* studies indicate that it may undergo oxidative demethylation by CYP3A4. Indeed, other CYP3A4 substrates, such as cimetidine, have been associated with an increase in colchicine plasma $t_{1/2}$ and the emergence of colchicine toxicity. The drug is contraindicated in patients with hepatic or renal impairment requiring concomitant therapy with CYP3A4 or *P*-glycoprotein inhibitors. Only 10-20% is excreted in the urine, although this increases in patients with liver disease. The kidney, liver, and spleen also contain high concentrations of colchicine, but it apparently is largely excluded from heart, skeletal muscle, and brain. The plasma $t_{1/2}$ of colchicine is ~9 hours, but the drug can be detected in leukocytes and in the urine for at least 9 days after a single intravenous dose.

Therapeutic Uses. A minimum of 3 days, but preferably 7 or 14 days, should elapse between courses of gout treatment with colchicine to avoid cumulative toxicity. Patients with hepatic or renal disease and dialysis patients should receive reduced doses and/or less frequent therapy. Great care should be exercised in prescribing colchicine for elderly patients, for whom the dose should be based on renal function. For those with cardiac, renal, hepatic, or GI disease, NSAIDs or glucocorticoids may be preferred.

Acute Gout. Colchicine dramatically relieves acute attacks of gout. It is effective in roughly two-thirds of patients if given within 24 hours of attack onset. Pain, swelling, and redness abate within 12 hours and are completely gone within 48-72 hours. In the past, the typical dosing regimen was 0.6 mg each hour until pain was relieved or diarrhea developed; the typical course of therapy ranged from 4-8 mg. The new regimen approved by the FDA in 2009 for adults recommends a total of only two doses taken 1 hour apart: 1.2 mg (two tablets) at the first sign of a gout flare followed by 0.6 mg (one tablet) 1 hour later. The dose must be adjusted in patients exposed to inhibitors of *P*-glycoprotein or CYP3A4 within the previous 14 days.

Prevention of Acute Gout. The main off-label indication for colchicine is in the prevention of recurrent gout, particularly in the early stages of antihyperuricemic therapy. The typical dose for prophylaxis is 0.6 mg taken orally 3 or 4 days/wk for patients who have <1 attack per year, 0.6 mg daily for patients who have >1 attack per

year, and 0.6 mg two or three times daily for patients who have severe attacks. The dose must be decreased for patients with impaired renal function.

Familial Mediterranean Fever. The administration of daily colchicine is useful for the prevention of attacks of familial Mediterranean fever and prevention of amyloidosis, which may complicate this disease. The dose for adults and children >12 years of age is 1.2-2.4 mg daily. The dose for patients as young as 4 years is reduced on the basis of age.

Adverse Effects. Exposure of the GI tract to large amounts of colchicine and its metabolites via enterohepatic circulation and the rapid rate of turnover of the GI mucosa may explain why the GI tract is particularly susceptible to colchicine toxicity. Nausea, vomiting, diarrhea, and abdominal pain are the most common untoward effects and the earliest signs of impending colchicine toxicity. Drug administration should be discontinued as soon as these symptoms occur. There is a latent period, which is not altered by dose or route of administration, of several hours or more between the administration of the drug and the onset of symptoms. A dosing study required as part of FDA approval demonstrated that one dose initially and a single additional dose after 1 hour was much less toxic than traditional hourly dosing for acute gout flares. Acute intoxication causes hemorrhagic gastropathy. Intravenous colchicine was previously used to treat acute gouty arthritis; however, this route obviates early GI side effects that can be a harbinger of serious systemic toxicity. The FDA suspended the U.S. marketing of all injectable dosage forms of colchicine in 2008. Other serious side effects of colchicine therapy include myelosuppression, leukopenia, granulocytopenia, thrombopenia, aplastic anemia, and rhabdomyolysis. Life-threatening toxicities are associated with administration of concomitant therapy with *P*-glycoprotein or CYP3A4 inhibitors.

Allopurinol

Allopurinol inhibits xanthine oxidase and prevents the synthesis of urate from hypoxanthine and xanthine. Allopurinol is used to treat hyperuricemia in patients with gout and to prevent it in those with hematological malignancies about to undergo chemotherapy (acute tumor lysis syndrome). Even though underexcretion rather than overproduction is the underlying defect in most gout patients, allopurinol remains effective therapy.

History. Allopurinol initially was synthesized as a candidate anti-neoplastic agent but was found to lack antineoplastic activity. Subsequent testing showed it to be an inhibitor of xanthine oxidase that was useful clinically for the treatment of gout.

Chemistry. Allopurinol is an analog of hypoxanthine. Its active metabolite, oxypurinol, is an analog of xanthine.

Mechanism of Action. Both allopurinol and its primary metabolite, oxypurinol (alloxanthine), inhibit xanthine oxidase and reduce urate production. Allopurinol competitively inhibits xanthine oxidase at low concentrations and is a noncompetitive inhibitor at high concentrations. Allopurinol also is a substrate for xanthine oxidase; the product of this reaction, oxypurinol, also is a noncompetitive inhibitor of the enzyme. The formation of oxypurinol, together with its long persistence in tissues, is responsible for much of the pharmacological activity of allopurinol.

In the absence of allopurinol, the dominant urinary purine is uric acid. During allopurinol treatment, the urinary purines include hypoxanthine, xanthine, and uric acid. Because each has its independent solubility, the concentration of uric acid in plasma is reduced and purine excretion increased, without exposing the urinary tract to an excessive load of uric acid. Despite their increased concentrations during allopurinol therapy, hypoxanthine and xanthine are efficiently excreted, and tissue deposition does not occur. There is a small risk of xanthine stones in patients with a very high urate load before allopurinol therapy, which can be minimized by liberal fluid intake and alkalization of the urine with sodium bicarbonate, potassium citrate, or citrate combinations such as modified Shohl's solution.

Allopurinol facilitates the dissolution of tophi and prevents the development or progression of chronic gouty arthritis by lowering the uric acid concentration in plasma below the limit of its solubility. The formation of uric acid stones virtually disappears with therapy, which prevents the development of nephropathy. Once significant renal injury has occurred, allopurinol cannot restore renal function but may delay disease progression.

The incidence of acute attacks of gouty arthritis may increase during the early months of allopurinol therapy as a consequence of mobilization of tissue stores of uric acid. Co-administration of colchicine helps suppress such acute attacks. After reduction of excess tissue stores of uric acid, the incidence of acute attacks decreases and colchicine can be discontinued.

In some patients, the allopurinol-induced increase in excretion of oxypurines is less than the reduction in uric acid excretion; this disparity primarily is a result of re-utilization of oxypurines and feedback inhibition of *de novo* purine biosynthesis.

Absorption, Distribution, and Elimination. Allopurinol is absorbed relatively rapidly after oral ingestion, and peak plasma concentrations are reached within 60-90 minutes. About 20% is excreted in the feces in 48-72 hours, presumably as unabsorbed drug, and 10-30% is excreted unchanged in the urine. The remainder undergoes metabolism, mostly to oxypurinol apparently by the catalytic activity of aldehyde oxidoreductase. Oxypurinol is excreted slowly in the urine by glomerular filtration, counterbalanced by some tubular reabsorption. The plasma $t_{1/2}$ of allopurinol and oxypurinol is ~1-2 hours and ~18-30 hours (longer in those with renal impairment), respectively. This allows for once-daily dosing and makes allopurinol the most commonly used antihyperuricemic agent.

Allopurinol and its active metabolite oxypurinol are distributed in total tissue water, with the exception of brain, where their concentrations are about one-third of those in other tissues. Neither compound is bound to plasma proteins. The plasma concentrations of the two compounds do not correlate well with therapeutic or toxic effects. The clinical pharmacology of allopurinol and its metabolite have been reviewed (Day et al., 2007).

Drug Interactions. Allopurinol increases the $t_{1/2}$ of probenecid and enhances its uricosuric effect, while probenecid increases the clearance of oxypurinol, thereby increasing dose requirements of allopurinol.

Allopurinol inhibits the enzymatic inactivation of mercaptopurine and its derivative azathioprine by xanthine oxidase. Thus, when allopurinol is used concomitantly with oral mercaptopurine or azathioprine, dosage of the antineoplastic agent must be reduced to one-fourth to one-third of the usual dose (see Chapters 35 and 61). This is of importance when treating gout in the transplant recipient. The risk of bone marrow suppression also is increased when allopurinol is administered with cytotoxic agents that are not metabolized by xanthine oxidase, particularly cyclophosphamide.

Allopurinol also may interfere with the hepatic inactivation of other drugs, including warfarin. Although the effect is variable, increased monitoring of prothrombin activity is recommended in patients receiving both medications.

It remains to be established whether the increased incidence of rash in patients receiving concurrent allopurinol and ampicillin should be ascribed to allopurinol or to hyperuricemia. Hypersensitivity reactions have been reported in patients with compromised renal function, especially those who are receiving a combination of allopurinol and a thiazide diuretic. The concomitant administration of allopurinol and theophylline leads to increased accumulation of an active metabolite of theophylline, 1-methylxanthine; the concentration of theophylline in plasma also may be increased (see Chapter 36).

Therapeutic Uses. Allopurinol (ZYLOPRIM, ALOPRIM, others) is available for oral and intravenous use. Oral therapy provides effective therapy for primary and secondary gout, hyperuricemia secondary to malignancies, and calcium oxalate calculi. Intravenous therapy is indicated for hyperuricemia secondary to cancer chemotherapy for patients unable to tolerate oral therapy.

Allopurinol is contraindicated in patients who have exhibited serious adverse effects or hypersensitivity reactions to the medication and in nursing mothers and children, except those with malignancy or certain inborn errors of purine metabolism (e.g., Lesch-Nyhan syndrome). Allopurinol generally is used in complicated hyperuricemia post-transplantation, to prevent acute tumor lysis syndrome, or in patients with hyperuricemia post-transplantation. If necessary, it can be used in conjunction with a uricosuric agent such as probenecid.

The goal of therapy is to reduce the plasma uric acid concentration to <6 mg/dL (<360 $\mu\text{mol/L}$). In the management of gout, it is customary to antecede allopurinol therapy with colchicine and to avoid starting allopurinol during an acute attack. Fluid intake should be sufficient to maintain daily urinary volume of >2 L; slightly alkaline urine is preferred. An initial daily dose of 100 mg in patients with estimated glomerular filtration rates >40 mg/min is increased by 100-mg increments at weekly intervals according to the antihyperuricemic effect achieved. Plasma uric acid concentration <6 mg/dL (<360 $\mu\text{mol/L}$) are attained in less than half of the patients on 300 mg/day, the most commonly prescribed dose. Achieving sufficient reduction of uric acid serum levels may require 400-600 mg/day. Those with hematological malignancies may need up to 800 mg/day beginning 2-3 days before the start of chemotherapy. Interindividual variability in drug response is high. Daily doses >300 mg should be divided. Dosage must be reduced in patients in proportion to the reduction in glomerular filtration

(e.g., 300 mg/day if creatinine clearance is >90 mL/min, 200 mg/day if creatinine clearance is between 60 and 90 mL/min, 100 mg/day if creatinine clearance is 30-60 mL/min, and 50-100 mg/day if creatinine clearance is <30 mL/min) (Terkeltaub, 2003).

The usual daily dose in children with secondary hyperuricemia associated with malignancies is 150-300 mg, depending on age.

Allopurinol also is useful in lowering the high plasma concentrations of uric acid in patients with Lesch-Nyhan syndrome and thereby prevents the complications resulting from hyperuricemia; there is no evidence that it alters the progressive neurological and behavioral abnormalities that are characteristic of the disease.

Adverse Effects. Allopurinol generally is well tolerated, but the drug occasionally induces drowsiness. The most common adverse effects are hypersensitivity reactions that may manifest after months or years of therapy. Serious hypersensitivity reactions preclude further use of the drug.

The cutaneous reaction caused by allopurinol is predominantly a pruritic, erythematous, or maculopapular eruption, but occasionally the lesion is urticarial or purpuric. Rarely, toxic epidermal necrolysis or Stevens-Johnson syndrome occurs, which can be fatal. The risk for Stevens-Johnson syndrome is limited primarily to the first 2 months of treatment. Because the rash may precede severe hypersensitivity reactions, patients who develop a rash should discontinue allopurinol. If indicated, desensitization to allopurinol can be carried out starting at 10-25 $\mu\text{g/day}$, with the drug diluted in oral suspension and doubled every 3-14 days until the desired dose is reached. This is successful in approximately half of patients (Terkeltaub, 2003). Oxypurinol has orphan drug status and is available for compassionate use in the U.S. for patients intolerant of allopurinol.

Fever, malaise, and myalgias also may occur. Such effects are noted in $\sim 3\%$ of patients with normal renal function and more frequently in those with renal impairment. Transient leukopenia or leukocytosis and eosinophilia are rare reactions that may require cessation of therapy. Hepatomegaly and elevated levels of transaminases in plasma and progressive renal insufficiency also may occur.

Febuxostat

Febuxostat is a novel xanthine oxidase inhibitor that was recently approved for treatment of hyperuricemia in patients with gout (Pascual et al., 2009).

Chemistry. Febuxostat is a two-ring molecule with substituted phenyl and thiazole rings.

Mechanism of Action. Febuxostat is a non-purine inhibitor of xanthine oxidase. While oxypurinol, the active metabolite of allopurinol, inhibits the reduced form of the enzyme, febuxostat forms a stable

Absorption, Distribution, and Elimination. Febuxostat is rapidly absorbed with maximum plasma concentrations between 1-1.5 hours post-dose. The absorption of radiolabeled compound was estimated to be at least 49%, however, the absolute bioavailability is unknown. Magnesium hydroxide and aluminum hydroxide delay absorption ~1 hour. Food reduces absorption slightly, but has no clinically significant effect on the reduction of serum uric acid concentration. Febuxostat is highly plasma protein bound and has a volume of distribution of 50 L. It is extensively metabolized by oxidation by CYPs 1A2, 2C8, and 2C9 and non-CYP enzymes conjugation via UGTs 1A1, 1A3, 1A9 and 2B7. The relative contribution of each metabolic route is not known. The oxidation of the isobutyl side chain leads to the formation of four pharmacologically active hydroxy metabolites, all of which occur in plasma at markedly lower concentrations than febuxostat. Febuxostat has a $t_{1/2}$ of 5-8 hours and is eliminated by both hepatic and renal pathways. Mild to moderate renal or hepatic impairment does not affect its elimination kinetics relevantly.

Therapeutic Use. Febuxostat (ULORIC; ADNEURIC [EUROPE]) is approved for hyperuric patients with gout attacks, but not recommended for treatment of asymptomatic hyperuricemia. It is available in 40 and 80-mg oral tablets. Three randomized controlled clinical trials that compared febuxostat with allopurinol showed that 40 mg/day febuxostat lowered serum uric acid to similar levels as 300 mg/day allopurinol. More patients reached the target concentration of 6.0 mg/dL (360 μ mol/L) on 80 mg/day febuxostat than on 300 mg/day allopurinol (Becker et al., 2005a; Becker et al., 2005b; Schumacher et al., 2008). Thus, therapy should be initiated with 40 mg/day and the dose increased if the target serum uric acid concentration is not reached within 2 weeks.

Common Adverse Events. The most common adverse reactions in clinical studies were liver function abnormalities, nausea, joint pain, and rash. Liver function should be monitored periodically. An increase in gout flares was frequently observed after initiation of therapy, due to reduction in serum uric acid levels resulting in mobilization of urate from tissue deposits. Concurrent prophylactic treatment with an NSAID or colchicine is usually required. There was also a numerically higher rate of myocardial infarction and stroke in patients on febuxostat than on allopurinol. It is currently unknown whether there is a causal relationship between the cardiovascular events and febuxostat therapy or whether these were due to chance. The FDA has imposed as a condition for approval that a prospective study designed to assess the drug's cardiovascular safety be performed. Meanwhile patients should be monitored for cardiovascular complications.

Drug Interactions. Plasma levels of drugs that are metabolized by xanthine oxidase (e.g., theophylline, mercaptopurine, azathioprine) can be expected to increase—possibly to toxic levels—when administered concurrently with febuxostat, although drug interaction studies with these drugs have not been conducted. Thus, febuxostat is contraindicated in patients on azathioprine, mercaptopurine, or theophylline. Based on *in vitro* studies, interactions between febuxostat and CYP inhibitors are likely, but interactions studies have not been performed in humans.

Rasburicase

Rasburicase (ELITEK) is a recombinant urate oxidase that catalyzes the enzymatic oxidation of uric acid into the soluble and inactive metabolite allantoin. It has been shown to lower urate levels more effectively than allopurinol (Bosly et al., 2003). It is indicated for the initial management of elevated plasma uric acid levels in pediatric patients with leukemia, lymphoma, and solid tumor malignancies who are receiving anticancer therapy expected to result in tumor lysis and significant hyperuricemia.

Produced by a genetically modified *Saccharomyces cerevisiae* strain, the therapeutic efficacy may be hampered by the production of antibodies against the drug. Hemolysis in glucose-6-phosphate dehydrogenase (G6PD)-deficient patients, methemoglobinemia, acute renal failure, and anaphylaxis have been associated with the use of rasburicase. Other frequently observed adverse reactions include vomiting, fever, nausea, headache, abdominal pain, constipation, diarrhea, and mucositis. Rasburicase causes enzymatic degradation of the uric acid in blood samples, and special handling is required to prevent spuriously low values for plasma uric acid in patients receiving the drug. The recommended dose of rasburicase is 0.15 mg/kg or 0.2 mg/kg as a single daily dose for 5 days, with chemotherapy initiated 4-24 hours after infusion of the first rasburicase dose.

Uricosuric Agents

Uricosuric agents increase the rate of excretion of uric acid. In humans, urate is filtered, secreted, and reabsorbed by the kidneys. Reabsorption predominates, such that the net the amount excreted usually is ~10% of that filtered. Reabsorption is mediated by an organic anion transporter family member, URAT-1, which can be inhibited. A number of other organic acid transporters, may also participate in urate exchange at the basolateral membrane of proximal tubule epithelial cells (Terkeltaub et al., 2006).

URAT-1 exchanges urate for either an organic anion such as lactate or nicotinate or less potently for an inorganic anion such as chloride. The monocarboxylate metabolite of the anti-tuberculous drug pyrazinamide, an organic anion, is a potent stimulator of urate reuptake. Uricosuric drugs such as probenecid, sulfipyrazone, benzbromarone, and losartan compete with urate for the transporter, thereby inhibiting its reabsorption via the urate-anion exchanger system. However, transport is bidirectional, and depending on dosage, some drugs, including salicylates, may either decrease or increase the excretion of uric acid. Decreased excretion usually occurs at a low dosage, while increased excretion is observed at a higher dosage. Not all agents show this phenomenon, and one uricosuric drug may either add to or inhibit the action of another.

Two mechanisms for a drug-induced decrease in urinary excretion of urate have been advanced; they are not mutually exclusive. The

first presumes that the small secretory movement of urate is inhibited by very low concentrations of the drug. Higher concentrations may inhibit urate reabsorption in the usual manner. The second proposal suggests that the urate-retaining anionic drug gains access to the intracellular fluid by an independent mechanism and promotes reabsorption of urate across the brush border by anion exchange.

There also are two mechanisms by which one drug may nullify the uricosuric action of another. First, the drug may inhibit the secretion of the uricosuric agent, thereby denying it access to its site of action, the luminal aspect of the brush border. Second, the inhibition of urate secretion by one drug may counterbalance the inhibition of urate reabsorption by the other.

Many compounds have incidental uricosuric activity by acting as exchangeable anions, but only probenecid is prescribed routinely for this purpose. Sulfapyrazone has been withdrawn from the U.S. market (see the previous edition of this book for the pharmacology of sulfapyrazone). Benzbromarone is an alternative uricosuric agent that is available in the E.U. Conversely, a number of drugs and toxins cause retention of urate; these have been reviewed elsewhere (Maaouf et al., 2004). The angiotensin II-receptor antagonist, losartan, has a modest uricosuric effect and may be an option for those who are intolerant to probenecid and are hypertensive.

Probenecid. Probenecid is a highly lipid-soluble benzoic acid derivative (pK_a 3.4).

Mechanism of Action

Inhibition of Organic Acid Transport. The actions of probenecid are confined largely to inhibition of the transport of organic acids across epithelial barriers. When tubular secretion of a substance is inhibited, its final concentration in the urine is determined by the degree of filtration, which in turn is a function of binding to plasma protein, and by the degree of reabsorption. The significance of each of these factors varies widely with different compounds. Usually, the end result is decreased tubular secretion of the compound, leading to decreased urinary and increased plasma concentration. Probenecid inhibits the reabsorption of uric acid by organic anion transporters, principally URAT-1. Uric acid is the only important endogenous compound whose excretion is known to be increased by probenecid. The uricosuric action of probenecid is blunted by the co-administration of salicylates.

Inhibition of Transport of Miscellaneous Substances. Probenecid inhibits the tubular secretion of a number of drugs, such as methotrexate and the active metabolite of clofibrate. It inhibits renal secretion of the inactive glucuronide metabolites of NSAIDs such as naproxen, ketoprofen, and indomethacin, and thereby can increase their plasma concentrations.

Inhibition of Monoamine Transport to CSF. Probenecid inhibits the transport of 5-hydroxyindoleacetic acid (5-HIAA) and other acidic metabolites of cerebral monoamines from the CSF to the plasma. The transport of drugs such as penicillin G also may be affected.

Inhibition of Biliary Excretion. Probenecid depresses the biliary secretion of certain compounds, including the diagnostic agents

indocyanine green and bromosulfophthalein (BSP). It also decreases the biliary secretion of rifampin, leading to higher plasma concentrations.

Absorption, Distribution, and Elimination. Probenecid is absorbed completely after oral administration. Peak concentrations in plasma are reached in 2-4 hours. The $t_{1/2}$ of the drug in plasma is dose dependent and varies from <5 hours to >8 hours over the therapeutic range. Between 85% and 95% of the drug is bound to plasma albumin. The 5-15% of unbound drug is cleared by glomerular filtration. The majority of the drug is secreted actively by the proximal tubule. The high lipid solubility of the undissociated form results in virtually complete absorption by backdiffusion unless the urine is markedly alkaline. A small amount of probenecid glucuronide appears in the urine. It also is hydroxylated to metabolites that retain their carboxyl function and have uricosuric activity.

Therapeutic Uses (Gout). Probenecid [PROBALAN, BENURYL (U.K.)] is marketed for oral administration. The starting dose is 250 mg twice daily, increasing over 1-2 weeks to 500-1000 mg twice daily. Probenecid increases urinary urate levels. Liberal fluid intake therefore should be maintained throughout therapy to minimize the risk of renal stones. Probenecid should not be used in gouty patients with nephrolithiasis or with overproduction of uric acid. Concomitant colchicine or NSAIDs are indicated early in the course of therapy to avoid precipitating an attack of gout, which may occur in $\leq 20\%$ of gouty patients treated with probenecid alone.

Combination with Penicillin. Probenecid was developed for the purpose of delaying the excretion of penicillin. Higher doses of probenecid are used as an adjuvant to prolong penicillin concentrations. This dosing method usually is confined to those being treated for gonorrhea or neurosyphilis infections or to cases in which penicillin resistance may be an issue (see Chapter 53).

Common Adverse Effects. Probenecid is well tolerated. Approximately 2% of patients develop mild GI irritation. The risk is increased at higher doses, and caution should be used in those with a history of peptic ulcer. It is ineffective in patients with renal insufficiency and should be avoided in those with creatinine clearance of <50 mL/min. Hypersensitivity reactions usually are mild and occur in 2-4% of patients. Serious hypersensitivity is extremely rare. The appearance of a rash during the concurrent administration of probenecid and penicillin G presents the physician with an awkward diagnostic dilemma. Substantial overdosage with probenecid results in CNS stimulation, convulsions, and death from respiratory failure.

Benzbromarone

Benzbromarone is a potent uricosuric agent that is used in Europe. It was withdrawn from the market in Europe in 2003, but was registered again with restrictions in some countries in 2004. Hepatotoxicity has been reported in conjunction with its use. The drug is absorbed readily after oral ingestion, and peak concentrations in blood are achieved in ~4 hours. It is metabolized to monobromine and dehalogenated derivatives, both of which have uricosuric activity, and is excreted primarily in the bile. The uricosuric action is blunted by aspirin or sulfapyrazone. No paradoxical retention of urate has been observed. It is a potent and reversible inhibitor of the urate-anion exchanger in the proximal tubule. As the micronized powder, it is effective in a single daily dose of 40-80 mg. It is effective in patients with renal insufficiency and may be prescribed to patients who are either allergic or

refractory to other drugs used for the treatment of gout. Preparations that combine allopurinol and benzbromarone are more effective than either drug alone in lowering serum uric acid levels, in spite of the fact that benzbromarone lowers plasma levels of oxypurinol, the active metabolite of allopurinol.

CLINICAL SUMMARY: TREATMENT OF GOUT

Gout is an inflammatory response to the precipitation of monosodium urate crystals in tissues. Although distal joints are typically affected, deposition of crystals can principally occur in any tissue and present as tophaceous gout or urate nephropathy if crystallization is localized in the renal medulla.

Treatment of Acute Gout. Acute gouty arthritis resolves spontaneously within a few days to several weeks. Anti-inflammatory therapy with NSAIDs, colchicines, and intra-articular or systemic glucocorticoids alleviates symptoms more quickly. The IL-1 β antagonist, anakinra, is under investigation for this indication.

Several NSAIDs reportedly are effective in the treatment of acute gout, particularly if treatment is initiated within 24 hours of symptom onset. When effective, NSAIDs should be given at relatively high doses for 3-4 days and then tapered for a total of 7-10 days. Indomethacin, naproxen, sulindac, celecoxib, and etoricoxib all have been found to alleviate inflammatory symptoms, although the first three are the only NSAIDs that have received FDA approval for the treatment of gout. Aspirin is not used because it can inhibit urate excretion at low doses, and through its uricosuric actions, can increase the risk of renal calculi at higher doses. In addition, aspirin can inhibit the actions of uricosuric agents. Likewise, apazone should not be used in acute gout because of the concern that its uricosuric effects may promote nephrolithiasis.

Glucocorticoids give rapid relief within hours of therapy. Systemic therapy is initiated with high doses that are then tapered rapidly (e.g., prednisone 30-60 mg/day for 3 days, then tapered over 10-14 days), depending on the size and number of affected joints. Intra-articular glucocorticoids are useful if only a few joints are involved and septic arthritis has been ruled out. Further information on these agents is available in Chapter 42.

Colchicine is thought to alleviate inflammation rapidly through multiple mechanisms, including the inhibition of neutrophil chemotaxis and activation. Symptoms resolve usually within 2-3 days, but adverse GI events are frequent, and toxicity may include bone

marrow depression. The therapeutic index of colchicine is narrow—especially in the elderly.

Prevention of Recurrent Attacks. Recurrent attacks of gout can be prevented with the use of NSAIDs or colchicine (e.g., 0.6 mg daily or on alternate days). These agents are used early in the course of uricosuric therapy when mobilization of urate is associated with a temporary increase in the risk of acute gouty arthritis.

Antihyperuricemic Therapy. Isolated hyperuricemia is not necessarily an indication for therapy, as not all of these patients develop gout. Persistently elevated uric acid levels, complicated by recurrent gouty arthritis, nephropathy, or subcutaneous tophi, can be lowered by allopurinol or febuxostat, which inhibit the formation of urate, or by uricosuric agents. Some physicians recommend measuring 24-hour urinary urate levels in patients who are on a low-purine diet to distinguish underexcretors from overproducers. However, tailored and empirical therapies have similar outcomes (Terkeltaub, 2003).

Probenecid and other uricosuric agents increase the rate of uric acid excretion by inhibiting its tubular reabsorption. They compete with uric acid for organic acid transporters, primarily URAT-1, which mediate urate exchange in the proximal tubule. Certain drugs, particularly thiazide diuretics (see Chapter 25) and immunosuppressant agents (especially cyclosporine) may impair urate excretion and thereby increase the risk of gout attacks. Probenecid generally is well tolerated but causes mild GI irritation in some patients. Other uricosuric agents, sulfinpyrazone and benzbromarone, are not available in the U.S.

Rasburicase lowers urate levels by enzymatic oxidation of uric acid into the soluble and inactive metabolite allantoin. It is approved for management of hyperuricemia in children secondary to malignancies. Routine use for hyperuricemia in adults would be limited by the risk of antibody development to uricase, which may result in hypersensitivity. A pegylated uricase form is under development.

Immunosuppressants, Tolerogens, and Immunostimulants

Alan M. Krensky, William M. Bennett,
and Flavio Vincenti

THE IMMUNE RESPONSE

The immune system evolved to discriminate self from nonself. Multicellular organisms were faced with the problem of destroying infectious invaders (microbes) or dysregulated self (tumors) while leaving normal cells intact. These organisms responded by developing a robust array of receptor-mediated sensing and effector mechanisms broadly described as innate and adaptive. Innate, or natural, immunity is primitive, does not require priming, and is of relatively low affinity, but is broadly reactive. Adaptive, or learned, immunity is antigen specific, depends on antigen exposure or priming, and can be of very high affinity. The two arms of immunity work closely together, with the innate immune system being most active early in an immune response and adaptive immunity becoming progressively dominant over time. The major effectors of innate immunity are complement, granulocytes, monocytes/macrophages, natural killer cells, mast cells, and basophils. The major effectors of adaptive immunity are B and T lymphocytes. B lymphocytes make antibodies; T lymphocytes function as helper, cytolytic, and regulatory (suppressor) cells. These cells are important in the normal immune response to infection and tumors but also mediate transplant rejection and auto-immunity. Immunoglobulins (antibodies) on the B-lymphocyte surface are receptors for a large variety of specific structural conformations. In contrast, T lymphocytes recognize antigens as peptide fragments in the context of self major histocompatibility complex (MHC) antigens (called human leukocyte antigens [HLAs] in humans) on the surface of antigen-presenting cells, such as dendritic cells, macrophages, and other cell types expressing MHC class I (HLA-A, -B, and -C) and class II

antigens (HLA-DR, -DP, and -DQ) in humans. Once activated by specific antigen recognition via their respective clonally restricted cell-surface receptors, both B and T lymphocytes are triggered to differentiate and divide, leading to release of soluble mediators (cytokines, lymphokines) that perform as effectors and regulators of the immune response.

The impact of the immune system in human disease is enormous. Developing vaccines against emerging infectious agents such as human immunodeficiency virus (HIV) and Ebola virus is among the most critical challenges facing the research community. Immune system-mediated diseases are significant medical problems. Immunological diseases are growing at epidemic proportions that require aggressive and innovative approaches to develop new treatments. These diseases include a broad spectrum of auto-immune diseases, such as rheumatoid arthritis, type I diabetes mellitus, systemic lupus erythematosus, and multiple sclerosis (MS); solid tumors and hematological malignancies; infectious diseases; asthma; and various allergic conditions. Furthermore, one of the great therapeutic opportunities for the treatment of many disorders is organ transplantation. However, immune system-mediated graft rejection remains the single greatest barrier to widespread use of this technology. An improved understanding of the immune system has led to the development of new therapies to treat immune system-mediated diseases.

This chapter briefly reviews drugs used to modulate the immune response in three ways: immunosuppression, tolerance, and immunostimulation. Four major classes of immunosuppressive drugs are discussed: glucocorticoids (Chapter 42), calcineurin inhibitors, antiproliferative and antimetabolic agents (Chapter 61), and antibodies. The “holy grail” of immunomodulation is

the induction and maintenance of immune tolerance, the active state of antigen-specific nonresponsiveness. Approaches expected to overcome the risks of infections and tumors with immunosuppression are reviewed. These include co-stimulatory blockade, donor-cell chimerism, soluble HLAs, and antigen-based therapies. A general discussion of the limited number of immunostimulant agents is presented, followed by an overview of active and passive immunization, and concluding with a brief case study of immunotherapy for MS.

IMMUNOSUPPRESSION

Immunosuppressive drugs are used to dampen the immune response in organ transplantation and autoimmune disease. In transplantation, the major classes of immunosuppressive drugs used today are:

- glucocorticoids
- calcineurin inhibitors
- anti-proliferative/antimetabolic agents
- biologicals (antibodies)

These drugs have met with a high degree of clinical success in treating conditions such as acute immune rejection of organ transplants and severe autoimmune diseases. However, such therapies require lifelong use and nonspecifically suppress the entire immune system, exposing patients to considerably higher risks of infection and cancer. The calcineurin inhibitors and glucocorticoids, in particular, are nephrotoxic and diabetogenic, respectively, thus restricting their usefulness in a variety of clinical settings.

Monoclonal and polyclonal antibody preparations directed at reactive T cells are important adjunct therapies and provide a unique opportunity to target specifically immune-reactive cells. Finally, newer small molecules and antibodies have expanded the arsenal of immunosuppressives. In particular, mammalian target of rapamycin (mTOR) inhibitors (sirolimus, everolimus) and anti-CD25 (interleukin-2 receptor [IL-2R]) antibodies (basiliximab, daclizumab) target growth-factor pathways, substantially limiting clonal expansion and thus potentially promoting tolerance. Immunosuppressive drugs used more commonly today are described in the rest of this section. Many more selective therapeutic agents under development are expected to revolutionize immunotherapy in the next decade.

General Approach to Organ Transplantation Therapy

Organ transplantation therapy is organized around five general principles. The first principle is careful patient preparation and selection

Table 35–1

Sites of Action of Selected Immunosuppressive Agents on T-Cell Activation

DRUG	SITE OF ACTION
Glucocorticoids	Glucocorticoid response elements in DNA (regulate gene transcription)
Muromonab-CD3	T-cell receptor complex (blocks antigen recognition)
Cyclosporine	Calcineurin (inhibits phosphatase activity)
Tacrolimus	Calcineurin (inhibits phosphatase activity)
Azathioprine	DNA (false nucleotide incorporation)
Mycophenolate mofetil	Inosine monophosphate dehydrogenase (inhibits activity)
Daclizumab, basiliximab	IL-2 receptor (block IL-2-mediated T-cell activation)
Sirolimus	Protein kinase involved in cell-cycle progression (mTOR) (inhibits activity)

IL, interleukin; mTOR, mammalian target of rapamycin.

of the best available ABO blood type-compatible HLA match for organ donation. Second, a multitiered approach to immunosuppressive drug therapy, similar to that in cancer chemotherapy, is employed. Several agents, each of which is directed at a different molecular target within the allograft response (Table 35–1; Hong and Kahan, 2000), are used simultaneously. Synergistic effects permit use of the various agents at relatively low doses, thereby limiting specific toxicities while maximizing the immunosuppressive effect. The third principle is that greater immunosuppression is required to gain early engraftment and/or to treat established rejection than to maintain long-term immunosuppression. Therefore, intensive induction and lower-dose maintenance drug protocols are employed. Fourth, careful investigation of each episode of transplant dysfunction is required, including evaluation for rejection, drug toxicity, and infection, keeping in mind that these various problems can and often do co-exist. Organ-specific problems (e.g., obstruction in the case of kidney transplants) also must be considered. The fifth principle, which is common to all drugs, is that a drug should be reduced or withdrawn if its toxicity exceeds its benefit.

Biological Induction Therapy. Induction therapy with polyclonal and monoclonal antibodies (mAbs) has been an important component of immunosuppression dating back to the 1960s, when Starzl and colleagues demonstrated the beneficial effect of antilymphocyte globulin (ALG) in the prophylaxis of rejection in renal transplant recipients. Over the past 40 years, several polyclonal antilymphocyte preparations have been used in renal transplantation; however, only two preparations currently are approved by the FDA for use in transplantation: lymphocyte immune globulin (ATGAM) and antithymocyte globulin (ATG; THYMOGLOBULIN) (Howard et al., 1997). Another important milestone in biological therapy was the development

of mAbs and the introduction of the murine anti-CD3 mAb (muromonab-CD3 or OKT3) (Ortho Multicenter Transplant Study Group, 1985). ATG is the most frequently used depleting agent. Lymphocyte immune globulin and OKT3 are rarely used because of poorer efficacy and acute side effects, respectively. Alemtuzumab, a humanized anti-CD52 monoclonal antibody that produces prolonged lymphocyte depletion, is approved for use in chronic lymphocytic leukemia but is increasingly used off label as induction therapy in transplantation.

In many transplant centers, induction therapy with biological agents is used to delay the use of the nephrotoxic calcineurin inhibitors or to intensify the initial immunosuppressive therapy in patients at high risk of rejection (i.e., repeat transplants, broadly presensitized patients, African-American patients, or pediatric patients). Most of the limitations of murine-based mAbs generally were overcome by the introduction of chimeric or humanized mAbs that lack antigenicity and have a prolonged serum $t_{1/2}$. Antibodies derived from transgenic mice carrying human antibody genes are labeled “humanized” (90-95% human) or “fully human” (100% human); antibodies derived from human cells are labeled “human.” However, all three types of antibodies probably are of equal efficacy and safety. Chimeric antibodies generally contain ~33% mouse protein and 67% human protein and can still produce an antibody response, resulting in reduced efficacy and $t_{1/2}$ compared to humanized antibodies. The anti-IL-2R mAbs (frequently referred to as anti-CD25) were the first biologicals proven to be effective as induction agents in randomized double-blind prospective trials (Vincenti et al., 1998).

Biological agents for induction therapy in the prophylaxis of rejection currently are used in ~70% of *de novo* transplant patients and have been propelled by several factors, including the introduction of the relatively safe anti-IL-2R antibodies and the emergence of ATG as a safer and more effective alternative to lymphocyte immune globulin or muromonab-CD3. Biologicals for induction can be divided into two groups: the depleting agents and the immune modulators. The depleting agents consist of lymphocyte immune globulin, ATG, and muromonab-CD3 mAb (the latter also produces immune modulation); their efficacy derives from their ability to deplete the recipient’s CD3-positive cells at the time of transplantation and antigen presentation. The second group of biological agents, the anti-IL-2R mAbs, do not deplete T lymphocytes, with the possible exception of T regulatory cells, but rather block IL-2-mediated T-cell activation by binding to the α chain of IL-2R.

More aggressive approaches have been recently utilized in patients with high levels of anti-HLA antibodies, donor-specific antibodies detected by cytotoxicity cross-match, or flow cytometry and humoral rejection. These therapies include plasmapheresis, intravenous immunoglobulin, and rituximab, a chimeric anti-CD20 monoclonal antibody (Akalin et al., 2003; Zachary et al., 2003; Vo et al., 2008).

Maintenance Immunotherapy. The basic immunosuppressive protocols use multiple drugs simultaneously. Therapy typically involves a calcineurin inhibitor, glucocorticoids, and mycophenolate (a purine metabolism inhibitor; see “Mycophenolate Mofetil”), each directed at a discrete site in T-cell activation (Suthanthiran et al., 1996). Glucocorticoids, azathioprine, cyclosporine, tacrolimus, mycophenolate, sirolimus, and various monoclonal and polyclonal antibodies all are approved for use in transplantation. Glucocorticoid-free regimens have achieved special prominence in recent successes in using

pancreatic islet transplants to treat patients with type I diabetes mellitus. Protocols employing rapid steroid withdrawal (within 1 week after transplantation) are being utilized in more than a third of renal transplant recipients. Short-term results are good, but the effects on long-term graft function are unknown (Vincenti et al., 2008). Recent data suggest that calcineurin inhibitors may shorten graft $t_{1/2}$ by their nephrotoxic effects (Nankivell et al., 2003). Protocols under evaluation include calcineurin dose reduction or switching from calcineurin to sirolimus-based immunosuppressive therapy at 3-4 months.

Therapy for Established Rejection. Although low doses of prednisone, calcineurin inhibitors, purine metabolism inhibitors, or sirolimus are effective in preventing acute cellular rejection, they are less effective in blocking activated T lymphocytes and thus are not very effective against established, acute rejection or for the total prevention of chronic rejection (Monaco et al., 1999). Therefore, treatment of established rejection requires the use of agents directed against activated T cells. These include glucocorticoids in high doses (pulse therapy), polyclonal antilymphocyte antibodies, or muromonab-CD3.

Adrenocortical Steroids

The introduction of glucocorticoids as immunosuppressive drugs in the 1960s played a key role in making organ transplantation possible. Their chemistry, pharmacokinetics, and drug interactions are described in Chapter 42. Prednisone, prednisolone, and other glucocorticoids are used alone and in combination with other immunosuppressive agents for treatment of transplant rejection and auto-immune disorders.

Mechanism of Action. The immunosuppressive effects of glucocorticoids have long been known, but the specific mechanisms of their immunosuppressive actions somewhat elusive. Glucocorticoids lyse (in some species) and induce the redistribution of lymphocytes, causing a rapid, transient decrease in peripheral blood lymphocyte counts. To effect longer-term responses, steroids bind to receptors inside cells; either these receptors, glucocorticoid-induced proteins, or interacting proteins regulate the transcription of numerous other genes (Chapter 42). Additionally, glucocorticoids curtail activation of NF- κ B, which increases apoptosis of activated cells (Auphan et al., 1995). Of central importance, key pro-inflammatory cytokines such as IL-1 and IL-6 are downregulated. T cells are inhibited from making IL-2 and proliferating. The activation of cytotoxic T lymphocytes is inhibited. Neutrophils and monocytes display poor chemotaxis and decreased lysosomal enzyme release. Therefore, glucocorticoids have broad anti-inflammatory effects on multiple components of cellular immunity. In contrast, they have relatively little effect on humoral immunity.

Therapeutic Uses. There are numerous indications for glucocorticoids. They commonly are combined with

other immunosuppressive agents to prevent and treat transplant rejection. High-dose pulses of intravenous methylprednisolone sodium succinate (SOLU-MEDROL, others) are used to reverse acute transplant rejection and acute exacerbations of selected auto-immune disorders. Glucocorticoids also are efficacious for treatment of graft-versus-host disease in bone-marrow transplantation. Glucocorticoids are routinely used to treat auto-immune disorders such as rheumatoid and other arthritides, systemic lupus erythematosus, systemic dermatomyositis, psoriasis and other skin conditions, asthma and other allergic disorders, inflammatory bowel disease, inflammatory ophthalmic diseases, auto-immune hematological disorders, and acute exacerbations of MS (see “Multiple Sclerosis”). In addition, glucocorticoids limit allergic reactions that occur with other immunosuppressive agents and are used in transplant recipients to block first-dose cytokine storm caused by treatment with muromonab-CD3 and to a lesser extent ATG (see “Antithymocyte Globulin”).

Toxicity. Unfortunately, the extensive use of steroids often results in disabling and life-threatening adverse effects. These effects include growth retardation in children, avascular necrosis of bone, osteopenia, increased risk of infection, poor wound healing, cataracts, hyperglycemia, and hypertension (Chapter 42). The advent of combined glucocorticoid/calcineurin inhibitor regimens has allowed reduced doses or rapid withdrawal of steroids, resulting in lower steroid-induced morbidities.

Calcineurin Inhibitors

Perhaps the most effective immunosuppressive drugs in routine use are the calcineurin inhibitors, cyclosporine and tacrolimus, which target intracellular signaling pathways induced as a consequence of T cell–receptor activation. Although they are structurally unrelated (Figure 35-1) and bind to distinct (albeit related) molecular targets, they inhibit normal T-cell signal transduction essentially by the same mechanism (Figure 35-2). Cyclosporine and tacrolimus do not act *per se* as immunosuppressive agents. Instead, these drugs bind to an immunophilin (cyclophilin for cyclosporine [see “Cyclosporine”] or FKBP-12 for tacrolimus [see “Tacrolimus”]), resulting in subsequent interaction with calcineurin to block its phosphatase activity. Calcineurin-catalyzed dephosphorylation is required for movement of a component of the nuclear factor of activated T lymphocytes (NFAT) into the nucleus (Figure 35-2). NFAT, in turn, is required to induce a number of cytokine genes, including that for interleukin-2 (IL-2), a prototypic T-cell growth and differentiation factor.

Tacrolimus. Tacrolimus (PROGRAF, FK506) is a macrolide antibiotic produced by *Streptomyces tsukubaensis* (Goto et al., 1987). Because of perceived slightly greater efficacy and ease of blood level monitoring, tacrolimus has become the preferred calcineurin inhibitor in most transplant centers (Ekberg et al., 2008).

Mechanism of Action. Like cyclosporine, tacrolimus inhibits T-cell activation by inhibiting calcineurin. Tacrolimus binds to an intracellular protein, FK506-binding protein-12 (FKBP-12), an immunophilin structurally related to cyclophilin. A complex of tacrolimus-FKBP-12, Ca^{2+} , calmodulin, and calcineurin then forms, and calcineurin phosphatase activity is inhibited. As described for cyclosporine and depicted in Figure 35-2, the inhibition of phosphatase activity prevents dephosphorylation and nuclear translocation of NFAT and inhibits T-cell activation. Thus, although the intracellular receptors differ, cyclosporine and tacrolimus target the same pathway for immunosuppression.

Disposition and Pharmacokinetics. Tacrolimus is available for oral administration as capsules (0.5, 1, and 5 mg) and as a solution for injection (5 mg/mL). Immunosuppressive activity resides primarily in the parent drug. Because of intersubject variability in pharmacokinetics, individualized dosing is required for optimal therapy. Whole blood, rather than plasma, is the most appropriate sampling compartment to describe tacrolimus pharmacokinetics. For tacrolimus, the trough drug level seems to correlate better with clinical events than it does for cyclosporine. Target concentrations in most centers are 10-15 ng/mL in the early preoperative period and 100-200 ng/mL 3 months after transplantation. Gastrointestinal absorption is incomplete and variable. Food decreases the rate and extent of absorption. Plasma protein binding of tacrolimus is 75-99%, involving primarily albumin and α_1 -acid glycoprotein. The $t_{1/2}$ of tacrolimus is ~12 hours. Tacrolimus is extensively metabolized in the liver by CYP3A; at least some of the metabolites are active. The bulk of excretion of the parent drug and metabolites is in the feces. Less than 1% of administered tacrolimus is excreted unchanged in the urine.

Therapeutic Uses. Tacrolimus is indicated for the prophylaxis of solid-organ allograft rejection in a manner similar to cyclosporine (see “Cyclosporine”) and is used off label as rescue therapy in patients with rejection episodes despite “therapeutic” levels of cyclosporine.

Recommended initial oral doses are 0.2 mg/kg/day for adult kidney transplant patients, 0.1-0.15 mg/kg/day for adult liver transplant patients, 0.075 mg/kg/day for adult heart transplant patients, and 0.15-0.2 mg/kg/day for pediatric liver transplant patients in two divided doses 12 hours apart. These dosages are intended to achieve typical blood trough levels in the 5- to 20-ng/mL range.

Toxicity. Nephrotoxicity, neurotoxicity (e.g., tremor, headache, motor disturbances, seizures), GI complaints, hypertension, hyperkalemia, hyperglycemia, and diabetes all are associated with tacrolimus use. As with cyclosporine, nephrotoxicity is limiting. Tacrolimus has a negative effect on pancreatic islet β cells, and glucose intolerance and diabetes mellitus are well-recognized complications of tacrolimus-based immunosuppression. As with other immunosuppressive agents,

Figure 35–1. Chemical structures of immunosuppressive drugs.

there is an increased risk of secondary tumors and opportunistic infections. Notably, tacrolimus does not adversely affect uric acid or LDL cholesterol. Diarrhea and alopecia are commonly noted in patients on concomitant mycophenolate therapy.

Drug Interactions. Because of its potential for nephrotoxicity, tacrolimus blood levels and renal function should be monitored closely, especially when tacrolimus is used with other potentially nephrotoxic drugs. Co-administration with cyclosporine results in additive or synergistic nephrotoxicity; therefore, a delay of at least 24 hours is required when switching a patient from cyclosporine to tacrolimus. Because tacrolimus is metabolized mainly by CYP3A,

the potential interactions described in the following section for cyclosporine also apply for tacrolimus.

Cyclosporine

Chemistry. Cyclosporine (cyclosporin A), a cyclic polypeptide of 11 amino acids, is produced by the fungus *Beauveria nivea*. Because cyclosporine is lipophilic and highly hydrophobic, it is formulated for clinical administration using castor oil or other strategies to ensure solubilization.

Mechanism of Action. Cyclosporine suppresses some humoral immunity but is more effective against T cell–dependent immune

Figure 35-2. Mechanisms of action of cyclosporine, tacrolimus, and sirolimus on T lymphocytes. Both cyclosporine and tacrolimus bind to immunophilins (cyclophilin and FK506-binding protein [FKBP], respectively), forming a complex that binds the phosphatase calcineurin and inhibits the calcineurin-catalyzed dephosphorylation essential to permit movement of the nuclear factor of activated T cells (NFAT) into the nucleus. NFAT is required for transcription of interleukin-2 (IL-2) and other growth- and differentiation-associated cytokines (lymphokines). Sirolimus (rapamycin) works at a later stage in T-cell activation, downstream of the IL-2 receptor. Sirolimus also binds FKBP, but the FKBP-sirolimus complex binds to and inhibits the mammalian target of rapamycin (mTOR), a kinase involved in cell-cycle progression (proliferation). TCR, T-cell receptor. (From Pattison et al., 1997, with permission. Copyright © Lippincott Williams & Wilkins. <http://lww.com>.)

mechanisms such as those underlying transplant rejection and some forms of auto-immunity. It preferentially inhibits antigen-triggered signal transduction in T lymphocytes, blunting expression of many lymphokines, including IL-2, and the expression of anti-apoptotic proteins. Cyclosporine forms a complex with cyclophilin, a cytoplasmic-receptor protein present in target cells (Figure 35-2). This complex binds to calcineurin, inhibiting Ca $^{2+}$ -stimulated dephosphorylation of the cytosolic component of NFAT (Schreiber and Crabtree, 1992). When cytoplasmic NFAT is dephosphorylated, it translocates to the nucleus and complexes with nuclear components required for complete T-cell activation, including transactivation of IL-2 and other lymphokine genes. Calcineurin phosphatase activity is inhibited after physical interaction with the cyclosporine/cyclophilin complex. This prevents NFAT dephosphorylation such that NFAT does not enter the nucleus, gene transcription is not activated, and the T lymphocyte fails to respond to specific

antigenic stimulation. Cyclosporine also increases expression of transforming growth factor β (TGF- β), a potent inhibitor of IL-2-stimulated T-cell proliferation and generation of cytotoxic T lymphocytes (CTLs) (Khanna et al., 1994).

Disposition and Pharmacokinetics. Cyclosporine can be administered intravenously or orally. The intravenous preparation (SANDIMMUNE, others) is provided as a solution in an ethanol-polyoxyethylated castor oil vehicle that must be further diluted in 0.9% sodium chloride solution or 5% dextrose solution before injection. The oral dosage forms include soft gelatin capsules and oral solutions. Cyclosporine supplied in the original soft gelatin capsule is absorbed slowly, with 20-50% bioavailability. A modified microemulsion formulation (NEORAL) has become the most widely used preparation. It has more uniform and slightly increased bioavailability compared to the original formulation. It is provided as 25-mg and 100-mg soft gelatin

capsules and a 100-mg/mL oral solution. Because the original and microemulsion formulations are not bioequivalent, they cannot be used interchangeably without supervision by a physician and monitoring of drug concentrations in plasma. Generic preparations of both NEORAL and SANDIMMUNE, now widely available, are bioequivalent by FDA criteria. When switching between formulations, increased surveillance is recommended to ensure that drug levels remain in the therapeutic range. This need for increased monitoring is based on anecdotal experience rather than validated differences. *Because SANDIMMUNE and NEORAL differ in terms of their pharmacokinetics and definitely are not bioequivalent, their generic versions cannot be used interchangeably.* This has been a source of confusion to pharmacists and patients. Transplant units need to educate patients that SANDIMMUNE and its generics are not the same as NEORAL and its generics, such that one preparation cannot be substituted for another without risk of inadequate immunosuppression or increased toxicity.

Blood is most conveniently sampled before the next dose (a C_0 or trough level). Although convenient to obtain, C_0 concentrations do not reflect the area under the drug concentration curve (AUC) as a measure of cyclosporine exposure in individual patients. As a practical solution to this problem and to better measure the overall exposure of a patient to the drug, it has been proposed that levels be taken 2 hours after a dose administration (so-called C_2 levels) (Cole et al., 2003). Some studies have shown a better correlation of C_2 with the AUC, but no single time point can simulate the exposure as measured by more frequent drug sampling. In complex patients with delayed absorption, such as diabetics, the C_2 level may underestimate the peak cyclosporine level obtained, and in others who are rapid absorbers, the C_2 level may have peaked before the blood sample is drawn. In practice, if a patient has clinical signs or symptoms of toxicity, or if there is unexplained rejection or renal dysfunction, a pharmacokinetic profile can be used to estimate that person's exposure to the drug. Many clinicians, particularly those caring for transplant patients some time after the transplant, monitor cyclosporine blood levels only when a clinical event (e.g., renal dysfunction or rejection) occurs. In that setting, either a C_0 or C_2 level helps to ascertain whether inadequate immunosuppression or drug toxicity is present. As described above, cyclosporine absorption is incomplete following oral administration and varies with the individual patient and the formulation used. The elimination of cyclosporine from the blood generally is biphasic, with a terminal $t_{1/2}$ of 5-18 hours (Noble and Markham, 1995). After intravenous infusion, clearance is ~5-7 mL/min/kg in adult recipients of renal transplants, but results differ by age and patient populations. For example, clearance is slower in cardiac transplant patients and more rapid in children. Thus, the inter-subject variability is so large that individual monitoring is required.

After oral administration of cyclosporine (as NEORAL), the time to peak blood concentrations is 1.5-2 hours (Noble and Markham, 1995). Administration with food delays and decreases absorption. High- and low-fat meals consumed within 30 minutes of administration decrease the AUC by ~13% and the maximum concentration by 33%. This makes it imperative to individualize dosage regimens for outpatients.

Cyclosporine is distributed extensively outside the vascular compartment. After intravenous dosing, the steady-state volume of distribution reportedly is as high as 3-5 L/kg in solid-organ transplant recipients.

Only 0.1% of cyclosporine is excreted unchanged in urine. Cyclosporine is extensively metabolized in the liver by CYP3A and to a lesser degree by the GI tract and kidneys. At least 25 metabolites have been identified in human bile, feces, blood, and urine. All of the metabolites have reduced biological activity and toxicity compared to the parent drug. Cyclosporine and its metabolites are excreted principally through the bile into the feces, with ~6% being excreted in the urine. Cyclosporine also is excreted in human milk. In the presence of hepatic dysfunction, dosage adjustments are required. No adjustments generally are necessary for dialysis or renal failure patients.

Therapeutic Uses. Clinical indications for cyclosporine are kidney, liver, heart, and other organ transplantation; rheumatoid arthritis; and psoriasis. Its use in dermatology is discussed in Chapter 65. Cyclosporine generally is recognized as the agent that ushered in the modern era of organ transplantation, increasing the rates of early engraftment, extending kidney graft survival, and making cardiac and liver transplantation possible. Cyclosporine usually is combined with other agents, especially glucocorticoids and either azathioprine or mycophenolate and, most recently, sirolimus.

The dose of cyclosporine varies, depending on the organ transplanted and the other drugs used in the specific treatment protocol(s). The initial dose generally is not given before the transplant because of the concern about nephrotoxicity. Especially for renal transplant patients, therapeutic algorithms have been developed to delay cyclosporine or tacrolimus introduction until a threshold renal function has been attained. The amount of the initial dose and reduction to maintenance dosing is sufficiently variable that no specific recommendation is provided here. Dosing is guided by signs of rejection (too low a dose), renal or other toxicity (too high a dose), and close monitoring of blood levels. Great care must be taken to differentiate renal toxicity from rejection in kidney transplant patients. Ultrasound-guided allograft biopsy is the best way to assess the reason for renal dysfunction. Because adverse reactions have been ascribed more frequently to the intravenous formulation, this route of administration is discontinued as soon as the patient can take the drug orally.

In rheumatoid arthritis, cyclosporine is used in severe cases that have not responded to methotrexate. Cyclosporine can be combined with methotrexate, but the levels of both drugs must be monitored closely. In psoriasis, cyclosporine is indicated for treatment of adult immunocompetent patients with severe and disabling disease for whom other systemic therapies have failed. Because of its mechanism of action, there is a theoretical basis for the use of cyclosporine in a variety of other T cell-mediated diseases. Cyclosporine reportedly is effective in Behçet's acute ocular syndrome, endogenous uveitis, atopic dermatitis, inflammatory bowel disease, and nephrotic syndrome, even when standard therapies have failed.

Toxicity. The principal adverse reactions to cyclosporine therapy are renal dysfunction and hypertension; tremor, hirsutism, hyperlipidemia, and gum hyperplasia also are frequently encountered. Hypertension occurs in ~50% of renal transplant and almost all cardiac transplant patients. Hyperuricemia may lead to worsening of

gout, increased P-glycoprotein activity, and hypercholesterolemia. Nephrotoxicity occurs in the majority of patients and is the major reason for cessation or modification of therapy (Nankivell et al., 2003). Recent reviews of calcineurin inhibitor nephrotoxicity are available (Burdmann et al., 2003). Combined use of calcineurin inhibitors and glucocorticoids is particularly diabetogenic, although this apparently is more problematic in patients treated with tacrolimus (see “Tacrolimus” section earlier). Especially at risk are obese patients, African-American or Hispanic transplant recipients, or those with a family history of type II diabetes or obesity. Cyclosporine, as opposed to tacrolimus, is more likely to produce elevations in LDL cholesterol (Artz et al., 2003).

Drug Interactions. Cyclosporine interacts with a wide variety of commonly used drugs, and close attention must be paid to drug interactions. Any drug that affects microsomal enzymes, especially CYP3A, may impact cyclosporine blood concentrations.

Substances that inhibit this enzyme can decrease cyclosporine metabolism and increase blood concentrations. These include Ca^{2+} channel blockers (e.g., verapamil, nifedipine), antifungal agents (e.g., fluconazole, ketoconazole), antibiotics (e.g., erythromycin), glucocorticoids (e.g., methylprednisolone), HIV-protease inhibitors (e.g., indinavir), and other drugs (e.g., allopurinol, metoclopramide). Grapefruit juice inhibits CYP3A and the P-glycoprotein multidrug efflux pump and should be minimized by patients taking cyclosporine because these effects can increase cyclosporine blood concentrations. In contrast, drugs that induce CYP3A activity can increase cyclosporine metabolism and decrease blood concentrations. Such drugs include antibiotics (e.g., nafcillin, rifampin), anticonvulsants (e.g., phenobarbital, phenytoin), and others (e.g., octreotide, ticlopidine). In general, close monitoring of cyclosporine blood levels and the levels of other drugs is required when such combinations are used.

Interactions between cyclosporine and sirolimus (also see “Drug Interactions” in the sirolimus section) have led to the recommendation that administration of the two drugs be separated by time. Sirolimus aggravates cyclosporine-induced renal dysfunction, while cyclosporine increases sirolimus-induced hyperlipidemia and myelosuppression. Other drug interactions of concern include additive nephrotoxicity when cyclosporine is co-administered with nonsteroidal anti-inflammatory drugs (NSAIDs) and other drugs that cause renal dysfunction; elevation of methotrexate levels when the two drugs are co-administered; and reduced clearance of other drugs, including prednisolone, digoxin, and statins.

ISATX247. This is a new oral semisynthetic structural analog of cyclosporine. The cyclosporine molecule is modified at the first amino acid residue. It is more potent on a weight basis than cyclosporine *in vitro* for calcineurin inhibition. Some preclinical studies show reduced nephrotoxicity, and thus the drug is in clinical development as a primary immunosuppressive drug. Phase 2 clinical trials are in process and thus far show similar or less nephrotoxicity with less frequent glucose intolerance compared to tacrolimus-treated patients (Vincenti and Kirk, 2008).

Janus Kinase Inhibitors/CP-690550. Cytokine receptors are enticing targets for modulation by new small immunosuppressive molecules. Janus kinase (JAK) inhibitors are a class of drugs that inhibit important cytoplasmic tyrosine kinases that are involved in cell signaling. The molecule CP-690550 currently is in clinical trials. As an

immunosuppressive drug, this compound inhibits JAK3, which is found primarily on hematopoietic cells. In preclinical studies, this JAK3 inhibitor has been tolerated without nephrotoxicity, malignancy, or other important side effects. To date, all studies have shown non-inferiority with other standard immunosuppressive regimens (Vincenti and Kirk, 2008).

Protein Kinase C Inhibitors/AEB071. Various isoforms of PKC are important mediators in signaling pathways distal to the T-cell receptor and co-stimulators. AEB071 is a low-molecular-weight compound that blocks T-cell activation by inhibition of PKC, thus producing immunosuppression by a different mechanism than calcineurin inhibitors. Clinical studies are ongoing. Early trials using PKC inhibitors in combination with calcineurin inhibitors (CNIs) followed by discontinuation of the CNI had to be stopped because acute rejections occurred when the CNIs were discontinued (Vincenti and Kirk, 2008).

Anti-Proliferative and Antimetabolic Drugs

Sirolimus

Sirolimus (rapamycin; RAPAMUNE) is a macrocyclic lactone (Figure 35–1) produced by *Streptomyces hygroscopicus*.

Mechanism of Action. Sirolimus inhibits T-lymphocyte activation and proliferation downstream of the IL-2 and other T-cell growth factor receptors (Figure 35–2). Like cyclosporine and tacrolimus, therapeutic action of sirolimus requires formation of a complex with an immunophilin, in this case FKBP-12. However, the sirolimus–FKBP-12 complex does not affect calcineurin activity. It binds to and inhibits a protein kinase, designated mTOR, which is a key enzyme in cell-cycle progression. Inhibition of mTOR blocks cell-cycle progression at the $G_1 \rightarrow S$ phase transition. In animal models, sirolimus not only inhibits transplant rejection, graft-versus-host disease, and a variety of auto-immune diseases, but its effect also lasts several months after discontinuing therapy, suggesting a tolerizing effect (see “Tolerance”) (Groth et al., 1999). A newer indication for sirolimus is the avoidance of calcineurin inhibitors, even when patients are stable, to protect kidney function (Flechner et al., 2008).

Disposition and Pharmacokinetics. After oral administration, sirolimus is absorbed rapidly and reaches a peak blood concentration within ~1 hour after a single dose in healthy subjects and within ~2 hours after multiple oral doses in renal transplant patients. Systemic availability is ~15%, and blood concentrations are proportional to doses between 3 and 12 mg/m². A high-fat meal decreases peak blood concentration by 34%; sirolimus therefore should be taken consistently either with or without food, and blood levels should be monitored closely. About 40% of sirolimus in plasma is protein bound, especially to albumin. The drug partitions into formed elements of blood, with a blood-to-plasma ratio of 38 in renal transplant patients. Sirolimus is extensively metabolized by CYP3A4 and is transported by P-glycoprotein. Seven major metabolites have been identified in whole blood. Metabolites also are detectable in feces and urine, with the bulk of total excretion being in feces. Although some of its metabolites are active, sirolimus itself is the major active

component in whole blood and contributes >90% of the immunosuppressive effect. The blood $t_{1/2}$ after multiple doses in stable renal transplant patients is 62 hours (Zimmerman and Kahan, 1997). A loading dose of three times the maintenance dose will provide nearly steady-state concentrations within 1 day in most patients.

Therapeutic Uses. Sirolimus is indicated for prophylaxis of organ transplant rejection usually in combination with a reduced dose of calcineurin inhibitor and glucocorticoids. In patients experiencing or at high risk for calcineurin inhibitor–associated nephrotoxicity, sirolimus has been used with glucocorticoids and mycophenolate to avoid permanent renal damage. Sirolimus dosing regimens are relatively complex with blood levels generally targeted between 5–15 ng/mL. It is recommended that the daily maintenance dose be reduced by approximately one-third in patients with hepatic impairment (Watson et al., 1999). Sirolimus also has been incorporated into stents to inhibit local cell proliferation and blood vessel occlusion.

Toxicity. The use of sirolimus in renal transplant patients is associated with a dose-dependent increase in serum cholesterol and triglycerides that may require treatment. Although immunotherapy with sirolimus *per se* is not nephrotoxic, patients treated with cyclosporine plus sirolimus have impaired renal function compared to patients treated with cyclosporine and either azathioprine or placebo. Sirolimus also may prolong delayed graft function in deceased donor kidney transplants, presumably because of its antiproliferative action (Smith et al., 2003). Renal function therefore must be monitored closely in such patients. Lymphocele, a known surgical complication associated with renal transplantation, is increased in a dose-dependent fashion by sirolimus, requiring close postoperative follow-up. Other adverse effects include anemia, leukopenia, thrombocytopenia, mouth ulcer, hypokalemia, proteinuria, and GI effects. Delayed wound healing may occur with sirolimus use. As with other immunosuppressive agents, there is an increased risk of neoplasms, especially lymphomas, and infections. Sirolimus is not recommended in liver and lung transplants due to the risk of hepatic artery thrombosis and bronchial anastomotic dehiscence, respectively.

Drug Interactions. Because sirolimus is a substrate for CYP3A4 and is transported by P-glycoprotein, close attention to interactions with other drugs that are metabolized or transported by these proteins is required. As noted above, cyclosporine and sirolimus interact, and their administration should be separated by time. Dose adjustment may be required when sirolimus is co-administered with diltiazem or rifampin. Dose adjustment apparently is not required when sirolimus is co-administered with acyclovir, digoxin, glyburide, nifedipine, norgestrel/ethinyl estradiol, prednisolone, or trimethoprim-sulfamethoxazole. This list is incomplete, and blood levels and potential drug interactions must be monitored closely.

Everolimus

Everolimus [40-*O*-(2-hydroxyethyl)-rapamycin] is closely related chemically and clinically to sirolimus but

has distinct pharmacokinetics. The main difference is a shorter $t_{1/2}$ and thus a shorter time to achieve steady-state concentrations of the drug. Dosage on a milligram per kilogram basis is similar to that of sirolimus. Aside from the shorter $t_{1/2}$, no studies have compared everolimus with sirolimus in standard immunosuppressive regimens (Eisen et al., 2003). As with sirolimus, the combination of a calcineurin inhibitor and an mTOR inhibitor produces worse renal function at 1 year than does calcineurin inhibitor therapy alone, suggesting a drug interaction between the mTOR inhibitors and the calcineurin inhibitors that enhances toxicity and reduces rejection. The toxicity of everolimus and the drug interactions reported to date seem to be the same as with sirolimus.

Azathioprine

Azathioprine (IMURAN, others) is a purine antimetabolite. It is an imidazolyl derivative of 6-mercaptopurine (see Figure 61–11).

Mechanism of Action. Following exposure to nucleophiles such as glutathione, azathioprine is cleaved to 6-mercaptopurine, which in turn is converted to additional metabolites that inhibit *de novo* purine synthesis (Chapter 61). A fraudulent nucleotide, 6-thio-IMP, is converted to 6-thio-GMP and finally to 6-thio-GTP, which is incorporated into DNA. Cell proliferation thereby is inhibited, impairing a variety of lymphocyte functions. Azathioprine appears to be a more potent immunosuppressive agent than 6-mercaptopurine, which may reflect differences in drug uptake or pharmacokinetic differences in the resulting metabolites.

Disposition and Pharmacokinetics. Azathioprine is well absorbed orally and reaches maximum blood levels within 1–2 hours after administration. The $t_{1/2}$ of azathioprine is ~10 minutes, while that of its metabolite, 6-mercaptopurine, is ~1 hour. Other metabolites have a $t_{1/2}$ of up to 5 hours. Blood levels have limited predictive value because of extensive metabolism, significant activity of many different metabolites, and high tissue levels attained. Azathioprine and mercaptopurine are moderately bound to plasma proteins and are partially dialyzable. Both are rapidly removed from the blood by oxidation or methylation in the liver and/or erythrocytes. Renal clearance has little impact on biological effectiveness or toxicity.

Therapeutic Uses. Azathioprine was first introduced as an immunosuppressive agent in 1961, helping to make allogeneic kidney transplantation possible. It is indicated as an adjunct for prevention of organ transplant rejection and in severe rheumatoid arthritis. Although the dose of azathioprine required to prevent organ rejection and minimize toxicity varies, 3–5 mg/kg/day is the usual starting dose. Lower initial doses (1 mg/kg/day) are used in treating rheumatoid arthritis. Complete blood count and liver function tests should be monitored.

Toxicity. The major side effect of azathioprine is bone marrow suppression, including leukopenia (common), thrombocytopenia (less

common), and/or anemia (uncommon). Other important adverse effects include increased susceptibility to infections (especially varicella and herpes simplex viruses), hepatotoxicity, alopecia, GI toxicity, pancreatitis, and increased risk of neoplasia.

Drug Interactions. Xanthine oxidase, an enzyme of major importance in the catabolism of azathioprine metabolites, is blocked by allopurinol. If azathioprine and allopurinol are used concurrently, the azathioprine dose must be decreased to 25-33% of the usual dose; it is best not to use these two drugs together. Adverse effects resulting from co-administration of azathioprine with other myelosuppressive agents or angiotensin-converting enzyme inhibitors include leukopenia, thrombocytopenia, and anemia as a result of myelosuppression.

Mycophenolate Mofetil

Mycophenolate mofetil (MMF; CELL-CEPT) is the 2-morpholinoethyl ester of mycophenolic acid (MPA).

Mechanism of Action. MMF is a prodrug that is rapidly hydrolyzed to the active drug, MPA, a selective, noncompetitive, reversible inhibitor of inosine monophosphate dehydrogenase (IMPDH), an important enzyme in the *de novo* pathway of guanine nucleotide synthesis. B and T lymphocytes are highly dependent on this pathway for cell proliferation, while other cell types can use salvage pathways; MPA therefore selectively inhibits lymphocyte proliferation and functions, including antibody formation, cellular adhesion, and migration.

Disposition and Pharmacokinetics. MMF undergoes rapid and complete metabolism to MPA after oral or intravenous administration. MPA, in turn, is metabolized to the inactive phenolic glucuronide MPAG. The parent drug is cleared from the blood within a few minutes. The $t_{1/2}$ of MPA is ~16 hours. Negligible (<1%) amounts of MPA are excreted in the urine. Most (87%) is excreted in the urine as MPAG. Plasma concentrations of MPA and MPAG are increased in patients with renal insufficiency. In early renal transplant patients (<40 days after transplant), plasma concentrations of MPA after a single dose of MMF are about half of those found in healthy volunteers or stable renal transplant patients.

Therapeutic Uses. MMF is indicated for prophylaxis of transplant rejection, and it typically is used in combination with glucocorticoids and a calcineurin inhibitor but not with azathioprine. Combined treatment with sirolimus is possible, although potential drug interactions necessitate careful monitoring of drug levels.

For renal transplants, 1 g is administered orally or intravenously (over 2 hours) twice daily (2 g/day). A higher dose, 1.5 g twice daily (3 g/day), may be recommended for African-American renal transplant patients and all liver and cardiac transplant patients. MMF is increasingly used off label in systemic lupus.

Toxicity. The principal toxicities of MMF are gastrointestinal and hematologic. These include leukopenia, pure red cell aplasia, diarrhea, and vomiting. There also is an increased incidence of some infections, especially sepsis associated with cytomegalovirus; progressive multifocal leukoencephalopathy also has been reported in conjunction with the administration of MMF. Tacrolimus in combination with MMF

has been associated with activation of polyoma viruses such as BK virus, which can cause interstitial nephritis difficult to distinguish from acute rejection (Hirsch et al., 2002). Excessive immunosuppression is suspected to be responsible for this adverse effect, not necessarily this widely used drug combination. The use of mycophenolate in pregnancy is associated with congenital anomalies and increased risk of pregnancy loss. Women of childbearing potential taking mycophenolate must use effective contraception.

Drug Interactions. Potential drug interactions between MMF and several other drugs commonly used by transplant patients have been studied. There appear to be no untoward effects produced by combination therapy with cyclosporine, trimethoprim-sulfamethoxazole, or oral contraceptives. Unlike cyclosporine, tacrolimus delays elimination of MMF by impairing the conversion of MPA to MPAG. This may enhance GI toxicity. Co-administration with antacids containing aluminum or magnesium hydroxide leads to decreased absorption of MMF; thus, these drugs should not be administered simultaneously. MMF should not be administered with cholestyramine or other drugs that affect enterohepatic circulation. Such agents decrease plasma MPA concentrations, probably by binding free MPA in the intestines. Acyclovir and ganciclovir may compete with MPAG for tubular secretion, possibly resulting in increased concentrations of both MPAG and the antiviral agents in the blood, an effect that may be compounded in patients with renal insufficiency.

A delayed-release tablet form of MPA (MYFORTIC) also is available. It does not release MPA under acidic conditions (pH <5) such as in the stomach but is highly soluble in neutral pH present in the intestine. The enteric coating results in a delay in the time to reach maximum MPA concentrations and may improve GI tolerability, although data are sparse and not convincing (Darji et al., 2008).

Other Anti-Proliferative and Cytotoxic Agents. Many of the cytotoxic and antimetabolic agents used in cancer chemotherapy (Chapter 61) are immunosuppressive due to their action on lymphocytes and other cells of the immune system. Other cytotoxic drugs that have been used off label as immunosuppressive agents include methotrexate, cyclophosphamide, thalidomide (THALOMID), and chlorambucil (LEUKERAN). Methotrexate is used for treatment of graft-versus-host disease, rheumatoid arthritis, psoriasis, and some cancers. Cyclophosphamide and chlorambucil are used in leukemia and lymphomas and a variety of other malignancies. Cyclophosphamide also is FDA approved for childhood nephrotic syndrome and is used widely for treatment of severe systemic lupus erythematosus and other vasculitides such as Wegener's granulomatosis. Leflunomide (ARAVA, others) is a pyrimidine-synthesis inhibitor indicated for the treatment of adults with rheumatoid arthritis (Prakash and Jarvis, 1999). This drug has found increasing empirical use in

the treatment of polyomavirus nephropathy seen in immunosuppressed renal transplant recipients. There are no controlled studies showing efficacy compared with control patients treated with only withdrawal or reduction of immunosuppression alone in BK virus nephropathy. The drug inhibits dihydroorotate dehydrogenase in the *de novo* pathway of pyrimidine synthesis. It is hepatotoxic and can cause fetal injury when administered to pregnant women.

Fingolimod (FTY720). This is the first agent in a new class of small molecules, sphingosine-1-phosphate receptor (S1P-R) agonists (Figure 35–1). This S1P receptor prodrug reduces recirculation of lymphocytes from the lymphatic system to the blood and peripheral tissues, including inflammatory lesions and organ grafts.

Therapeutic Uses. The drug has not been as effective as standard regimens in phase III trials, and further drug development has been limited (Vincenti and Kirk, 2008).

Mechanism of Action. Unlike other immunosuppressive agents, FTY720 acts via “lymphocyte homing.” It specifically and reversibly sequesters host lymphocytes into the lymph nodes and Peyer’s patches and thus away from the circulation. This protects the graft from T cell–mediated attack. Although FTY720 sequesters lymphocytes, it does not impair either T- or B-cell functions. FTY720 is phosphorylated by sphingosine kinase-2, and the FTY720-phosphate product is a potent agonist of S1P receptors. Altered lymphocyte traffic induced by FTY720 clearly results from its effect on S1P receptors.

Toxicity. Lymphopenia, the most common side effect of FTY720, is predicted from its pharmacological effect and is fully reversible upon drug discontinuation. Of greater concern is the negative chronotropic effect of FTY720 on the heart, which has been observed with the first dose in up to 30% of patients. In most patients, the heart rate returns to baseline within 48 hours, with the remainder returning to baseline thereafter.

Biological Immunosuppression Antibodies and Fusion Receptor Protein

Both polyclonal and monoclonal antibodies against lymphocyte cell-surface antigens are widely used for prevention and treatment of organ transplant rejection. Polyclonal antisera are generated by repeated injections of human thymocytes (ATG) or lymphocytes (antilymphocyte globulin, ALG) into animals such as horses, rabbits, sheep, or goats and then purifying the serum immunoglobulin fraction. Although highly effective immunosuppressive agents, these preparations vary in efficacy and toxicity from batch to batch. The advent of hybridoma technology to produce monoclonal antibodies was a major advance in immunology (Kohler and Milstein, 1975). It now is possible to make essentially unlimited amounts of a single antibody of a defined specificity (Figure 35–3). These monoclonal reagents

Figure 35–3. Generation of monoclonal antibodies. Mice are immunized with the selected antigen, and spleen or lymph node is harvested and B cells separated. These B cells are fused to a suitable B-cell myeloma that has been selected for its inability to grow in medium supplemented with hypoxanthine, aminopterin, and thymidine (HAT). Only myelomas that fuse with B cells can survive in HAT-supplemented medium. The hybridomas expand in culture. Those of interest based on a specific screening technique are then selected and cloned by limiting dilution. Monoclonal antibodies can be used directly as supernatants or ascites fluid experimentally but are purified for clinical use. HPRT, hypoxanthine–guanine phosphoribosyl transferase. (Reproduced with permission from Krensky A.M. and Clayberger C. Transplantation immunobiology. In: *Pediatric Nephrology*, 5th ed. (Avner E.D., Harmon W.E., Niauder P., eds) Lippincott Williams & Wilkins, Philadelphia, 2004. (<http://lww.com>).

have overcome the problems of variability in efficacy and toxicity seen with the polyclonal products, but they are more limited in their target specificity.

The first-generation murine monoclonal antibodies have been replaced by newer humanized or fully human monoclonal antibodies that lack antigenicity, have a prolonged $t_{1/2}$, and can be mutagenized to alter their affinity to Fc receptors. Another class of biological agents being developed for both auto-immunity and transplantation are fusion receptor proteins. These agents usually consist of the ligand-binding domains of receptors bound to the Fc region of an immunoglobulin (usually IgG₁) to provide a longer $t_{1/2}$. Examples of such agents include abatacept (CTLA4-Ig) and belatacept (a second-generation CTLA4-Ig), discussed later in “Co-stimulatory Blockade.” Thus, polyclonal and monoclonal antibodies as well as fusion receptor proteins have a place in immunosuppressive therapy.

Antithymocyte Globulin

ATG is a purified gamma globulin from the serum of rabbits immunized with human thymocytes (Regan et al., 1999). It is provided as a sterile, freeze-dried product for intravenous administration after reconstitution with sterile water.

Mechanism of Action. ATG contains cytotoxic antibodies that bind to CD2, CD3, CD4, CD8, CD11a, CD18, CD25, CD44, CD45, and HLA class I and II molecules on the surface of human T lymphocytes (Bourdage and Hamlin, 1995). The antibodies deplete circulating lymphocytes by direct cytotoxicity (both complement and cell mediated) and block lymphocyte function by binding to cell surface molecules involved in the regulation of cell function.

Therapeutic Uses. ATG is used for induction immunosuppression, although the only approved indication is in the treatment of acute renal transplant rejection in combination with other immunosuppressive agents (Mariat et al., 1998). Antilymphocyte-depleting agents (THYMOGLOBULIN, ATGAM, and OKT3) have been neither rigorously tested in clinical trials nor registered for use as induction immunosuppression. However, a meta-analysis (Szczecz et al., 1997) showed that antilymphocyte induction improves graft survival. A course of antithymocyte-globulin treatment often is given to renal transplant patients with delayed graft function to avoid early treatment with the nephrotoxic calcineurin inhibitors and thereby aid in recovery from ischemic reperfusion injury. The recommended dose for acute rejection of renal grafts is 1.5 mg/kg/day (over 4-6 hours) for 7-14 days. Mean T-cell counts fall by day 2 of therapy. ATG also is used for acute rejection of other types of organ transplants and for prophylaxis of rejection (Wall, 1999).

Toxicity. Polyclonal antibodies are xenogeneic proteins that can elicit major side effects, including fever and chills with the potential for hypotension. Premedication with corticosteroids, acetaminophen, and/or an antihistamine and administration of the antiserum by slow infusion (over 4-6 hours) into a large-diameter vessel minimize such reactions. Serum sickness and glomerulonephritis can occur; anaphylaxis is a rare event. Hematologic complications include leukopenia and thrombocytopenia. As with other immunosuppressive agents, there is an increased risk of infection and malignancy, especially when multiple immunosuppressive agents are combined. No drug interactions have been described; anti-ATG antibodies develop, although they do not limit repeated use.

Monoclonal Antibodies

Anti-CD3 Monoclonal Antibodies. Antibodies directed at the ϵ chain of CD3, a trimeric molecule adjacent to the T-cell receptor on the surface of human T lymphocytes, have been used with considerable efficacy since the early 1980s in human transplantation. The original mouse IgG_{2a} antihuman CD3 monoclonal antibody, muromonab-CD3 (OKT3, ORTHOCLONE OKT3), still is used to reverse glucocorticoid-resistant rejection episodes (Cosimi et al., 1981).

Mechanism of Action. Muromonab-CD3 binds to the ϵ chain of CD3, a monomorphic component of the T-cell receptor complex involved in antigen recognition, cell signaling, and proliferation. Antibody treatment induces rapid internalization of the T-cell receptor, thereby preventing subsequent antigen recognition. Administration of the antibody is followed rapidly by depletion and extravasation of a majority of T cells from the bloodstream and peripheral lymphoid organs such as lymph nodes and spleen. This absence of detectable T cells from the usual lymphoid regions is secondary both to complement activation-induced cell death and to margination of T cells onto vascular endothelial walls and redistribution of T cells to non-lymphoid organs such as the lungs. Muromonab-CD3 also reduces function of the remaining T cells, as defined by lack of IL-2 production and great reduction in the production of multiple cytokines, perhaps with the exception of IL-4 and IL-10.

Therapeutic Uses. Muromonab-CD3 is indicated for treatment of acute organ transplant rejection (Ortho Multicenter Transplant Study Group, 1985).

Muromonab-CD3 is provided as a sterile solution containing 5 mg per ampule. The recommended dose is 5 mg/day (in adults; less for children) in a single intravenous bolus (<1 minute) for 10-14 days. Antibody levels increase over the first 3 days and then plateau. Circulating T cells disappear from the blood within minutes of administration and return within ~1 week after termination of therapy. Repeated use of muromonab-CD3 results in the immunization of the patient against the mouse determinants of the antibody, which can neutralize and prevent its immunosuppressive efficacy. Thus, repeated treatment with the muromonab-CD3 or other mouse monoclonal antibodies generally is contraindicated. The use of muromonab-CD3 for induction and rejection therapy has diminished substantially in the past 5 years because of its toxicity and the availability of ATG.

Toxicity. The major side effect of anti-CD3 therapy is the “cytokine release syndrome” (Ortho Multicenter Transplant Study Group, 1985). The syndrome typically begins 30 minutes after infusion of the antibody (but can occur later) and may persist for hours. Antibody binding to the T-cell receptor complex combined with Fc receptor-mediated cross-linking is the basis for the initial activating properties of this agent. The syndrome is associated with and attributed to increased serum levels of cytokines (including tumor necrosis factor- α [TNF- α], IL-2, IL-6, and interferon- γ [IFN- γ]), which are released by activated T cells and/or monocytes. In several studies, the production of TNF- α has been shown to be the major cause of the toxicity (Herbelin et al., 1995). The symptoms usually are worst with the first dose; frequency and severity decrease with subsequent doses. Common clinical manifestations include high fever, chills/rigor, headache, tremor, nausea, vomiting, diarrhea, abdominal pain, malaise, myalgias, arthralgias, and generalized weakness. Less common complaints include skin reactions and cardiorespiratory and central nervous system (CNS) disorders, including aseptic meningitis. Potentially fatal pulmonary edema, acute respiratory distress syndrome, cardiovascular collapse, cardiac arrest, and arrhythmias have been described.

Administration of glucocorticoids before the injection of muromonab-CD3 prevents the release of cytokines, reduces first-dose reactions considerably, and now is a standard procedure. Volume status of patients also must be monitored carefully before therapy; steroids and other premedications should be given, and a fully competent resuscitation facility must be immediately available for patients receiving their first several doses of this therapy.

Other toxicities associated with anti-CD3 therapy include anaphylaxis and the usual infections and neoplasms associated with immunosuppressive therapy. “Rebound” rejection has been observed when muromonab-CD3 treatment is stopped. Anti-CD3 therapies may be limited by anti-idiotypic or antimurine antibodies in the recipient.

Currently, muromomab-CD3 rarely is used in transplantation. It has been replaced by ATG and alemtuzumab.

New-Generation Anti-CD3 Antibodies. Recently, genetically altered anti-CD3 monoclonal antibodies have been developed that are “humanized” to minimize the occurrence of anti-antibody responses and mutated to prevent binding to Fc receptors (Friend et al., 1999). The rationale for developing this new generation of anti-CD3 monoclonal antibodies is that they could induce selective immunomodulation in the absence of toxicity associated with conventional anti-CD3 monoclonal antibody therapy. In initial clinical trials, a humanized anti-CD3 monoclonal antibody that does not bind to Fc receptors reversed acute renal allograft rejection without causing the first-dose cytokine-release syndrome. Clinical efficacy of these agents in auto-immune diseases is being evaluated (Herold et al., 2002).

It is not clear whether any of the new generation of anti-CD3s will be developed for use in transplantation.

Anti-IL-2 Receptor (Anti-CD25) Antibodies. Daclizumab (ZENAPAX), a humanized murine complementarity-

determining region (CDR)/human IgG₁ chimeric monoclonal antibody, and basiliximab (SIMULECT), a murine-human chimeric monoclonal antibody, have been produced by recombinant DNA technology (Wiseman and Faulds, 1999). The composite daclizumab antibody consists of human (90%) constant domains of IgG₁ and variable framework regions of the Eu myeloma antibody and murine (10%) CDR of the anti-Tac antibody.

Mechanism of Action. Daclizumab has a somewhat lower affinity but a longer $t_{1/2}$ (20 days) than basiliximab. The exact mechanism of action of the anti-CD25 mAbs is not completely understood but likely results from the binding of the anti-CD25 mAbs to the IL-2 receptor on the surface of activated, but not resting, T cells (Vincenti et al., 1998; Amlot et al., 1995).

Significant depletion of T cells does not appear to play a major role in the mechanism of action of these mAbs. However, other mechanisms of action may mediate the effect of these antibodies. In a study of daclizumab-treated patients, there was a moderate decrease in circulating lymphocytes staining with 7G7, a fluorescein-conjugated antibody that binds a different α -chain epitope than that recognized and bound by daclizumab (Vincenti et al., 1998). Similar results were obtained in studies with basiliximab (Amlot et al., 1995). These findings indicate that therapy with the anti IL-2R mAbs results in a relative decrease of the expression of the α chain, either from depletion of coated lymphocytes or modulation of the α chain secondary to decreased expression or increased shedding. There also is recent evidence that the β chain may be downregulated by the anti-CD25 antibody. Recent evidence suggests that T-regulatory cells are transiently depleted during anti-CD25 therapy (Bluestone et al., 2008).

Therapeutic Uses. Anti-IL-2-receptor monoclonal antibodies are used for prophylaxis of acute organ rejection in adult patients. There are two anti-IL-2R preparations for use in clinical transplantation: daclizumab and basiliximab (Vincenti et al., 1998).

In phase III trials, daclizumab was administered in five doses (1 mg/kg given intravenously over 15 minutes in 50-100 mL of normal saline) starting immediately preoperatively, and subsequently at biweekly intervals. The $t_{1/2}$ of daclizumab was 20 days, resulting in saturation of the IL-2R α on circulating lymphocytes for up to 120 days after transplantation. In these trials, daclizumab was used with maintenance immunosuppressive regimens (cyclosporine, azathioprine, and steroids; cyclosporine and steroids). Subsequently, daclizumab was successfully used with a maintenance triple-therapy regimen—either with cyclosporine or tacrolimus, steroids, and MMF substituting for azathioprine (Pescovitz et al., 2003). In phase III trials, basiliximab was administered in a fixed dose of 20 mg preoperatively and on days 0 and 4 after transplantation (Kahan et al., 1999). This regimen of basiliximab resulted in a concentration of ≥ 0.2 $\mu\text{g/mL}$, sufficient to saturate IL-2R on circulating lymphocytes for 25-35 days after transplantation.

The $t_{1/2}$ of basiliximab was 7 days. In the phase III trials, basiliximab was used with a maintenance regimen consisting of

cyclosporine and prednisone. In one randomized trial, basiliximab was found to be safe and effective when used in a maintenance regimen consisting of cyclosporine, MMF, and prednisone (Lawen et al., 2000).

There presently is no marker or test to monitor the effectiveness of anti-IL-2R therapy. Saturation of an α chain on circulating lymphocytes during anti-IL-2R mAb therapy does not predict rejection. The duration of IL-2R blockade by basiliximab was similar in patients with or without acute rejection episodes (34 ± 14 days versus 37 ± 14 days, mean \pm SD) (Kovarik et al., 1999). In another daclizumab trial, patients with acute rejection were found to have circulating and intragraft lymphocytes with saturated IL-2R (Vincenti et al., 2001). A possible explanation is that those patients who reject despite anti-IL-2R blockade do so through a mechanism that bypasses the IL-2 pathway due to cytokine-cytokine receptor redundancy (i.e., IL-7, IL-15).

Toxicity. No cytokine-release syndrome has been observed with these antibodies, but anaphylactic reactions can occur. Although lymphoproliferative disorders and opportunistic infections may occur, as with the depleting antilymphocyte agents, the incidence ascribed to anti-CD25 treatment appears remarkably low. No significant drug interactions with anti-IL-2-receptor antibodies have been described (Hong and Kahan, 1999).

Alemtuzumab. Alemtuzumab (CAMPATH) is a humanized mAb that has been approved for use in chronic lymphocytic leukemia. The antibody targets CD52, a glycoprotein expressed on lymphocytes, monocytes, macrophages, and natural killer cells; thus, the drug causes extensive lympholysis by inducing apoptosis of targeted cells. It has achieved some use in renal transplantation because it produces prolonged T- and B-cell depletion and allows drug minimization. Large controlled studies of efficacy or safety are not available. Although short-term results are promising, further clinical experience is needed before alemtuzumab is accepted into the clinical armamentarium for transplantation.

Anti-TNF Reagents. TNF has been implicated in the pathogenesis of several immune-mediated intestinal, skin, and joint diseases. For example, patients with rheumatoid arthritis have elevated levels of TNF- α in their joints, while patients with Crohn's disease have elevated levels of TNF- α in their stools. As a result, a number of anti-TNF agents have been developed for the treatment of these disorders.

Infliximab (REMICADE) is a chimeric anti-TNF- α monoclonal antibody containing a human constant region and a murine variable region. It binds with high affinity to TNF- α and prevents the cytokine from binding to its receptors.

In one trial, infliximab plus methotrexate improved the signs and symptoms of rheumatoid arthritis more than methotrexate alone.

Patients with active Crohn's disease who had not responded to other immunosuppressive therapies also improved when treated with infliximab, including those with Crohn's-related fistulae. Infliximab is approved in the U.S. for treating the symptoms of rheumatoid arthritis and is typically used in combination with methotrexate in patients who do not respond to methotrexate alone. Infliximab also is approved for treatment of symptoms of moderate to severe Crohn's disease in patients who have failed to respond to conventional therapy and in treatment to reduce the number of draining fistulae in Crohn's disease patients (Chapter 47). Other FDA-approved indications include ankylosing spondylitis, plaque psoriasis, psoriatic arthritis, and ulcerative colitis. About one of six patients receiving infliximab experiences an infusion reaction characterized by fever, urticaria, hypotension, and dyspnea within 1-2 hours after antibody administration. The development of antinuclear antibodies, and rarely a lupus-like syndrome, has been reported after treatment with infliximab.

Although not a monoclonal antibody, etanercept (ENBREL) is mechanistically related to infliximab because it also targets TNF- α . Etanercept contains the ligand-binding portion of a human TNF- α receptor fused to the Fc portion of human IgG₁, and binds to TNF- α and prevents it from interacting with its receptors. It is approved in the U.S. for treatment of the symptoms of rheumatoid arthritis in patients who have not responded to other treatments, as well as for treatment of ankylosing spondylitis, plaque psoriasis, polyarticular juvenile idiopathic arthritis, and psoriatic arthritis. Etanercept can be used in combination with methotrexate in patients who have not responded adequately to methotrexate alone. Injection-site reactions (i.e., erythema, itching, pain, or swelling) have occurred in more than one-third of etanercept-treated patients.

Adalimumab (HUMIRA) is another anti-TNF product for intravenous use. This recombinant human IgG₁ monoclonal antibody was created by phage display technology and is approved for use in rheumatoid arthritis, ankylosing spondylitis, Crohn's disease, juvenile idiopathic arthritis, plaque psoriasis, and psoriatic arthritis.

Toxicity. All anti-TNF agents (i.e., infliximab, etanercept, adalimumab) increase the risk for serious infections, lymphomas, and other malignancies. For example, fatal hepatosplenic T-cell lymphomas have been reported in adolescent and young adult patients with Crohn's disease treated with infliximab in conjunction with azathioprine or 6-mercaptopurine.

IL-1 Inhibition

Plasma IL-1 levels are increased in patients with active inflammation (Moltó and Olivé, 2009; see also Chapter 34). In addition to the naturally occurring IL-1 receptor antagonist (IL-1RA), several IL-1 receptor

antagonists are in development and a few have been approved for clinical use. Anakinra is an FDA-approved recombinant, non-glycosylated form of human IL-1RA for the management of joint disease in rheumatoid arthritis. It can be used alone or in combination with anti-TNF agents such as etanercept (ENBREL), infliximab (REMICADE), or adalimumab (HUMIRA). Canakinumab (ILARIS) is an IL-1 β monoclonal antibody approved by the FDA in June 2009 for Cryoprin-associated periodic syndromes (CAPS), a group of rare inherited inflammatory diseases associated with overproduction of IL-1 that includes Familial Cold Autoinflammatory and Muckle-Wells Syndromes (Lachmann et al., 2009). Canakinumab is also being evaluated for use in chronic obstructive pulmonary disease (Church et al., 2009). Rilonacept (IL-1 TRAP) is another IL-1 blocker (a fusion protein that binds IL-1) that is now being evaluated in a phase 3 study for gout (Terkeltaub et al., 2009). IL-1 is an inflammatory mediator of joint pain associated with elevated uric acid crystals.

Lymphocyte Function–Associated Antigen-1 (LFA-1) Inhibition

Efalizumab. (RAPTIVA) is a humanized IgG₁ mAb targeting the CD11a chain of lymphocyte function–associated antigen-1 (LFA-1). Efalizumab binds to LFA-1 and prevents the LFA-1–intercellular adhesion molecule (ICAM) interaction to block T-cell adhesion, trafficking, and activation.

Pretransplant therapy with anti-CD11a prolonged survival of murine skin and heart allografts and monkey heart allografts (Nakamura et al., 1996). A randomized, multicenter trial of a murine anti-ICAM-1 mAb (enlimomab) failed to reduce the rate of acute rejection or to improve delayed graft function of cadaveric renal transplants (Salmela et al., 1999). This may have been due to either the murine nature of the mAb or the redundancy of the ICAMs. Efalizumab also is approved for use in patients with psoriasis. In a phase I/II open-label, dose-ranging, multidose, multicenter trial, efalizumab (dose, 0.5 mg/kg or 2 mg/kg) was administered subcutaneously for 12 weeks after renal transplantation (Vincenti et al., 2001; Vincenti et al., 2007). Both doses of efalizumab decreased the incidence of acute rejection. Pharmacokinetic and pharmacodynamic studies showed that efalizumab produced saturation and 80% modulation of CD11a within 24 hours of therapy. In a subset of 10 patients who received the higher dose efalizumab (2 mg/kg) with full-dose cyclosporine, MMF, and steroids, three patients developed post-transplant lymphoproliferative diseases. Progressive multifocal leukoencephalopathy (PML) also has occurred during therapy with efalizumab. Although efalizumab appears to be an effective immunosuppressive agent, it may be best used in a lower dose and with an immunosuppressive regimen that spares calcineurin inhibitors. Several trials are being conducted with efalizumab in renal, liver, and islet cell transplantation.

Alefacept

(AMEVIVE) is a human LFA-3-IgG1 fusion protein. The LFA-3 portion of alefacept binds to CD2 on T lymphocytes, blocking the interaction between LFA-3 and CD2 and interfering with T-cell activation. Alefacept is FDA approved for use in psoriasis.

Treatment with alefacept has been shown to produce a dose-dependent reduction in T-effector memory cells (CD45, RO+) but not in naïve cells (CD45, RA+). This effect has been related to its efficacy in psoriatic disease and is of significant interest in transplantation because T-effector memory cells have been associated with co-stimulation blockade resistant and depletion induction-resistant rejection. Alefacept will delay rejection in non-human primate (NHP) cardiac transplantation and has recently been shown to have synergistic potential when used with co-stimulation blockade and/or sirolimus-based regimens in NHPs (Vincenti and Kirk, 2008). A phase II randomized, open-label, parallel-group, multicenter study to assess the safety and efficacy of maintenance therapy with alefacept in kidney transplant recipients currently is under way.

Targeting B Cells

Most of the advances in transplantation can be attributed to drugs designed to inhibit T-cell responses. As a result, T cell–mediated acute rejection has become much less of a problem, while B cell–mediated responses such as antibody-mediated rejection and other effects of donor-specific antibodies have become more evident. Thus, several agents, both biologicals and small molecules with B-cell specific effects now are being considered for development in transplantation, including humanized monoclonal antibodies to CD20 and inhibitors of the two B cell–activation factors BLYS and APRIL and their respective receptors.

TOLERANCE

Immunosuppression has concomitant risks of opportunistic infections and secondary tumors. Therefore, the ultimate goal of research on organ transplantation and auto-immune diseases is to induce and maintain immunological tolerance, the active state of antigen-specific nonresponsiveness (Krensky and Clayberger, 1994). Tolerance, if attainable, would represent a true cure for conditions discussed earlier in this section without the side effects of the various immunosuppressive therapies. The calcineurin inhibitors prevent tolerance induction in some, but not all, preclinical models (Van Parijs and Abbas, 1998). In these same model systems, sirolimus does not prevent tolerance and may even promote tolerance induction (Li et al., 1998). Several other promising approaches are being evaluated in clinical

trials. Because they remain experimental, they are discussed only briefly here.

Co-stimulatory Blockade. Induction of specific immune responses by T lymphocytes requires two signals: an antigen-specific signal via the T-cell receptor and a co-stimulatory signal provided by the interaction of molecules such as CD28 on the T lymphocyte and CD80 and CD86 on the antigen-presenting cell (Figure 35–4; Khoury et al., 1999).

In preclinical studies, inhibition of the co-stimulatory signal has been shown to induce tolerance (Weaver et al., 2008). Experimental approaches to inhibit co-stimulation include a

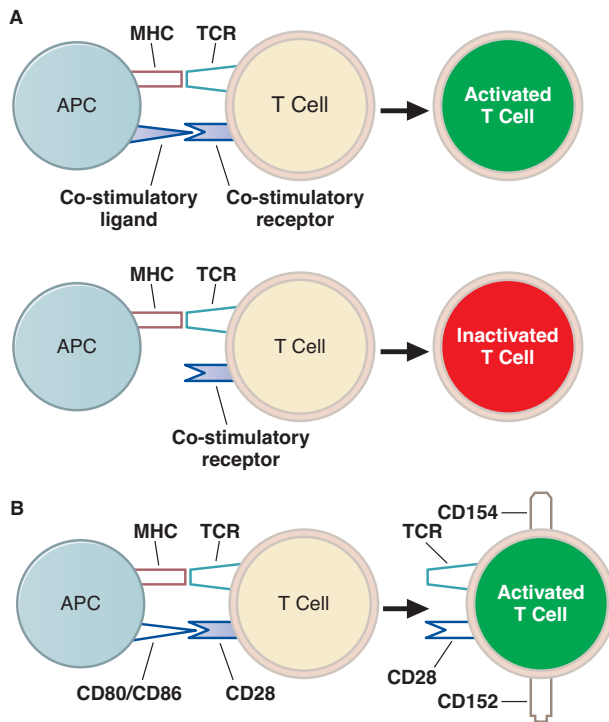

Figure 35–4. Co-stimulation. **A.** Two signals are required for T-cell activation. Signal 1 is via the T-cell receptor (TCR), and signal 2 is via a co-stimulatory receptor–ligand pair. Both signals are required for T-cell activation. Signal 1 in the absence of signal 2 results in an inactivated T cell. **B.** One important co-stimulatory pathway involves CD28 on the T cell and B7-1 (CD80) and B7-2 (CD86) on the antigen-presenting cell (APC). After a T cell is activated, it expresses additional co-stimulatory molecules. CD152 is CD40 ligand, which interacts with CD40 as a co-stimulatory pair. CD154 (CTLA4) interacts with CD80 and CD86 to dampen or downregulate an immune response. Antibodies against CD80, CD86, and CD152 are being evaluated as potential therapeutic agents. CTLA4-Ig, a chimeric protein consisting of part of an immunoglobulin molecule and part of CD154, also has been tested as a therapeutic agent. (Adapted with permission from Clayberger, C., and Krensky, A.M. Mechanisms of allograft rejection. In, *Immunologic Renal Diseases*. (Nielson, E.G., and Couser, W.G., eds) Lippincott-Raven, Philadelphia, 2001. (<http://lww.com>).)

recombinant fusion protein molecule, CTLA4-Ig, and anti-CD80 and/or anti-CD86 mAbs. The antibodies h1F1 and h3D1 are humanized anti-CD80 and anti-CD86 mAbs, respectively. *In vitro*, h1F1 and h3D1 block CD28-dependent T-cell proliferation and decrease mixed lymphocyte reactions. These mAbs must be used in tandem, because either CD80 or CD86 is sufficient to stimulate T cells via CD28. In nonhuman primates, anti-CD80 and anti-CD86 mAbs were proven effective in renal transplantation, either as monotherapy or in combination with steroids or cyclosporine (Weaver et al., 2008), but did not induce durable tolerance. A phase I study of h1F1 and h3D1 in renal transplant recipients was performed in patients receiving maintenance therapy consisting of cyclosporine, MMF, and steroids (Vincenti, 2002). Although the results of this study showed that h1F1 and h3D1 are relatively safe and possibly effective, clinical development was not further pursued.

CTLA4-Ig (abatacept) contains the binding region of CTLA4, which is a CD28 homolog, and the constant region of the human IgG₁. CTLA4-Ig competitively inhibits CD28. Numerous animal studies have confirmed the efficacy of CTLA4-Ig in inhibiting alloimmune responses, resulting in successful organ transplantation. More recently, CTLA4-Ig was shown to be effective in the treatment of rheumatoid arthritis. However, CTLA4-Ig was less effective when utilized in nonhuman primate models of renal transplantation. Belatacept (LEA29Y) (Figure 35–5) is a second-generation CTLA4-Ig with two amino acid substitutions. Belatacept has higher affinity for CD80 (2-fold) and CD86 (4-fold), yielding a 10-fold increase in potency *in vitro* as compared to CTLA4-Ig. Preclinical renal transplant studies in nonhuman primates showed that belatacept did not induce tolerance but did prolong graft survival.

Figure 35–5. Structure of belatacept, a CTLA4Ig congener. For details, see the text and Figure 35–4.

In a large phase II clinical trial, belatacept was administered intravenously initially every 2 weeks then every 4 or 8 weeks without calcineurin inhibitors and compared to a cyclosporine-based regimen (Vincenti et al., 2005). Belatacept showed comparable efficacy to cyclosporine but was associated with better renal function. Recent reports from phase III trials show similar results to phase II except that the more intense regimen was no more efficacious than the lower intensity regimen but was associated with more infections and post-transplant lymphoproliferative disease (PTLD) (Emamaullee et al., 2009). Because of the risk of PTLT, EBV negative patients should not be treated with belatacept. Belatacept may be approved for maintenance biologic therapy in renal transplantation soon.

A second co-stimulatory pathway involves the interaction of CD40 on activated T cells with CD40 ligand (CD154) on B cells, endothelium, and/or antigen-presenting cells (Figure 35–4). Among the purported activities of anti-CD154 antibody treatment is the blockade of B7 expression induced by immune activation. Two humanized anti-CD154 monoclonal antibodies have been used in clinical trials in renal transplantation and auto-immune diseases. The development of these antibodies, however, is on hold because of associated thromboembolic events. An alternative approach to block the CD154–CD40 pathway is to target CD40 with monoclonal antibodies. These antibodies are undergoing trials in non-Hodgkin's lymphoma but are also likely to be developed for auto-immunity and transplantation.

Donor Cell Chimerism

Another promising approach is induction of chimerism (co-existence of cells from two genetic lineages in a single individual) by any of a variety of protocols that first dampen or eliminate immune function in the recipient with ionizing radiation, drugs such as cyclophosphamide, and/or antibody treatment and then provide a new source of immune function by adoptive transfer (transfusion) of bone marrow or hematopoietic stem cells (Starzl et al., 1997). Upon reconstitution of immune function, the recipient no longer recognizes new antigens provided during a critical period as “nonself.” Such tolerance is long lived and is less likely to be complicated by the use of calcineurin inhibitors. Although the most promising approaches in this arena have been therapies that promote the development of mixed or macrochimerism, in which substantial numbers of donor cells are present in the circulation, some microchimerization approaches also have shown promise in the development of long-term unresponsiveness.

Soluble HLA

In the pre-cyclosporine era, blood transfusions were shown to be associated with improved outcomes in renal transplant patients (Opelz and Terasaki, 1978). These findings gave rise to donor-specific transfusion protocols that improved outcomes (Opelz et al., 1997). After the introduction of cyclosporine, however, these effects of blood transfusions disappeared, presumably due to the efficacy of this drug in blocking T-cell activation. Nevertheless, the existence of tolerance-promoting effects of transfusions is irrefutable. It is possible that this effect is due to HLA molecules on the surface of cells or in soluble forms. Recently, soluble HLA and peptides corresponding to linear sequences of HLA molecules have been shown to induce immunological tolerance in animal models via a variety of mechanisms (Murphy and Krensky, 1999).

Antigens

Specific antigens provided in a variety of forms (generally as peptides) induce immunological tolerance in preclinical models of diabetes mellitus, arthritis, and MS. Clinical trials of such approaches are under way. The past decade has witnessed a revolution in our understanding of the basis of immune tolerance. It is now well established that antigen/MHC complex binding to the T cell–receptor/CD3 complex coupled with soluble and membrane-bound co-stimulatory signals initiates a cascade of signaling events that lead to productive immunity. In addition, the immune response is regulated by a number of negative signaling events that control cell survival and expansion. *In vitro* and preclinical *in vivo* studies have demonstrated that one can selectively inhibit immune responses to specific antigens without the associated toxicity of established immunosuppressive therapies (Van Parijs and Abbas, 1998). With these insights comes the promise of specific immune therapies to treat the vast array of immune disorders from auto-immunity to transplant rejection. These new therapies will take advantage of a combination of drugs that target the primary T-cell receptor–mediated signal, either by blocking cell-surface receptor interactions or inhibiting early signal transduction events. The drugs will be combined with therapies that effectively block co-stimulation to prevent cell expansion and differentiation of those cells that have engaged antigen while maintaining a non-inflammatory milieu.

IMMUNOSTIMULATION

General Principles

In contrast to immunosuppressive agents that inhibit the immune response in transplant rejection and auto-immunity, a few immunostimulatory drugs have been developed with applicability to infection, immunodeficiency, and cancer. Problems with such drugs include systemic (generalized) effects at one extreme or limited efficacy at the other.

Immunostimulants

Levamisole. Levamisole (ERGAMISOL) was synthesized originally as an anthelmintic but appears to “restore” depressed immune function of B lymphocytes, T lymphocytes, monocytes, and macrophages. Its only clinical indication was as adjuvant therapy with 5-fluorouracil after surgical resection in patients with Dukes' stage C colon cancer (Moertel et al., 1990). Because of its risk for fatal agranulocytosis, levamisole was withdrawn from the U.S. market in 2005.

Thalidomide. Thalidomide (THALOMID) is best known for the severe, life-threatening birth defects it caused when administered to pregnant women. For this reason, it is available only under a restricted distribution program and can be prescribed only by specially registered physicians who understand the risk of teratogenicity if thalidomide is used during pregnancy. *Thalidomide should never be taken by women who are pregnant or who could become pregnant while taking the drug.* Nevertheless, it is indicated for the treatment of patients

with erythema nodosum leprosum (Chapter 56) and multiple myeloma. In addition, it has orphan drug status for mycobacterial infections, Crohn's disease, HIV-associated wasting, Kaposi sarcoma, lupus, myelofibrosis, brain malignancies, leprosy, graft-versus-host disease, and aphthous ulcers.

Its mechanism of action is unclear (see Figure 62–4). Reported immunological effects vary substantially under different conditions. For example, thalidomide has been reported to decrease circulating TNF- α in patients with erythema nodosum leprosum but to increase it in patients who are HIV seropositive. Alternatively, it has been suggested that the drug affects angiogenesis (Paravar and Lee, 2008). The anti-TNF- α effect has led to its evaluation as a treatment for severe, refractory rheumatoid arthritis.

Lenalidomide. Lenalidomide (REVLIMID), 3-(4-amino-1-oxo 1, 3-dihydro-2H-isindol-2-yl) piperidine-2,6-dione, is a thalidomide analog with immunomodulatory and anti-angiogenic properties. Lenalidomide is FDA approved for the treatment of patients with transfusion-dependent anemia due to low- or intermediate risk myelodysplastic syndromes associated with a deletion 5q cytogenetic abnormality with or without additional cytogenetic abnormalities.

The usual starting dose is 10 mg/day. Because lenalidomide causes significant neutropenia and thrombocytopenia in almost all patients, patients have to be closely monitored with weekly blood counts and lenalidomide dose adjusted according to the labeling information. Lenalidomide also is associated with a significant risk for deep vein thrombosis. Lenalidomide carries the same risk of teratogenicity as thalidomide, and pregnancy has to be avoided. Lenalidomide's availability is limited to a special distribution program administered by the manufacturer.

Bacillus Calmette-Guérin (BCG). Live BCG (TICE BCG, THERACYS) is an attenuated, live culture of the bacillus of Calmette and Guérin strain of *Mycobacterium bovis* that induces a granulomatous reaction at the site of administration. By unclear mechanisms, this preparation is active against tumors and is indicated for the treatment and prophylaxis of carcinoma *in situ* of the urinary bladder and for prophylaxis of primary and recurrent stage Ta and/or T1 papillary tumors after transurethral resection (Patard et al., 1998). Adverse effects include hypersensitivity, shock, chills, fever, malaise, and immune complex disease.

Recombinant Cytokines

Interferons. Although interferons (α , β , and γ) initially were identified by their antiviral activity, these agents also have important immunomodulatory activities (Ransohoff, 1998). The interferons bind to specific cell-surface receptors that initiate a series of intracellular events: induction of certain enzymes, inhibition of cell

proliferation, and enhancement of immune activities, including increased phagocytosis by macrophages and augmentation of specific cytotoxicity by T lymphocytes.

Recombinant IFN- α -2b (INTRON A) is obtained from *Escherichia coli* by recombinant expression. It is a member of a family of naturally occurring small proteins with molecular weights of 15,000–27,600 Da, produced and secreted by cells in response to viral infections and other inducers. IFN- α -2b is indicated in the treatment of a variety of tumors, including hairy cell leukemia, malignant melanoma, follicular lymphoma, and AIDS-related Kaposi sarcoma (Sinkovics and Horvath, 2000). It also is indicated for infectious diseases, chronic hepatitis B, and condylomata acuminata. In addition, it is supplied in combination with ribavirin (REBETRON) for treatment of chronic hepatitis C in patients with compensated liver function not treated previously with IFN- α -2b or who have relapsed after IFN- α -2b therapy (Lo Iacono et al., 2000).

Flu-like symptoms, including fever, chills, and headache, are the most common adverse effects after IFN- α -2b administration. Adverse experiences involving the cardiovascular system (e.g., hypotension, arrhythmias, and rarely cardiomyopathy and myocardial infarction) and CNS (e.g., depression, confusion) are less frequent side effects. All α interferons carry a boxed warning regarding development of pulmonary hypertension.

IFN- γ -1b (ACTIMMUNE) is a recombinant polypeptide that activates phagocytes and induces their generation of oxygen metabolites that are toxic to a number of microorganisms. It is indicated to reduce the frequency and severity of serious infections associated with chronic granulomatous disease and to delay the time to progression in severe malignant osteopetrosis. IFN- γ -1b is not effective and may increase mortality in patients with idiopathic pulmonary fibrosis. Adverse reactions include fever, headache, rash, fatigue, GI distress, anorexia, weight loss, myalgia, and depression.

IFN- β -1a (AVONEX, REBIF), a 166–amino acid recombinant glycoprotein, and IFN- β -1b (BETASERON), a 165–amino acid recombinant protein, have antiviral and immunomodulatory properties. They are FDA-approved for the treatment of relapsing MS to reduce the frequency of clinical exacerbations (see “Multiple Sclerosis”). The mechanism of their action in MS is unclear. Flu-like symptoms (e.g., fever, chills, myalgia) and injection-site reactions have been common adverse effects.

Further discussion of the use of these and other interferons in the treatment of viral diseases can be found in Chapter 58.

Interleukin-2. Human recombinant IL-2 (aldesleukin, PROLEUKIN; des-alanyl-1, serine-125 human IL-2) is produced by recombinant DNA technology in *E. coli* (Taniguchi and Minami, 1993). This recombinant form differs from native IL-2 in that it is not glycosylated, has no amino-terminal alanine, and has a serine substituted for the cysteine at amino acid 125 (Doyle et al., 1985). The potency of the preparation is represented in International Units in a lymphocyte proliferation assay such that 1.1 mg of recombinant IL-2 protein equals 18 million IU. Aldesleukin has the following *in vitro* biological activities of native IL-2: enhancement of lymphocyte proliferation and growth of IL-2-dependent cell lines, enhancement of lymphocyte-mediated cytotoxicity and killer cell activity, and induction of IFN- γ activity (Whittington and Faulds, 1993). *In vivo* administration of aldesleukin in animals produces multiple immunological effects in a dose-dependent manner. Cellular immunity is profoundly activated with lymphocytosis, eosinophilia, thrombocytopenia, and release of multiple cytokines (e.g., TNF, IL-1, IFN- γ). Aldesleukin is indicated for the treatment of adults with metastatic renal cell carcinoma and melanoma.

Administration of aldesleukin has been associated with serious cardiovascular toxicity resulting from capillary leak syndrome, which involves loss of vascular tone and leak of plasma proteins and fluid into the extravascular space. Hypotension, reduced organ perfusion, and death may occur. An increased risk of disseminated infection due to impaired neutrophil function also has been associated with aldesleukin treatment.

Immunization

Immunization may be active or passive. Active immunization involves stimulation with an antigen to develop immunological defenses against a future exposure. Passive immunization involves administration of preformed antibodies to an individual who is already exposed or is about to be exposed to an antigen.

Vaccines. Active immunization, vaccination, involves administration of an antigen as a whole, killed (inactivated) organism; attenuated (live) organism; or a specific protein or peptide constituent of an organism. Booster doses often are required, especially when killed organisms are used as the immunogen. In the U.S., vaccination has sharply curtailed or practically eliminated a variety of major infections, including diphtheria, measles, mumps, pertussis, rubella, tetanus, *Haemophilus influenzae* type b, and pneumococcus.

Although most vaccines have targeted infectious diseases, a new generation of vaccines may provide complete or limited protection

from specific cancers or auto-immune diseases. Because T cells optimally are activated by peptides and co-stimulatory ligands that are present on antigen-presenting cells (APCs), one approach for vaccination has consisted of immunizing patients with APCs expressing a tumor antigen. The first generation of anticancer vaccines used whole cancer cells or tumor-cell lysates as a source of antigen in combination with various adjuvants, relying on host APCs to process and present tumor-specific antigens (Sinkovics and Horvath, 2000). These anticancer vaccines resulted in occasional clinical responses and are being tested in prospective clinical trials. Second-generation anticancer vaccines utilized specific APCs incubated *ex vivo* with antigen or transduced to express antigen and subsequently reinfused into patients. In laboratory animals, immunization with dendritic cells previously pulsed with MHC class I-restricted peptides derived from tumor-specific antigens led to pronounced antitumor cytotoxic T-lymphocyte responses and protective tumor immunity (Tarte and Klein, 1999). Finally, multiple studies have demonstrated the efficacy of DNA vaccines in small- and large-animal models of infectious diseases and cancer (Lewis and Babiuk, 1999). The advantage of DNA vaccination over peptide immunization is that it permits generation of entire proteins, enabling determinant selection to occur in the host without having to restrict immunization to patients bearing specific HLA alleles. However, a safety concern about this technique is the potential for integration of the plasmid DNA into the host genome, possibly disrupting important genes and thereby leading to phenotypic mutations or carcinogenicity. A final approach to generate or enhance immune responses against specific antigens consists of infecting cells with recombinant viruses that encode the protein antigen of interest. Different types of viral vectors that can infect mammalian cells, such as vaccinia, avipox, lentivirus, adenovirus, or adenovirus-associated virus, have been used.

Immune Globulin. Passive immunization is indicated when an individual is deficient in antibodies because of a congenital or acquired immunodeficiency, when an individual with a high degree of risk is exposed to an agent and there is inadequate time for active immunization (e.g., measles, rabies, hepatitis B), or when a disease is already present but can be ameliorated by passive antibodies (e.g., botulism, diphtheria, tetanus). Passive immunization may be provided by several different products (Table 35–2). Nonspecific immunoglobulins or highly specific immunoglobulins may be provided based on the indication. The protection provided usually lasts 1-3 months. Immune globulin is derived from pooled plasma of adults by an alcohol-fractionation procedure. It contains largely IgG (95%) and is indicated for antibody-deficiency disorders, exposure to infections such as hepatitis A and measles, and specific immunological diseases such as immune thrombocytopenic purpura and Guillain-Barré syndrome. In contrast, specific immune globulins (“hyperimmune”) differ from other immune globulin preparations in that donors are selected for high titers of the desired antibodies.

Table 35–2

Selected Immune Globulin Preparations

GENERIC NAME	COMMON SYNONYMS	ORIGIN	BRAND NAME
Antithymocyte globulin	ATG	Rabbit	THYMOGLOBULIN
Botulism immune globulin intravenous	BIG-IV	Human	BABYBIG
Cytomegalovirus immune globulin intravenous	CMV-IGIV	Human	CYTOGAM
Hepatitis B immune globulin	HBIG	Human	HEPAGAM B, HYPERHEP B S/D, NABI-HB
Immune globulin intramuscular	Gamma globulin, IgG, IGIM	Human	GAMASTAN S/D
Immune globulin intravenous	IVIG	Human	CARIMUNE NF, FLEBOGAMMA 5%, GAMMAGARD LIQUID, GAMUNEX, IVEEGAM EN, OCTAGAM, PRIVIGEN
Immune globulin subcutaneous	IGSC	Human	VIVAGLOBIN
Lymphocyte immune globulin	ALG, antithymocyte globulin (equine), ATG (equine)	Equine	ATGAM
Rabies immune globulin	RIG	Human	HYPERRAB S/D, IMO GAM RABIES-HT
Rho(D) immune globulin intramuscular	Rho[D] IGIM	Human	HYPERRHO S/D, RHOGAM
Rho(D) immune globulin intravenous	Rho[D] IGIV	Human	RHOPHYLAC, WINRHO SDF
Rho(D) immune globulin microdose	Rho[D] IG microdose	Human	HYPERRHO S/D MICRODOSE, MICRHOGAM
Tetanus immune globulin	TIG	Human	BAYTET
Vaccinia immune globulin intravenous	VIGIV	Human	Generic

Specific immune globulin preparations are available for hepatitis B, rabies, tetanus, varicella-zoster, cytomegalovirus, botulism, and respiratory syncytial virus. Rho(D) immune globulin is a specific hyperimmune globulin for prophylaxis against hemolytic disease of the newborn due to Rh incompatibility between mother and fetus. All such plasma-derived products carry the theoretical risk of transmission of infectious disease.

Rho(D) Immune Globulin. The commercial forms of Rho(D) immune globulin (Table 35–2) consist of IgG containing a high titer of antibodies against the Rh(D) antigen on the surface of red blood cells. All donors are carefully screened to reduce the risk of transmitting infectious diseases. Fractionation of the plasma is performed by precipitation with cold alcohol followed by passage through a viral clearance system (Bowman, 1998).

Mechanism of Action. Rho(D) immune globulin binds Rho antigens, thereby preventing sensitization (Peterec, 1995). Rh-negative women may be sensitized to the “foreign” Rh antigen on red blood cells via the fetus at the time of birth, miscarriage, ectopic pregnancy, or any transplacental hemorrhage. If the women go on to have a primary immune response, they will make antibodies to Rh antigen that can cross the placenta and damage subsequent fetuses by lysing red blood cells. This syndrome, called hemolytic disease of the newborn, is life-threatening. The form due to Rh incompatibility is largely preventable by Rho(D) immune globulin.

Therapeutic Use. Rho(D) immune globulin is indicated whenever fetal red blood cells are known or suspected to have entered the circulation of an Rh-negative mother unless the fetus is known to also

be Rh negative. The drug is given intramuscularly. The $t_{1/2}$ of circulating immunoglobulin is ~21–29 days.

Toxicity. Injection-site discomfort and low-grade fever have been reported. Systemic reactions are extremely rare, but myalgia, lethargy, and anaphylactic shock have been reported. As with all plasma-derived products, there is a theoretical risk of transmission of infectious diseases.

Intravenous Immunoglobulin (IVIG). In recent years, indications for the use of IVIG have expanded beyond replacement therapy for agammaglobulinemia and other immunodeficiencies to include a variety of bacterial and viral infections, and an array of auto-immune and inflammatory diseases as diverse as thrombocytopenic purpura, Kawasaki disease, and auto-immune skin, neuromuscular, and neurological diseases.

Although the mechanism of action of IVIG in immune modulation remains largely unknown, proposed mechanisms include modulation of expression and function of Fc receptors on leukocytes and endothelial cells, interference with complement activation and cytokine production, provision of anti-idiotypic antibodies (Jerne’s network theory), and effects on the activation and effector function of T and B lymphocytes. Although IVIG is effective in many auto-immune diseases, its spectrum of efficacy and appropriate dosing (especially duration of therapy) are unknown. Additional controlled studies of IVIG are needed to identify proper dosing, cost-benefit, and quality-of-life parameters.

A CASE STUDY: IMMUNOTHERAPY FOR MULTIPLE SCLEROSIS

Clinical Features and Pathology. MS is a demyelinating inflammatory disease of the CNS white matter that displays a triad of pathogenic symptoms: mononuclear cell infiltration, demyelination, and scarring (gliosis). The peripheral nervous system is uninvolved. The disease, which may be episodic or progressive, occurs in early to middle adulthood with prevalence increasing from late adolescence to 35 years of age and then declining. MS is roughly 3-fold more common in females than in males and occurs mainly in higher latitudes of the temperate climates. Epidemiologic studies suggest a role for environmental factors in the pathogenesis of MS; despite many suggestions, associations with infectious agents have proven inconclusive, even though several viruses can cause similar demyelinating diseases in laboratory animals and humans. A stronger linkage is the genetic one: people of northern European ancestry have a higher susceptibility to MS, and studies in twins and siblings suggest a strong genetic component of susceptibility to MS.

Specifically, MS is a complex genetic disease in which multiple allelic variants lead to disease susceptibility. Although there is long-range linkage disequilibrium in the MHC region, HLA-DR2 clearly is associated with risk of developing MS ($p = 10^{-228}$), as is HLA-B*4402. Genome-wide association studies have identified predominantly immune-related variants associated with disease risk, including the IL-2RA chain ($p = 10^{-27}$), IL-7R chain ($p = 10^{-20}$), CLEC16A ($p = 10^{-15}$), CD58 (LFA-3, $p = 10^{-10}$), and CD226 ($p = 10^{-8}$) (IMSGC, 2007; IMSGC, 2008; Hafler, 2008). It is estimated that >200 common allelic variants will be uncovered as genome-wide association studies become properly powered. Interestingly, these variants are strikingly common among the different auto-immune diseases.

There also is substantial evidence of an auto-immune component to MS: in MS patients, there are activated T cells that are reactive to different myelin antigens, including myelin basic protein (MBP). In addition, there is evidence for the presence of auto-antibodies to myelin oligodendrocyte glycoprotein (MOG) and to MBP that can be eluted from the CNS plaque tissue, although it appears unlikely that high-affinity auto-antibodies are present in the circulation. These antibodies may act with pathogenic T cells to produce some of the cellular pathology of MS. The neurophysiological result is altered conduction (both positive and negative) in myelinated fibers within the CNS (cerebral white matter, brain stem, cerebellar tracts,

optic nerves, spinal cord); some alterations appear to result from exposure of voltage-dependent K^+ channels that normally are covered by myelin.

Attacks are classified by type and severity and likely correspond to specific degrees of CNS damage and pathological processes. Thus, physicians refer to relapsing-remitting MS (the form in 85% of younger patients), secondary progressive MS (progressive neurological deterioration following a long period of relapsing-remitting disease), and primary progressive MS (~15% of patients, wherein deterioration with relatively little inflammation is apparent at onset). De Jager and Hafler (2007) have reviewed current concepts of the etiology, natural history, and current therapy of MS.

Pharmacotherapy for MS. Specific therapies are aimed at resolving acute attacks, reducing recurrences and exacerbations, and slowing the progression of disability (Table 35–3). Nonspecific therapies focus on maintaining function and quality of life. For acute attacks, pulse glucocorticoids often are employed (typically, 1 g/day of methylprednisolone administered intravenously for 3–5 days). There is no evidence that tapered doses of oral prednisone are useful or even desirable.

For reducing the recurrence of relapsing-remitting attacks, immunomodulatory therapies are approved: β -1 interferons [IFN- β -1a, IFN- β -1b], and glatiramer acetate (GA; COPAXONE). The interferons suppress the proliferation of T lymphocytes, inhibit their movement into the CNS from the periphery, and shift the cytokine profile from pro- to anti-inflammatory types.

Random polymers that contain amino acids commonly used as MHC anchors and T cell-receptor contact residues have been proposed as possible “universal APLs (altered peptide ligands).” GA is a random-sequence polypeptide consisting of four amino acids [alanine (A), lysine (K), glutamate (E), and tyrosine (Y) at a molar ratio of A:K:E:Y of 4.5:3.6:1.5:1] with an average length of 40–100 amino acids. Directly labeled GA binds efficiently to different murine H2 I-A molecules, as well as to their human counterparts, the MHC class II DR molecules, but does not bind MHC class II DQ or MHC class I molecules *in vitro*. In phase III clinical trials, GA, administered subcutaneously to patients with relapsing-remitting MS, decreased the rate of exacerbations by ~30% (De Jager and Hafler, 2007). *In vivo* administration of GA induces highly cross-reactive CD4⁺ T cells that are immune deviated to secrete Th2 cytokines and prevents the appearance of new lesions detectable by magnetic resonance imaging. This represents one of the first successful uses of an

agent that ameliorates auto-immune disease by altering signals through the T cell–receptor complex.

For relapsing-remitting attacks and for secondary progressive MS, the alkylating agent cyclophosphamide (De Jager and Hafler, 2007) and the anthracenedione-derivative mitoxantrone (NOVANTRONE, others) currently are used in patients refractory to other immunomodulators. These agents, primarily used for cancer chemotherapy, have significant toxicities (see Chapter 61 for structures and pharmacology). Although cyclophosphamide in patients with MS may not be limited by an accumulated dose exposure, mitoxantrone generally can be tolerated only up to an accumulated dose of 100-140 mg/m² (Crossley, 1984). However,

because decreases in left-ventricular ejection fraction (LVEF) and frank congestive heart failure have occurred in patients who have received <100 mg/m², the FDA now recommends that LVEF be evaluated before initiating therapy, prior to each dose, and annually after patients have finished treatment to detect late-occurring cardiac toxicity. The utility of interferon therapy in patients with secondary progressive MS is unclear. In primary progressive MS, with no discrete attacks and less observed inflammation, suppression of inflammation seems to be less helpful. A minority of patients at this stage will respond to high doses of glucocorticoids. Table 35–3 summarizes current immunomodulatory therapies for MS.

Table 35–3

Pharmacotherapy of Multiple Sclerosis

THERAPEUTIC AGENT	BRAND NAME (DOSE, REGIMEN)	INDICATIONS	RESULTS	MECHANISM OF ACTION
IFN-β-1a	AVONEX (30 μg, IM, weekly) REBIFF (22 or 44 μg, SC, 3 times weekly)	Treatment of RRMS	Reduction of relapses by one-third Reduction of new MRI T2 lesions and the volume of enlarging T2 lesions Reduction in the number and volume of Gd-enhancing lesions Slowing of brain atrophy	Acts on blood-brain barrier by interfering with T-cell adhesion to the endothelium by binding VLA-4 on T cells or by inhibiting the T-cell expression of MMP Reduction in T cell activation by interfering with HLA class II and co-stimulatory molecules B7/CD28 and CD40:CD40L Immune deviation of Th2 over Th1 cytokine profile
IFN-β-1b	BETASERON (0.25 mg, SC, every other day after 6-week titration)	Treatment of RRMS	Same as IFN-β-1a, above	Same as IFN-β-1a, above
Glatiramer acetate	COPAXONE (20 mg, SC, daily)	Treatment of RRMS	Reduction of relapses by one-third Reduction in the number and volume of Gd-enhancing lesions	Induces T-helper type 2 cells that enter the CNS; mediates bystander suppression at sites of inflammation
Mitoxantrone	NOVANTRONE, generic (12 mg/m ² , as short [5–15 minute] IV infusion every 3 months)	Worsening forms of RRMS SPMS	Reduction in relapses by 67% Slowed progression on EDSS, ambulation index, and MRI disease activity	Intercalates DNA (see Chapter 61) Suppresses cellular and humoral immune response

EDSS, Expanded Disability Status Scale, a neurologic assessment scale for MS pathology. Gd, gadolinium, used in Gd-enhanced MRI to assess the number and size of inflammatory brain lesions; IFN, interferon; IM, intramuscularly; IV, intravenously; MMP, matrix metalloprotease; MS, multiple sclerosis; RRMS, relapsing-remitting MS; SC, subcutaneously; SPMS, secondary progressive MS; MRI, magnetic resonance imaging.

Each of the agents mentioned in this section has side effects and contraindications that may be limiting: infections (for glucocorticoids), hypersensitivity and pregnancy (for immunomodulators), and prior anthracycline/anthracenedione use, mediastinal irradiation, or cardiac disease (mitoxantrone). With all of these agents, it is clear that the earlier they are used, the more effective they are in preventing disease relapses. What is not clear is whether any of these agents will prevent or diminish the later onset of secondary progressive disease, which causes the more severe form of disability. Given the fluctuating nature of this disease, only long-term studies lasting decades will answer this question.

A number of other new immunomodulatory therapies have either recently been approved by the FDA or are completing phase III trials. The monoclonal antibody, natalizumab (TYSABRI), directed against the adhesion molecule α_4 integrin, antagonizes interactions with integrin heterodimers containing α_4 integrin, such as $\alpha_4\beta_1$ integrin that is expressed on the surface of activated lymphocytes and monocytes. Preclinical data suggest that an interaction of $\alpha_4\beta_1$ integrin with vascular-cellular adhesion molecule (VCAM)-1 is critical for T-cell trafficking from the periphery into the CNS (Steinman, 2004); thus, blocking this interaction would hypothetically inhibit disease exacerbations. Phase III clinical trials demonstrated a significant decrease in the number of new lesions as determined by magnetic resonance imaging and clinical attacks in MS patients receiving natalizumab (Polman et al., 2006). Postmarketing use of natalizumab has been associated with the development of progressive multifocal leukoencephalopathy, and availability has been limited to a special distribution program (TOUCH) administered by the manufacturer. Monoclonal antibodies directed against the IL-2 receptor and against CD52 (alemtuzumab; CAMPATH) are also in phase III clinical trials. The pharmacotherapy of MS has been reviewed by De Jager and Hafler (2007); the utility of immunotherapy for auto-immune diseases has been reviewed by Steinman (2004).

CLINICAL SUMMARY

Most transplant centers employ some combination of immunosuppressive drugs with antilymphocyte induction therapy with either a monoclonal or polyclonal antibody agent. Maintenance immunosuppression consists of a calcineurin inhibitor (cyclosporine or tacrolimus), glucocorticoids, and an antimetabolite (azathioprine or mycophenolate). Mycophenolate has largely replaced azathioprine as part of the standard immunosuppressive regimen after transplantation. At present, a number of centers are conducting trials with new drug combinations including either cyclosporine or tacrolimus in combination with glucocorticoids and mycophenolate, with or without antibody-induction therapy or fingolimod with cyclosporine. Sirolimus is being used to limit exposure to the nephrotoxic calcineurin inhibitors, while

steroid avoidance or minimization strategies are used increasingly. Newer immunosuppressive agents are providing more effective control of rejection and permitting transplantation to become an accepted procedure with a number of different organs, including kidney, liver, pancreas, and heart. The apparent effectiveness of new drug combinations has resulted in a resurgence of interest in reducing or avoiding glucocorticoids and calcineurin inhibitors.

Pulmonary Pharmacology

Peter J. Barnes

INTRODUCTION

Pulmonary pharmacology concerns understanding how drugs act on the lung and the pharmacological therapy of pulmonary diseases. Much of pulmonary pharmacology is concerned with the effects of drugs on the airways and the therapy of airway obstruction, particularly asthma and chronic obstructive pulmonary disease (COPD), which are among the most common chronic diseases in the world. Both asthma and COPD are characterized by chronic inflammation of the airways, although there are marked differences in inflammatory mechanisms and response to therapy between these diseases (Barnes, 2008b). After a brief introduction to asthma and COPD, this chapter discusses the pharmacotherapy of obstructive airways disease, particularly bronchodilators, which act mainly by reversing airway smooth muscle contraction, and anti-inflammatory drugs, which suppress the inflammatory response in the airways. This chapter focuses on the pulmonary pharmacology of β_2 agonists and corticosteroids; the basic pharmacology of these classes of agents is presented elsewhere (Chapters 12 and 42). In presenting the details of pharmacotherapy of asthma and COPD, the chapter also covers the physiology and molecular pathology surrounding these conditions, deriving knowledge of the diseases by assessing their responses to various classes of drugs.

This chapter also discusses other drugs used to treat obstructive airway diseases, such as mucolytics and respiratory stimulants, and covers the drug therapy of cough, the most common respiratory symptom, as well as drugs used to treat pulmonary hypertension. Drugs used in the treatment of lung infections, including tuberculosis (Chapter 56), are covered elsewhere.

MECHANISMS OF ASTHMA

Asthma is a chronic inflammatory disease of the airways that is characterized by activation of mast cells, infiltration of eosinophils, and T helper 2 (T_H2) lymphocytes (Figure 36–1) (Barnes, 2008b). Mast cell activation by allergens and physical stimuli releases bronchoconstrictor mediators, such as histamine, leukotriene D_4 , and prostaglandin D_2 , which cause bronchoconstriction, microvascular leakage, and plasma exudation (Chapters 32 and 33). Increased numbers of mast cells in airway smooth muscle are a characteristic of asthma. Many of the symptoms of asthma are due to airway smooth muscle contraction, and therefore bronchodilators are important as symptom relievers. Whether airway smooth muscle is intrinsically abnormal in asthma is not clear, but increased contractility of airway smooth muscle may contribute to airway hyperresponsiveness, the physiological hallmark of asthma. The mechanism of chronic inflammation in asthma is still not well understood. It may initially be driven by allergen exposure, but it appears to become autonomous so that asthma is essentially incurable. The inflammation may be orchestrated by dendritic cells that regulate T_H2 cells that drive eosinophilic inflammation and also IgE formation by B lymphocytes. Airway epithelium plays an important role through the release of multiple inflammatory mediators and through the release of growth factors in an attempt to repair the damage caused by inflammation. The inflammatory process in asthma is mediated through the release of >100 inflammatory mediators (Barnes et al., 1998a). Complex cytokine networks, including chemokines and growth factors, play important roles in orchestrating the inflammation process (Barnes, 2008a).

Figure 36–1. Cellular mechanisms of asthma. Myriad inflammatory cells are recruited and activated in the airways, where they release multiple inflammatory mediators, which can also arise from structural cells. These mediators lead to bronchoconstriction, plasma exudation and edema, vasodilation, mucus hypersecretion, and activation of sensory nerves. Chronic inflammation leads to structural changes, including subepithelial fibrosis (basement membrane thickening), airway smooth muscle hypertrophy and hyperplasia, angiogenesis, and hyperplasia of mucus-secreting cells.

Chronic inflammation may lead to structural changes in the airways, including an increase in the number and size of airway smooth muscle cells, blood vessels, and mucus-secreting cells. A characteristic histological feature of asthma is collagen deposition (fibrosis) below the basement membrane of the airway epithelium (Figure 36–1). This appears to be the result of eosinophilic inflammation and is found even at the onset of asthmatic symptoms. The complex inflammation of asthma is suppressed by corticosteroids in most patients, but even if asthma is well controlled, the inflammation and symptoms return if corticosteroids are discontinued. Asthma usually starts in early childhood, then may disappear during adolescence and reappear in adulthood. It is characterized by variable airflow obstruction and typically shows a good therapeutic response to bronchodilators and corticosteroids. Asthma severity usually does

not change, so that patients with mild asthma rarely progress to severe asthma and patients with severe asthma usually have this from the onset, although some patients, particularly with late-onset asthma, show a progressive loss of lung function like patients with COPD. Patients with severe asthma may have a pattern of inflammation more similar to COPD and are characterized by reduced responsiveness to corticosteroids (Wenzel and Busse, 2007).

MECHANISMS OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Chronic obstructive pulmonary disease involves inflammation of the respiratory tract with a pattern that differs from that of asthma. In COPD, there is a predominance of neutrophils, macrophages, and cytotoxic

Figure 36–2. Cellular mechanisms in chronic obstructive pulmonary disease. Cigarette smoke and other irritants activate epithelial cells and macrophages in the lung to release mediators that attract circulating inflammatory cells, including monocytes (which differentiate to macrophages within the lung), neutrophils, and T lymphocytes (T_H1 and T_C1 cells). Fibrogenic factors released from epithelial cells and macrophages lead to fibrosis of small airways. Release of proteases results in alveolar wall destruction (emphysema) and mucus hypersecretion (chronic bronchitis).

T-lymphocytes (T_C1 cells). The inflammation predominantly affects small airways, resulting in progressive small airway narrowing and fibrosis (chronic obstructive bronchiolitis) and destruction of the lung parenchyma with destruction of the alveolar walls (emphysema) (Figure 36–2) (Barnes, 2008b). These pathological changes result in airway closure on expiration, leading to air trapping and hyperinflation, particularly on exercise (dynamic hyperinflation). This accounts for shortness of breath on exertion and exercise limitation that are characteristic symptoms of COPD.

Bronchodilators reduce air trapping by dilating peripheral airways and are the mainstay of treatment in COPD. In contrast to asthma, the airflow obstruction of COPD tends to be progressive. The inflammation in the peripheral lung of COPD patients is mediated by

multiple inflammatory mediators and cytokines, although the pattern of mediators differs from that of asthma (Barnes, 2004; Barnes, 2008a). In marked contrast to asthma, the inflammation in COPD patients is largely corticosteroid resistant, and there are currently no effective anti-inflammatory treatments for this disease. In addition to pulmonary disease, many patients with COPD have systemic manifestations (skeletal muscle wasting, weight loss, depression, osteoporosis, anemia) and comorbid diseases (ischemic heart disease, hypertension, congestive heart failure, diabetes) (Barnes and Celli, 2009). Whether these are due to spillover of inflammatory mediators from the lung or due to common causal mechanisms (such as smoking) is not yet clear, but it may be important to treat the systemic components in the overall management of COPD.

TO THE LUNGS

Drugs may be delivered to the lungs by oral or parenteral routes and also by inhalation. The choice depends on the drug and on the respiratory disease.

Inhaled Route

Inhalation (Figure 36–3) is the preferred mode of delivery of many drugs with a direct effect on airways, particularly for asthma and COPD (Berger, 2009). It is the only way to deliver some drugs such as cromolyn sodium and anticholinergic drugs and is the preferred route of delivery for β_2 agonists and corticosteroids to reduce systemic side effects. Antibiotics may be delivered by inhalation in patients with chronic respiratory sepsis (e.g., in cystic fibrosis). Inhalation is also used to facilitate systemic drug delivery in other diseases (e.g., to avoid daily injections with insulin; see Chapter 43). The major advantage of inhalation is the delivery of drug to the airways in doses that are effective with a much lower risk of systemic side effects. This is particularly important with the use of inhaled corticosteroids (ICS), which largely avoids systemic side effects. In addition, drugs such as inhaled bronchodilators have a more rapid onset of action than when taken orally so that more rapid control of symptoms is possible.

Particle Size

The size of particles for inhalation is of critical importance in determining the site of deposition in the respiratory tract. The optimum size for particles to settle in the airways is 2–5 μm mass median aerodynamic diameter (MMAD). Larger particles settle out in the upper airways, whereas smaller particles remain suspended and are therefore exhaled. There is increasing interest in delivering drugs to small airways, particularly in COPD and severe asthma (Sturton et al., 2008). This involves delivering drug particles of $\sim 1 \mu\text{m}$ MMAD, which is now possible using drugs formulated in hydrofluoroalkane (HFA) propellant.

Pharmacokinetics

Of the total drug delivered, only 10–20% enters the lower airways with a conventional pressurized metered-dose inhaler (pMDI). The fate of the inhaled drug is poorly understood. Drugs are absorbed from the airway lumen and have direct effects on target cells of the airway. Drugs may also be absorbed into the bronchial circulation and then distributed to more peripheral airways. Whether drugs are metabolized in the airways is often uncertain, and there is little understanding of the factors that may influence local absorption and metabolism of inhaled drugs. Drugs with higher molecular weights tend to be retained to a greater extent in the airways. Nevertheless, several drugs have greater therapeutic efficacy when given by the inhaled route. The inhaled corticosteroid ciclesonide is a prodrug activated by esterases in the respiratory tract to the active principle des-ciclesonide. More extensive pulmonary distribution of a drug with a smaller MMAD increases alveolar deposition and thus is likely to increase absorption from the lungs into the general circulation resulting in more systemic side effects. Thus, although HFA pMDIs deliver more inhaled corticosteroid to smaller airways, there is also increased systemic absorption, so that the therapeutic ratio may not be changed.

Figure 36–3. Schematic representation of the deposition of inhaled drugs (e.g., corticosteroids, β_2 agonists). Inhalation therapy deposits drugs directly, but not exclusively, in the lungs. Distribution between lungs and oropharynx depends mostly on the particle size and the efficiency of the delivery method. Most material will be swallowed and absorbed, entering systemic circulation after undergoing the first-pass effect in the liver. Some drug will also be absorbed into the systemic circulation from the lungs. Use of a large-volume spacer will reduce the amount of drug deposited on oropharynx, thereby reducing amount swallowed and absorbed from GI tract, thus limiting systemic effects. MDI, metered-dose inhaler.

Delivery Devices

Several ways of delivering inhaled drugs are possible (Virchow et al., 2008).

Pressurized Metered-Dose Inhalers. Drugs are propelled from a canister with the aid of a propellant, previously with a chlorofluorocarbon (Freon) but now replaced by a hydrofluoroalkane (HFA) that is “ozone friendly.” These devices are convenient, portable, and typically deliver 100–400 doses of drug. It is necessary to coordinate inhalation with activation of the device, so it is important that patients are taught to use these devices correctly. Many patients find this difficult despite instruction.

Spacer Chambers. Large-volume spacer devices between the pMDI and the patient reduce the velocity of particles entering the upper airways and the size of the particles by allowing evaporation of liquid propellant. This reduces the amount of drug that impinges on the oropharynx and increases the proportion of drug inhaled into the lower airways. The need for careful coordination between activation and inhalation is also reduced because the pMDI can be activated into the chamber and the aerosol subsequently inhaled from the one-way valve. Perhaps the most useful application of spacer chambers is in the reduction of the oropharyngeal deposition of inhaled corticosteroids and the consequent reduction in the local side effects of these drugs. Large volume spacers also reduce the systemic side effects of drugs because less is deposited in the oropharynx, and therefore swallowed. It is the swallowed fraction of the drug absorbed from the GI tract that makes the greatest contribution to the systemic fraction. This is of particular importance in the use of certain inhaled steroids, such as beclomethasone dipropionate, which can be absorbed from the GI tract. Spacer devices are also useful in delivering inhaled drugs to small children who are not able to use a pMDI. Children as young as 3 years of age are able to use a spacer device fitted with a face mask.

Dry Powder Inhalers. Drugs may also be delivered as a dry powder using devices that scatter a fine powder dispersed by air turbulence on inhalation. These devices may be preferred by some patients (Chan, 2006) because careful coordination is not as necessary as with the pMDI, but some patients find that the dry powder is an irritant. Children <7 years of age find it difficult to use a dry powder inhaler (DPI) because they may not be able to generate sufficient inspiratory flow. DPIs have been developed to deliver peptides and proteins, such as insulin (e.g., EXUBERA, AFRESA), systemically.

Nebulizers. Two types of nebulizer are available. Jet nebulizers are driven by a stream of gas (air or oxygen), whereas ultrasonic nebulizers use a rapidly vibrating piezo-electric crystal and thus do not require a source of compressed gas. The nebulized drug may be inspired during tidal breathing, and it is possible to deliver much higher doses of drug compared with pMDI. Nebulizers are therefore useful in treating acute exacerbations of asthma and COPD, for delivering drugs when airway obstruction is extreme (e.g., in severe COPD), for delivering inhaled drugs to infants and small children who cannot use the other inhalation devices, and for giving drugs such as antibiotics when relatively high doses must be delivered. Small handheld nebulizers (soft mist inhalers) are now also available.

Oral Route

Drugs for treatment of pulmonary diseases may also be given orally. The oral dose is much higher than the inhaled dose required to achieve

the same effect (typically by a ratio of ~20:1), so that systemic side effects are more common. *When there is a choice of inhaled or oral route for a drug (e.g., β_2 agonist or corticosteroid), the inhaled route is always preferable, and the oral route should be reserved for the few patients unable to use inhalers (e.g., small children, patients with physical problems such as severe arthritis of the hands).* Theophylline is ineffective by the inhaled route and therefore must be given systemically. Corticosteroids may have to be given orally for parenchymal lung diseases (e.g., in interstitial lung diseases), although it may be possible in the future to deliver such drugs into alveoli using specially designed inhalation devices with a small particle size.

Parenteral Route

The intravenous route should be reserved for delivery of drugs in the severely ill patient who is unable to absorb drugs from the GI tract. Side effects are generally frequent due to the high plasma concentrations.

BRONCHODILATORS

Bronchodilator drugs relax constricted airway smooth muscle *in vitro* and cause immediate reversal of airway obstruction in asthma *in vivo*. They also prevent bronchoconstriction (and thereby provide bronchoprotection). Three main classes of bronchodilator are in current clinical use:

- β_2 Adrenergic agonists (sympathomimetics)
- Theophylline (a methylxanthine)
- Anticholinergic agents (muscarinic receptor antagonists)

Drugs such as cromolyn sodium, which prevent bronchoconstriction, have no direct bronchodilator action and are ineffective once bronchoconstriction has occurred. Anti-leukotrienes (leukotriene receptor antagonists and 5'-lipoxygenase inhibitors) have a small bronchodilator effect in some asthmatic patients and appear to prevent bronchoconstriction. Corticosteroids, although gradually improving airway obstruction, have no direct effect on contraction of airway smooth muscle and are not therefore considered to be bronchodilators.

β_2 ADRENERGIC AGONISTS

Inhaled β_2 agonists are the bronchodilator treatment of choice in asthma because they are the most effective bronchodilators and have minimal side effects when used correctly. Systemic, short-acting, and nonselective β agonists, such as isoproterenol (isoprenaline) or metaproterenol, should only be used as a last resort.

Chemistry. The development of β_2 agonists is based on substitutions in the catecholamine structure of norepinephrine and epinephrine (Chapter 12). The catechol ring consists of hydroxyl groups in the 3 and 4 positions of the benzene ring (Figure 36–4). Norepinephrine

Figure 36–4. Chemical structure of some adrenergic agonists showing development from catecholamines by substitutions on the catechol nucleus and side chain.

differs from epinephrine only in the terminal amine group; in general, further modification at this site confers β receptor selectivity. Further substitution of the terminal amine resulted in β_2 receptor selectivity, as in albuterol (salbutamol) and terbutaline. Exogenous catecholamines are rapidly metabolized by catechol-*O*-methyl transferase (COMT), which methylates in the 3-hydroxyl position, and accounts for the short duration of action of catecholamines. Modification of the catechol ring, as in albuterol and terbutaline, prevents this degradation and therefore prolongs the effect. Catecholamines are also broken down in sympathetic nerve terminals and in the GI tract by monoamine oxidase (MAO), which cleaves the side chain. Isoproterenol, which is a substrate for MAO, is metabolized in the gut, making absorption variable. Substitution in the amine group confers resistance to MAO and ensures reliable absorption. Many other β_2 -selective agonists have now been introduced and, although there may be differences in potency, there are no clinically significant differences in selectivity. Inhaled β_2 -selective drugs in current clinical use (apart from rimiterol [not available in the U.S.] that is broken down by COMT) have a similar duration of action (3–6 hours). The inhaled long-acting inhaled β_2 agonists salmeterol and formoterol have a much longer duration of effect, providing bronchodilation and bronchoprotection for >12 hours (Kips and Pauwels, 2001). Formoterol has a bulky substitution in the aliphatic chain and has a moderate lipophilicity, which appears to keep the drug in the membrane close to the receptor, so it behaves as a slow-release drug. Salmeterol has a long aliphatic chain, and its long duration may be due to binding within the receptor binding cleft (“exosite”) that anchors the drug in the binding cleft. Once-daily β_2 agonists, such as indacaterol, with a duration of action >24 hours, are now in development (Cazzola and Matera, 2008).

Mode of Action

Occupation of β_2 receptors by agonists results in the activation of the G_s -adenylyl cyclase-cAMP-PKA pathway, resulting in phosphorylation events leading to bronchial smooth muscle relaxation (Figure 36–5). β Agonists produce bronchodilation by directly stimulating β_2 receptors in airway smooth muscle, and *in vitro* relax human bronchi and lung strips (indicating an effect on peripheral airways). *In vivo* there is a rapid decrease in airway resistance. β_2 Receptors have been localized to airway smooth muscle of all airways by direct receptor binding techniques and autoradiographic mapping studies.

The molecular mechanisms by which β agonists induce relaxation of airway smooth muscle include:

- Lowering of $[Ca^{2+}]_i$ concentration by active removal of Ca^{2+} from the cytosol into intracellular stores and out of the cell
- Acute inhibition of the PLC-IP₃ pathway and its mobilization of cellular Ca^{2+} (prolonged use can upregulate expression of PLC β_1)
- Inhibition of myosin light chain kinase activation
- Activation of myosin light chain phosphatase
- Opening of a large conductance Ca^{2+} -activated K^+ channel (K_{Ca}), which repolarizes the smooth muscle cell and may stimulate the sequestration of Ca^{2+} into intracellular stores. β_2 Receptors may also couple to K_{Ca} via G_s so that relaxation of airway smooth muscle may occur independently of an increase in cAMP.

Several actions of β_2 agonists are mediated not by PKA but by other cAMP-regulated proteins, such as the exchange protein activated by cAMP (EPAC) (Holz et al., 2006). β_2 Agonists act as *functional antagonists* and reverse bronchoconstriction irrespective of

Figure 36–5. Molecular actions of β_2 agonists to induce relaxation of airway smooth muscle cells. Activation of β_2 receptors (β_2 AR) results in activation of adenylyl cyclase (AC) via a stimulatory G protein (G_s), leading to an increase in intracellular cyclic AMP and activation of PKA. PKA phosphorylates a variety of target substrates, resulting in opening of Ca^{2+} -activated K^+ channels (K_{Ca}), thereby facilitating hyperpolarization, decreased phosphoinositide (PI) hydrolysis, increased Na^+/Ca^{2+} exchange, increased Na^+, Ca^{2+} -ATPase activity, and decreased myosin light chain kinase (MLCK) activity. β_2 Receptors may also couple to K_{Ca} via G_s . PDE, cyclic nucleotide phosphodiesterase.

the contractile agent. This is an important property for the treatment of asthma because many bronchoconstrictor mechanisms (neurotransmitters and mediators) are likely to be contributory. In COPD the major mechanism of action is likely to be reduction of cholinergic neural bronchoconstriction.

β_2 Receptors are localized to several different airway cells, where they may have additional effects. Thus, β_2 agonists may cause bronchodilation *in vivo* not only via a direct action on airways smooth muscle, but also indirectly by inhibiting the release of bronchoconstrictor mediators from inflammatory cells and of bronchoconstrictor neurotransmitters from airway nerves. These mechanisms include:

- Prevention of mediator release from isolated human lung mast cells (via β_2 receptors).
- Prevention of microvascular leakage and thus the development of bronchial mucosal edema after exposure to mediators, such as histamine and leukotriene D_4 .
- Increase in *mucus secretion* from submucosal glands and *ion transport* across airway epithelium; these effects may enhance mucociliary clearance, and thereby reverse the defective clearance found in asthma.
- Reduction in *neurotransmission* in human airway cholinergic nerves by an action at presynaptic β_2 receptors to inhibit acetylcholine release. This may contribute to their bronchodilator effect by reducing reflex cholinergic bronchoconstriction.

Although these additional effects of β_2 agonists may be relevant to the prophylactic use of these drugs against various challenges, their rapid bronchodilator action is probably attributable to a direct effect on airway smooth muscle.

Anti-Inflammatory Effects

Whether β_2 agonists have anti-inflammatory effects in asthma is controversial. The inhibitory effects of β_2 agonists on mast cell mediator release and microvascular leakage are clearly anti-inflammatory, suggesting that β_2 agonists may modify *acute* inflammation. However, β_2 agonists do not appear to have a significant inhibitory effect on the *chronic* inflammation of asthmatic airways, which is suppressed by corticosteroids. This has now been confirmed by several biopsy and bronchoalveolar lavage studies in patients with asthma who are taking regular β_2 agonists (including long-acting inhaled β_2 agonists), that demonstrate no significant reduction in the number or activation in inflammatory cells in the airways, in contrast to resolution of the inflammation that occurs with ICS. This may be related to the fact that effects of β_2 agonists on macrophages, eosinophils, and lymphocytes are rapidly desensitized.

Clinical Use

Short-Acting β_2 Agonists. Inhaled short-acting β_2 agonists are the most widely used and effective bronchodilators in

the treatment of asthma due to their functional antagonism of bronchoconstriction. When inhaled from pMDI or DPI, they are convenient, easy to use, rapid in onset, and without significant systemic side effects. In addition to their acute bronchodilator effect, these agents are effective in protecting against various challenges, such as exercise, cold air, and allergens. Short-acting β_2 agonists are the bronchodilators of choice in treating acute severe asthma. The nebulized route of administration is easier and safer than intravenous administration and just as effective. Inhalation is preferable to the oral administration because systemic side effects are less, and inhalation may be more effective. Short-acting inhaled β_2 agonists, such as albuterol, should be used “as required” by symptoms and not on a regular basis in the treatment of mild asthma; increased use indicates the need for more anti-inflammatory therapy.

Oral β_2 agonists are occasionally indicated as an additional bronchodilator. Slow-release preparations (e.g., slow-release albuterol and bambuterol [a prodrug that slowly releases terbutaline but is not commercially available in the U.S.]) may be indicated in nocturnal asthma; however, these agents are less useful than inhaled β agonists because of an increased risk of side effects. Several short-acting β_2 agonists are available. With the exception of rimiterol (which retains the catechol ring structure and is therefore susceptible to rapid enzymatic degradation), they are resistant to uptake and enzymatic degradation by COMT and MAO. There is little to choose between the various short-acting β_2 agonists currently available; all are usable by inhalation and orally, have a similar duration of action (~3–4 hours; less in severe asthma), and similar side effects. Differences in β_2 selectivity have been claimed but are not clinically important. Drugs in clinical use include albuterol (salbutamol), lev-albuterol, metaproterenol, terbutaline, as well as several not available in the U.S., fenoterol, tulobuterol, rimiterol, and pirbuterol.

Long-Acting Inhaled β_2 Agonists. The long-acting inhaled β_2 agonists (LABA) salmeterol, formoterol, and arformoterol have proved to be a significant advance in asthma and COPD therapy. These drugs have a bronchodilator action of >12 hours and also protect against bronchoconstriction for a similar period (Kips and Pauwels, 2001). They improve asthma control (when given twice daily) compared with regular treatment with short-acting β_2 agonists (four to six times daily).

Tolerance to the bronchodilator effect of formoterol and the bronchoprotective effects of formoterol and salmeterol have been demonstrated, but this is a small loss of protection that does not appear to be progressive and is of doubtful clinical significance. Although both drugs have a similar duration of effect in clinical studies, there are differences. Formoterol has a more rapid onset of action and is an almost full agonist, whereas salmeterol is a partial agonist with a slower onset of action. These differences might confer a theoretical advantage for formoterol in more severe asthma, whereas it may also make it more

likely to induce tolerance. However, no significant clinical differences between salmeterol and formoterol have been found in the treatment of patients with severe asthma (Nightingale et al., 2002).

In COPD, LABA are effective bronchodilators that may be used alone or in combination with anticholinergics or ICS. LABA improve symptoms and exercise tolerance by reducing both air trapping and exacerbations. In asthma patients, LABA should never be used alone because they do not treat the underlying chronic inflammation; rather, LABA should always be used in combination with ICS (preferably in a fixed-dose combination inhaler). LABA are an effective add-on therapy to ICS and are more effective than increasing the dose of ICS when asthma is not controlled at low doses.

Combination Inhalers. Combination inhalers that contain a LABA and a corticosteroid (e.g., fluticasone/salmeterol [ADVAIR], budesonide/formoterol [SYMBICORT]) are now widely used in the treatment of asthma and COPD. In asthma there is a strong scientific rationale for combining a LABA with a corticosteroid because these treatments have complementary synergistic actions (Barnes, 2002). The combination inhaler is more convenient for patients, simplifies therapy, and improves compliance with ICS because the patients perceive clinical benefit, but there may be an additional advantage because delivering the two drugs in the same inhaler ensures they are delivered simultaneously to the same cells in the airways, allowing the beneficial molecular interactions between LABA and corticosteroids to occur. It is likely that these inhalers will become the preferred therapy for all patients with persistent asthma. These combination inhalers are also more effective in COPD patients than LABA and ICS alone, but the mechanisms accounting for this beneficial interaction are less well understood than in patients with asthma.

Recently, a combination inhaler that contains formoterol and budesonide was shown to be more effective for relieving acute symptoms than either terbutaline or formoterol alone, suggesting that the inhaled corticosteroids may also be contributing to the benefit (Rabe et al., 2006). This may make it possible to control asthma with a single inhaler both for maintenance and relief of symptoms.

Stereoselective β_2 Agonists. Albuterol is a racemic mixture of active *R*- and inactive *S*-isomers. Animal studies suggest that the *S*-isomer may increase airway responsiveness, providing a rationale for the development of *R*-albuterol (levalbuterol). Although the *R*-isomer is more potent than racemic *R/S*-albuterol in some studies, careful dose responses show no advantage in terms of efficacy and no evidence that the *S*-albuterol is detrimental in asthmatic patients (Lotvall et al., 2001). Because levalbuterol is more expensive than normally used racemic albuterol, this therapy has no clear clinical advantage (Barnes, 2006b). Stereoselective formoterol (*R*, *R*-formoterol, arformoterol) has now been developed as a nebulized solution but also appears to offer no clinical advantage over racemic formoterol (Madaan, 2009).

β_2 Receptor Polymorphisms. Several single nucleotide polymorphisms and haplotypes of the human β_2 adrenergic receptor gene (*ADRB2*), which affect the structure of β_2 receptors, have been described. The common variants are Gly¹⁶Arg and Gln²⁷Glu, which have *in vitro* effects on receptor desensitization, but clinical studies have shown inconsistent effects on the bronchodilator responses to short- and long-acting β_2 agonists (Hawkins et al., 2008). Some studies have shown that patients with the common homozygous Arg¹⁶Arg variant have more frequent adverse effects and a poorer response to short-acting β_2 agonists than heterozygotes or Gly¹⁶Gly homozygotes, but overall these differences are small, and there appears to be no clinical value in measuring *ADRB2* genotype. No differences have been found with responses to LABA between these genotypes (Bleecker et al., 2007).

Side Effects. Unwanted effects are dose related and due to stimulation of extrapulmonary β receptors (Table 36–1 and Chapter 12). Side effects are not common with inhaled therapy but quite common with oral or intravenous administration.

- **Muscle tremor** due to stimulation of β_2 receptors in skeletal muscle is the most common side effect. It may be more troublesome with elderly patients and so is a more frequent problem in COPD patients.
- **Tachycardia and palpitations** are due to reflex cardiac stimulation secondary to peripheral vasodilation, from direct stimulation of atrial β_2 receptors (human heart has a relatively high proportion of β_2 receptors; see Chapter 12), and possibly also from stimulation of myocardial β_1 receptors as the doses of β_2 agonist are increased. These side effects tend to disappear with continued use of the drug, reflecting the development of tolerance. There can be a dose-related prolongation of the corrected QT interval (QTc).
- **Hypokalemia** is a potentially serious side effect. This is due to β_2 receptor stimulation of potassium entry into skeletal muscle, which may be secondary to a rise in insulin secretion. Hypokalemia might be serious in the presence of hypoxia, as in acute asthma, when there may be a predisposition to cardiac arrhythmias (Chapter 29). In practice, however, significant arrhythmias after nebulized β_2 agonists are rarely observed in acute asthma or COPD patients.

Table 36–1

Side Effects of β_2 Agonists

- Muscle tremor (direct effect on skeletal muscle β_2 receptors)
- Tachycardia (direct effect on atrial β_2 receptors, reflex effect from increased peripheral vasodilation via β_2 receptors)
- Hypokalemia (direct β_2 effect on skeletal muscle uptake of K⁺)
- Restlessness
- Hypoxemia (increased \dot{V}/\dot{Q} mismatch due to reversal of hypoxic pulmonary vasoconstriction)

- **Ventilation-perfusion (\dot{V}/\dot{Q}) mismatch** due to pulmonary vasodilation in blood vessels previously constricted by hypoxia, resulting in the shunting of blood to poorly ventilated areas and a fall in arterial oxygen tension. Although in practice the effect of β_2 agonists on Pao₂ is usually very small (<5 mm Hg fall), occasionally in severe COPD it can be large, although it may be prevented by giving additional inspired oxygen (O₂).
- **Metabolic effects** (increase in free fatty acid, insulin, glucose, pyruvate, and lactate) are usually seen only after large systemic doses.

Tolerance. Continuous treatment with an agonist often leads to tolerance (desensitization, subsensitivity), which may be due to down-regulation of the receptor (Chapter 12). For this reason there have been many studies of bronchial β receptor function after prolonged therapy with β_2 agonists. Tolerance of non-airway β_2 receptor-mediated responses, such as tremor and cardiovascular and metabolic responses, is readily induced in normal and asthmatic subjects. Tolerance of human airway smooth muscle to β_2 agonists *in vitro* has been demonstrated, although the concentration of agonist necessary is high and the degree of desensitization is variable. In normal subjects, bronchodilator tolerance is not a consistent finding after high-dose inhaled albuterol. In asthmatic patients tolerance to the bronchodilator effects of β_2 agonists has not usually been found. However, tolerance develops to the bronchoprotective effects of β_2 agonists, and this is more marked with indirect bronchoconstrictors that activate mast cells (e.g., adenosine, allergen, and exercise) than with direct bronchoconstrictors, such as histamine and methacholine. The reason for the relative resistance of airway smooth muscle β_2 responses to desensitization remains uncertain but may reflect the large receptor reserve: >90% of β_2 receptors may be lost without any reduction in the relaxation response. The high level of *ADRB2* expression in airway smooth muscle compared with peripheral lung may also contribute to the resistance to tolerance because a high rate of β receptor synthesis is likely. In addition, the expression of GRK2, which phosphorylates and inactivates occupied β_2 receptors, is very low in airway smooth muscle (McGraw and Liggett, 1997). By contrast there is no receptor reserve in inflammatory cells, GRK2 expression is high, and tolerance to β_2 agonists rapidly develops at these sites.

Experimental studies have shown that corticosteroids prevent the development of tolerance in airway smooth muscle, and prevent and reverse the fall in pulmonary β receptor density (Mak et al., 1995). However, ICS fail to prevent the tolerance to the bronchoprotective effect of inhaled β_2 agonists, possibly because they do not reach airway smooth muscle in a high enough concentration.

Long-Term Safety. Because of a possible relationship between adrenergic drug therapy and the rise in asthma deaths in several countries during the early 1960s, doubts were cast on the long-term safety of β agonists. A causal relationship between β agonist use and mortality has never been firmly established, although in retrospective studies this would not be possible. A particular β_2 agonist, fenoterol, was linked to the rise in asthma deaths in New Zealand in the early 1990s because significantly more of the fatal cases were prescribed fenoterol than the case-matched control patients. An epidemiological study examined the links between drugs prescribed for asthma and death or near death from asthma attacks, based on computerized records of prescriptions. There was

a marked increase in the risk of death with high doses of all inhaled β_2 agonists (Spitzer et al., 1992). The risk was greater with fenoterol, but when the dose is adjusted to the equivalent dose for albuterol, there is no significant difference in the risk for these two drugs. The link between high β_2 agonist usage and increased asthma mortality does not prove a causal association because patients with more severe and poorly controlled asthma, who are more likely to have an increased risk of fatal attacks, are more likely to be using higher doses of β_2 agonist inhalers and less likely to be using effective anti-inflammatory treatment. Indeed, in the patients who used regular inhaled steroids there was a significant reduction in risk of death (Suissa et al., 2000).

Regular use of inhaled β_2 agonists has also been linked to increased asthma morbidity. Regular use of fenoterol was associated with worse asthma control and a small increase in airway hyperresponsiveness compared with patients using fenoterol “on demand” for symptom control over a 6-month period (Sears et al., 1990). However, this was not found in a study with regular albuterol (Dennis et al., 2000). There is some evidence that regular inhaled β_2 agonists may increase allergen-induced asthma and sputum eosinophilia (Mcivor et al., 1998). A possible mechanism is that β_2 agonists upregulate expression of PLC β_1 , resulting in augmentation of the bronchoconstrictor responses to cholinergic agonists and mediators (McGraw et al., 2003). Short-acting inhaled β_2 agonists should only be used on demand for symptom control, and if they are required frequently (more than three times weekly), an ICS is needed.

The safety of LABA in asthma remains controversial. A large study of the safety of salmeterol showed an excess of respiratory deaths and near deaths in patients prescribed salmeterol, but these deaths occurred mainly in African Americans living in inner cities who were not taking ICS (Nelson et al., 2006). Similar data have also raised concerns about formoterol. This may be predictable because LABA do not treat the underlying chronic inflammation of asthma. However, concomitant treatment with ICS appears to obviate such risk, so it is recommended that LABA should only be used when ICS are also prescribed (preferably in the form of a combination inhaler so that the LABA can never be taken without the inhaled corticosteroids) (Jaeschke et al., 2008). All LABA approved in the U.S. carry a black box warning cautioning against overuse. Studies are underway to examine their long-term safety profile, especially in children with asthma. There are less safety concerns with LABA use in COPD. No major adverse effects were reported in a large study over 3 years in COPD patients and in several other studies (Calverley et al., 2007; Rodrigo et al., 2008).

Future Developments

β_2 Agonists will continue to be the bronchodilators of choice for asthma in the foreseeable future because they are effective in all patients and have few or no side effects when used in low doses. It would be difficult to find a bronchodilator that improves on the efficacy and safety of inhaled β_2 agonists. Although some concerns have been expressed about the long-term effects of short-acting inhaled β_2 agonists, when used as required for symptom control, inhaled β_2 agonists appear safe. Use of large doses of inhaled β_2 agonists indicates poor asthma control; such patients should be assessed and appropriate controller medication used. LABA are a very useful option for long-term control in asthma and COPD. In asthma patients LABA should probably only be used if the patient is receiving concomitant ICS. There is little advantage to be

gained by improving β_2 receptor selectivity because most of the side effects of these agents are due to β_2 receptor stimulation (muscle tremor, tachycardia, hypokalemia). Several once daily inhaled β_2 agonists, such as indacaterol and carmoterol, are now in clinical development (Cazzola and Matera, 2008).

METHYLXANTHINES

Methylxanthines, such as theophylline, which are related to caffeine, have been used in the treatment of asthma since 1930, and theophylline is still widely used in developing countries because it is inexpensive. Theophylline became more useful with the availability of rapid plasma assays and the introduction of reliable slow-release preparations. However, the frequency of side effects and the relative low efficacy of theophylline have led to reduced use in many countries because inhaled β_2 agonists are far more effective as bronchodilators and ICS have a greater anti-inflammatory effect. In patients with severe asthma and COPD it still remains a very useful drug, however.

Chemistry. Theophylline is a methylxanthine similar in structure to the common dietary xanthines caffeine and theobromine. Several substituted derivatives have been synthesized, but only two appear to have any advantage over theophylline: the 3-propyl derivative, enprofylline, which is more potent as a bronchodilator and may have fewer toxic effects because it does not antagonize adenosine receptors; and doxofylline (7-[1,3-dioxalan-2-ylmethyl] theophylline), a novel methylxanthine available in some countries (Dini and Cogo, 2001). Doxofylline, which has a dioxolane group at position 7, has an inhibitory effect on phosphodiesterases (PDEs) similar to that of theophylline but is less active as an adenosine antagonist and may have a more favorable side-effect profile. Many salts of theophylline have also been marketed; the most common is aminophylline, which is the ethylenediamine salt used to increase its solubility at neutral pH. Other salts either do not have any advantage (e.g., oxtriphylline [choline theophyllinate]) or are virtually inactive (e.g., acephylline). Thus, theophylline remains the major methylxanthine in clinical use.

Mechanism of Action. The mechanisms of action of theophylline are still uncertain. In addition to its bronchodilator action, theophylline has many nonbronchodilator effects that may be relevant to its effects in asthma and COPD (Figure 36–6). Many of these molecular effects are seen only at high concentrations that exceed the therapeutic range, however. Several molecular mechanisms of action have been proposed:

- *Inhibition of phosphodiesterases.* Theophylline is a nonselective PDE inhibitor, but the degree of inhibition is relatively

Figure 36–6. Theophylline affects multiple cell types in the airway.

minimal at concentrations of theophylline that are within the so-called therapeutic range. PDE inhibition and the concomitant elevation of cellular cAMP and cyclic guanosine monophosphate (cGMP) almost certainly account for the bronchodilator action of theophylline, but PDE inhibition is unlikely to account for the nonbronchodilator effects of theophylline that are seen at lower concentrations. Inhibition of PDE should lead to synergistic interaction with β agonists through an increase in cAMP (Figure 36–5), but this has not been convincingly demonstrated in clinical studies. Several isoenzyme families of PDE have now been recognized and those important in smooth muscle relaxation include PDE3, PDE4, and PDE5. Theophylline is a weak inhibitor of all PDE isoenzymes.

- **Adenosine receptor antagonism.** Theophylline antagonizes adenosine receptors at therapeutic concentrations. Adenosine causes bronchoconstriction in airways from asthmatic patients by releasing histamine and leukotrienes. Adenosine antagonism is unlikely to account for the anti-inflammatory effects of theophylline but may be responsible for serious side effects, including cardiac arrhythmias and seizures through the antagonism of A_1 receptors. Of interest may be the adenosine A_{2B} receptor on mast cells, which is activated by adenosine in asthmatic patients (Wilson, 2008).
- **Interleukin-10 release.** IL-10 has a broad spectrum of anti-inflammatory effects, and there is evidence that its secretion is reduced in asthma. IL-10 release is increased by theophylline, and this effect may be mediated via inhibition of PDE activities, although this has not been seen at the low doses that are effective in asthma (Oliver et al., 2001).
- **Effects on gene transcription.** Theophylline prevents the translocation of the pro-inflammatory transcription factor NF- κ B into the nucleus, potentially reducing the expression of inflammatory

genes in asthma and COPD. Inhibition of NF- κ B appears to be due to a protective effect against the degradation of the inhibitory protein I- κ B α (Ichiyama et al., 2001). However, these effects are seen at high concentrations and may be mediated by inhibition of PDE.

- **Effects on apoptosis.** Prolonged survival of granulocytes due to a reduction in apoptosis may be important in perpetuating chronic inflammation in asthma (eosinophils) and COPD (neutrophils). Theophylline promotes apoptosis in eosinophils and neutrophils *in vitro*. This is associated with a reduction in the anti-apoptotic protein Bcl-2 (Chung et al., 2000). This effect is not mediated via PDE inhibition, but in neutrophils may be mediated by antagonism of adenosine A_{2A} receptors (Yasui et al., 2000). Theophylline also induces apoptosis in T lymphocytes, reducing their survival; this effect appears to be mediated via PDE inhibition (Ohta and Yamashita, 1999).
- **Histone deacetylase activation.** Recruitment of histone deacetylase-2 (HDAC2) by glucocorticoid receptors switches off inflammatory genes. Therapeutic concentrations of theophylline activate HDAC, thereby enhancing the anti-inflammatory effects of corticosteroids (Cosio et al., 2004; Ito et al., 2002). This mechanism is independent of PDE inhibition or adenosine receptor antagonism and appears to be mediated by inhibition of PI3-kinase- δ , which is activated by oxidative stress (Marwick et al., 2009). The anti-inflammatory effects of theophylline are inhibited by a HDAC inhibitor, trichostatin A. Low doses of theophylline increase HDAC activity in bronchial biopsies of asthmatic patients and correlate with the reduction in eosinophil numbers in the biopsy.
- **Other effects.** Several other effects of theophylline have been described, including an increase in circulating catecholamines, inhibition of calcium influx into inflammatory cells, inhibition of prostaglandin effects, and antagonism of tumor necrosis

Table 36-2

Factors Affecting Clearance of Theophylline

Increased clearance

- Enzyme induction (mainly CYP1A2) by co-administered drugs (e.g., rifampicin, barbiturates, ethanol)
- Smoking (tobacco, marijuana) via CYP1A2 induction
- High-protein, low-carbohydrate diet
- Barbecued meat
- Childhood

Decreased clearance

- CYP inhibition (cimetidine, erythromycin, ciprofloxacin, allopurinol, fluvoxamine, zileuton, zafirlukast)
- Congestive heart failure
- Liver disease
- Pneumonia
- Viral infection and vaccination
- High-carbohydrate diet
- Old age

factor (TNF) α . These effects are generally seen only at concentrations of theophylline that are above the therapeutic range in asthma and are therefore unlikely to contribute to the anti-inflammatory actions of theophylline observed in asthmatics.

Nonbronchodilator Effects. Theophylline has clinical benefit in asthma and COPD at plasma concentrations <10 mg/L, sufficiently low that such effects are unlikely to be explained by theophylline's bronchodilator action. There is increasing evidence that theophylline has anti-inflammatory effects in asthma (Barnes, 2003). For example, chronic oral treatment with theophylline inhibits the late response to inhaled allergen and reduces infiltration of eosinophils and CD4⁺ lymphocytes into the airways after allergen challenge. In patients with mild asthma, low doses of theophylline ($C_p \sim 5$ mg/L) reduce the numbers of eosinophils seen in bronchial biopsies, bronchoalveolar lavage, and induced sputum (Lim et al., 2001); conversely, in severe asthma, withdrawal of theophylline results in increased numbers of activated CD4⁺ cells and eosinophils in bronchial biopsies (Kidney et al., 1995). In patients with COPD, theophylline reduces the total number and proportion of neutrophils in induced sputum, the concentration of IL-8, and neutrophil chemotactic responses (Culpitt et al., 2002). Theophylline withdrawal in COPD patients results in worsening of disease. *In vitro* theophylline is able to increase responsiveness to corticosteroids and to reverse corticosteroid resistance in cells from COPD subjects (Ito et al., 2002).

Pharmacokinetics and Metabolism. There is a close relationship between improvement in airway function and serum theophylline concentration. Below 10 mg/L, therapeutic effects in terms of bronchodilation are small; above 20 mg/L additional benefits are outweighed by side effects, so that the therapeutic range was generally taken to be 10-20 mg/L (55-110 μ M). Even within that range, toxicity can be observed, making theophylline a difficult drug to use. However, recent

studies suggest that theophylline has anti-asthma effects other than bronchodilation below 10mg/L, so the therapeutic range is now taken as 5-15 mg/L. The dose of theophylline required to give these therapeutic concentrations varies among subjects, largely because of differences in clearance of the drug. In addition, there may be differences in bronchodilator response to theophylline; furthermore, with acute bronchoconstriction, higher concentrations may be required to produce bronchodilation. Theophylline is rapidly and completely absorbed, but there are large interindividual variations in clearance, due to differences in hepatic metabolism (Table 36-3). Theophylline is metabolized in the liver, mainly by CYP1A2, and a large number of factors are known to influence hepatic metabolism of theophylline (Zhang and Kaminsky, 1995):

- *Increased* clearance is seen in children (1-16 years of age), and in cigarette and marijuana smokers, due to induction of CYP1A2. Concurrent administration of phenytoin, phenobarbital, and rifampin increases activity of CYPs, especially CYP1A2, resulting in increased metabolic breakdown, so that higher doses may be required.
- *Reduced* clearance occurs in liver disease, pneumonia, and heart failure; doses must be reduced to half and plasma levels monitored carefully. Decreased clearance is also seen with coadministration of certain drugs, including erythromycin, certain quinolone antibiotics (ciprofloxacin, but not ofloxacin), allopurinol, cimetidine (but not ranitidine), fluvoxamine, the 5'-lipoxygenase inhibitor zileuton, and the leukotriene receptor antagonist zafirlukast, all of which interfere with CYP function. Thus, if a patient on maintenance theophylline requires a course of erythromycin, the dose of theophylline should be halved. Viral infections and vaccination may also reduce clearance.

Because of these variations in clearance, individualization of theophylline dosage is required and plasma concentrations should be measured 4 hours after the last dose with slow-release preparations when steady state has been achieved. There is no significant circadian variation in theophylline metabolism, although there may be delayed absorption at night related to supine posture.

Preparations and Routes of Administration. *Intravenous* aminophylline has been used for many years in the treatment of acute severe asthma. The recommended dose is 6 mg/kg given intravenously over 20-30 minutes, followed by a maintenance dose of 0.5 mg/kg per hour. If the patient is already taking theophylline, or there are any factors that decrease clearance, these doses should be halved and the plasma level checked more frequently. Nebulized β_2 agonists are now preferred over intravenous aminophylline for acute exacerbations of asthma and COPD.

Oral immediate-release theophylline tablets or elixir, which are rapidly absorbed, give wide fluctuations in plasma levels, and are not recommended. Several sustained-release preparations are now available that are absorbed at a constant rate and provide steady plasma concentrations over a 12- to 24-hour period. Both slow-release aminophylline and theophylline are available and are equally effective (although the ethylene diamine component of aminophylline has been implicated in allergic reactions). For continuous treatment twice daily therapy (~ 8 mg/kg twice daily) is needed. Recently, once-daily preparations have gained popularity. For nocturnal asthma a single dose of slow-release theophylline at night is often effective. Once optimal doses have been determined,

Table 36–3

Side Effects of Theophylline and Mechanisms

SIDE EFFECT	PROPOSED MECHANISM
Nausea and vomiting	PDE4 inhibition
Headaches	PDE4 inhibition
Gastric discomfort	PDE4 inhibition
Diuresis	A ₁ receptor antagonism
Behavioral disturbance (?)	?
Cardiac arrhythmias	PDE3 inhibition, A ₁ receptor antagonism
Epileptic seizures	A ₁ receptor antagonism

PDE, phosphodiesterase; A, adenosine.

routine monitoring of plasma concentrations is usually not necessary, unless a change in clearance is suspected or evidence of toxicity emerges.

Clinical Use. In patients with acute asthma, intravenous aminophylline is less effective than nebulized β_2 agonists and should therefore be reserved for those patients who fail to respond to, or are intolerant of, β agonists. Theophylline should not be added routinely to nebulized β_2 agonists because it does not increase the bronchodilator response and may increase their side effects (Parameswaran et al., 2000). Indeed, the role of theophylline in the contemporary management of asthma and COPD has been questioned. However, there is good evidence that theophylline may provide an additional bronchodilator effect even when maximally effective doses of β_2 agonist have been given (Rivington et al., 1995). Thus, if adequate bronchodilation is not achieved by a β agonist alone, theophylline may be added to the maintenance therapy with benefit. Addition of low-dose theophylline to either a high or low dose of ICS in patients who are not adequately controlled provides better symptom control and lung function than doubling the dose of inhaled steroid (Evans et al., 1997; Lim et al., 2000; Ukena et al., 1997), although it is less effective as an add-on therapy than a LABA (Wilson et al., 2000). Theophylline may be useful in patients with nocturnal asthma because slow-release preparations are able to provide therapeutic concentrations overnight, although it is less effective than a LABA (Shah et al., 2003). Studies have also documented the steroid-sparing effects of theophylline. Although theophylline is less effective than a β_2 agonist and corticosteroids, a minority of asthmatic patients appears to derive unexpected benefit; even patients on oral steroids may show a deterioration in lung function when theophylline is withdrawn (Brenner et al., 1988; Kidney et al., 1995). Theophylline has been used as a controller in the management of mild persistent asthma, although it is usually found to be less effective than low doses of inhaled corticosteroids (Seddon et al., 2006). Although LABA are more effective as an add-on therapy, theophylline is considerably less expensive and may be the only affordable add-on treatment when the costs of medication are limiting (Bateman et al., 2008).

Theophylline is still used as a bronchodilator in COPD, but inhaled anticholinergics and β_2 agonists are preferred (Rabe et al., 2007). Theophylline tends to be added to these inhaled bronchodilators

in more severe patients and has been shown to give additional clinical improvement when added to a long-acting β_2 agonist (Ram et al., 2002). Intravenous aminophylline is less effective in treating acute exacerbations than nebulized β_2 agonists and has a much higher incidence of adverse effects (Barr et al., 2003; Duffy et al., 2005). As in asthmatics, patients with severe COPD deteriorate when theophylline is withdrawn from their treatment regimen. A theoretical advantage of theophylline is that its systemic administration may have effects on small airways, resulting in reduction of hyperinflation and thus a reduction in dyspnea.

Side Effects. Unwanted effects of theophylline are usually related to plasma concentration and tend to occur at $C_p > 15$ mg/L. However, many patients develop side effects even at low plasma concentrations. To some extent, side effects may be reduced by gradually increasing the dose until therapeutic concentrations are achieved. The most common side effects are headache, nausea, and vomiting (due to inhibition of PDE4), abdominal discomfort, and restlessness (Table 36–3). There may also be increased acid secretion (due to PDE inhibition) and diuresis (due to inhibition of adenosine A₁ receptors). Theophylline may lead to behavioral disturbance and learning difficulties in schoolchildren, although it is difficult to design adequate controls for such studies. At high concentrations, cardiac arrhythmias may occur as a consequence of inhibition of cardiac PDE3 inhibition and antagonism of cardiac A₁ receptors. At very high concentrations, seizures may occur due to central A₁ receptor antagonism. Use of low doses of theophylline, targeting plasma concentrations of 5–10 mg/L, largely avoids side effects and drug interactions and makes it less necessary to monitor plasma concentrations (unless checking for compliance).

Summary and Future Developments

Theophylline use has been declining, partly because of the problems with side effects, but mainly because more effective therapy with ICS has been introduced. Oral theophylline remains a useful treatment in some patients with difficult asthma and appears to have effects beyond those provided by steroids. Rapid-release theophylline preparations are the only affordable anti-asthma medication in some developing countries. There is increasing evidence that theophylline has some anti-asthma effect at doses that are lower than those needed for bronchodilation, and plasma levels of 5–15 mg/L are recommended.

Given theophylline's anti-inflammatory effects, there is a strong scientific rationale for combining low-dose theophylline with ICS, particularly in patients with more severe asthma and in COPD. Adding a low dose of theophylline gives better control of asthma than doubling the dose of ICS in uncontrolled patients, and is a less expensive alternative add-on therapy than a LABA or antileukotriene. Theophylline reverses corticosteroid resistance in COPD cells by restoring HDAC2 to normal levels (Cosio et al., 2004) and accelerates the recovery from acute exacerbations of COPD through this mechanism (Cosio et al., 2009). In COPD, low-dose theophylline

is the first drug to demonstrate clear anti-inflammatory effects; thus, theophylline may have a role in preventing progression of this disease (Culpitt et al., 2002).

MUSCARINIC CHOLINERGIC ANTAGONISTS

Chemical antagonism of the effects of acetylcholine at muscarinic receptors in the lung for the relief of asthma is not a new idea. *Datura stramonium* (jimson weed) and related species of the nightshade family contain a mixture of muscarinic antagonists (atropine, hyoscyamine, scopolamine) and were smoked for relief of asthma two centuries ago. Subsequently, the purified plant alkaloid atropine was introduced for treating asthma. Due to the significant side effects of atropine, particularly drying of secretions, less soluble quaternary compounds, such as atropine methylnitrate and ipratropium bromide, have been developed. These compounds are topically active and are not significantly absorbed from the respiratory or GI tracts. The basic pharmacology of the antimuscarinic agents is presented in Chapter 9.

Mode of Action

These agents are competitive antagonists of ACh binding to muscarinic cholinergic receptors; thus these drugs block the effects of endogenous ACh at muscarinic receptors, including the direct constrictor effect on bronchial smooth muscle mediated via the M_3 - G_q -PLC- IP_3 - Ca^{2+} pathway (Chapter 3). Their predicted efficacy stems from the role played by the parasympathetic nervous system in regulating bronchomotor tone. Multiple and diverse stimuli cause reflex increases in parasympathetic activity that contribute to bronchoconstriction. The effects of ACh on the respiratory system include not only bronchoconstriction but also increased tracheobronchial secretion and stimulation of the chemoreceptors of the carotid and aortic bodies. Thus antimuscarinic drugs might be expected to antagonize these effects of acetylcholine. One complicating factor studied in animal models is that myriad inflammatory mediators involved in the pathogenesis of asthma and COPD may also induce components of muscarinic responsiveness, such as $G\alpha_q$ and ρ , and contribute to hyperresponsiveness of the airway (Chiba et al., 2008). Thus, the contractility of bronchial smooth muscle and antagonism of muscarinic responsiveness could be moving targets in asthma and COPD.

Basic research is demonstrating that the muscarinic agonists are not functionally equivalent, however. Recent

research has focused on the differential capacity of muscarinic antagonists to act as antagonists, as inverse agonists inhibiting the constitutive activity of the M_3 receptor, and as modulators of upregulation of M_3 receptor expression (Casarosa et al., 2009). Such differences may have clinical relevance for long-term use of these compounds, where tolerance and withdrawal/rebound could be major issues. In this regard, a long-term study of tiotropium demonstrates no loss of its capacity for bronchodilation over 4 years (Tashkin et al., 2008).

In animals and man there is a small degree of resting bronchomotor tone that is probably due to tonic vagal nerve impulses that release acetylcholine in the vicinity of airway smooth muscle because it can be blocked by anticholinergic drugs. Acetylcholine may also be released from other airway cells, including epithelial cells (Wessler and Kirkpatrick, 2008). The synthesis of acetylcholine in epithelial cells is increased by inflammatory stimuli (such as $TNF-\alpha$), which increase the expression of choline acetyltransferase, which could contribute to cholinergic effects in airway diseases. Muscarinic receptors are expressed in airway smooth muscle of small airways that do not appear to be innervated by cholinergic nerves; these receptors may be a mechanism of cholinergic narrowing in peripheral airways that could be relevant in COPD, responding to locally synthesized, non-neuronal ACh.

Myriad mechanical, chemical, and immunological stimuli elicit reflex bronchoconstriction via vagal pathways, and cholinergic pathways may play an important role in regulating acute bronchomotor responses in animals. These observations suggested that cholinergic mechanisms might underlie airway hyperresponsiveness and acute bronchoconstrictor responses in asthma, with the implication that anticholinergic drugs would be effective bronchodilators. These drugs may afford protection against acute challenge by sulfur dioxide, inert dusts, cold air, and emotional factors, but they are less effective against antigen challenge, exercise, and fog. This is not surprising because anticholinergic drugs will only inhibit reflex ACh-mediated bronchoconstriction and have no blocking effect on the *direct* effects of inflammatory mediators, such as histamine and leukotrienes, on bronchial smooth muscle. Furthermore, cholinergic antagonists probably have little or no effect on mast cells, microvascular leak, or the chronic inflammatory response.

Theoretically, anticholinergics may reduce airway mucus secretion and reduce mucus clearance, but this is generally not observed in clinical studies. Oxitropium bromide (not available in the U.S.) in high doses reduces mucus hypersecretion in patients with COPD with chronic bronchitis.

Clinical Use. In asthmatic patients, anticholinergic drugs are less effective as bronchodilators than β_2 agonists and offer less efficient protection against bronchial challenges. These drugs may be more effective in older patients with asthma in whom there is an element of fixed airway obstruction. Anticholinergics are currently used as an additional bronchodilator in asthmatic patients not controlled on a LABA. Nebulized anticholinergic drugs are effective in acute severe asthma but less effective than β_2 agonists. Nevertheless, in the acute and chronic treatment of asthma, anticholinergic drugs may have an additive effect with β_2 agonists and should therefore be considered

Figure 36–7. Anticholinergic drugs inhibit vagally mediated airway tone, thereby producing bronchodilation. This effect is small in normal airways but is greater in airways of patients with chronic obstructive pulmonary disease (COPD), which are structurally narrowed and have higher resistance to airflow because airway resistance is inversely related to the fourth power of the radius (r). ACh, acetylcholine.

when control of asthma is not adequate with nebulized β_2 agonists. A muscarinic antagonist should be considered when there are problems with theophylline or when inhaled β_2 agonists cause a troublesome tremor in elderly patients.

In COPD, anticholinergic drugs may be as effective as or even superior to β_2 agonists. Their relatively greater effect in COPD than in asthma may be explained by an inhibitory effect on vagal tone, which, although not necessarily increased in COPD, may be the only reversible element of airway obstruction and one that is exaggerated by geometric factors in the narrowed airways of COPD patients (Figure 36–7). Anticholinergic drugs reduce air trapping and improve exercise tolerance in COPD patients.

Therapeutic Choices. Ipratropium bromide (ATROVENT, others) is available as a pMDI and nebulized preparation. The onset of bronchodilation is relatively slow and is usually maximal 30–60 minutes after inhalation, but may persist for 6–8 hours. It is usually given by MDI three to four times daily on a regular basis, rather than intermittently for symptom relief, in view of its slow onset of action.

Oxipropium bromide (not available in the U.S.) is a quaternary anticholinergic bronchodilator that is similar to ipratropium bromide in terms of receptor blockade. It is available in higher doses

by inhalation and may therefore have a more prolonged effect. Thus, it may be useful in some patients with nocturnal asthma.

Combination inhalers of an anticholinergic and β_2 agonist, such as ipratropium/albuterol (COMBIVENT, DUONEB, others), are popular, particularly among patients with COPD. Several studies have demonstrated additive effects of these two drugs, thus providing an advantage over increasing the dose of β_2 agonist in patients who have side effects.

Tiotropium bromide is a long-acting anticholinergic drug that is suitable for once-daily dosing as a DPI (SPIRIVA) or via a soft mist mini-nebulizer device (not available in the U.S.) (Barr et al., 2006). Tiotropium binds to all muscarinic receptor subtypes but dissociates very slowly from M_3 and M_1 receptors, giving it a degree of kinetic receptor selectivity for these receptors compared with M_2 receptors, from which it dissociates more rapidly. Thus, compared with ipratropium, tiotropium is less likely to antagonize M_2 -mediated inhibition of ACh release (the resulting increase in ACh could counteract the blockade of M_3 receptor-mediated bronchoconstriction) (Chapter 9). It is an effective bronchodilator in patients with COPD and is more effective than ipratropium four times daily without any loss of efficacy over a 1-year treatment period. Over a 4-year period, tiotropium improves lung function and health status and reduces exacerbations and all-cause mortality, although there is no effect on disease progression (Tashkin et al., 2008). As a result, tiotropium is becoming the bronchodilator of choice for COPD patients.

Adverse Effects. Inhaled anticholinergic drugs are generally well tolerated. On stopping inhaled anticholinergics, a small rebound increase in airway responsiveness has been described, but the clinical relevance of this is uncertain. Systemic side effects after ipratropium bromide and tiotropium bromide are uncommon during normal clinical use because there is little systemic absorption. Because cholinergic agonists can stimulate *mucus secretion*, there has been concern that anticholinergics may reduce secretion and lead to more viscous mucus. However, ipratropium bromide, even in high doses, has no detectable effect on mucociliary clearance in either normal subjects or in patients with airway disease. A significant unwanted effect is the unpleasant *bitter taste* of inhaled ipratropium, which may contribute to poor compliance. Nebulized ipratropium bromide may precipitate *glaucoma* in elderly patients due to a direct effect of the nebulized drug on the eye. This may be prevented by nebulization with a mouthpiece rather than a face mask. Reports of *paradoxical bronchoconstriction* with ipratropium bromide, particularly when given by nebulizer, were largely explained as effects of the hypotonic nebulizer solution and by antibacterial additives, such as benzalkonium chloride and ethylenediaminetetraacetic acid (EDTA). This problem has not been described with tiotropium. Occasionally, bronchoconstriction may occur with ipratropium bromide given by MDI. It is possible that this is due to blockade of prejunctional M_2 receptors on airway cholinergic nerves that normally inhibit acetylcholine release. Tiotropium causes dryness of the mouth in 10–15% of patients, but this usually disappears during continued therapy. Urinary retention is occasionally seen in elderly patients.

Future Developments. Anticholinergics are the bronchodilators of choice in COPD and therefore have a growing market. Several long-acting muscarinic antagonists are now in clinical development,

including glycopyrrolate and aclidinium (Cazzola, 2009; Hansel et al., 2005). Dual-action drugs that are both muscarinic antagonists and β_2 agonist (MABA) are also in clinical development (Ray and Alcaraz, 2009).

NOVEL CLASSES OF BRONCHODILATORS

Several new classes of bronchodilator are under development, but it is difficult to foresee a more effective bronchodilator than a LABA for asthma and a long-acting anticholinergic for COPD. Inventing new classes of bronchodilators has been difficult; several agents have had problems with vasodilator side effects because they relaxed vascular smooth muscle to a greater extent than airway smooth muscle. Nonetheless, there are several classes of bronchodilators under development, as described next.

Magnesium Sulfate. Increasing evidence indicates that magnesium sulfate (MgSO_4) is useful as an additional bronchodilator in patients with acute severe asthma. Intravenous or nebulized MgSO_4 benefits adults and children with severe exacerbations (forced expiratory volume in 1 second [$\text{FEV}_{1\text{L}}$] <30% of predicted value), giving improvement in lung function when added to nebulized β_2 agonist and a reduction in hospital admissions (Mohammed and Goodacre, 2007). The treatment is cheap and well tolerated, although the clinical benefit appears small. Side effects include flushing and nausea but are usually minor. Magnesium sulfate appears to act as a bronchodilator and may reduce cytosolic Ca^{2+} concentrations in airway smooth muscle cells. The concentration of magnesium is lower in serum and erythrocytes of asthmatic patients than in normal controls and correlates with airway hyperresponsiveness (Emelyanov et al., 1999), although the improvement in acute severe asthma after magnesium does not correlate with plasma concentrations. More studies are needed before intravenous and inhaled MgSO_4 are routinely recommended for the management of acute severe asthma. There are too few studies in acute exacerbations of COPD to make any firm recommendation (Skorodin et al., 1995).

K^+ Channel Openers. K^+ channels are involved in recovery of excitable cells after depolarization and are important in stabilization of cells. K^+ channel openers such as cromakalim or levcromakalim (the *levo*-isomer of cromakalim) open ATP-dependent K^+ channels in smooth muscle, leading to membrane hyperpolarization and relaxation of airway smooth muscle (Black et al., 1990). This suggests that K^+ channel activators may be useful as bronchodilators (Pelaia et al., 2002). Clinical studies in asthma, however, have been disappointing, with no bronchodilation or protection against bronchoconstrictor challenges. The cardiovascular side effects of these drugs (postural hypotension, flushing) limit the oral dose; furthermore, inhaled formulations are problematic. New developments include K^+ channel openers that open Ca^{2+} -activated large conductance K^+ channels (maxi-K channels) that are also opened by β_2 agonists; these drugs may be better tolerated. Maxi-K channel openers also inhibit mucus secretion and cough, and they may be of particular value in the treatment of COPD.

Atrial Natriuretic Peptides. Atrial natriuretic peptide (ANP) activates membrane-bound guanylyl cyclase and increases cellular cyclic GMP, leading to bronchodilation by mechanisms similar to those of NO on smooth muscle (Chapter 3). ANP and the related peptide urodilatin are bronchodilators in asthma and give effects comparable to those of β_2 agonists (Angus et al., 1993; Fluge et al., 1999). Because ANP and congeners work via a mechanism distinct from that of β_2 agonists, they may give additional bronchodilation that may be useful in acute severe asthma when β_2 receptor function might be impaired.

Vasoactive Intestinal Polypeptide Analogs. Vasoactive intestinal polypeptide (VIP) is a 28 amino acid peptide that binds to two GPCRs, VPAC_1 and VPAC_2 , both of which couple primarily to G_s to stimulate the adenylyl cyclase-cAMP-PKA pathway leading to relaxation of smooth muscle. VIP is a potent dilator of human airway smooth muscle *in vitro* but is not effective in patients because it is rapidly metabolized (plasma $t_{1/2}$ ~2 minutes); in addition, VIP causes vasodilator side effects. More stable analogs of VIP, such as Ro 25-1533, which selectively stimulates VIP receptors in airway smooth muscle (via the VPAC_2 receptor), have been synthesized. Inhaled Ro 25-1533 has a rapid bronchodilator effect in asthmatic patients but is not as prolonged as formoterol (Linden et al., 2003).

Other Inhibitors of Smooth Muscle Contraction. Agents that inhibit the contractile machinery of airway smooth muscle, including rho kinase inhibitors, inhibitors of myosin light chain kinase, and myosin inhibitors, are also in development. Because these agents also cause vasodilation, it will be necessary to administer them by inhalation.

CORTICOSTEROIDS

Corticosteroids are used in the treatment of several inflammatory lung diseases. Oral corticosteroids were introduced for the treatment of asthma shortly after their discovery in the 1950s and remain the most effective controller therapy available for asthma. However, their considerable side effects have prompted considerable research into discovering new or related agents that retain the beneficial action on airways without the adverse effects. The introduction of ICS (inhaled corticosteroids), initially as a way of reducing the requirement for oral steroids, has revolutionized the treatment of chronic asthma (Barnes et al., 1998b). Because asthma is a chronic inflammatory disease, ICS are considered as first-line therapy in all but the mildest of patients. In marked contrast, ICS are much less effective in COPD and should only be used in patients with severe disease who have frequent exacerbations. Oral corticosteroids remain the mainstay of treatment of several other pulmonary diseases, such as sarcoidosis, interstitial lung diseases, and pulmonary eosinophilic syndromes. The general pharmacology of corticosteroids is presented in Chapter 42.

Chemistry. The adrenal cortex secretes cortisol (hydrocortisone) and, by modification of its structure, it was possible to develop derivatives, such as prednisone, prednisolone, and dexamethasone, with enhanced corticosteroid effects but with reduced mineralocorticoid activity (Chapter 42). These derivatives with potent glucocorticoid actions were effective in asthma when given systemically but had no anti-asthmatic activity when given by inhalation. Further substitution in the 17 α ester position resulted in steroids with high topical activity, such as beclomethasone dipropionate, triamcinolone, flunisolide, budesonide, and fluticasone propionate, which are potent in the skin (dermal blanching test) and were later found to have significant anti-asthma effects when given by inhalation (Figure 36–8).

Mechanism of Action. Corticosteroids enter target cells and bind to glucocorticoid receptors (GR) in the cytoplasm (Chapter 42). There is only one type of GR that binds corticosteroids and no evidence for the existence of subtypes that might mediate different aspects of corticosteroid action (Barnes, 2006a). The steroid-GR complex moves into the nucleus, where it binds to specific sequences on the upstream regulatory elements of certain target genes, resulting in increased (or rarely, decreased) transcription of the gene, with subsequent increased (or decreased) synthesis of the gene products. GR may also interact with protein transcription factors and coactivator molecules in the nucleus and thereby influence the synthesis of certain proteins independently of any direct interaction with DNA. The repression of transcription factors, such as activator protein-1 (AP-1) and NF- κ B, is likely to account for many of the anti-inflammatory

effects of steroids in asthma. In particular, corticosteroids reverse the activating effect of these pro-inflammatory transcription factors on histone acetylation by recruiting HDAC2 to inflammatory genes that have been activated through acetylation of associated histones (Figure 36–9). GRs are acetylated when corticosteroids are bound and bind to DNA in this acetylated state as dimers, whereas the acetylated GR has to be deacetylated by HDAC2 in order to interact with inflammatory genes and NF- κ B (Ito et al., 2006).

There may be additional mechanisms that are also important in the anti-inflammatory actions of corticosteroids. Corticosteroids have potent inhibitory effects on MAP kinase signaling pathways through the induction of MKP-1, which may inhibit the expression of multiple inflammatory genes (Clark, 2003).

Anti-Inflammatory Effects in Asthma. The mechanisms of action of corticosteroids in asthma are still poorly understood, but their efficacy is most likely related to their anti-inflammatory properties. Corticosteroids have widespread effects on gene transcription, increasing the transcription of several anti-inflammatory genes and suppressing transcription of many inflammatory genes. Steroids have inhibitory effects on many inflammatory and structural cells that are activated in asthma and prevent the recruitment of inflammatory cells into the airways (Figure 36–10). Studies of bronchial biopsies in asthma have demonstrated a reduction in the number and activation of inflammatory cells in the epithelium and submucosa after regular ICS, together with a healing of the damaged epithelium. Indeed, in patients with mild asthma the inflammation may be completely resolved after inhaled steroids.

Figure 36–8. Chemical structures of commonly used inhaled corticosteroids, showing changes from hydrocortisone nucleus.

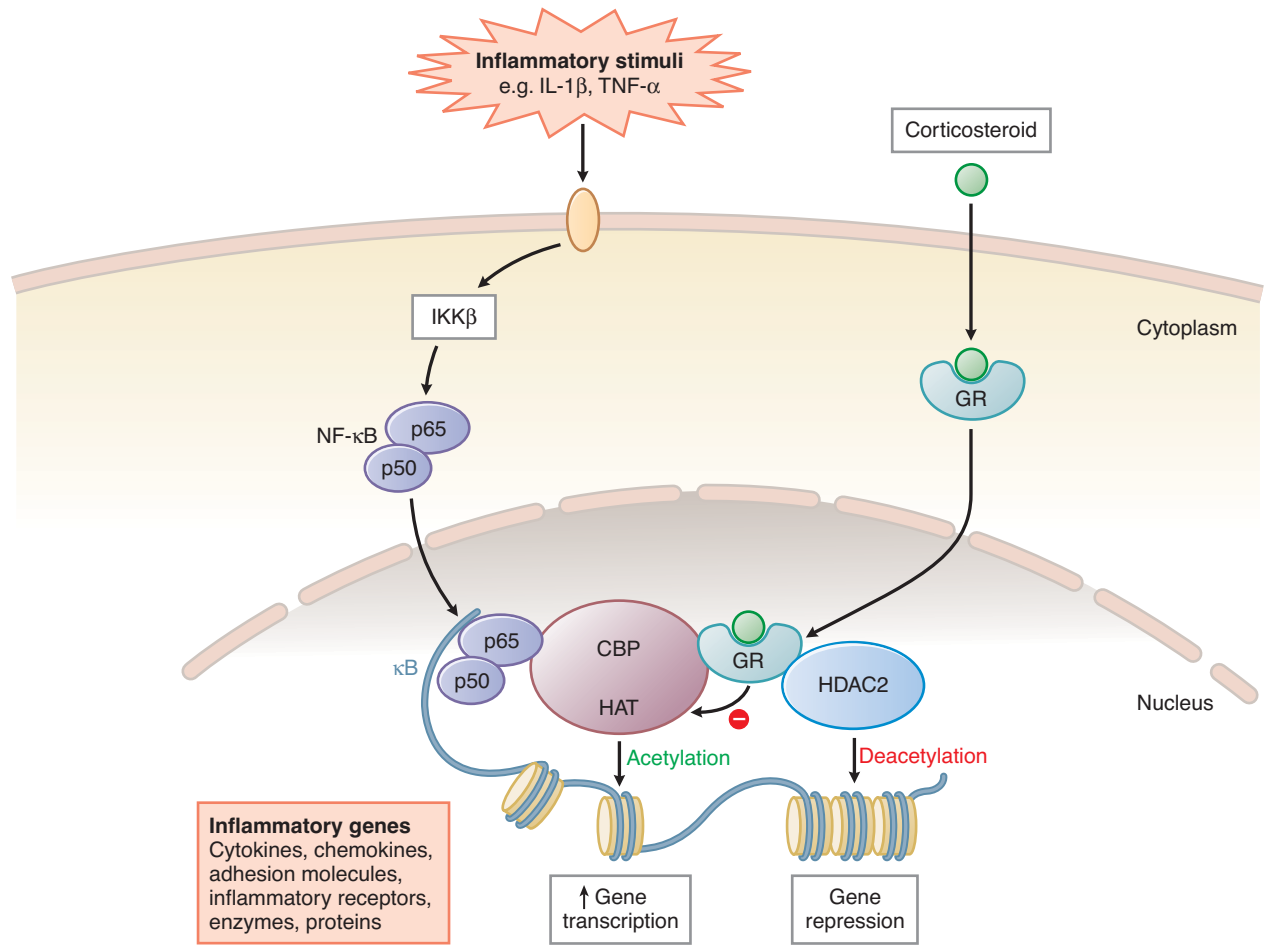

Figure 36–9. Mechanism of anti-inflammatory action of corticosteroids in asthma. Inflammatory genes are activated by inflammatory stimuli (IL-1 β , TNF- α , etc.), resulting in activation of IKK β (inhibitor of I- κ B kinase- β), which activates the transcription factor nuclear factor κ B (NF- κ B). A dimer of p50 and p65 NF- κ B proteins translocates to the nucleus and binds to specific κ B recognition sites and also to coactivators, such as CREB-binding protein (CBP), which have intrinsic histone acetyltransferase (HAT) activity. This results in acetylation of core histones and consequent increased expression of genes encoding multiple inflammatory proteins. Cytosolic glucocorticoid receptors (GR) bind corticosteroids; the receptor-ligand complexes translocate to the nucleus and bind to coactivators to inhibit HAT activity in two ways: directly and, more importantly, by recruiting histone deacetylase-2 (HDAC2), which reverses histone acetylation, leading to the suppression of activated inflammatory genes.

Steroids potently inhibit the formation of cytokines (e.g., IL-1, IL-3, IL-4, IL-5, IL-9, IL-13, TNF- α , and granulocyte-macrophage colony-stimulating factor, GM-CSF) that are secreted in asthma by T-lymphocytes, macrophages, and mast cells. Corticosteroids also decrease eosinophil survival by inducing apoptosis. Corticosteroids inhibit the expression of multiple inflammatory genes in airway epithelial cells, probably the most important action of ICS in suppressing asthmatic inflammation. Corticosteroids also prevent and reverse the increase in vascular permeability due to inflammatory mediators in animal studies and may therefore lead to resolution of airway edema. Steroids have a direct inhibitory effect on mucus glycoprotein secretion from airway submucosal glands, as well as indirect inhibitory effects by down-regulation of inflammatory stimuli that stimulate mucus secretion.

Corticosteroids have no direct effect on contractile responses of airway smooth muscle; improvement in lung function after ICS is presumably due to an effect on the chronic airway inflammation and airway hyperresponsiveness. A single dose of ICS has no effect on the early response to allergen (reflecting their lack of effect on mast cell mediator release) but inhibits the late response (which may be due to an effect on macrophages, eosinophils, and airway wall edema) and also inhibits the increase in airway hyperresponsiveness.

ICS have rapid anti-inflammatory effects, reducing airway hyperresponsiveness and inflammatory mediator concentrations in sputum within a few hours (Erin et al., 2008). However, it may take several weeks or months to achieve maximal effects on airway hyperresponsiveness, presumably reflecting the slow healing of the damaged inflamed airway. It is important to recognize that

Figure 36–10. Effect of corticosteroids on inflammatory and structural cells in the airways.

corticosteroids *suppress* inflammation in the airways but do not cure the underlying disease. When steroids are withdrawn there is a recurrence of the same degree of airway hyperresponsiveness, although in patients with mild asthma it may take several months to return.

Effect on β_2 Adrenergic Responsiveness. Corticosteroids increase β adrenergic responsiveness, but whether this is relevant to their effect in asthma is uncertain. Steroids potentiate the effects of β agonists on bronchial smooth muscle and prevent and reverse β receptor desensitization in airways *in vitro* and *in vivo* (Barnes, 2002; Giermycz et al., 2008). At a molecular level, corticosteroids increase the transcription of the β_2 receptor gene in human lung *in vitro* and in the respiratory mucosa *in vivo* and also increase the stability of its messenger RNA. They also prevent or reverse uncoupling of β_2 receptors to G_s . In animal systems, corticosteroids prevent down-regulation of β_2 receptors.

β_2 Agonists also enhance the action of GR, resulting in increased nuclear translocation of liganded GR receptors and enhancing the binding of GR to DNA. This effect has been demonstrated in sputum macrophages of asthmatic patients after an ICS and inhaled LABA (Usmani et al., 2005). This suggests that β_2 agonists and corticosteroids enhance each other's beneficial effects in asthma therapy.

Pharmacokinetics. The pharmacokinetics of oral corticosteroids are described in Chapter 42. The pharmacokinetics of inhaled corticosteroids are important in relation to systemic effects (Barnes et al., 1998b). The fraction of steroid that is inhaled into the lungs acts locally on the airway mucosa but may be absorbed from the airway and alveolar surface. Thus, a portion of an inhaled dose reaches the systemic circulation. Furthermore, the fraction of inhaled steroid that is deposited in the oropharynx is swallowed and absorbed from the gut. The absorbed fraction may be metabolized in the liver (first-pass metabolism) before reaching the systemic circulation (Figure 36–3). The use of a spacer chamber reduces oropharyngeal deposition and therefore reduces systemic absorption of ICS, although this effect is minimal in corticosteroids with a high first-pass metabolism. Mouth rinsing and discarding the rinse have a similar effect, and this procedure should be used with high-dose dry powder steroid inhalers with which spacer chambers cannot be used.

Beclomethasone dipropionate and ciclesonide are prodrugs that release the active corticosteroid after the ester group is cleaved by esterases in the lung. Ciclesonide is available as a MDI (ALVESCO) for asthma and as a nasal spray for allergic rhinitis (OMNARIS). Budesonide and fluticasone propionate have a greater first-pass metabolism than beclomethasone dipropionate and are therefore less likely to produce systemic effects at high inhaled doses.

Inhaled Corticosteroids in Asthma. Inhaled corticosteroids are recommended as first-line therapy for all patients with persistent asthma. They should be started in any patient who needs to use a β_2 agonist inhaler for symptom control more than twice weekly. They are effective in mild, moderate, and severe asthma and in children as well as adults (Barnes et al., 1998b). Although it was recommended that ICS be initiated at a relatively high dose and then the dose reduced once control was achieved, there is no evidence that this is more effective than starting with the maintenance dose. Dose-response studies for ICS are relatively flat, with most of the benefit derived from doses <400 μg beclomethasone dipropionate or equivalent (Adams et al., 2008). However, some patients (with relative corticosteroid resistance) may benefit from higher doses (up to 2000 $\mu\text{g}/\text{day}$).

For most patients, ICS should be used twice daily, a regimen that improves compliance once control of asthma has been achieved (which may require four-times daily dosing initially or a course of oral steroids if symptoms are severe). Administration once daily of some steroids (e.g., budesonide, mometasone, and ciclesonide) is effective when doses ≤ 400 μg are needed. If a dose >800 μg daily via pMDI is used, a spacer device should be employed to reduce the risk of oropharyngeal side effects. ICS may be used in children in the same way as in adults; at doses ≤ 400 $\mu\text{g}/\text{day}$ there is no evidence of significant growth suppression (Pedersen, 2001). The dose of ICS should be the minimal dose that controls asthma; once control is achieved, the dose should be slowly reduced (Hawkins et al., 2003). Nebulized corticosteroids (e.g., budesonide) are useful in the treatment of small children who are not able to use other inhaler devices.

Inhaled Corticosteroids in Chronic Obstructive Pulmonary Disease. Patients with COPD occasionally respond to steroids, and these patients are likely to have concomitant asthma. Corticosteroids have no objective short-term benefit on airway function in patients with true COPD, although these agents often produce subjective benefit because of their euphoric effect. Corticosteroids do not appear to have any significant anti-inflammatory effect in COPD; there appears to be an active resistance mechanism, which may be explained by impaired activity of HDAC2 as a result of oxidative stress (Barnes, 2009). ICS have no effect on the progression of COPD, even when given to patients with presymptomatic disease; additionally, ICS have no effect on mortality (Calverley et al., 2007; Yang et al., 2007). ICS reduce the number of exacerbations in patients with severe COPD ($\text{FEV}_1 < 50\%$ predicted) who have frequent exacerbations and are recommended in these patients, although there is debate about whether these effects are due to inappropriate analysis of the data (Suissa et al., 2008). Oral corticosteroids are used to treat acute exacerbations of COPD, but the effect is very small (Niewoehner et al., 1999).

Patients with cystic fibrosis, which involves inflammation of the airways, are also resistant to high doses of ICS.

Systemic Steroids. Intravenous steroids are indicated in acute asthma if lung function is $<30\%$ predicted and in patients who show no significant improvement with nebulized β_2 agonist. Hydrocortisone is the steroid of choice because it has the most rapid onset (5-6 hours after administration), compared with 8 hours with prednisolone. The required dose is uncertain; it is common to give hydrocortisone 4 mg/kg initially, followed by a maintenance dose of 3 mg/kg every

6 hours. Methylprednisolone is also available for intravenous use, but there is no evidence that the high doses previously used (1 g) are more effective. Intravenous therapy is usually given until a satisfactory response is obtained, and then oral prednisolone may be substituted. Oral prednisolone (40-60 mg) has a similar effect to intravenous hydrocortisone and is easier to administer. A high dose of inhaled fluticasone propionate (2000 μg daily) is as effective as a course of oral prednisolone in controlling acute exacerbations of asthma in a family practice setting and in children in an emergency department setting, although this route of delivery is more expensive (Levy et al., 1996; Manjra et al., 2000).

Prednisolone and prednisone are the most commonly used oral steroids. Clinical improvement with oral steroids may take several days; the maximal beneficial effect is usually achieved with 30-40 mg prednisone daily, although a few patients may need 60-80 mg daily to achieve control of symptoms. The usual maintenance dose is ~ 10 -15 mg/day. Short courses of oral steroids (30-40 mg prednisolone daily for 1-2 weeks) are indicated for exacerbations of asthma; the dose may be tapered over 1 week after the exacerbation is resolved (the taper is not strictly necessary after a short course of therapy, but patients find it reassuring). Oral steroids are usually given as a single dose in the morning because this coincides with the normal diurnal increase in plasma cortisol and produces less adrenal suppression than if given in divided doses or at night. Alternate-day treatment has the advantage of less adrenal suppression, although in many patients control of asthma is not optimal on this regimen.

Adverse Effects. Corticosteroids inhibit ACTH and cortisol secretion by a negative feedback effect on the pituitary gland (Chapter 42). Hypothalamic-pituitary-adrenal (HPA) axis suppression depends on dose and usually only occurs with doses of prednisone >7.5 -10 mg/day. Significant suppression after short courses of corticosteroid therapy is not usually a problem, but prolonged suppression may occur after several months or years. *Steroid doses after prolonged oral therapy must be reduced slowly.* Symptoms of "steroid withdrawal syndrome" include lassitude, musculoskeletal pains, and, occasionally, fever. HPA suppression with inhaled steroids is usually seen only when the daily inhaled dose exceeds 2000 μg beclomethasone dipropionate or its equivalent daily.

Side effects of long-term oral corticosteroid therapy include fluid retention, increased appetite, weight gain, osteoporosis, capillary fragility, hypertension, peptic ulceration, diabetes, cataracts, and psychosis. Their frequency tends to increase with age. Very occasionally adverse reactions (such as anaphylaxis) to intravenous hydrocortisone have been described, particularly in aspirin-sensitive asthmatic patients.

The incidence of systemic side effects after ICS is an important consideration, particularly in children (Barnes et al., 1998b) (Table 36-4). Initial studies suggested that adrenal suppression occurred only with inhaled doses >1500 -2000 $\mu\text{g}/\text{day}$. More sensitive measurements of systemic effects include indices of bone metabolism, such as serum osteocalcin and urinary pyridinium cross-links, and in children, knemometry, which may be increased with inhaled doses as low as 400 $\mu\text{g}/\text{day}$ beclomethasone dipropionate in some patients. The clinical relevance of these measurements is not yet clear, however. Nevertheless, it is important to reduce the likelihood of systemic effects by using the lowest dose of inhaled steroid

Table 36–4

Side Effects of Inhaled Corticosteroids**Local side effects**

Psychiatric disturbances (euphoria, depression)
Pneumonia

needed to control the asthma, and by use of a large-volume spacer to reduce oropharyngeal deposition.

Several systemic effects of inhaled steroids have been described and include dermal thinning and skin capillary fragility (relatively common in elderly patients after high-dose inhaled steroids). Other side effects, such as cataract formation and osteoporosis, are reported but often in patients who are also receiving courses of oral steroids. There has been particular concern about the use of inhaled steroids in children because of growth suppression (Pedersen, 2001). Most studies have been reassuring that doses ≤ 400 $\mu\text{g}/\text{day}$ have not been associated with impaired growth; on the contrary, there may even be a growth spurt as asthma is better controlled. There is some evidence that use of high-dose ICS is associated with cataract and glaucoma, but it is difficult to dissociate the effects of ICS from the effects of courses of oral steroids that these patients usually require.

ICS may have *local side effects* due to the deposition of inhaled steroid in the oropharynx. The most common problem is hoarseness and weakness of the voice (dysphonia) due to atrophy of the vocal cords following laryngeal deposition of steroid; it may occur in up to 40% of patients and is noticed particularly by patients who need to use their voices during their work (lecturers, teachers, and singers). Throat irritation and coughing after inhalation are common with MDI and appear to be due to additives because these problems are not usually seen if the patient switches to a DPI. There is no evidence for atrophy of the lining of the airway. Oropharyngeal candidiasis occurs in $\sim 5\%$ of patients. There is no evidence for increased lung infections, including tuberculosis, in patients with asthma. Growing evidence suggests that high doses of ICS increase the risk of pneumonia in patients with COPD (Singh et al., 2009); although this is reported with high doses of fluticasone propionate, a similar increase in pneumonia has not been found with budesonide, which may be explained by its lower systemic effects (Sin et al., 2009).

It may be difficult to extrapolate systemic side effects of corticosteroids using data from normal subjects. In asthmatic patients, systemic absorption from the lung is reduced, presumably because

of reduced and more central deposition of the inhaled drug in more severe patients (Brutsche et al., 2000; Harrison et al., 2001); most of the inhaled drug deposits in larger airways, thereby limiting effects in the smaller airways where inflammation is also found, especially in patients with severe asthma. Corticosteroid MDIs with HFA propellants produce smaller aerosol particles and may have a more peripheral deposition, making them useful in treating patients with more severe asthma.

Therapeutic Choices. Numerous ICS are now available including beclomethasone dipropionate (QVAR), triamcinolone, flunisolide (AEROBID), budesonide (PULMICORT, others), fluticasone hemihydrate (AEROSPAN), fluticasone propionate (FLOVENT), mometasone furoate (ASMANEX), and ciclesonide (ALVESCO). All are equally effective as anti-asthma drugs, but there are differences in their pharmacokinetics: Budesonide, fluticasone, mometasone, and ciclesonide have a lower oral bioavailability than beclomethasone dipropionate because they are subject to greater first-pass hepatic metabolism; this results in reduced systemic absorption from the fraction of the inhaled drug that is swallowed (Derendorf et al., 2006) and thus reduced adverse effects. At high doses (>1000 μg), budesonide and fluticasone propionate have less systemic effects than beclomethasone dipropionate and triamcinolone, and they are preferred in patients who need high doses of ICS and in children. Ciclesonide is another choice; it is a prodrug that is converted to the active metabolite by esterases in the lung, giving it a low oral bioavailability and a high therapeutic index (Manning et al., 2008).

When doses of inhaled steroid exceed 800 μg beclomethasone dipropionate or equivalent daily, a large volume spacer is recommended to reduce oropharyngeal deposition and systemic absorption in the case of beclomethasone dipropionate. All currently available ICS are absorbed from the lung into the systemic circulation, so that some systemic absorption is inevitable. However, the amount of drug absorbed does not appear to have clinical effects in doses of <800 μg beclomethasone dipropionate equivalent. Although there are potency differences among corticosteroids, there are relatively few comparative studies, partly because dose comparison of corticosteroids is difficult due to their long time course of action and the relative flatness of their dose-response curves. Triamcinolone and flunisolide appear to be the least potent, with beclomethasone dipropionate and budesonide approximately of equal potency; fluticasone propionate is approximately twice as potent as beclomethasone dipropionate.

Future Developments. Early treatment with ICS in both adults and children may give a greater improvement in

lung function than if treatment is delayed (O'Byrne et al., 2006), likely reflecting the fact that corticosteroids are able to modify the underlying inflammatory process and prevent structural changes (fibrosis, smooth muscle hyperplasia, etc.) in the airway that occur as a result of chronic inflammation. ICS are currently recommended for patients with persistent asthmatic symptoms. There is evidence for airway inflammation in patients with episodic asthma, but at present ICS are recommended only when there are chronic symptoms (e.g., need for an inhaled β_2 agonist more than twice a week).

New corticosteroids with fewer systemic effects would be desirable. Corticosteroids that are rapidly metabolized in the airways ("soft steroids"), such as butixocort and tipredane, proved disappointing in clinical trials; they are probably metabolized too rapidly to achieve sufficient concentration and duration to cause an anti-inflammatory effect. There is a search for corticosteroids that are metabolized rapidly in the circulation after absorption from the lungs. The anti-inflammatory actions of corticosteroids may be mediated via different molecular mechanisms from side effects (which are endocrine and metabolic actions of corticosteroids). It has been possible to develop corticosteroids that dissociate the DNA-binding effect of corticosteroids (which mediates most of the adverse effects) from the inhibitory effect on transcription factors such as NF- κ B (which mediates much of the anti-inflammatory effect). Such "dissociated steroids" or selective glucocorticoid receptor agonists (SEGRAs) should, theoretically, retain anti-inflammatory activity but have a reduced risk of adverse effects; achieving this separation of desired and adverse effects is difficult *in vivo* (Schacke et al., 2007). Nonsteroidal SEGRAs are now in development.

Corticosteroid resistance is a major barrier to effective therapy in patients with severe asthma, in asthmatic patients who smoke, and in patients with COPD and cystic fibrosis (Barnes and Adcock, 2009). "Steroid-resistant" asthma is thought to be due to reduced anti-inflammatory actions of corticosteroids. Major strides have been made in understanding the molecular mechanisms for this corticosteroid resistance and in the development of therapies that have the potential to reverse this resistance and restore steroid responsiveness.

Cromones

Cromolyn sodium (sodium cromoglycate) is a derivative of khellin, an Egyptian herbal remedy and was found to protect against allergen challenge without any bronchodilator effect. A structurally related drug, *nedocromil* sodium, which has a similar pharmacological profile to cromolyn, was subsequently developed. Although cromolyn was popular in the past because of its good safety profile, its use has

sharply declined with the more widespread use of the more effective ICS, particularly in children. Neither cromolyn nor nedocromil is available in the U.S. for respiratory indications. For further information, consult earlier editions of this text.

MEDIATOR ANTAGONISTS

Many inflammatory mediators have been implicated in asthma and COPD, suggesting that inhibition of synthesis or receptors of these mediators may be beneficial (Barnes, 2004; Barnes et al., 1998a). However, specific inhibitors have been largely disappointing in both asthma and COPD treatment. Both H_1 antihistamines and anti-leukotrienes have been applied to airway disease, but their added benefit over β_2 agonists and corticosteroids is slight. The variability in patient response to anti-leukotriene agents may focus our attention on the roles of leukotriene synthesis, action, and metabolism to some, but not all, asthmatic disease.

Antihistamines. Histamine mimics many of the features of asthma and is released from mast cells in acute asthmatic responses, suggesting that antihistamines may be useful in asthma therapy. There is little evidence that histamine H_1 receptor antagonists provide any useful clinical benefit, as demonstrated by a meta-analysis (van Ganse et al., 1997). Newer antihistamines, including cetirizine and azelastine, have some beneficial effects, but this may be unrelated to H_1 receptor antagonism. Antihistamines are not recommended in the routine management of asthma.

Anti-leukotrienes. There is considerable evidence that cysteinyl-leukotrienes (LTs) are produced in asthma and that they have potent effects on airway function, inducing bronchoconstriction, airway hyperresponsiveness, plasma exudation, mucus secretion, and eosinophilic inflammation (Figure 36–11; also see Chapter 33 and Peters-Golden and Henderson, 2007). These data suggested that blocking the leukotriene pathways with leukotriene modifiers could be useful in the treatment of asthma, leading to the development of 5'-lipoxygenase (5-LO) enzyme inhibitors (of which zileuton [ZYFLO] is the only drug marketed) and several antagonists of the *cys-LT₁* receptor, including montelukast (SINGULAIR), zafirlukast (ACCOLATE), and pranlukast (not available in the U.S.).

Clinical Studies. Anti-leukotrienes have been intensively investigated in clinical studies (Calhoun, 2001). Leukotriene antagonists inhibit the bronchoconstrictor effect of inhaled LTD₄ in normal and asthmatic volunteers, and they also inhibit bronchoconstriction induced by a variety of challenges, including allergen, exercise, and cold air, by approximately 50%. With aspirin challenge, in aspirin-sensitive asthmatic patients, there is almost complete inhibition of the response (Szczeklik and Stevenson, 2003). Similar results have been obtained with the 5-LO inhibitor zileuton. This suggests there may be no advantage in blocking LTB₄ in addition to cysteinyl-LTs, in treating asthma. These drugs are active by oral administration, possibly an important advantage in chronic treatment.

In patients with mild to moderate asthma, anti-leukotrienes cause a significant improvement in lung function and asthma

Figure 36–11. Effects of cysteinyl-leukotrienes on the airways and their inhibition by anti-leukotrienes. AS, aspirin sensitive; 5-LO, 5'-lipoxygenase; LT, leukotriene; PAF, platelet-activating factor.

symptoms, with a reduction in the use of rescue inhaled β_2 agonists. Several studies show evidence for a bronchodilator effect, with an improvement in baseline lung function, suggesting that leukotrienes are contributing to the baseline bronchoconstriction in asthma, although this varies among patients. However, anti-leukotrienes are considerably less effective than inhaled corticosteroids in the treatment of mild asthma and cannot be considered the treatment of first choice (Ducharme, 2003). Anti-leukotrienes are indicated as an add-on therapy in patients who are not well controlled on ICS. The added benefit is small, equivalent to doubling the dose of ICS, and less effective than adding a LABA (Ducharme et al., 2006).

In patients with severe asthma who are not controlled on high doses of ICS and LABA, anti-leukotrienes do not appear to provide any additional benefit (Robinson et al., 2001). Theoretically, anti-leukotrienes should be of particular value in patients with aspirin-sensitive asthma because they block the airway response to aspirin challenge; however, their benefit is no greater here than in other types of asthma (Dahlen et al., 2002). Anti-leukotrienes are effective in preventing exercise-induced asthma, with efficacy similar to that of LABA (Coreno et al., 2000). Anti-leukotrienes also have a weak effect in rhinitis that may be additive with the effects of an antihistamine (Nathan, 2003).

Studies have demonstrated weak anti-inflammatory effects of anti-leukotrienes in reducing eosinophils in sputum and biopsies

(Minoguchi et al., 2002), but this is much less marked than with ICS and there is no additional anti-inflammatory effect when added to an ICS (O'Sullivan et al., 2003). Anti-leukotrienes therefore appear to act mainly as anti-bronchoconstrictor drugs, and they are clearly less broadly effective than β_2 agonists because they antagonize only one of several bronchoconstrictor mediators.

In COPD, Cys-LTs are not elevated in exhaled breath condensate, and cys-LT₁ receptor antagonists have no role in the therapy of COPD (Barnes, 2004). By contrast, LTB₄, a potent neutrophil chemoattractant, is elevated in COPD, indicating that 5-LO inhibitors that inhibit LTB₄ synthesis may have some potential benefit by reducing neutrophil inflammation. However, a pilot study failed to indicate any clear benefit of a 5-LO inhibitor in COPD patients (Gompertz and Stockley, 2002).

Adverse Effects. Zileuton, zafirlukast, and montelukast are all associated with rare cases of hepatic dysfunction; thus liver-associated enzymes should be monitored. Several cases of Churg-Strauss syndrome have been associated with the use of zafirlukast and montelukast. Churg-Strauss syndrome is a very rare vasculitis that may affect the heart, peripheral nerves, and kidney and is associated with increased circulating eosinophils and asthma. It is uncertain whether the reported cases are due to a reduction in oral or inhaled corticosteroid dose or are a direct effect of the drug. Cases of Churg-Strauss syndrome have been described in patients on anti-leukotrienes who

were not on concomitant corticosteroid therapy, suggesting there is a causal link (Nathani et al., 2008).

Future Developments. One of the major advantages of anti-leukotrienes is their effectiveness in tablet form. This may increase compliance with chronic therapy and makes treatment of children easier. Montelukast is effective as a once-daily preparation (10 mg in adults, 5 mg in children). In addition, oral administration may treat concomitant allergic rhinitis. However, the currently available clinical studies indicate a relatively modest effect on lung function and symptom control, which is less for every clinical parameter measured than with ICS. This is not surprising: There are many mediators besides cys-LTs involved in the pathophysiology of asthma, and it is unlikely that antagonism of a single mediator would be as effective as steroids, which inhibit multiple aspects of the inflammatory process in asthma. Similarly, if anti-leukotrienes are functioning in asthma as bronchodilators and anti-constrictors, it is unlikely that they will be as effective as a β_2 agonist, which will counteract bronchoconstriction regardless of the spasmogen. It is likely that anti-leukotrienes will be used less in the future because combination inhalers are the mainstay of asthma therapy.

An interesting feature of the clinical studies is that some patients appear to show better responses than others, suggesting that leukotrienes may play a more important role in some patients. The variability in response to anti-leukotrienes may reflect differences in production of or responses to leukotrienes in different patients, and this in turn may be related to polymorphisms of 5-LO, LTC₄ synthase, or cys-LT₁ receptors that are involved in the synthesis of leukotrienes (Tantisira and Drazen, 2009).

It is unlikely that further advances can be made in cys-LT₁-receptor antagonists if montelukast, a once-daily drug, is giving maximal receptor blockade. Cys-LT₂ receptors may be important in vascular and airway smooth muscle proliferative effects of cys-LT and are not inhibited by current cys-LT₁-receptor antagonists (Back, 2002). The role of the cys-LT₂ receptor in asthma is unknown, as is the value of its blockade. 5-LO inhibitors have some potential in COPD, cystic fibrosis, and possible severe asthma as LTB₄ may contribute to neutrophil chemoattraction in the lungs of these conditions.

IMMUNOMODULATORY THERAPIES

Immunosuppressive Therapy

Immunosuppressive therapy (e.g., methotrexate, cyclosporine A, gold, intravenous immunoglobulin) has been considered in asthma when other treatments have been unsuccessful or to reduce the dose of oral steroids required. However, immunosuppressive treatments are less effective and have a greater propensity to side effects than oral corticosteroids and therefore cannot be routinely recommended. The role of immunosuppressive therapy in COPD and cystic fibrosis has not been evaluated.

Anti-IgE Receptor Therapy

Increased specific IgE is a fundamental feature of allergic asthma. Omalizumab is a humanized monoclonal

antibody that blocks the binding of IgE to high-affinity IgE receptors (FcεR1) on mast cells and thus prevents their activation by allergens (Figure 36–12) (Avila, 2007). It also blocks binding on IgE to low-affinity IgE receptors (FcεRII, CD23) on other inflammatory cells, including T and B lymphocytes, macrophages, and possibly eosinophils, to inhibit chronic inflammation. Omalizumab also reduces levels of circulating IgE.

Clinical Use. Omalizumab is used for the treatment of patients with severe asthma. The antibody is administered by subcutaneous injection every 2–4 weeks, and the dose is determined by the titer of circulating IgE. Omalizumab reduces the requirement for oral and inhaled corticosteroids and markedly reduces asthma exacerbations. It is also beneficial in treating allergic rhinitis. Because of its very high cost, this treatment is generally used only in patients with very severe asthma who are poorly controlled even on oral corticosteroids and in patients with very severe concomitant allergic rhinitis (Walker et al., 2006). It may not be useful in concomitant atopic dermatitis due to the high levels of circulating IgE that cannot be neutralized. It may also be of value in protecting against anaphylaxis during specific immunotherapy. The major side effect of omalizumab is an anaphylactic response, which is uncommon (<0.1%) (Cox et al., 2007).

Specific Immunotherapy

Theoretically, specific immunotherapy with common allergens should be effective in preventing asthma. Although this treatment is effective in allergic rhinitis due to single allergens, there is little evidence that desensitizing injections to common allergens are effective in controlling chronic asthma (Rolland et al., 2009). Overall, the benefits of specific immunotherapy in asthma are small, and there are no well-designed studies comparing this treatment with effective treatments such as ICS. Sublingual immunotherapy is safer, but its role in asthma therapy has not yet been defined. Because there is a risk of anaphylactic and local reactions, and because the course of treatment is time consuming, this form of therapy cannot be routinely recommended for asthma.

The cellular mechanisms of specific immunotherapy are of interest. Specific immunotherapy induces the secretion of the anti-inflammatory cytokine IL-10 from regulatory helper T-lymphocytes (T_{reg}) and this blocks co-stimulatory signal transduction in T cells (via CD28) so that they are unable to react to allergens presented by antigen-presenting cells (Larche et al., 2006). Applying an understanding of the cellular processes involved might lead to safer and more effective approaches in the future. More specific immunotherapies may be developed with cloned allergen epitopes, T-cell peptide fragments of allergens, CpG oligonucleotides, and vaccines of conjugates of allergen and toll-like receptor (TLR)-9 to stimulate T_H1 immunity and suppress T_H2 immunity (Broide, 2009).

Figure 36–12. Immunoglobulin (Ig)E plays a central role in allergic diseases. Blocking IgE using an antibody, such as omalizumab, is a rational therapeutic approach. IgE may activate high-affinity receptors (FcεRI) on mast cells as well as low-affinity receptors (FcεRII, CD23) on other inflammatory cells. Omalizumab prevents these interactions and the resulting inflammation. cys-LT, cysteinyl-leukotriene; IL, interleukin; PG, prostaglandin.

New Drugs in Development for Asthma and Chronic Obstructive Pulmonary Disease

Novel Mediator Antagonists. Blocking the receptors or synthesis of inflammatory mediators is a logical approach to the development of new treatments for asthma and COPD. However, in both diseases many different mediators are involved, and therefore blocking a single mediator is unlikely to be very effective, unless it plays a unique and key role in the disease process (Barnes, 2004; Barnes et al., 1998a). Several specific mediator antagonists have been found to be ineffective in asthma, including antagonists/inhibitors of thromboxane, platelet-activating factor, bradykinin, and tachykinins. However, these blockers have often not been tested in COPD, in which different mediators are involved. A number of other approaches are under study, as noted next.

CRTh2 Antagonists. Chemotactic factor for T_H2 cells has been identified as prostaglandin D₂, which acts on a DP₂ receptor (Chapter 33). Several CRTh2 antagonists are now in development for asthma with promising initial results (Pettipher et al., 2007).

Endothelin Antagonists. Endothelin has been implicated in some of the structural changes that occur in asthma and COPD. Endothelin antagonists are approved for the treatment of pulmonary hypertension and might be useful in treating the structural changes that occur in asthma and COPD, but so far they have not been tested.

Antioxidants. Oxidative stress is important in severe asthma and COPD and may contribute to corticosteroid resistance. Existing antioxidants include vitamins C and E and *N*-acetyl-cysteine. These drugs have weak effects, but more potent antioxidants are in development (Kirkham and Rahman, 2006).

Inducible Nitric Oxide Synthase Inhibitors. NO production is increased in asthma and COPD as a result of increased inducible NO synthase (iNOS) expression in the airways (Chapter 3). NO and oxidative stress generate peroxynitrite anion (O=N-O⁻), which may nitrate proteins, leading to altered cell function. Several selective iNOS inhibitors are now in development (Hobbs et al., 1999), and one of these, L-N⁶-(1-imminoethyl)lysine (L-NIL), gives a profound and long-lasting reduction in the concentrations of NO in exhaled breath (Hansel et al., 2003). An iNOS inhibitor was found to be ineffective in asthma, however (Singh et al., 2007).

Cytokine Modifiers. Cytokines play a critical role in perpetuating and amplifying the inflammation in asthma and COPD, suggesting that anti-cytokines may be beneficial as therapies (Barnes, 2008a). Although most attention has focused on inhibition of cytokines, some cytokines are anti-inflammatory and may have therapeutic potential.

IL-5 plays a pivotal role in eosinophilic inflammation and is also involved in eosinophil survival and priming. It is an attractive target in asthma because it is essential for eosinophilic inflammation, there do not appear to be any other cytokines with a similar role, and lack of IL-5 in gene knockout mice does not have any deleterious effect. Anti-IL-5 antibodies inhibit eosinophilic inflammation and airway hyperresponsiveness in animal models of asthma, and they markedly reduce circulating and airway eosinophils in asthma patients but have no effect on airway hyperresponsiveness or clinical features of asthma (Flood-Page et al., 2007; Leckie et al., 2000). In carefully selected patients with severe asthma and persistent eosinophilia despite high doses of corticosteroids, there is a significant reduction in exacerbations (Haldar et al., 2009). Blocking

IL-4 and IL-13, which determine IgE synthesis (Figure 36–12), has so far proved to be ineffective in clinical studies.

TNF- α may play a key role in amplifying airway inflammation, through the activation of NF- κ B, AP-1, and other transcription factors. TNF- α production is increased in asthma and COPD, and it may be associated with the cachexia and weight loss that occur in some patients with severe COPD. In COPD patients and in patients with severe asthma, anti-TNF- α blocking antibodies have been ineffective, at the expense of increasing infections and malignancies (Rennard et al., 2007; Wenzel et al., 2009).

Chemokine Receptor Antagonists. Many chemokines are involved in asthma and COPD and play a key role in recruitment of inflammatory cells, such as eosinophils, neutrophils, macrophages, and lymphocytes into the lungs. Chemokine receptors are attractive targets because they are hepta-spanning membrane proteins; small molecule inhibitors are now in development (Donnelly and Barnes, 2006; Viola and Luster, 2008). In asthma, CCR3 antagonists, which should block eosinophil recruitment into the airways, are the most favored target, but several small molecule CCR3 antagonists have failed in development because of toxicity. In COPD, CXCR2 antagonists, which prevent neutrophil and monocyte chemotaxis due to CXCL chemokines such as CXCL1 and CXCL8, have been effective in animal models of COPD and in neutrophilic inflammation in normal subjects, and are now in clinical trials in COPD patients.

Protease Inhibitors

Several proteolytic enzymes are involved in the chronic inflammation of airway diseases. Mast cell tryptase has several effects on airways, including increasing responsiveness of airway smooth muscle to constrictors, increasing plasma exudation, potentiating eosinophil recruitment, and stimulating fibroblast proliferation. Some of these effects are mediated by activation of the proteinase-activated receptor PAR2. Tryptase inhibitors have so far proved to be disappointing in clinical studies.

Proteases are involved in the degradation of connective tissue in COPD, particularly enzymes that break down elastin fibers, such as neutrophil elastase and matrix metalloproteinases (MMP), which are involved in emphysema. Neutrophil elastase inhibitors have been difficult to develop, and there are no positive clinical studies in COPD patients. MMP9 appears to be the predominant elastolytic enzyme in emphysema, and several selective inhibitors are now in development.

New Anti-Inflammatory Drugs

Phosphodiesterase Inhibitors. The preservation and elevation of cellular cyclic AMP in inflammatory cells often reduces cell activation and release of inflammatory mediators. PDE4 is the predominant PDE isoform in inflammatory cells, including mast cells, eosinophils, neutrophils, T lymphocytes, macrophages, and structural cells such as sensory nerves and epithelial cells (Houslay et al., 2005), suggesting that PDE4 inhibitors could be useful as an anti-inflammatory treatment in both asthma and COPD. In animal models of asthma, PDE4 inhibitors reduce eosinophil infiltration and responses to allergen, whereas in COPD they are effective against smoke-induced inflammation and emphysema. Several PDE4 inhibitors have been tested clinically, but with disappointing results; their usefulness has been limited by side effects, particularly nausea, vomiting, headaches, and diarrhea. In COPD, an oral PDE4 inhibitor, roflumilast, has some effect in reducing exacerbations and improving lung function, but

side effects also limit its efficacy (Fabbri et al., 2009). Of the four subfamilies of PDE4, PDE4D is the major form whose inhibition is associated vomiting; inhibition of PDE4B is important for anti-inflammatory effects. Thus, selective PDE4B inhibitors may have a greater therapeutic index. Inhaled PDE4 inhibitors to reduce systemic absorption and adverse responses have proved to be ineffective. PDE5 inhibitors are vasodilators that are used in the treatment of pulmonary hypertension.

NF- κ B Inhibitors. NF- κ B plays an important role in the orchestration of chronic inflammation (Figure 36–9); many of the inflammatory genes that are expressed in asthma and COPD are regulated by this transcription factor (Barnes and Karin, 1997). This has prompted a search for specific blockers of these transcription factors. NF- κ B is naturally inhibited by the inhibitory protein I κ B, which is degraded after activation by specific kinases. Small molecule inhibitors of the I κ B kinase IKK2 (or IKK β) are in clinical development (Karin et al., 2004; Kishore et al., 2003). These drugs may be of particular value in COPD, where corticosteroids are largely ineffective. However, there are concerns that inhibition of NF- κ B may cause side effects such as increased susceptibility to infections, which has been observed in gene disruption studies when components of NF- κ B are inhibited.

Mitogen-Activated Protein Kinase Inhibitors. There are three major MAP kinase pathways, and there is increasing recognition that these pathways are involved in chronic inflammation (Delhase et al., 2000). There has been particular interest in the p38 MAP kinase pathway that is blocked by a novel class of drugs, such as SB203580 and RWJ67657. These drugs inhibit the synthesis of many inflammatory cytokines, chemokines, and inflammatory enzymes (Cuenda and Rousseau, 2007). The p38 MAPK inhibitors are in development for the treatment of asthma (they inhibit T_H2 cytokine synthesis) and for COPD (they inhibit neutrophilic inflammation and signaling of inflammatory cytokines and chemokines). However, clinical studies have revealed marked adverse effects and toxicities; inhaled delivery is being explored.

Mucoregulators

Many pharmacological agents may influence the secretion of mucus in the airways, but there are few drugs that have demonstrably useful clinical effects on mucus hypersecretion (Rogers and Barnes, 2006). Mucus hypersecretion occurs in chronic bronchitis, COPD, cystic fibrosis, and asthma. In chronic bronchitis, mucus hypersecretion is related to chronic irritation by cigarette smoke and may involve neural mechanisms and the activation of neutrophils to release enzymes such as neutrophil elastase and proteinase-3 that have powerful stimulatory effects on mucus secretion. Mast cell-derived chymase is also a potent mucus secretagogue. This suggests that several classes of drugs may be developed to control mucus hypersecretion.

A major problem in assessing the effects of drugs on mucus hypersecretion is the difficulty in accurately quantifying airway mucus production, quality, and clearance. Several current drugs for airway disease might affect mucus production. Systemic anticholinergic drugs appear to reduce mucociliary clearance, but this is not observed with either ipratropium bromide or tiotropium bromide, presumably reflecting their poor absorption from the respiratory tract. β_2 Agonists increase mucus production and mucociliary clearance and have been shown to increase ciliary beat

frequency *in vitro*. Because inflammation leads to mucus hypersecretion, anti-inflammatory treatments should reduce mucus hypersecretion; ICS are very effective in reducing increased mucus production in asthma.

Sensory nerves and neuropeptides are important in the secretory activities of the submucosal gland (which predominates in proximal airways) and goblet cell (more notable in peripheral airways). Opioids and K⁺ channel openers inhibit mucus secretion mediated via sensory neuropeptide release; peripherally acting opioids may be developed to control mucus hypersecretion due to irritants in the future (Rogers, 2002).

Mucolytics

Several agents can reduce the viscosity of sputum *in vitro*. One group are derivatives of cysteine that reduce the disulfide bridges that bind glycoproteins to other proteins such as albumin and secretory IgA. These drugs also act as antioxidants and may therefore reduce airway inflammation. Only *N*-acetylcysteine (MUCOMYST, others) is available in the U.S.; carbocysteine, methyleysteine, erdosteine, and bromhexine are available elsewhere. Orally administered, these agents are relatively well tolerated, but clinical studies in chronic bronchitis, asthma, and bronchiectasis have been disappointing. A systematic review of several small studies showed a small benefit in terms of reducing exacerbations, with most of the benefit from *N*-acetylcysteine; whether this relates to the mucolytic activity of *N*-acetylcysteine or to its action as an antioxidant is unclear (Poole and Black, 2001). A large controlled study of oral *N*-acetylcysteine in COPD patients showed no effect in disease progress or in preventing exacerbations, although there was some benefit in the patients not treated with inhaled corticosteroids (Decramer et al., 2005), as confirmed in a subsequent study of carbocysteine in COPD patients not treated with other medications (Zheng et al., 2008). *N*-acetylcysteine is not currently recommended for COPD management.

DNase (dornase alfa, PULMOZYME) reduces mucus viscosity in sputum of patients with cystic fibrosis and is indicated if there is significant symptomatic and lung function improvement after a trial of therapy (Henke and Ratjen, 2007). There is no evidence that dornase alfa is effective in COPD or asthma, however.

The epidermal growth factor receptor (EGFR) plays a critical role in airway mucus secretion from goblet cells and submucosal glands and appears to mediate the mucus secretory response to several secretagogues, including oxidative stress, cigarette smoke, inflammatory cytokines, and activated TLRs (Burgel and Nadel, 2004). Small molecule inhibitors of EGFR kinase, such as gefitinib and erlotinib, have been developed for use as anticancer therapies and are currently being assessed as treatments for mucus hypersecretion in COPD patients.

Expectorants

Expectorants are oral drugs that are supposed to enhance the clearance of mucus. Although expectorants were once commonly prescribed, there is little or no objective evidence for their efficacy. Such drugs are often emetics that are given in sub-emetic doses on the basis that gastric irritation may stimulate an increase in mucus clearance via a reflex mechanism. However, there is no good evidence for this assumption. Lacking evidence for their efficacy, the FDA has removed most expectorants from the market in a review of over-the-counter drugs. With the exception of guaifenesin, no agents are

approved as expectorants in the U.S. In patients who find it difficult to clear mucus, adequate hydration and inhalation of steam may be of some benefit.

ANTITUSSIVES

Despite the fact that cough is a common symptom of airway disease, its mechanisms are poorly understood, and current treatment is unsatisfactory (Pavord and Chung, 2008). Viral infections of the upper respiratory tract are the most common cause of cough; postviral cough is usually self-limiting and commonly patient-medicated. Their wide use notwithstanding, over-the-counter cough medications are largely ineffective (Dicpinigaitis, 2009a). Because cough is a defensive reflex, its suppression may be inappropriate in bacterial lung infection. Before treatment with antitussives, it is important to identify underlying causal mechanisms that may require therapy.

Whenever possible, treat the underlying cause, not the cough. Asthma commonly presents as cough, and the cough will usually respond to ICS. A syndrome characterized by cough in association with sputum eosinophilia but no airway hyperresponsiveness and termed *eosinophilic bronchitis* also responds to ICS (Birring et al., 2003). Nonasthmatic cough does not respond to ICS but sometimes responds to anticholinergic therapy. The cough associated with postnasal drip of sinusitis responds to antibiotics (if warranted), nasal decongestants, and intranasal steroids. The cough associated with ACE inhibitors (in ~15% of patients treated) responds to lowering the dose or withdrawal of the drug and substitution of an AT₁ receptor antagonist (Chapter 26). Gastroesophageal reflux is a common cause of cough through a reflex mechanism and occasionally as a result of acid aspiration into the lungs. This cough may respond to suppression of gastric acid with an H₂ receptor antagonist or a proton pump inhibitor (Chapter 45), although even large doses may not always be effective (Chang et al., 2006). Some patients have a chronic cough with no obvious cause, and this chronic idiopathic cough may be due to airway sensory neural hyperesthesia (Haque et al., 2005).

Opiates. Opiates have a central mechanism of action on μ opioid receptors in the medullary cough center, but there is some evidence that they may have additional peripheral action on cough receptors in the proximal airways. Codeine and pholcodine (not available in the U.S.) are commonly used, but there is little evidence that they are clinically effective, particularly on postviral cough; in addition, they are associated with sedation and constipation (Dicpinigaitis, 2009a). Morphine and methadone are effective but indicated only for intractable cough associated with bronchial carcinoma. A peripherally acting opioid agonist, 443C81, does not appear to be effective for cough.

Dextromethorphan. Dextromethorphan is a centrally active *N*-methyl-D-aspartate (NMDA) receptor antagonist. It may also antagonize opioid receptors. Despite the fact that it is in numerous over-the-counter cough suppressants and used commonly to treat cough, it is poorly effective. In children with acute nocturnal cough, it is not significantly different from placebo in reducing cough

(Dicpinigaitis, 2009a). It can cause hallucinations at higher doses and has significant abuse potential.

Benzonatate. (TESSALON, others), a local anesthetic, acts peripherally by anesthetizing the stretch receptors located in the respiratory passages, lungs, and pleura. By dampening the activity of these receptors, benzonatate may reduce the cough reflex at its source. The recommended dose is 100 mg, three times/day, and up to 600 mg/day, if needed. Although clinical studies shortly after its approval showed some efficacy, benzonatate, 200 mg, was not effective in suppressing experimentally-induced cough in a recent clinical trial (Dicpinigaitis et al., 2009b). Side effects include dizziness and dysphagia. Seizures and cardiac arrest have occurred following an acute ingestion. Severe allergic reactions have been reported in patients allergic to para-aminobenzoic acid, a metabolite of benzonatate.

Other Drugs. Several other drugs reportedly have small benefits in protecting against cough challenges or in reducing cough in pulmonary diseases (Dicpinigaitis, 2009a). These drugs include moguisteine (not available in the U.S.), which acts peripherally and appears to open ATP-sensitive K⁺ channels; baclofen, a GABA_B-selective agonist; and theobromine, a naturally occurring methylxanthine. Although the expectorant guaifenesin is not typically known as a cough suppressant, it is significantly better than placebo in reducing acute viral cough and inhibits cough-reflex sensitivity in patients with upper respiratory tract infections (Dicpinigaitis et al., 2009b).

Novel Antitussives. There is clearly a need to develop new more effective therapies for cough, particularly drugs that act peripherally in order to avoid sedation. There are close analogies between chronic cough and sensory hyperesthesia, so new therapies are likely to arise from pain research (Barnes, 2007).

Transient Receptor Potential V1 Antagonists. TRPV1 (previously called the vanilloid receptor) is a member of the transient receptor potential (TRP) family of ion channels activated by capsaicin, H⁺, and bradykinin, all of which are potent tussive agents. TRPV1 antagonists block cough induced by capsaicin and bradykinin and are effective in some models of cough (McLeod et al., 2008). A side effect of these drugs is loss of temperature regulation and hyperthermia, which has prevented clinical development.

Transient Receptor Potential A1 Antagonists. TRPA1 is emerging as a more promising novel target for antitussives. This channel is activated by oxidative stress and many irritants and may be sensitized by inflammatory cytokines (Taylor-Clark et al., 2009). Several selective TRPA1 antagonists are now in development.

DRUGS FOR DYSPNEA AND VENTILATORY CONTROL

Drugs for Dyspnea

Bronchodilators should reduce breathlessness in patients with airway obstruction. Chronic oxygen may have a beneficial effect, but in a few patients dyspnea may be extreme. Drugs that reduce breathlessness may also depress ventilation in parallel and may therefore be dangerous in severe asthma and COPD. Some patients show

a beneficial response to dihydrocodeine and diazepam; however, these drugs must be used with great caution because of the risk of ventilatory depression. Slow-release morphine tablets may also be helpful in COPD patients with extreme dyspnea (Currow and Abernethy, 2007). Nebulized morphine may also reduce breathlessness in COPD and could act in part on opioid receptors in the lung. Nebulized furosemide has some efficacy in treating dyspnea from a variety of causes, but the evidence is not yet sufficiently convincing to recommend this as routine therapy (Newton et al., 2008).

Ventilatory Stimulants

Several classes of drug stimulate ventilation and are indicated when ventilatory *drive* is inadequate. Nikethamide and ethamivan were originally introduced as respiratory stimulants, but effective doses are close to those causing convulsions so the use of these agents has ceased. More selective respiratory stimulants have been developed and are indicated if ventilation is impaired as a result of overdose with sedatives, in postanesthetic respiratory depression, and in idiopathic hypoventilation. Respiratory stimulants are rarely indicated in COPD because respiratory drive is already maximal and further stimulation of ventilation may be counterproductive because of the increase in energy expenditure caused by the drugs.

Doxapram (DOPRAM, others). At low doses (0.5 mg/kg IV), doxapram stimulates carotid chemoreceptors; at higher doses it stimulates medullary respiratory centers. Its effect is transient; thus, intravenous infusion (0.3-3 mg/kg per minute) is needed for sustained effect. Unwanted effects include nausea, sweating, anxiety, and hallucinations. At higher doses, increased pulmonary and systemic pressures may occur. Both the kidney and the liver participate in the clearance of doxapram, which should be used with caution if hepatic or renal function is impaired. In COPD, the infusion of doxapram is restricted to 2 hours. The use of doxapram to treat ventilatory failure in COPD has now largely been replaced by noninvasive ventilation (Greenstone and Lasserson, 2003).

Almitrine. Almitrine bismesylate is a piperazine derivative that appears to selectively stimulate peripheral chemoreceptors and is without central actions (Winkelmann et al., 1994). It is ineffective in patients with surgically removed carotid bodies. Almitrine stimulates ventilation only when there is hypoxia. Long-term use of almitrine is associated with peripheral neuropathy, limiting its availability in most countries.

Acetazolamide. The carbonic anhydrase inhibitor acetazolamide (Chapter 25) induces metabolic acidosis and thereby stimulates ventilation, but it is not widely used because the metabolic imbalance it produces may be detrimental in the face of respiratory acidosis. It has a very small beneficial effect in respiratory failure in COPD patients (Jones and Greenstone, 2001). The drug has proved useful in prevention of high altitude sickness (Basnyat and Murdoch, 2003).

Naloxone. Naloxone is a competitive opioid antagonist that is indicated only if ventilatory depression is due to overdose of opioids.

Flumazenil. Flumazenil is a benzodiazepine receptor antagonist that can reverse respiratory depression due to overdose of benzodiazepines (Gross et al., 1996).

PHARMACOTHERAPY OF PULMONARY ARTERIAL HYPERTENSION

Pulmonary arterial hypertension (PAH) is characterized by vascular proliferation and remodeling of small pulmonary arteries, resulting in a progressive increase in pulmonary vascular resistance, which may lead to right heart failure and death (Morrell et al., 2009). PAH involves dysfunction of pulmonary vascular endothelial and smooth muscle cells and their interplay and results from an imbalance in vasoconstrictor and vasodilator mediators.

Vasodilators are the mainstay of drug therapy for PAH (Barnes and Liu, 1995). However, the vasodilators used to treat systemic hypertension are problematic: they lower systemic blood pressure, which may result in reduced pulmonary perfusion. Calcium channel blockers, such as nifedipine, are poorly effective, but a few patients may benefit. There have been important advances in the development of more selective pulmonary vasodilators, based on a better understanding of the pathophysiology of PAH (McLaughlin et al., 2009). In PAH, there is an increase in the vasoconstrictor mediators endothelin-1, thromboxane A_2 , and serotonin, and a decrease in the vasodilating mediators prostacyclin (PGI_2), NO, and VIP (Figure 36–13) (Humbert et al., 2004). Therapies aim at antagonizing the vasoconstrictive mediators and enhancing vasodilation. Because different classes of vasodilators work through different mechanisms, it may be possible to increase efficacy while reducing adverse effects by using combinations of agents from different classes in therapy of PAH.

Primary (idiopathic and familial) pulmonary hypertension (PPAH), where there is no identifiable cause, is uncommon. Most cases of pulmonary hypertension are associated with connective tissue disorders, such as systemic sclerosis, or they are secondary to hypoxic lung diseases, such as interstitial lung disease and COPD, where chronic hypoxia leads to hypoxic pulmonary vasoconstriction. Secondary pulmonary hypertension in COPD rarely requires specific therapy. In secondary pulmonary hypertension due to chronic hypoxia, the initial treatment is correction of hypoxia using supplementary O_2 therapy, including ambulatory oxygen, with the aim of increasing O_2 saturation to $>90\%$. Right heart failure is treated initially with diuretics. Anticoagulants are indicated for the treatment of pulmonary hypertension secondary to chronic thromboembolic disease, but they may also be indicated for patients with severe pulmonary hypertension who have an increased risk of venous thrombosis.

Prostacyclin. Prostacyclin (PGI_2 ; Epoprostenol) is produced by endothelial cells in the pulmonary circulation and directly relaxes pulmonary vascular smooth muscle cells by increasing intracellular cyclic AMP concentrations (see Chapter 33). Reduced prostacyclin production in PAH has led to the therapeutic use of poprostenol and other stable prostacyclin derivatives (Gomberg-Maitland and Olschewski, 2008). Functionally and physiologically, PGI_2 opposes the effects of TXA_2 .

Intravenous poprostenol (FLOLAN, others) is effective in lowering pulmonary arterial pressures, improving exercise performance, and prolonging survival in PPAH. Because of its short plasma $t_{1/2}$, prostacyclin must be administered by continuous intravenous infusion using an infusion pump. Common side effects are headache, flushing, diarrhea, nausea, and jaw pain. Continuous intravenous infusion is inconvenient and very expensive. This has led to the development of more stable prostacyclin analogs. Treprostinil (REMODULIN) is given by continuous subcutaneous infusion or as an inhalation (TYVASO), consisting of four daily treatment sessions with nine breaths per session. Oral beraprost sodium appears to be somewhat less effective and its effect seems to diminish after 3 months of therapy, so it has not been approved in most countries. Iloprost (VENTAVIS) is a stable analog that is given by inhalation, but it needs to be given by nebulizer six to nine times daily. It is associated with the vasodilator side effects of prostacyclin, including syncope. It may also cause cough and bronchoconstriction because it sensitizes airway sensory nerves.

Endothelin Receptor Antagonists

Endothelin-1 (ET-1) is a potent pulmonary vasoconstrictor that is produced in increased amounts in PAH. ET-1 contracts vascular smooth muscle cells and causes proliferation mainly via ET_A receptors. ET_B receptors mediate the release of prostacyclin and NO from endothelial cells. Several endothelin antagonists are now on the market for the treatment of PPAH (see Chapter 26).

Bosentan (TRACLEER) was the first ET antagonist developed and is an antagonist of both ET_A and ET_B receptors. Several long-term clinical trials have now established the efficacy of oral bosentan in reducing symptoms and improving mortality in PPAH. Starting dose is 62.5 mg twice daily for 4 weeks, then increasing to the maintenance dose of 125 mg twice daily. The drug is generally well tolerated. Adverse effects include abnormal liver function tests, anemia, headaches, peripheral edema, and nasal congestion. Given the risk of serious liver injury, liver aminotransferases should be monitored monthly. A class effect is a risk of testicular atrophy and infertility; bosentan is potentially teratogenic.

Ambrisentan (LETAIRIS) is selective ET_A receptor antagonist. It is given orally once daily at a dose of 5–10 mg. The theoretical advantage of blocking only ET_A receptors is that ET_B receptors may continue to stimulate release of PGI_2 and NO, giving a greater therapeutic effect. However, its clinical efficacy is similar to that of bosentan, as are its adverse effects. Use of ambrisentan also requires monthly monitoring of liver aminotransferases. *Sitaxsentan* (not available in the U.S.) is similar to ambrisentan but may be less likely to cause liver dysfunction.

Phosphodiesterase 5 Inhibitors

Nitric oxide activates soluble guanylate cyclase to increase cyclic GMP, which is hydrolyzed to 5'GMP by PDE5 (Chapter 27). Elevation of cGMP in smooth muscle causes relaxation (Chapter 3),

Figure 36–13. Interactions of endothelium and vascular smooth muscle in pulmonary artery hypertension (PAH). **A.** In normal pulmonary artery, there is a balance between constrictor and relaxant influences that may be viewed as competition between Ca²⁺ signaling pathways and cyclic nucleotide signaling pathways in vascular smooth muscle (VSM). Endothelin (ET-1) binds to the ET_A receptor on VSM cells and activates the G_q-PLC-IP₃ pathway to increase cytosolic Ca²⁺; ET-1 may also couple to G_i to inhibit cyclic AMP (cAMP) production. In depolarizing VSM cells, Ca²⁺ may enter via the L-type Ca²⁺ channel (Ca_v1.2). Endothelial cells also produce relaxant factors, prostacyclin (PGI₂) and NO. NO stimulates the soluble guanylyl cyclase (cGC), causing accumulation of cyclic GMP (cGMP) in VSM cells; PGI₂ binds to the IP prostanoid receptor and stimulates the G_s-adenylyl cyclase pathway to enhance cAMP accumulation; elevation of these cyclic nucleotides promotes VSM relaxation (see Chapter 3). **B.** In PAH, ET-1 production is enhanced, production of PGI₂ and NO is reduced, and the balance is shifted toward constriction and proliferation of vascular smooth muscle. **C.** In treating PAH, ET_A receptor antagonists can reduce the constrictor effects of ET-1, and Ca²⁺ channel antagonists can further reduce Ca²⁺-dependent contraction. Exogenous PGI₂ and NO can be supplied to promote vasodilation (relaxation of VSM); inhibition of PDE5 can enhance the relaxant effect of NO by inhibiting the degradation of cGMP, thereby promoting intracellular accumulation of cGMP and relaxation of VSM. Thus, these drugs can reduce Ca²⁺ signaling and enhance cyclic nucleotide signaling, restoring the balance between the forces of contraction/proliferation and relaxation/anti-proliferation. Remodeling and deposition of extracellular matrix by adjacent fibroblasts is influenced positively and negatively by the same contractile and relaxant signaling pathways, respectively.

which the inhibition of PDE5 prolongs and accentuates. In the pulmonary bed, inhibition of PDE5 induces vasodilation.

Sildenafil. Sildenafil (REVATIO) is a selective PDE5 inhibitor that is given at a dose (20 mg three times daily orally) that is lower than used for erectile dysfunction (100 mg; Chapter 27). It is effective in lowering pulmonary resistance and improving exercise tolerance in patients with PAH. Side effects include headache, flushing, dyspepsia, and visual disturbances.

Tadalafil. Tadalafil (ADCIRCA) has a longer duration of action than sildenafil so may be suitable for once-daily dosing. It is approved for World Health Organization group 1 PAH to improve exercise ability.

chapter

Hematopoietic Agents: Growth Factors, Minerals, and Vitamins

Kenneth Kaushansky
and Thomas J. Kipps

The finite life span of most mature blood cells requires their continuous replacement, a process termed *hematopoiesis*. New cell production must respond to basal needs and states of increased demand. Red blood cell production can increase >20-fold in response to anemia or hypoxemia, white blood cell production increases dramatically in response to a systemic infection, and platelet production can increase 10- to 20-fold when platelet consumption results in thrombocytopenia.

The regulation of blood cell production is complex. Hematopoietic stem cells are rare bone marrow cells that manifest self-renewal and lineage commitment, resulting in cells destined to differentiate into the nine distinct blood-cell lineages. For the most part, this process occurs in the marrow cavities of the skull, vertebral bodies, pelvis, and proximal long bones; it involves interactions among hematopoietic stem and progenitor cells and the cells and complex macromolecules of the marrow stroma, and is influenced by a number of soluble and membrane-bound hematopoietic growth factors. A number of these hormones and cytokines have been identified and cloned, permitting their production in quantities sufficient for therapeutic use. Clinical applications range from the treatment of primary hematologic diseases to use as adjuncts in the treatment of severe infections and in the management of patients who are undergoing cancer chemotherapy or marrow transplantation.

Hematopoiesis also requires an adequate supply of minerals (e.g., iron, cobalt, and copper) and vitamins (e.g., folic acid, vitamin B₁₂, pyridoxine, ascorbic acid, and riboflavin); deficiencies generally result in

characteristic anemias, or, less frequently, a general failure of hematopoiesis (Hoffbrand and Herbert, 1999; Wrighting and Andrews, 2008). Therapeutic correction of a specific deficiency state depends on the accurate diagnosis of the anemic state, knowledge about the correct dose, the use of these agents in various combinations, and the expected response. This chapter deals with the growth factors, vitamins, minerals, and drugs that affect the blood and blood-forming organs.

Hematopoietic Growth Factors

History. Modern concepts of hematopoietic cell growth and differentiation arose in the 1950s when cells from the spleen and marrow were shown to play an important role in the restoration of hematopoietic tissue in irradiated animals. In 1961, Till and McCulloch demonstrated that individual hematopoietic cells could form macroscopic hematopoietic colonies in the spleens of irradiated mice. Their work established the concept of discrete hematopoietic stem cells, which can be experimentally identified, albeit in retrospect (i.e., the presence of a multilineage clonal splenic colony appearing 11 days after transplantation implied that a single cell lodged and expanded into several cell lineages). This concept now has been expanded to include normal human marrow cells. Moreover, such cells now can be prospectively identified.

The basis for identifying soluble growth factors was provided by Sachs and independently by Metcalf, who developed clonal, *in vitro* assays for hematopoietic progenitor cells. Initially, such hematopoietic colonies developed only in the presence of conditioned culture medium from leukocytes or tumor cell lines.

Individual growth factors then were isolated based on their activities in clonal *in vitro* assays. Many of these same assays were instrumental in purifying a hierarchy of progenitor cells committed to individual and combinations of mature blood cells (Akashi, 2000; Nakorn, 2003).

The existence of a circulating growth factor that controls red blood cell development was first suggested by the experiments of Paul Carnot in 1906. He observed an increase in the red-cell count in rabbits injected with serum obtained from anemic animals and postulated the existence of a factor that he called hemopoietin. However, it was not until the 1950s that Reissmann, Erslev, and Jacobsen and coworkers defined the origin and actions of the hormone, now called erythropoietin. Subsequently, extensive studies of erythropoietin were carried out in patients with anemia and polycythemia, leading to the purification of erythropoietin from urine and the subsequent cloning of the erythropoietin gene. The high-level expression of erythropoietin in cell lines has allowed for its purification and use in humans with anemia.

Similarly, the existence of specific leukocyte growth factors was suggested by the capacity of different conditioned culture media to induce the *in vitro* growth of colonies containing different combinations of granulocytes and monocytes. An activity that stimulated the production of both granulocytes and monocytes was purified from murine lung-conditioned medium, leading to cloning of granulocyte/macrophage colony-stimulating factor (G-CSF), first from mice (Gough et al., 1984) and subsequently from humans (Wong, 1985). Finding an activity that stimulated the exclusive production of neutrophils permitted the cloning of granulocyte colony-stimulating factor (G-CSF) (Welte et al., 1985). Subsequently, a megakaryocyte colony-stimulating factor termed thrombopoietin was purified and cloned (Kaushansky, 1998).

The growth factors that support lymphocyte growth were not identified using *in vitro* colony-forming assays but rather using assays that measured the capacity of the cytokine to promote lymphocyte proliferation *in vitro*. This permitted the identification of the growth-promoting properties of interleukin (IL)-7, IL-4, or IL-15 for all lymphocytes, B cells, or NK cells, respectively (Goodwin et al., 1989; Grabstein et al., 1994). Again, recombinant expression of these cDNAs permitted production of sufficient quantities of biologically active growth factors for clinical investigations, allowing for the demonstration of the potential clinical utility of such factors.

Growth Factor Physiology. Steady-state hematopoiesis encompasses the production of >400 billion blood cells each day. This production is tightly regulated and can be increased several fold with increased demand. The hematopoietic organ also is unique in adult physiology in that several mature cell types are derived from a much smaller number of multipotent progenitors, which develop from a more limited number of pluripotent hematopoietic stem cells. Such cells are capable of maintaining their own number and differentiating under the influence of cellular and humoral factors to produce the large and diverse number of mature blood cells.

Stem cell differentiation can be described as a series of steps that produce so-called burst-forming

units (BFU) and colony-forming units (CFU) for each of the major cell lines. These early progenitors (BFU and CFU) are capable of further proliferation and differentiation, increasing their number by some 30-fold. Subsequently, colonies of morphologically distinct cells form under the control of an overlapping set of additional growth factors (G-CSF, M-CSF, erythropoietin, and thrombopoietin). Proliferation and maturation of the CFU for each cell line can amplify the resulting mature cell product by another 30-fold or more, generating >1000 mature cells from each committed stem cell.

Hematopoietic and lymphopoietic growth factors are glycoproteins produced by a number of marrow cells and peripheral tissues. They are active at very low concentrations and typically affect more than one committed cell lineage. Most interact synergistically with other factors and also stimulate production of additional growth factors, a process called *networking*. Growth factors generally exert actions at several points in the processes of cell proliferation and differentiation and in mature cell function. However, the network of growth factors that contributes to any given cell lineage depends absolutely on a nonredundant, lineage-specific factor, such that absence of factors that stimulate developmentally early progenitors is compensated for by redundant cytokines, but loss of the lineage-specific factor leads to a specific cytopenia. Some of the overlapping and nonredundant effects of the more important hematopoietic growth factors are illustrated in Figure 37–1 and listed in Table 37–1.

ERYTHROPOIESIS STIMULATING AGENTS

Erythropoiesis stimulating agent (ESA) is the term given to a pharmacological substance that stimulates red blood cell production. Although erythropoietin is not the sole growth factor responsible for erythropoiesis, it is the most important regulator of the proliferation of committed erythroid progenitors (CFU-E) and their immediate progeny. In its absence, severe anemia is invariably present, commonly seen in patients with renal failure. Erythropoiesis is controlled by a feedback system in which a sensor in the kidney detects changes in oxygen delivery to modulate the erythropoietin secretion. The sensor mechanism is now understood at the molecular level (Maxwell et al., 2001). Hypoxia-inducible factor (HIF-1) is a heterodimeric (HIF-1 α and

Figure 37–1. Sites of action of hematopoietic growth factors in the differentiation and maturation of marrow cell lines. A self-sustaining pool of marrow stem cells differentiates under the influence of specific hematopoietic growth factors to form a variety of hematopoietic and lymphopoietic cells. Stem cell factor (SCF), ligand (FL), interleukin-3 (IL-3), and granulocyte-macrophage colony-stimulating factor (GM-CSF), together with cell–cell interactions in the marrow, stimulate stem cells to form a series of burst-forming units (BFU) and colony-forming units (CFU): CFU-GEMM (granulocyte, erythrocyte, monocyte and megakaryocyte), CFU-GM (granulocyte and macrophage), CFU-Meg (megakaryocyte), BFU-E (erythrocyte), and CFU-E (erythrocyte). After considerable proliferation, further differentiation is stimulated by synergistic interactions with growth factors for each of the major cell lines—granulocyte colony-stimulating factor (G-CSF), monocyte/macrophage-stimulating factor (M-CSF), thrombopoietin, and erythropoietin. Each of these factors also influences the proliferation, maturation, and in some cases the function of the derivative cell line (Table 37–1).

HIF-1 β) transcription factor that enhances expression of multiple hypoxia-inducible genes, such as vascular endothelial growth factor and erythropoietin. HIF-1 α is labile due to its prolyl hydroxylation and subsequent polyubiquitination and degradation, aided by the von Hippel-Lindau (VHL) protein. During states of hypoxia, the prolyl hydroxylase is inactive, allowing the accumulation of HIF-1 α and activating erythropoietin expression, which in turn stimulates a rapid expansion of erythroid progenitors. Specific alteration of VHL leads to an oxygen-sensing defect, characterized by constitutively elevated levels of HIF-1 α and erythropoietin, with a resultant polycythemia (Gordeuk et al., 2004). Recently, a potential role for a second isoform of

HIF, HIF-2 α , was identified in erythropoiesis because genetic gain-of-function mutation of that gene induces erythrocytosis in patients (Percy et al., 2008).

Erythropoietin is encoded by a single copy gene on human chromosome 7 that is expressed primarily in peritubular interstitial cells of the kidney. Erythropoietin contains 193 amino acids, of which the first 27 are cleaved during secretion. The final hormone is heavily glycosylated and has a molecular mass of ~30,000 Da. After secretion, erythropoietin binds to a receptor on the surface of committed erythroid progenitors in the marrow and is internalized. With anemia or hypoxemia, synthesis rapidly increases by 100-fold or more, serum erythropoietin levels rise, and marrow progenitor cell survival,

Table 37–1**Hematopoietic Growth Factors****ERYTHROPOIETIN (EPO)**

- Stimulates proliferation and maturation of committed erythroid progenitors to increase red cell production

STEM CELL FACTOR (SCF, c-kit ligand, Steel factor) and FLT-3 LIGAND (FL)

- Act synergistically with a wide range of other colony-stimulating factors and interleukins to stimulate pluripotent and committed stem cells
- FL also stimulates both dendritic and NK cells (anti-tumor response)
- SCF also stimulates mast cells and melanocytes

INTERLEUKINS*IL-1, IL-3, IL-5, IL-6, IL-9, and IL-11*

- Act synergistically with each other and SCF, GM-CSF, G-CSF, and EPO to stimulate BFU-E, CFU-GEMM, CFU-GM, CFU-E, and CFU-Meg growth
- Numerous immunologic roles, including stimulation of B cell and T cell growth

IL-5

- Controls eosinophil survival and differentiation

IL-6

- IL-6 stimulates human myeloma cells to proliferate
- IL-6 and IL-11 stimulate BFU-Meg to increase platelet production

IL-1, IL-2, IL-4, IL-7, and IL-12

- Stimulate growth and function of T cells, B cells, NK cells, and monocytes
- Co-stimulate B, T, and LAK cells

IL-8 and IL-10

- Numerous immunological activities involving B and T cell functions
- IL-8 acts as a chemotactic factor for basophils and neutrophils

GRANULOCYTE-MACROPHAGE COLONY-STIMULATING FACTOR (GM-CSF)

- Acts synergistically with SCF, IL-1, IL-3, and IL-6 to stimulate CFU-GM, and CFU-Meg to increase neutrophil and monocyte production
- With EPO may promote BFU-E formation
- Enhances migration, phagocytosis, superoxide production, and antibody-dependent cell-mediated toxicity of neutrophils, monocytes, and eosinophils
- Prevents alveolar proteinosis

GRANULOCYTE COLONY-STIMULATING FACTOR (G-CSF)

- Stimulates CFU-G to increase neutrophil production
- Enhances phagocytic and cytotoxic activities of neutrophils

MONOCYTE/MACROPHAGE COLONY-STIMULATING FACTOR (M-CSF, CSF-1)

- Stimulates CFU-M to increase monocyte precursors
- Activates and enhances function of monocyte/macrophages

MACROPHAGE COLONY-STIMULATING FACTOR (M-CSF)

- Stimulates CFU-M to increase monocyte/macrophage precursors
- Acts in concert with tissues and other growth factors to determine the proliferation, differentiation, and survival of a range of cells of the mononuclear phagocyte system

THROMBOPOIETIN (TPO, *Mpl* ligand)

- Stimulates the self-renewal and expansion of hematopoietic stem cells
- Stimulates stem cell differentiation into megakaryocyte progenitors
- Selectively stimulates megakaryocytopoiesis to increase platelet production
- Acts synergistically with other growth factors, especially IL-6 and IL-11

ABBREVIATIONS: BFU, burst-forming unit; CFU, colony-forming unit; E, erythrocyte; G, granulocyte; M, macrophage; Meg, megakaryocyte; NK cells, natural killer cells; LAK cells, lymphokine-activated killer cells.

proliferation, and maturation are dramatically stimulated. This finely tuned feedback loop can be disrupted by kidney disease, marrow damage, or a deficiency in iron or an essential vitamin. With an infection or an inflammatory state, erythropoietin secretion, iron delivery, and progenitor proliferation all are suppressed by inflammatory cytokines, but this accounts for only part of the resultant anemia; interference with iron metabolism also is an effect of inflammatory mediator effects on the hepatic protein hepcidin (Nemeth et al., 2004).

Recombinant human erythropoietin (epoetin alfa) is nearly identical to the endogenous hormone except for two subtle differences. First, the carbohydrate modification pattern of epoetin alfa differs slightly from the native protein, but this difference apparently does not alter kinetics, potency, or immunoreactivity of the drug. However, modern assays can detect these differences (Skibeli et al., 2001) and identify athletes who use the recombinant product for “blood doping.” The second difference probably is related to the manufacturing process because one commercially available form of the drug was recently associated with the development of anti-recombinant erythropoietin antibodies that cross-react with the patient’s own erythropoietin, potentially causing pure red-cell aplasia (Macdougall, 2004). Most of these cases were caused by one preparation of the drug shortly after albumin was removed from the formulation (Casadevall, 2003).

Preparations. Available preparations of epoetin alfa include EPOGEN, PROCRIT, and EPREX, supplied in single-use vials containing 2000-40,000 units/mL for intravenous or subcutaneous administration. When injected intravenously, epoetin alfa is cleared from plasma with a $t_{1/2}$ of 4-8 hours. However, the effect on marrow progenitors lasts much longer, and once-weekly dosing can be sufficient to achieve an adequate response. Although allergic reactions have been reported with the administration of epoetin alfa, no consistent pattern of significant allergic reactions has emerged; except as noted earlier, antibodies have not been detected even after prolonged administration.

More recently, a novel erythropoiesis-stimulating protein, darbepoetin alfa (ARANESP), has been approved for clinical use in patients with indications similar to those for epoetin alfa. It is a genetically modified form of erythropoietin in which four amino acids have been mutated such that additional carbohydrate side chains are added during its synthesis, prolonging the circulatory survival of the drug to 24-26 hours (Jelkmann, 2002).

Therapeutic Uses, Monitoring, and Adverse Effects. Recombinant erythropoietin therapy, in conjunction with adequate iron intake, can be highly effective in a number of anemias, especially those associated with a

poor erythropoietic response. There is a clear dose–response relationship between the epoetin alfa dose and the rise in hematocrit in anephric patients, with eradication of their anemia at higher doses (Eschbach et al., 1987). Epoetin alfa also is effective in the treatment of anemias associated with surgery, AIDS, cancer chemotherapy, prematurity, and certain chronic inflammatory conditions. Darbepoetin alfa also has been approved for use in patients with anemia associated with chronic kidney disease and is under review for several other indications.

During erythropoietin therapy, absolute or functional iron deficiency may develop. Functional iron deficiency (i.e., normal ferritin levels but low transferrin saturation) presumably results from the inability to mobilize iron stores rapidly enough to support the increased erythropoiesis. Virtually all patients eventually will require supplemental iron to increase or maintain transferrin saturation to levels that will adequately support stimulated erythropoiesis. Supplemental iron therapy is recommended for all patients whose serum ferritin is $<100 \mu\text{g/L}$ or whose serum transferrin saturation is $<20\%$.

During initial therapy and after any dosage adjustment, the hematocrit is determined once a week (HIV-infected and cancer patients) or twice a week (renal failure patients) until it has stabilized in the target range and the maintenance dose has been established; the hematocrit then is monitored at regular intervals. If the hematocrit increases by >4 points in any 2-week period, the dose should be decreased. Due to the time required for erythropoiesis and the erythrocyte half-life, hematocrit changes lag behind dosage adjustments by 2-6 weeks. The dose of darbepoetin should be decreased if the hemoglobin increase exceeds 1 g/dL in any 2-week period because of the association of excessive rate of rise of hemoglobin with adverse cardiovascular events.

During hemodialysis, patients receiving epoetin alfa or darbepoetin may require increased anticoagulation. Serious thromboembolic events have been reported, including migratory thrombophlebitis, microvascular thrombosis, pulmonary embolism, and thrombosis of the retinal artery and temporal and renal veins. The risk of thrombotic events, including vascular access thromboses, was higher in adults with ischemic heart disease or congestive heart failure receiving epoetin alfa therapy with the goal of reaching a normal hematocrit (42%) than in those with a lower target hematocrit of 30%. A large meta-analysis indicated that there was a relative risk of 1.6 for developing venous thromboembolic events associated with erythropoietic therapies (Bennett et al., 2008). The higher risk of cardiovascular events from erythropoietic therapies may be associated with higher hemoglobin or higher rates of rise of hemoglobin. The hemoglobin level should be managed to avoid exceeding a target level of 12 g/dL . ESA use is associated with increased rates of cancer recurrence and decreased on-study survival in patients in whom the drugs are administered for cancer-induced or for chemotherapy-induced anemia. The magnitude of the effect was

estimated as ~17% based on a meta-analysis of nearly 14,000 cancer patients (Bohlius et al., 2008). The cause(s) of this effect is presently unclear, but some studies suggest that tumor cells bearing the erythropoietin receptor are more likely to be affected by the use of ESAs (Henke et al., 2003). Although epoetin alfa is not associated with direct pressor effects, blood pressure may rise, especially during the early phases of therapy when the hematocrit is increasing. ESAs should not be used in patients with preexisting uncontrolled hypertension. Patients may require initiation of, or increases in, antihypertensive therapy. Hypertensive encephalopathy and seizures have occurred in chronic renal failure patients treated with epoetin alfa. The incidence of seizures appears to be higher during the first 90 days of therapy with epoetin alfa in patients on dialysis (occurring in ~2.5% of patients) when compared with subsequent 90-day periods. Headache, tachycardia, edema, shortness of breath, nausea, vomiting, diarrhea, injection site stinging, and flu-like symptoms (e.g., arthralgias and myalgias) also have been reported in conjunction with epoetin alfa therapy. Pure red-cell aplasia in association with neutralizing antibodies to native erythropoietin has been observed in patients treated with specific epoetin alfa formulations (see earlier discussion). Resistance to therapy can be caused by multiple factors (see following discussion).

Anemia of Chronic Renal Failure. Patients with anemia secondary to chronic kidney disease are ideal candidates for epoetin alfa therapy because the disorder represents a pure erythropoietin deficiency state. The response in predialysis, peritoneal dialysis, and hemodialysis patients depends on the severity of the renal failure, the erythropoietin dose and route of administration, and iron availability (Besarab et al., 1999; Kaufman et al., 1998). The subcutaneous route of administration is preferred over the intravenous route because absorption is slower and the amount of drug required is reduced by 20-40%.

The dose of epoetin alfa should be adjusted to obtain a gradual rise in the hematocrit over a 2- to 4-month period to a final hematocrit of 33-36%. Treatment to hematocrit levels >36% is not recommended because patients treated to a hematocrit >40% showed a higher incidence of myocardial infarction and death (Besarab et al., 1998). The drug should not be used to replace emergency transfusion in patients who need immediate correction of a life-threatening anemia.

Patients are started on doses of 80-120 units/kg of epoetin alfa, given subcutaneously, three times a week. It can be given on a once-weekly schedule, but somewhat more drug is required for an equivalent effect. If the response is poor, the dose should be progressively increased. The final maintenance dose of epoetin alfa can vary from as little as 10 units/kg to >300 units/kg, with an average dose of 75 units/kg, three times a week. Children <5 years of age generally require a higher dose. Resistance to therapy is common in patients who develop an inflammatory illness or become iron deficient, so close monitoring of general health and iron status is essential. Less common causes of resistance include occult blood loss, folic acid deficiency, carnitine deficiency, inadequate dialysis, aluminum toxicity, and osteitis fibrosa cystica secondary to hyperparathyroidism.

The most common side effect of epoetin alfa therapy is aggravation of hypertension, which occurs in 20-30% of patients and most often is associated with a rapid rise in hematocrit. Blood pressure

usually can be controlled either by increasing antihypertensive therapy or ultrafiltration in dialysis patients or by reducing the epoetin alfa dose to slow the hematocrit response.

Darbepoetin alfa also is approved for use in patients who are anemic secondary to chronic kidney disease. The recommended starting dose is 0.45 µg/kg administered intravenously or subcutaneously once weekly, with dose adjustments depending on the response. Like epoetin alfa, side effects tend to occur when patients experience a rapid rise in hemoglobin concentration; a rise of <1 g/dL every 2 weeks generally has been considered safe.

Anemia in AIDS Patients. Epoetin alfa therapy has been approved for the treatment of HIV-infected patients, especially those on zidovudine therapy (Fischl et al., 1990). Excellent responses to doses of 100-300 units/kg, given subcutaneously three times a week, generally are seen in patients with zidovudine-induced anemia. In the face of advanced disease, marrow damage, and elevated serum erythropoietin levels (>500 IU/L), therapy is less effective.

Cancer-Related Anemias. Epoetin alfa therapy, 150 units/kg three times a week or 450-600 units/kg once a week, can reduce the transfusion requirement in cancer patients undergoing chemotherapy. Evidence-based guidelines for the therapeutic use of recombinant erythropoietin in patients with cancer have been published (Rizzo et al., 2002). Briefly, the guidelines recommend the use of epoetin alfa in patients with chemotherapy-associated anemia when hemoglobin levels fall below 10 g/dL, basing the decision to treat less severe anemia (Hb, 10-12 g/dL) on clinical circumstances. For anemia associated with hematologic malignancies, the guidelines support the use of recombinant erythropoietin in patients with low-grade myelodysplastic syndrome, although the evidence that the drug is effective in anemic patients with multiple myeloma, non-Hodgkin's lymphoma, or chronic lymphocytic leukemia not receiving chemotherapy is less robust. A baseline serum erythropoietin level may help to predict the response; most patients with blood levels >500 IU/L are unlikely to respond to any dose of the drug. Most patients treated with epoetin alfa experienced an improvement in their anemia, sense of well-being, and quality of life (Littlewood et al., 2001). This improved sense of well-being, particularly in cancer patients, may not be solely due to the rise in the hematocrit. Erythropoietin receptors have been demonstrated in cells of the central nervous system (CNS), and erythropoietin has been found to act as a cytoprotectant in several models of CNS ischemia. Thus high levels of the hormone may directly affect cancer patients' sense of well-being.

Darbepoetin alfa also has been tested in cancer patients undergoing chemotherapy and preliminary studies appear promising. However, recent case reports have suggested a direct effect of both epoetin alfa and darbepoetin alfa in stimulation of tumor cells. For example, patients with cancer of the head and neck randomized to receive recombinant erythropoietin had a statistically significant increase in likelihood of tumor progression during the duration of the study (Henke et al., 2003). A meta-analysis of a large number of patients and clinical trials estimates the risk at ~10% higher than non-treated cancer patients (Bohlius et al., 2008). This finding is being evaluated by the FDA and warrants serious attention.

Surgery and Autologous Blood Donation. Epoetin alfa has been used perioperatively to treat anemia and reduce the need for erythrocyte transfusion. Patients undergoing elective orthopedic and cardiac procedures have been treated with 150-300 units/kg of epoetin alfa once

daily for the 10 days preceding surgery, on the day of surgery, and for 4 days after surgery. As an alternative, 600 units/kg can be given on days 21, 14, and 7 before surgery, with an additional dose on the day of surgery. This can correct a moderately severe preoperative anemia (i.e., hematocrit 30-36%) and reduce the need for transfusion. Epoetin alfa also has been used to improve autologous blood donation (Goodnough et al., 1989). However, the potential benefit generally is small, and the expense is considerable. Patients treated for 3-4 weeks with epoetin alfa (300-600 units/kg twice a week) are able to donate only 1 or 2 more units than untreated patients, and most of the time this goes unused. Still, the ability to stimulate erythropoiesis for blood storage can be invaluable in the patient with multiple alloantibodies to red blood cells.

Other Uses. Epoetin alfa has received orphan drug status from the FDA for the treatment of the anemia of prematurity, HIV infection, and myelodysplasia. In the latter case, even very high doses >1000 units/kg two to three times a week have had limited success. The utility of very high-dose therapy in other hematologic disorders, such as sickle cell anemia, is still under study. Highly competitive athletes have used epoetin alfa to increase their hemoglobin levels (“blood doping”) and improve performance. Unfortunately, this misuse of the drug has been implicated in the deaths of several athletes and is strongly discouraged.

MYELOID GROWTH FACTORS

The myeloid growth factors are glycoproteins that stimulate the proliferation and differentiation of one or more myeloid cell lines. They also enhance the function of mature granulocytes and monocytes. Recombinant forms of several growth factors have been produced, including granulocyte-macrophage colony-stimulating factor (GM-CSF) (Wong et al., 1985), granulocyte colony-stimulating factor (G-CSF) (Welte et al., 1985), IL-3 (Yang et al., 1986), macrophage colony-stimulating g factor (M-CSF) or CSF-1 (Kawasaki et al., 1985), and stem cell factor (SCF) (Huang et al., 1990) (Table 37-1).

The myeloid growth factors are produced naturally by a number of different cells, including fibroblasts, endothelial cells, macrophages, and T cells (Figure 37-2). They are active at extremely low concentrations and act via membrane receptors of the cytokine receptor superfamily to activate the JAK/STAT signal transduction pathway. GM-CSF is capable of stimulating the proliferation, differentiation, and function of a number of the myeloid cell lineages (Figure 37-1). It acts synergistically with other growth factors, including erythropoietin, at the level of the BFU. GM-CSF stimulates the CFU-GEMM, CFU-GM, CFU-M, CFU-E, and CFU-Meg to increase cell production. It also enhances the migration, phagocytosis, superoxide production, and antibody-dependent cell-mediated toxicity of neutrophils, monocytes, and eosinophils (Weisbart et al., 1987).

Figure 37-2. Cytokine-cell interactions. Macrophages, T cells, B cells, and marrow stem cells interact *via* several cytokines (IL-1, IL-2, IL-3, IL-4, IFN [interferon]- γ , GM-CSF, and G-CSF) in response to a bacterial or a foreign antigen challenge. See Table 37-1 for the functional activities of these various cytokines.

The activity of G-CSF is restricted to neutrophils and their progenitors, stimulating their proliferation, differentiation, and function. It acts primarily on the CFU-G, although it also can play a synergistic role with IL-3 and GM-CSF in stimulating other cell lines. G-CSF enhances phagocytic and cytotoxic activities of neutrophils. Unlike GM-CSF, G-CSF has little effect on monocytes, macrophages, and eosinophils and reduces inflammation by inhibiting IL-1, tumor necrosis factor, and interferon gamma. G-CSF also mobilizes primitive hematopoietic cells, including hematopoietic stem cells, from the marrow into the peripheral blood (Sheridan et al., 1992). This observation has virtually transformed the practice of stem cell transplantation, such that >90% of all such procedures today use G-CSF-mobilized peripheral blood stem cells as the donor product.

Granulocyte-Macrophage Colony-Stimulating Factor. Recombinant human GM-CSF (sargramostim) is a 127-amino acid glycoprotein produced in yeast. Except for the substitution of a leucine in position 23 and variable levels of glycosylation, it is identical to endogenous human GM-CSF. Although sargramostim, like natural GM-CSF, has a wide range of effects on cells in culture, its primary therapeutic effect is to stimulate myelopoiesis. The initial clinical application of sargramostim was in patients undergoing autologous bone marrow transplantation. By shortening the duration of neutropenia, transplant morbidity was significantly

reduced without a change in long-term survival or risk of inducing an early relapse of the malignant process (Brandt et al., 1988). GM-CSF has also been tested as an adjuvant for immunotherapy, based on its stimulation of dendritic cell growth and development. However, its use in that setting is not discussed in this chapter.

The role of GM-CSF therapy in allogeneic transplantation is less clear. Its effect on neutrophil recovery is less pronounced in patients receiving prophylactic treatment for graft-versus-host disease (GVHD), and studies have failed to show a significant effect on transplant mortality, long-term survival, the appearance of GVHD, or disease relapse. However, it may improve survival in transplant patients who exhibit early graft failure (Nemunaitis et al., 1990). It also has been used to mobilize CD34-positive progenitor cells for peripheral blood stem cell collection for transplantation after myeloablative chemotherapy (Haas et al., 1990). Sargramostim has been used to shorten the period of neutropenia and reduce morbidity in patients receiving intensive cancer chemotherapy (Gerhartz et al., 1993). It also stimulates myelopoiesis in some patients with cyclic neutropenia, myelodysplasia, aplastic anemia, or AIDS-associated neutropenia.

Sargramostim (LEUKINE) is administered by subcutaneous injection or slow intravenous infusion at doses of 125-500 $\mu\text{g}/\text{m}^2$ per day. Plasma levels of GM-CSF rise rapidly after subcutaneous injection and then decline with a $t_{1/2}$ of 2-3 hours. When given intravenously, infusions should be maintained over 3-6 hours. With the initiation of therapy, there is a transient decrease in the absolute leukocyte count secondary to margination and sequestration in the lungs. This is followed by a dose-dependent, biphasic increase in leukocyte counts over the next 7-10 days. Once the drug is discontinued, the leukocyte count returns to baseline within 2-10 days. When GM-CSF is given in lower doses, the response is primarily neutrophilic, whereas monocytosis and eosinophilia are observed at larger doses. After hematopoietic stem cell transplantation or intensive chemotherapy, sargramostim is given daily during the period of maximum neutropenia until a sustained rise in the granulocyte count is observed. Frequent blood counts are essential to avoid an excessive rise in the granulocyte count. The dose may be increased if the patient fails to respond after 7-14 days of therapy. However, higher doses are associated with more pronounced side effects, including bone pain, malaise, flu-like symptoms, fever, diarrhea, dyspnea, and rash. An acute reaction to the first dose, characterized by flushing, hypotension, nausea, vomiting, and dyspnea, with a fall in arterial oxygen saturation due to granulocyte sequestration in the pulmonary circulation occurs in sensitive patients. With prolonged administration, a few patients may develop a capillary leak syndrome, with peripheral edema and pleural and pericardial effusions. Other serious side effects include transient supraventricular arrhythmia, dyspnea, and elevation of serum creatinine, bilirubin, and hepatic enzymes.

Granulocyte Colony-Stimulating Factor. Recombinant human G-CSF filgrastim (NEUPOGEN) is a 175-amino acid glycoprotein produced in *Escherichia coli*. Unlike natural G-CSF, it is not glycosylated and carries an

extra N-terminal methionine. The principal action of filgrastim is the stimulation of CFU-G to increase neutrophil production (Figure 37-1). It also enhances the phagocytic and cytotoxic functions of neutrophils.

Filgrastim is effective in the treatment of severe neutropenia after autologous hematopoietic stem cell transplantation and high-dose cancer chemotherapy (Lieschke and Burgess, 1992). Like GM-CSF, filgrastim shortens the period of severe neutropenia and reduces morbidity secondary to bacterial and fungal infections. When used as a part of an intensive chemotherapy regimen, it can decrease the frequency of hospitalization for febrile neutropenia and interruptions in the chemotherapy protocol; a positive impact on patient survival has not been demonstrated. G-CSF also is effective in the treatment of severe congenital neutropenias. In patients with cyclic neutropenia, G-CSF therapy will increase the level of neutrophils and shorten the length of the cycle sufficiently to prevent recurrent bacterial infections (Hammond et al., 1989). Filgrastim therapy can improve neutrophil counts in some patients with myelodysplasia or marrow damage (moderately severe aplastic anemia or tumor infiltration of the marrow). The neutropenia of AIDS patients receiving zidovudine also can be partially or completely reversed. Filgrastim is routinely used in patients undergoing peripheral blood stem cell (PBSC) collection for stem cell transplantation. It promotes the release of CD34⁺ progenitor cells from the marrow, reducing the number of collections necessary for transplant. Moreover, filgrastim-mobilized PBSCs appear more capable of rapid engraftment. PBSC-transplanted patients require fewer days of platelet and red blood cell transfusions and a shorter duration of hospitalization than do patients receiving autologous bone marrow transplants. Finally, G-CSF-induced mobilization of stem cells into the circulation has been promoted as a way to enhance repair of other damaged organs in which PBSC might play a role. For example, many anecdotal reports have claimed improved cardiac function following the treatment of myocardial infarction patients with G-CSF. However, a meta-analysis of these studies have failed to demonstrate an overall benefit (Abdel-Latif et al., 2008).

Filgrastim is administered by subcutaneous injection or intravenous infusion over at least 30 minutes at doses of 1-20 $\mu\text{g}/\text{kg}$ per day. The usual starting dose in a patient receiving myelosuppressive chemotherapy is 5 $\mu\text{g}/\text{kg}$ per day. The distribution and clearance rate from plasma ($t_{1/2}$ of 3.5 hours) are similar for both routes of administration. As with GM-CSF therapy, filgrastim given daily after hematopoietic stem cell transplantation or intensive cancer

chemotherapy will increase granulocyte production and shorten the period of severe neutropenia. Frequent blood counts should be obtained to determine the effectiveness of the treatment and guide dosage adjustment. In patients who received intensive myelosuppressive cancer chemotherapy, daily administration of G-CSF for ≥ 14 –21 days may be necessary to correct the neutropenia. With less intensive chemotherapy, < 7 days of treatment may suffice. In AIDS patients on zidovudine or patients with cyclic neutropenia, chronic G-CSF therapy often is required.

One indication for G-CSF presently under investigation is its use to increase the number of peripheral blood neutrophils in leukocyte donors. For many years it had been hoped that, like platelet transfusions for the bleeding associated with severe thrombocytopenia, neutrophil transfusion could diminish the infectious complications of neutropenia. However, given the short circulatory $t_{1/2}$ of neutrophils (~ 6 hours) and the need for large numbers of cells, the practical collection of sufficient cell numbers has eluded hematologists. With few complications of therapy in > 15 years of clinical experience, G-CSF now has been used to increase peripheral neutrophil counts in prospective donors and neutrophil transfusions (Hubel et al., 2002). Although initial results were modest, the therapy is likely to be optimized and greater efficacy is anticipated.

Adverse reactions to filgrastim include mild to moderate bone pain in patients receiving high doses over a protracted period, local skin reactions following subcutaneous injection, and rare cutaneous necrotizing vasculitis. Patients with a history of hypersensitivity to proteins produced by *E. coli* should not receive the drug. Marked granulocytosis, with counts $> 100,000/\mu\text{L}$, can occur in patients receiving filgrastim over a prolonged period of time. However, this is not associated with any reported clinical morbidity or mortality and rapidly resolves once therapy is discontinued. Mild to moderate splenomegaly has been observed in patients on long-term therapy.

Pegylated recombinant human G-CSF pegfilgrastim (NEULASTA) is generated through conjugation of a 20,000-Da polyethylene glycol moiety to the N-terminal methionyl residue of the 175–amino acid G-CSF glycoprotein produced in *E. coli*. The clearance of pegfilgrastim by glomerular filtration is minimized, thus making neutrophil-mediated clearance the primary route of elimination. Consequently the circulating $t_{1/2}$ of pegfilgrastim is longer than that of filgrastim, allowing for more sustained duration of action and less frequent dosing. Clinical studies suggest that neutrophil-mediated clearance of pegfilgrastim may be self-regulating and therefore specific to each patient's hematopoietic recovery (Crawford, 2002). As such, the recommended dose for pegfilgrastim is fixed at 6 mg administered subcutaneously.

The therapeutic roles of other growth factors still need to be defined, although IL-3 and IL-6 have been removed from testing due to poor efficacy and/or significant toxicity. M-CSF may play a role in stimulating monocyte and macrophage production, although with significant side effects, including splenomegaly and thrombocytopenia. Stem cell factor (SCF) has been shown to augment peripheral blood

mobilization of primitive hematopoietic progenitor cells (Moskowitz et al., 1997).

Thrombopoietic Growth Factors

Interleukin-11. Interleukin-11 was cloned based on its activity to promote proliferation of an IL-6–dependent myeloma cell line (Du and Williams, 1994). The 23,000-Da cytokine contains 178 amino acids and stimulates hematopoiesis, intestinal epithelial cell growth, and osteoclasto-genesis and inhibits adipogenesis. Interleukin-11 enhances megakaryocyte maturation *in vitro* (Teramura et al., 1992), and its *in vivo* administration to animals modestly increases peripheral blood platelet counts (Neben et al., 1993). Clinical trials in patients who previously demonstrated significant chemotherapy-induced thrombocytopenia demonstrated that administration of the recombinant cytokine was associated with less severe thrombocytopenia and reduced use of platelet transfusions (Tepler et al., 1996), leading to its approval for clinical use by the FDA.

Recombinant human IL-11 oprelvekin (NEUMEGA) is a bacterially derived 19,000-Da polypeptide of 177 amino acids that differs from the native protein only because it lacks the amino terminal proline residue and is not glycosylated. The recombinant protein has a 7-hour $t_{1/2}$ after subcutaneous injection. In normal subjects, daily administration of oprelvekin leads to a thrombopoietic response in 5–9 days.

The drug is available in single-use vials containing 5 mg and is administered to patients at 25–50 $\mu\text{g}/\text{kg}$ per day subcutaneously. Oprelvekin is approved for use in patients undergoing chemotherapy for nonmyeloid malignancies that displayed severe thrombocytopenia (platelet count $< 20,000/\mu\text{L}$) on a prior cycle of the same chemotherapy, and it is administered until the platelet count returns to $> 100,000/\mu\text{L}$. The major complications of therapy are fluid retention and associated cardiac symptoms, such as tachycardia, palpitation, edema, and shortness of breath; this is a significant concern in elderly patients and often requires concomitant therapy with diuretics. Fluid retention reverses upon drug discontinuation, but volume status should be carefully monitored in elderly patients, those with a history of heart failure, or those with preexisting fluid collections in the pleura, pericardium, or peritoneal cavity. Also reported are blurred vision, injection-site rash or erythema, and paresthesias.

Thrombopoietin. The cloning and expression of recombinant thrombopoietin, a cytokine that predominantly stimulates megakaryopoiesis, is potentially another milestone in the development of hematopoietic growth factors as therapeutic agents (Lok et al., 1994) (Table 37–1). Thrombopoietin is a 45,000- to 75,000-Da glycoprotein containing 332 amino acids that is produced by the liver, marrow stromal cells,

and many other organs. In both humans and mice, genetic elimination of thrombopoietin or its receptor reduces the platelet counts to 10% of normal values. Moreover, blood levels of the hormone are inversely related to the blood platelet count, together indicating that the hormone is the primary regulator of platelet production.

Administration of recombinant thrombopoietin leads to a log-linear increase in the platelet count in mice, rats, dogs, and nonhuman primates (Harker, 1999) that begins on the third day of administration. In a number of human preclinical trials in several models of chemotherapy- and radiation-induced myelosuppression, thrombopoietin accelerated the recovery of platelet counts and other hematologic parameters (Kaushansky et al., 1998). Of note, however, the agent failed to substantially affect hematopoietic recovery when administered after myeloablative therapy and stem cell transplantation, unless given to the stem cell donor (Fibbe et al., 1995).

Two forms of recombinant thrombopoietin have been developed for clinical use. One is a truncated version of the native polypeptide, termed *recombinant human megakaryocyte growth and development factor* (rHuMGDF), which is produced in bacteria and then covalently modified with polyethylene glycol to increase the circulatory $t_{1/2}$. The second is the full-length polypeptide termed *recombinant human thrombopoietin* (rHuTPO), which is produced in mammalian cells. In vitro, both drugs are equally potent in stimulating megakaryocyte growth.

In clinical trials, both drugs are safe in the patient populations selected for study. However, efficacy results using these agents have been mixed. In a small number of patients with gynecological cancers who were receiving carboplatin (Vadhan-Raj et al., 2000), rHuTPO therapy reduced the duration of severe thrombocytopenia and the need for platelet transfusions. In a similar study of patients treated with carboplatin plus cyclophosphamide, patients receiving a cycle of chemotherapy supplemented with G-CSF plus thrombopoietin had higher platelet counts at nadir and a shorter median duration of severe thrombocytopenia than they did after cycles of therapy supplemented only with G-CSF (Basser et al., 2000). When used to augment peripheral blood counts in preparation for platelet donation, a single dose of thrombopoietin in the platelet donors tripled their platelet counts, allowed for a threefold increase in the number of platelets that could be collected in a single apheresis, and led to a fourfold increase in the mean platelet count noted in transfusion recipients (Kuter et al., 2001). However, this particular regimen was associated with several instances of anti-recombinant thrombopoietin antibodies that cross-reacted with the native hormone, resulting in subsequent thrombocytopenia (Li et al., 2001).

In several studies, although the drug was safe, rHuMGDF was not effective. In two studies of patients treated for 7 days with

standard aggressive therapy for acute leukemia, the addition of recombinant thrombopoietin failed to accelerate platelet recovery (Archimbaud et al., 1999). A similar lack of efficacy was seen when the drug was used following autologous peripheral blood stem cell transplantation (Bolwell et al., 2000). Failure to improve hematopoiesis in some of these trials may have resulted from the dosing regimen employed; the optimal dose and schedule of administration in various clinical settings need to be established. After a single bolus injection, platelet counts showed a detectable increase by day 4, peaked by 12-14 days, and then returned to normal over the next 4 weeks. The peak platelet response follows a log-linear dose response. Platelet activation and aggregation are not affected, and patients are not at increased risk of thromboembolic disease, unless the platelet count is allowed to rise to very high levels. These kinetics need to be taken into account when planning therapy in cancer chemotherapy patients.

Due to concerns over the immunogenicity of these agents, and to other considerations, efforts now are under way to develop small molecular mimics of recombinant thrombopoietin, discovered either through screening of phage display peptide libraries or of small organic molecules that have been developed for clinical use. Two of these agents are FDA approved for use in patients with immune thrombocytopenic purpura (ITP) who have failed to respond to more conventional treatments. *Romiplostim* (NPLATE) contains four copies of a small peptide that binds with high affinity to the thrombopoietin receptor, grafted onto an immunoglobulin scaffold. Romiplostim was found safe and efficacious in two randomized controlled studies in patients with ITP. Overall, ~84% of patients responded to the drug with substantial increases in platelet levels, of which approximately half were durable (platelets >50,000/ μ L for 6 of the last 8 weeks of study) (Kuter et al., 2008). The drug is administered weekly by subcutaneous injection, starting with a dose of 1 μ g/kg, titrated to a maximum of 10 μ g/kg, until platelet count increases above 50,000/ μ L. *Eltrombopag* (PROMACTA) is a small organic molecule that binds specifically to the thrombopoietin receptor and is administered orally. The safety and efficacy of eltrombopag were evaluated in two double-blind placebo-controlled clinical studies of >200 adult patients with chronic ITP who had completed at least one prior treatment course and who had severe thrombocytopenia (Bussel et al., 2007). These studies demonstrated that 70-81% of patients with ITP can be expected to respond to a 6-week course of 50-75 mg/day of eltrombopag. The recommended starting dose is 30 g per day, titrated to 75 mg depending on platelet response. Several of these agents are in clinical trials.

Drugs Effective in Iron Deficiency and Other Hypochromic Anemias

IRON AND IRON SALTS

Iron deficiency is the most common nutritional cause of anemia in humans. It can result from inadequate iron

intake, malabsorption, blood loss, or an increased requirement, as with pregnancy. When severe, it results in a characteristic microcytic, hypochromic anemia. However, the impact of iron deficiency is not limited to the erythron (Dallman, 1982). Iron also is an essential component of myoglobin; heme enzymes such as the cytochromes, catalase, and peroxidase; and the metalloflavoprotein enzymes, including xanthine oxidase and the mitochondrial enzyme α -glycerophosphate oxidase. Iron deficiency can affect metabolism in muscle independently of the effect of anemia on oxygen delivery. This may reflect a reduction in the activity of iron-dependent mitochondrial enzymes. Iron deficiency also has been associated with behavioral and learning problems in children, abnormalities in catecholamine metabolism, and possibly, impaired heat production. Awareness of the ubiquitous role of iron has stimulated considerable interest in the early and accurate detection of iron deficiency and in its prevention.

History. The modern understanding of iron metabolism began in 1937 with the work of McCance and Widdowson on iron absorption and excretion and Heilmeyer and Plotner's measurement of iron in plasma (Beutler, 2002). In 1947, Laurell described a plasma iron transport protein that he called *transferrin* (Laurell, 1951). Hahn and coworkers first used radioactive isotopes to measure iron absorption and define the role of the intestinal mucosa to regulate this function (Hahn, 1948). In the next decade, Huff and associates initiated isotopic studies of internal iron metabolism. The subsequent development of practical clinical measurements of serum iron, transferrin saturation, plasma ferritin, and red-cell protoporphyrin permitted the definition and detection of the body's iron store status and iron-deficient erythropoiesis. In 1994, Feder and colleagues identified the HFE gene, which is mutated in type 1 hemochromatosis, on the short arm of chromosome 6 at 6p21.3 (Feder et al., 1996). In 2000, Ganz and colleagues discovered a peptide produced by the liver, which was termed *hepcidin* (Park et al., 2001). Soon thereafter hepcidin was found to be the master regulator of iron homeostasis and to play a role in anemia of chronic disease (Ganz, 2003; Ganz and Nemeth, 2009).

Iron and the Environment. Iron exists in the environment largely as ferric oxide or hydroxide or as polymers. In this state, its biological availability is limited unless solubilized by acid or chelating agents. For example, bacteria and some plants produce high-affinity chelating agents that extract iron from the surrounding environment. Most mammals have little difficulty in acquiring iron; this is explained by an ample iron intake and perhaps also by a greater efficiency in absorbing iron. Humans, however, appear to be an exception. Although total dietary intake of elemental iron in humans usually exceeds requirements, the bioavailability of the iron in the diet is limited.

Metabolism of Iron. The body store of iron is divided between essential iron-containing compounds and excess iron, which is held in storage. Quantitatively,

Table 37–2

The Body Content of Iron

	MG/KG OF BODY WEIGHT	
	MALE	FEMALE
Essential iron		
Hemoglobin	31	28
Myoglobin and enzymes	6	5
Storage iron	13	4
Total	50	37

hemoglobin dominates the essential fraction (Table 37–2). This protein, with a molecular weight of 64,500 Da, contains four atoms of iron per molecule, amounting to 1.1 mg (20 μ mol) of iron per milliliter of red blood cells. Other forms of essential iron include myoglobin and a variety of heme and nonheme iron-dependent enzymes. Ferritin is a protein-iron storage complex that exists as individual molecules or as aggregates. Apoferritin has a molecular weight of ~450,000 and is composed of 24 polypeptide subunits that form an outer shell, within which resides a storage cavity for polynuclear hydrous ferric oxide phosphate. More than 30% of the weight of ferritin may be iron (4000 atoms of iron per ferritin molecule). Ferritin aggregates, referred to as hemosiderin and visible by light microscopy, constitute about one-third of normal stores, a fraction that increases as stores enlarge. The two predominant sites of iron storage are the reticuloendothelial system and the hepatocytes, although some storage also occurs in muscle.

Internal exchange of iron is accomplished by the plasma protein transferrin (Garrick and Garrick, 2009). This 76-kDa β_1 -glycoprotein has two binding sites for ferric iron. Iron is delivered from transferrin to intracellular sites by means of specific transferrin receptors in the plasma membrane. The iron-transferrin complex binds to the receptor, and the ternary complex is internalized through clathrin-coated pits by receptor-mediated endocytosis. A proton-pumping ATPase lowers the pH of the intracellular vesicular compartment (the endosomes) to ~5.5. Iron subsequently dissociates and the receptor returns the apotransferrin to the cell surface, where it is released into the extracellular environment.

Cells regulate their expression of transferrin receptors and intracellular ferritin in response to the iron supply (De Domenico et al., 2008). The synthesis of apoferritin and transferrin receptors is regulated post-transcriptionally by two iron-regulatory proteins 1 and 2

(IRP1 and IRP2). Double knockout of the genes encoding these proteins is embryonic lethal, and conditional double knockout of these genes in the intestine results in cellular iron depletion and death of intestinal epithelial cells (Galy et al., 2008). These IRPs are cytosolic RNA-binding proteins that bind to iron regulating elements (IREs) present in the 5' or 3' untranslated regions of mRNA encoding apoferritin or the transferrin receptors, respectively. Binding of these IRPs to the 5' IRE of apoferritin mRNA represses translation, whereas binding to the 3' IRE of mRNA encoding the transferrin receptors enhances transcript stability, thereby increasing protein production. When iron is abundant, IRP2 undergoes rapid proteolysis and IRP1 is converted from a RNA-binding protein into aconitase, an enzyme that catalyzes the interconversion of citrate and isocitrate. This results in increased production of apoferritin and reduced production of transferrin receptors. Conversely, when iron is in short supply, these IRPs accumulate, thereby repressing translation of apoferritin while enhancing production of transferrin receptors.

The flow of iron through the plasma amounts to a total of 30–40 mg per day in the adult (~0.46 mg/kg of body weight) (Finch and Huebers, 1982). The major internal circulation of iron involves the erythron and reticuloendothelial cells (Figure 37–3). About 80% of the iron in plasma goes to the erythroid marrow to be packaged into new erythrocytes; these normally circulate for ~120 days before being catabolized by the reticuloendothelial system. At that time, a portion of the iron is immediately returned to the plasma bound to transferrin while another portion is incorporated into the ferritin stores of reticuloendothelial cells and returned to the circulation more gradually. Isotopic studies indicate some degree of iron wastage in this process, in which defective cells or unused portions of their iron are transferred to the reticuloendothelial cell during maturation, bypassing the circulating blood. With abnormalities in erythrocyte maturation, the predominant portion of iron assimilated by the erythroid marrow may be rapidly localized in the reticuloendothelial cells as defective red-cell precursors are broken down; this is termed *ineffective erythropoiesis*. The rate of iron turnover in plasma may be reduced by half or more with red-cell aplasia, with all the iron directed to the hepatocytes for storage.

The most remarkable feature of iron metabolism is the degree to which body stores are conserved. Only 10% of the total is lost per year by normal men (i.e., ~1 mg/day). Two-thirds of this iron is excreted from the gastrointestinal (GI) tract as extravasated red cells, iron in bile, and iron in exfoliated mucosal cells. The other third is accounted for by small amounts of iron in desquamated skin and in the urine. Physiological losses of iron in men vary over a narrow range, from 0.5 mg

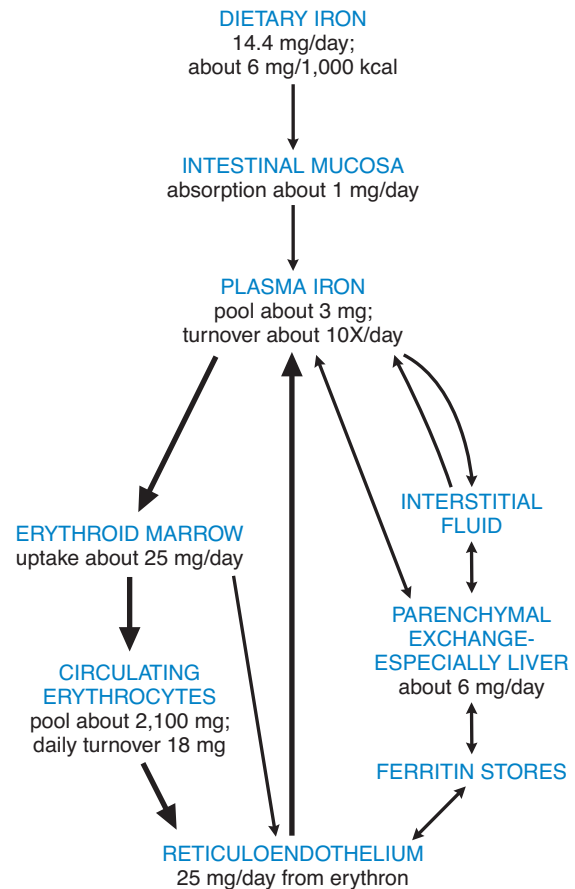

Figure 37–3. Pathways of iron metabolism in humans (excretion omitted).

in the iron-deficient individual to 1.5–2 mg per day when excessive iron is consumed. Additional losses of iron occur in women due to menstruation. Although the average loss in menstruating women is ~0.5 mg per day, 10% of menstruating women lose >2 mg per day. Pregnancy and lactation impose an even greater requirement for iron (Table 37–3). Other causes of iron loss include blood donation, the use of anti-inflammatory drugs that cause bleeding from the gastric mucosa, and GI disease with associated bleeding. Two much rarer causes are the hemosiderinuria that follows intravascular hemolysis, and pulmonary siderosis, where iron deposited in the lungs becomes unavailable to the rest of the body.

The limited physiological losses of iron point to the primary importance of absorption in determining the body's iron content (Garrick and Garrick, 2009). After acidification and partial digestion of food in the stomach, iron is presented to the intestinal mucosa as either

inorganic iron or heme iron. A ferrireductase, duodenal cytochrome B (Dcytb), located on luminal surface of absorptive cells of the duodenum and upper small intestine, reduces the iron to the ferrous state, which is the substrate for the divalent metal (ion) transporter 1 (DMT1). DMT1 transports the iron to basolateral membrane, where it is taken up by another transporter, ferroportin (Fpn; SLC40A1), and subsequently reoxidized to Fe³⁺, primarily by hephaestin (Hp; HEPH), a transmembrane copper-dependent ferroxidase. Apo-transferrin (Tf) binds the resultant oxidized iron.

Mucosal cell iron transport and the delivery of iron to transferrin from reticuloendothelial stores are both determined by the human hemochromatosis protein, which is a major histocompatibility complex class 1 molecule encoded by the HFE gene (for *High Fe*) located on the short arm of chromosome 6 at 6p21.3. Regulation is finely tuned to prevent iron overload in times of iron excess while allowing for increased absorption and mobilization of iron stores with iron deficiency. A predominant negative regulator of iron absorption in the small intestine is hepcidin, a 25-amino acid peptide made by hepatocytes (Ganz, 2003). The synthesis of hepcidin is greatly stimulated by inflammation or by iron overload. A deficient hepcidin response to iron loading can contribute to iron overload and one type of hemochromatosis. In anemia of chronic disease, hepcidin production can be increased up to 100-fold, potentially accounting for characteristic features of this condition, namely poor GI uptake and enhanced sequestration of iron in the reticuloendothelial system.

Normal iron absorption is ~1 mg per day in adult men and 1.4 mg per day in adult women; 3–4 mg of dietary iron is the most that normally can be absorbed. Increased iron absorption is seen whenever iron stores are depleted or when erythropoiesis is increased or ineffective. Patients with hereditary hemochromatosis due to HFE mutations demonstrate increased iron absorption and loss of the normal regulation of iron delivery to transferrin by reticuloendothelial cells (Ajioka and Kushner, 2003). The resulting increased saturation of transferrin permits abnormal iron deposition in non-hematopoietic tissues.

Iron Requirements and the Availability of Dietary Iron.

Iron requirements are determined by obligatory physiological losses and the needs imposed by growth. Thus adult men require only 13 μg/kg per day (~1 mg), whereas menstruating women require ~21 μg/kg per day (~1.4 mg). In the last two trimesters of pregnancy, requirements increase to ~80 μg/kg per day (5–6 mg), and infants have similar requirements due to their rapid growth. These requirements (Table 37-4) must be considered in the context of the amount of dietary iron available for absorption.

In developed countries, the normal adult diet contains ~6 mg of iron per 1000 calories, providing an average daily intake for adult men of between 12 and 20 mg and for adult women of between 8 and 15 mg. Foods high in iron (>5 mg/100 g) include organ meats such as liver and heart, brewer's yeast, wheat germ, egg yolks, oysters, and certain dried beans and fruits; foods low in iron (<1 mg/100 g) include milk and milk products and most nongreen vegetables. The content of iron in food is affected further by the manner of its preparation because iron may be added from cooking in iron pots.

Although the iron content of the diet obviously is important, of greater nutritional significance is the bioavailability of iron in food. Heme iron, which constitutes only 6% of dietary iron, is far more available and is absorbed independent of the diet composition; it therefore represents 30% of iron absorbed (Conrad and Umbreit, 2002).

The nonheme fraction nonetheless represents far the largest amount of dietary iron ingested by the economically underprivileged. In a vegetarian diet, nonheme iron is absorbed very poorly because of the inhibitory action of a variety of dietary components, particularly phosphates. Ascorbic acid and meat facilitate the absorption of nonheme iron. Ascorbate forms complexes with and/or reduces ferric to ferrous iron. Meat facilitates the absorption of iron by stimulating production of gastric acid; other effects also may be involved. Either of these substances can increase availability several fold. Thus assessment of available dietary iron should include both the amount of iron ingested and an estimate of its availability (Figure 37-4) (Monsen et al., 1978).

A comparison of iron requirements with available dietary iron is seen in Table 37-4. Obviously, pregnancy and infancy represent periods of negative balance. Menstruating women also are at

Table 37-4

Daily Iron Intake and Absorption

SUBJECT	IRON REQUIREMENT (mg/kg)	AVAILABLE IRON (mg/kg)		SAFETY FACTOR AVAILABLE/REQUIREMENT
		POOR DIET	GOOD DIET	
Infant	67	33	66	0.5–1
Child	22	48	96	2–4
Adolescent (male)	21	30	60	1.5–3
Adolescent (female)	20	30	60	1.5–3
Adult (male)	13	26	52	2–4
Adult (female)	21	18	36	1–2
Mid-to-late pregnancy	80	18	36	0.22–0.45

risk, whereas iron balance in adult men and nonmenstruating women is reasonably secure. The difference between dietary supply and requirements is reflected in the size of iron stores, which are low or absent when iron balance is precarious and high when iron balance is favorable (Table 37-2). Thus in infants after the third month of life and in pregnant women after the first trimester, stores of iron are negligible. Menstruating women have approximately one-third the stored iron found in adult men, indicative of the extent to which the additional average daily loss of ~0.5 mg of iron affects iron balance.

Iron Deficiency. Iron deficiency is the most common nutritional disorder (McLean et al., 2009). The prevalence of iron-deficiency anemia in the U.S. is on the order of 1-4% and depends on the economic status of the population. In developing countries, up to 20-40%

of infants and pregnant women may be affected. Better iron balance has resulted from the practice of fortifying flour, the use of iron-fortified formulas for infants, and the prescription of medicinal iron supplements during pregnancy.

Iron-deficiency anemia results from dietary intake of iron that is inadequate to meet normal requirements (nutritional iron deficiency), blood loss, or interference with iron absorption (Clark, 2009). This can have a genetic basis, as in iron-refractory iron deficiency anemia in which patients have iron deficiency that is unresponsive to oral iron, but partially responsive to parenteral iron (Finberg, 2009). Poor oral absorption also can be acquired, as in conditions associated with impaired oral absorption of vitamin B₁₂ (Fernandez-Banares et al., 2009), or following partial gastrectomy. More severe iron deficiency is usually the result of blood loss, either from the GI tract, or in women, from the uterus. Finally, treatment of patients with erythropoietin can result in a functional iron deficiency.

Iron deficiency in infants and young children can lead to behavioral disturbances and can impair development, which may not be fully reversible. Iron deficiency in children also can lead to an increased risk of lead toxicity secondary to pica and an increased absorption of heavy metals. Premature and low-birthweight infants are at greatest risk for developing iron deficiency, especially if they are not breast-fed and/or do not receive iron-fortified formula. After the age of 2-3 years, the requirement for iron declines until adolescence when rapid growth combined with irregular dietary habits again increases the risk of iron deficiency. Adolescent girls are at greatest risk; the dietary iron intake of most girls ages 11-18 is insufficient to meet their requirements.

Figure 37-4. Effect of iron status on the absorption of nonheme iron in food. The percentages of iron absorbed from diets of low, medium, and high bioavailability in individuals with iron stores of 0, 250, 500, and 1000 mg are portrayed. Figure 37–5. Sequential changes (from left to right) in the development of iron deficiency in the adult. Red rectangles indicate abnormal test results. RE marrow Fe, reticuloendothelial hemosiderin; RBC, red blood cells. (Adapted from Hillman RS and Finch CA. *Red Cell Manual*, 7th ed. FA Davis Co., Philadelphia, 1997. Used with permission.)

The recognition of iron deficiency rests on an appreciation of the sequence of events that lead to depletion of iron stores. A negative balance first results in a reduction of iron stores and eventually a parallel decrease in red-cell iron and iron-related enzymes (Figure 37–5). In adults, depletion of iron stores may be recognized by a plasma ferritin <12 μg/L and the absence of reticuloendothelial hemosiderin in the marrow aspirate. Iron-deficient erythropoiesis is identified by a decreased saturation of transferrin to <16% and/or by an increase above normal in red-cell protoporphyrin. Iron-deficiency anemia is associated with a recognizable decrease in the concentration of hemoglobin in blood. However, the physiological variation in hemoglobin levels is so great that only about half the individuals with iron-deficient erythropoiesis are identified from their anemia. Moreover, so-called normal hemoglobin and iron values in infancy and childhood are lower because of the more restricted supply of iron in young children (Dallman et al., 1980).

In mild iron deficiency, identifying the underlying cause is more important than any symptoms related to the deficiency state. Because of the frequency of iron deficiency in infants and in menstruating or pregnant women, the need for exhaustive evaluation of such individuals usually is determined by the severity of the anemia. However, iron deficiency in men or postmenopausal women necessitates a search for a site of bleeding.

Although the presence of microcytic anemia is the most common indicator of iron deficiency, laboratory tests—such as measurement of transferrin saturation, red-cell protoporphyrin, and plasma ferritin—are required to distinguish iron deficiency from other causes of microcytosis. Such measurements are particularly useful when circulating red cells are not yet microcytic because of the

recent nature of blood loss, but iron supply nonetheless limits erythropoiesis. More difficult is the differentiation of true iron deficiency from iron-deficient erythropoiesis due to inflammation. In the latter condition, iron stores actually are increased, but the release of iron from reticuloendothelial cells is blocked, the concentration of iron in plasma is decreased, and the supply of iron to the erythroid marrow becomes inadequate. The increased stores of iron in this condition may be demonstrated directly by examination of an aspirate of marrow or may be inferred from determination of an elevated plasma concentration of ferritin.

Treatment of Iron Deficiency

General Therapeutic Principles. The response of iron-deficiency anemia to iron therapy is influenced by several factors, including the severity of anemia, the ability of the patient to tolerate and absorb medicinal iron, and the presence of other complicating illnesses. Therapeutic effectiveness is best measured by the resulting increase in the rate of production of red cells. The magnitude of the marrow response to iron therapy is proportional to the severity of the anemia (level of erythropoietin stimulation) and the amount of iron delivered to marrow precursors.

The patient's ability to tolerate and absorb medicinal iron is a key factor in determining the rate of response to therapy. The small intestine regulates absorption, and with increasing doses of oral iron,

limits the entry of iron into the bloodstream. This provides a natural ceiling on how much iron can be supplied by oral therapy. In the patient with a moderately severe iron-deficiency anemia, tolerable doses of oral iron will deliver, at most, 40-60 mg of iron per day to the erythroid marrow. This is an amount sufficient for production rates of two to three times normal.

Complicating illness also can interfere with the response of an iron-deficiency anemia to iron therapy. By decreasing the number of red-cell precursors, intrinsic disease of the marrow can blunt the response. Inflammatory illnesses suppress the rate of red-cell production, both by reducing iron absorption and reticuloendothelial release and by direct inhibition of erythropoietin and erythroid precursors. Continued blood loss can mask the response as measured by recovery of the hemoglobin or hematocrit.

Clinically, the effectiveness of iron therapy is best evaluated by tracking the reticulocyte response and the rise in the hemoglobin or the hematocrit. An increase in the reticulocyte count is not observed for at least 4-7 days after beginning therapy. A measurable increase in the hemoglobin level takes even longer. A decision as to the effectiveness of treatment should not be made for 3-4 weeks after the start of treatment. An increase of ≥ 20 g/L in the concentration of hemoglobin by that time should be considered a positive response, assuming that no other change in the patient's clinical status can account for the improvement and that the patient has not been transfused.

If the response to oral iron is inadequate, the diagnosis must be reconsidered. A full laboratory evaluation should be conducted, and poor compliance by the patient or the presence of a concurrent inflammatory disease must be explored. A source of continued bleeding obviously should be sought. If no other explanation can be found, an evaluation of the patient's ability to absorb oral iron should be considered. There is no justification for merely continuing oral iron therapy beyond 3-4 weeks if a favorable response has not occurred.

Once a response to oral iron is demonstrated, therapy should be continued until the hemoglobin returns to normal. Treatment may be extended if it is desirable to replenish iron stores. This may require a considerable period of time because the rate of absorption of iron by the intestine will decrease markedly as iron stores are reconstituted. The prophylactic use of oral iron should be reserved for patients at high risk, including pregnant women, women with excessive menstrual blood loss, and infants. Iron supplements also may be of value for rapidly growing infants who are consuming substandard diets and for adults with a recognized cause of chronic blood loss. Except for infants, in whom the use of supplemented formulas is routine, the use of over-the-counter mixtures of vitamins and minerals to prevent iron deficiency should be discouraged.

Therapy with Oral Iron. Orally administered ferrous sulfate is the treatment of choice for iron deficiency. Ferrous salts are absorbed about three times as well as ferric salts, and the discrepancy becomes even greater

at high dosages. Variations in the particular ferrous salt have relatively little effect on bioavailability; the sulfate (FEOSOL, others), fumarate (HEMOCYTE, FEOSTAT, others), succinate, gluconate (FERGON, others), aspartate, other ferrous salts, and polysaccharide-ferrihydrite complex (NIFEREX, others), are absorbed to approximately the same extent. The effective dose of all of these preparations is based on iron content.

Other iron compounds have utility in fortification of foods. Reduced iron (metallic iron, elemental iron) is as effective as ferrous sulfate, provided that the material employed has a small particle size. Large-particle ferrum reductum and iron phosphate salts have a much lower bioavailability, and their use for the fortification of foods is undoubtedly responsible for some of the confusion concerning effectiveness. Ferric edetate has been shown to have good bioavailability and to have advantages for maintenance of the normal appearance and taste of food.

The amount of iron, rather than the mass of the total salt in iron tablets, is important. It also is essential that the coating of the tablet dissolve rapidly in the stomach. Surprisingly, because iron usually is absorbed in the upper small intestine, certain delayed-release preparations have been reported to be effective and have been said to be even more effective than ferrous sulfate when taken with meals. However, reports of absorption from such preparations vary. Because a number of forms of delayed-release preparations are on the market and information on their bioavailability is limited, the effectiveness of most such preparations must be considered questionable.

A variety of substances designed to enhance the absorption of iron has been marketed, including surface-acting agents, carbohydrates, inorganic salts, amino acids, and vitamins. When present in an amount of ≥ 200 mg, ascorbic acid increases the absorption of medicinal iron by at least 30%. However, the increased uptake is associated with a significant increase in the incidence of side effects; therefore, the addition of ascorbic acid seems to have little advantage over increasing the amount of iron administered. It is inadvisable to use preparations that contain other compounds with therapeutic actions of their own, such as vitamin B₁₂, folate, or cobalt, because the patient's response to the combination cannot easily be interpreted.

The average dose for the treatment of iron-deficiency anemia is ~200 mg of iron per day (2-3 mg/kg), given in three equal doses of 65 mg. Children weighing 15-30 kg can take half the average adult dose; small children and infants can tolerate relatively large doses of iron, e.g., 5 mg/kg. The dose used is a compromise between the desired therapeutic action and the toxic effects. Prophylaxis and mild nutritional iron deficiency may be managed with modest doses. When the object is the prevention of iron deficiency in pregnant women, e.g., doses of 15 to 30 mg of iron per day are adequate to meet the 3- to 6-mg daily requirement of the last two trimesters. When the purpose is to treat iron-deficiency anemia, but the circumstances do not demand haste, a total dose of ~100 mg (35 mg three times daily) may be used.

The responses expected for different dosage regimens of oral iron are given in Table 37-5. These effects are modified by the severity of the iron-deficiency anemia and by the time of ingestion of iron relative to meals. Bioavailability of iron ingested with food is

Table 37-5

Average Response to Oral Iron

TOTAL DOSE OF IRON (mg/day)	ESTIMATED ABSORPTION		INCREASE IN BLOOD Hb (g/L/day)
	%	mg	
35	40	14	0.7
105	24	25	1.4
195	18	35	1.9
390	12	45	2.2

probably one-half or one-third of that seen in the fasting subject (Grebe et al., 1975). Antacids also reduce iron absorption if given concurrently. It is always preferable to administer iron in the fasting state, even if the dose must be reduced because of GI side effects. For patients who require maximal therapy to encourage a rapid response or to counteract continued bleeding, as much as 120 mg of iron may be administered four times a day. Sustained high rates of red-cell production require an uninterrupted supply of iron, and oral doses should be spaced equally to maintain a continuous high concentration of iron in plasma.

The duration of treatment is governed by the rate of recovery of hemoglobin and the desire to create iron stores. The former depends on the severity of the anemia. With a daily rate of repair of 2 g of hemoglobin per liter of whole blood, the red-cell mass usually is reconstituted within 1-2 months. Thus an individual with a hemoglobin of 50 g per liter may achieve a normal complement of 150 g/L in ~50 days, whereas an individual with a hemoglobin of 100 g/L may take only half that time. The creation of stores of iron requires many months of oral iron administration. The rate of absorption decreases rapidly after recovery from anemia, and after 3-4 months of treatment, stores may increase at a rate of not much more than 100 mg/month. Much of the strategy of continued therapy depends on the estimated future iron balance. Patients with an inadequate diet may require continued therapy with low doses of iron. If the bleeding has stopped, no further therapy is required after the hemoglobin has returned to normal. With continued bleeding, long-term, high-dose therapy clearly is indicated.

Untoward Effects of Oral Preparations of Iron.

Intolerance to oral preparations of iron primarily is a function of the amount of soluble iron in the upper GI tract and of psychological factors. Side effects include heartburn, nausea, upper gastric discomfort, and diarrhea or constipation. A good policy is to initiate therapy at a small dosage, to demonstrate freedom from symptoms at that level, and then gradually to increase the dosage to that desired. With a dose of 200 mg of iron per day divided into three equal portions, symptoms occur in ~25% of treated individuals versus 13% among those receiving placebo; this increases to ~40% when

the dosage of iron is doubled. Nausea and upper abdominal pain are increasingly common at high dosage. Constipation and diarrhea, perhaps related to iron-induced changes in the intestinal bacterial flora, are not more prevalent at higher dosage, nor is heartburn. If a liquid is given, one can place the iron solution on the back of the tongue with a dropper to prevent transient staining of teeth.

The normal individual apparently is able to control absorption of iron despite high intake, and it is only individuals with underlying disorders that augment the absorption of iron who run the hazard of developing iron overload (hemochromatosis). However, hemochromatosis is a relatively common genetic disorder, present in 0.5% of the population.

Iron Poisoning. Large amounts of ferrous salts are toxic, but fatalities are rare in adults. Most deaths occur in children, particularly between the ages of 12 and 24 months. As little as 1-2 g of iron may cause death, but 2-10 g usually is ingested in fatal cases. The frequency of iron poisoning relates to its availability in the household, particularly the supply that remains after a pregnancy. The colored sugar coating of many of the commercially available tablets gives them the appearance of candy. All iron preparations should be kept in childproof bottles.

Signs and symptoms of severe poisoning may occur within 30 minutes after ingestion or may be delayed for several hours. They include abdominal pain, diarrhea, or vomiting of brown or bloody stomach contents containing pills. Of particular concern are pallor or cyanosis, lassitude, drowsiness, hyperventilation due to acidosis, and cardiovascular collapse. If death does not occur within 6 hours, there may be a transient period of apparent recovery, followed by death in 12-24 hours. The corrosive injury to the stomach may result in pyloric stenosis or gastric scarring. Hemorrhagic gastroenteritis and hepatic damage are prominent findings at autopsy. In the evaluation of a child thought to have ingested iron, a color test for iron in the gastric contents and an emergency determination of the concentration of iron in plasma can be performed. If the latter is <63 μmol (3.5 mg/L), the child is not in immediate danger. However, vomiting should be induced when there is iron in the stomach, and an x-ray should be taken to evaluate the number of pills remaining in the small bowel (iron tablets are radiopaque). Iron in the upper GI tract can be precipitated by lavage with sodium bicarbonate or phosphate solution, although the clinical benefit is questionable. When the plasma concentration of iron is greater than the total iron-binding capacity (63 μmol ; 3.5 mg/L), deferoxamine should be administered (Chapter 67). Shock, dehydration, and acid-base abnormalities should be treated in the conventional manner. Most important is the speed of diagnosis and therapy. With early effective treatment, the mortality from iron poisoning can be reduced from as high as 45% to ~1%.

Therapy with Parenteral Iron. When oral iron therapy fails, parenteral iron administration may be an effective alternative (Silverstein and Rodgers, 2004). The rate of response to parenteral therapy is similar to that which

follows usual oral doses. Common indications are iron malabsorption (e.g., sprue, short bowel syndrome), severe oral iron intolerance, as a routine supplement to total parenteral nutrition, and in patients who are receiving erythropoietin (Eschbach et al., 1987). In particular, when hemodialysis patients are started on erythropoietin, oral iron therapy alone generally is insufficient to provide an optimal hemoglobin response. It therefore is recommended that sufficient parenteral iron be given to maintain a plasma ferritin level between 100 and 800 $\mu\text{g/L}$ and a transferrin saturation of 20-50% (Goodnough et al., 2000).

Parenteral iron also has been given to iron-deficient patients and pregnant women to create iron stores, something that would take months to achieve by the oral route. The belief that the response to parenteral iron, especially iron dextran, is faster than oral iron is open to debate. In otherwise healthy individuals, the rate of hemoglobin response is determined by the balance between the severity of the anemia (the level of erythropoietin stimulus) and the delivery of iron to the marrow from iron absorption and iron stores. When a large intravenous dose of iron dextran is given to a severely anemic patient, the hematologic response can exceed that seen with oral iron for 1-3 weeks. Subsequently, however, the response is no better than that seen with oral iron.

Parenteral iron therapy should be used only when clearly indicated because acute hypersensitivity, including anaphylactic and anaphylactoid reactions, can occur in 0.2-3% of patients (Faich and Strobos, 1999). Other reactions to intravenous iron include headache, malaise, fever, generalized lymphadenopathy, arthralgias, urticaria, and in some patients with rheumatoid arthritis, exacerbation of the disease.

Four iron formulations are available in the U.S. These are iron dextran (DEXFERRUM or INFED), sodium ferric gluconate (FERRELECT), ferumoxytol (FERAHEME), and iron sucrose (VENOFER). Ferumoxytol is a semisynthetic carbohydrate-coated superparamagnetic iron oxide nanoparticle that is approved for treatment of iron-deficiency anemia in patients with chronic kidney disease (Balakrishnan et al., 2009). The indications for the iron dextran preparations include treatment of any patient with documented iron deficiency and intolerance or irresponsiveness to oral iron. In contrast, the indications for the ferric gluconate and iron sucrose are limited to patients with chronic kidney disease who have a documented iron deficiency, although broader applications are being advocated (Wish, 2008). Iron dextran is the only preparation that can be given as a total-dose infusion, which is the entire dose of elemental iron required to replace iron stores. However, ferric gluconate and iron sucrose are administered as a fixed dose every week for several weeks until total iron stores are replenished.

Iron Dextran. Iron dextran injection (INFED or DEXFERRUM) is a colloidal solution of ferric oxyhydroxide complexed with polymerized dextran (molecular weight, $\sim 180,000$ Da) that contains 50 mg/mL of elemental iron. The use of low-molecular-weight iron dextran has reduced the incidence of toxicity relative to that observed with high molecular weight preparations (IMFERON) (Auerbach and Al Talib, 2008). Iron dextran can be administered by either intravenous (preferred) or intramuscular injection. When given by deep intramuscular injection, it is gradually mobilized via the lymphatics and transported to reticuloendothelial cells; the iron then is released from the dextran complex. Intravenous administration gives a more reliable response. Given intravenously in a dose <500 mg, the iron dextran complex is cleared exponentially with a plasma $t_{1/2}$ of 6 hours. When ≥ 1 g is administered intravenously as total dose therapy, reticuloendothelial cell clearance is constant at 10-20 mg/hour. This slow rate of clearance results in a brownish discoloration of the plasma for several days and an elevation of the serum iron for 1-2 weeks.

Once the iron is released from the dextran within the reticuloendothelial cells, it is either incorporated into stores or transported via transferrin to the erythroid marrow. Although a portion of the processed iron is rapidly made available to the marrow, a significant fraction is only gradually converted to usable iron stores. All of the iron eventually is released, although many months are required before the process is complete. During this time, the iron dextran stores in reticuloendothelial cells can confuse the clinician who attempts to evaluate the iron status of the patient.

Intramuscular injection of iron dextran should only be initiated after a test dose of 0.5 mL (25 mg of iron). If no adverse reactions are observed, the injections can proceed. The daily dose ordinarily should not exceed 0.5 mL (25 mg of iron) for infants weighing <4.5 kg (10 lb), 1 mL (50 mg of iron) for children weighing <9 kg (20 lb), and 2 mL (100 mg of iron) for other patients. Iron dextran should be injected only into the muscle mass of the upper outer quadrant of the buttock using a z-track technique (displacement of the skin laterally before injection). However, local reactions and the concern about malignant change at the site of injection (Weinbren et al., 1978) make intramuscular administration inappropriate except when the intravenous route is inaccessible.

A test injection of 0.5 mL of undiluted iron dextran or an equivalent amount (25 mg of iron) diluted in saline also should precede intravenous administration of a therapeutic dose of iron dextran. The patient should be observed for signs of immediate anaphylaxis and for an hour after injection for any signs of vascular instability or hypersensitivity, including respiratory distress, hypotension, tachycardia, or back or chest pain. When widely spaced total-dose infusion therapy is given, a test dose injection should be given before each infusion because hypersensitivity can appear at any time. Furthermore, the patient should be monitored closely throughout the infusion for signs of cardiovascular instability. Delayed hypersensitivity reactions also are observed, especially in patients with rheumatoid arthritis or a history of allergies. Fever, malaise, lymphadenopathy, arthralgias, and urticaria can develop days or weeks following injection and last for prolonged periods of time. Therefore, iron dextran should be used with extreme caution in patients with rheumatoid arthritis or other connective tissue diseases, and during the acute phase of an inflammatory illness. Once hypersensitivity is documented, iron dextran therapy must be abandoned.

Before initiating iron dextran therapy, the total dose of iron required to repair the patient's iron-deficient state should be calculated. Relevant factors are the hemoglobin deficit, the need to reconstitute iron stores, and continued excess losses of iron, as seen with hemodialysis and chronic GI bleeding. Iron dextran solution (50 mg/mL of elemental iron) can be administered undiluted in daily doses of 2 mL until the total dose is reached or given off label as a single total-dose infusion. In the latter case, the iron dextran should be diluted in 250-1000 mL of 0.9% saline and infused over an hour or more.

With repeated doses of iron dextran—especially multiple total-dose infusions such as those sometimes used in the treatment of chronic GI blood loss—accumulations of slowly metabolized iron dextran stores in reticuloendothelial cells can be impressive. The plasma ferritin level also can rise to levels associated with iron overload. Although disease-related hemochromatosis has been associated with an increased risk of infections and cardiovascular disease, this has not been shown to be true in hemodialysis patients treated with iron dextran (Owen, 1999). It seems prudent, however, to withhold the drug whenever the plasma ferritin rises above 800 $\mu\text{g/L}$.

Sodium Ferric Gluconate. Sodium ferric gluconate is an intravenous iron preparation with a molecular size of $\sim 295,000$ Da and an osmolality of 990 mOsm/kg^{-1} (Balakrishnan et al., 2009). Administration of ferric gluconate at doses ranging from 62.5-125 mg during hemodialysis is associated with transferrin saturation exceeding 100% (Zanen et al., 1996). Hemodialysis patients who had ferritin levels between 500 and 1200 ng/mL and transferrin saturations of $\leq 25\%$ while undergoing treatment with erythropoietin had improved hemoglobin values following treatment with ferric gluconate, resulting in reduced requirements for erythropoietin (Kapoian et al., 2008).

Unlike iron dextran, which requires processing by macrophages that may require several weeks, $\sim 80\%$ of sodium ferric gluconate is delivered to transferrin within 24 hours. Sodium ferric gluconate also has a lower risk of inducing serious anaphylactic reactions than iron dextran (Sengolge et al., 2005). No deaths were reported with 25 million infusions of sodium ferric gluconate, whereas there were 31 infusion-related deaths reported from approximately half the number of patients treated with iron dextran (Faich and Strobos, 1999). Thus, sodium ferric gluconate has become the preferred agent for parenteral iron therapy. Currently iron dextran is reserved for noncompliant patients or for those who are seriously inconvenienced by the multiple infusions that may be required for treatment with sodium ferric gluconate or iron sucrose.

Iron Sucrose. Iron sucrose is complex of polynuclear iron (III)-hydroxide in sucrose with a molecular weight of 252,000 Da and an osmolality of $1316 \text{ mOsm/kg}^{-1}$ (Balakrishnan et al., 2009). Following intravenous injection, the complex is taken up by the reticuloendothelial system, where it dissociates into iron and sucrose. Iron sucrose is generally administered in daily amounts of 100-200 mg within a 14-day period to a total cumulative dose of 1000 mg. It can be administered repeatedly to hemodialysis patients as maintenance therapy without inducing hypersensitivity (Aronoff et al., 2004).

Like sodium ferric gluconate, iron sucrose appears to be better tolerated and to cause fewer adverse events than iron dextran (Hayat, 2008). This agent is FDA-approved for the treatment of iron deficiency in patients with chronic kidney disease. However, iron sucrose has been used effectively to treat iron deficiency observed in

other clinical settings (al-Momen et al., 1996; Bodemar et al., 2004). However, one study reported that iron sucrose may be most likely of available parenteral iron preparations to induce renal tubular injury because of its high renal uptake (Zager et al., 2004), potentially resulting in tubulointerstitial damage with chronic repeated use (Agarwal, 2006).

Copper

Copper deficiency is extremely rare because the amount present in food is more than adequate to provide the needed body complement of slightly more than 100 mg. There is speculation that marginal deficiency of copper can contribute to development or progression of a number of chronic disorders, such as diabetes or cardiovascular disease (Uriu-Adams and Keen, 2005). However, there is no evidence that copper ever needs to be added to a normal diet, either prophylactically or therapeutically. Even in clinical states associated with hypocupremia (sprue, celiac disease, and nephrotic syndrome), effects of copper deficiency usually are not demonstrable. Anemia due to copper deficiency has been described in individuals who have undergone intestinal bypass surgery (Zidar et al., 1977), in those who are receiving parenteral nutrition (Dunlap et al., 1974), in malnourished infants (Graham and Cordano, 1976), and in patients ingesting excessive amounts of zinc (Hoffman et al., 1988).

Copper has redox properties similar to that of iron, which simultaneously is essential and potentially toxic to the cell (Kim et al., 2008). Cells have virtually no free copper. Instead copper is stored by metallothioneins and distributed by specialized chaperones to sites that make use of its redox properties (Lalioi et al., 2009). Transfer of copper to nascent cuproenzymes is performed by individual or collective activities of P-type ATPases, ATP7A and ATP7B, which are expressed in all tissues (Linz and Lutsenko, 2007). In mammals, the liver is the organ most responsible for the storage, distribution, and excretion of copper. Mutations in ATP7A or ATP7B that interfere with this function have been found responsible for Wilson's disease or Menkes syndrome (steely hair syndrome) (de Bie et al., 2007), respectively, which can result in life-threatening hepatic failure.

Copper deficiency in experimental animals interferes with the absorption of iron and its release from reticuloendothelial cells (Gambling et al., 2008). The associated microcytic anemia is related to a decrease in the availability of iron to the normoblasts, and perhaps even more importantly, to decreased mitochondrial production of heme. It may be that the specific defect in the latter case is a decrease in the activity of cytochrome oxidase. Other pathological effects involving the skeletal, cardiovascular, and nervous systems have been observed in copper-deficient experimental animals. In humans, the prominent findings have been leukopenia, particularly granulocytopenia, and anemia. Concentrations of iron in plasma are variable, and the anemia is not always microcytic. When a low plasma copper concentration is determined in the presence of leukopenia and anemia, a

therapeutic trial with copper is appropriate. Daily doses up to 0.1 mg/kg of cupric sulfate have been given by mouth, or 1-2 mg per day may be added to the solution of nutrients for parenteral administration. The daily U.S. Recommended Daily Allowance (RDA) of copper ranges from 1,300 µg for nursing women to 200 µg for infants 0-6 months of age.

Pyridoxine

Harris and associates first described pyridoxine-responsive anemia in 1956. Subsequent reports suggested that the vitamin might improve hematopoiesis in up to 50% of patients with either hereditary or acquired sideroblastic anemia. These patients characteristically have impaired hemoglobin synthesis and accumulate iron in the perinuclear mitochondria of erythroid precursor cells, so-called ringed sideroblasts. Hereditary sideroblastic anemia is an X-linked recessive trait with variable penetrance and expression that results from mutations in the erythrocyte form of δ -aminolevulinic synthase. Affected men typically show a dual population of normal red cells and microcytic, hypochromic cells in the circulation. In contrast, idiopathic acquired sideroblastic anemia and the sideroblastic anemias associated with a number of drugs, inflammatory states, neoplastic disorders, and preleukemic syndromes show a variable morphological picture. Moreover, erythrokinetic studies demonstrate a spectrum of abnormalities, from a hypoproliferative defect with little tendency to accumulate iron to marked ineffective erythropoiesis with iron overload of the tissues (Solomon and Hillman, 1979).

Oral therapy with pyridoxine is of proven benefit in correcting the sideroblastic anemias associated with the antituberculosis drugs isoniazid and pyrazinamide, which act as vitamin B₆ antagonists. A daily dose of 50 mg of pyridoxine completely corrects the defect without interfering with treatment, and routine supplementation of pyridoxine often is recommended (see Chapter 56). In contrast, if pyridoxine is given to counteract the sideroblastic abnormality associated with administration of levodopa, the effectiveness of levodopa in controlling Parkinson's disease is decreased. Pyridoxine therapy does not correct the sideroblastic abnormalities produced by chloramphenicol or lead.

Patients with idiopathic acquired sideroblastic anemia generally fail to respond to oral pyridoxine, and those individuals who appear to have a pyridoxine-responsive anemia require prolonged therapy with large doses of the vitamin, 50-500 mg per day. Unfortunately, the early enthusiasm for treatment with pyridoxine was not reinforced by results of later studies. Moreover, even when a patient with sideroblastic anemia responds, the improvement is only partial because both the ringed sideroblasts and the red-cell defect persist, and the hematocrit rarely returns to normal. Nonetheless, in view of the low toxicity of oral pyridoxine, a therapeutic trial with pyridoxine is appropriate.

As shown in studies of normal subjects, oral pyridoxine in a dosage of 100 mg three times daily produces a maximal increase in red-cell pyridoxine kinase and the major pyridoxal phosphate-dependent

enzyme glutamic-aspartic aminotransferase (Solomon and Hillman, 1978). For an adequate therapeutic trial, the drug is administered for at least 3 months while the response is monitored by measuring the reticulocyte index and the hemoglobin concentration. The occasional patient who is refractory to oral pyridoxine may respond to parenteral administration of pyridoxal phosphate. However, oral pyridoxine in doses of 200-300 mg per day produces intracellular concentrations of pyridoxal phosphate equal to or greater than those generated by therapy with the phosphorylated vitamin.

Riboflavin

Pure red-cell aplasia that responded to the administration of riboflavin was reported in patients with protein depletion and complicating infections. Lane and associates induced riboflavin deficiency in humans and demonstrated that a hypoproliferative anemia resulted within a month. The spontaneous appearance in humans of red-cell aplasia due to riboflavin deficiency undoubtedly is rare, if it occurs at all. It has been described in combination with infection and protein deficiency, both of which are capable of producing a hypoproliferative anemia. However, it seems reasonable to include riboflavin in the nutritional management of patients with gross, generalized malnutrition.

B₁₂, Folic Acid, and the Treatment of Megaloblastic Anemias

Vitamin B₁₂ and folic acid are dietary essentials (Varela-Moreiras et al., 2009). A deficiency of either vitamin impairs DNA synthesis in any cell in which chromosomal replication and division are taking place. Because tissues with the greatest rate of cell turnover show the most dramatic changes, the hematopoietic system is especially sensitive to deficiencies of these vitamins. An early sign of deficiency is megaloblastic anemia. Abnormal macrocytic red blood cells are produced, and the patient becomes severely anemic. Recognized in the 19th century, this pattern of abnormal hematopoiesis, termed *pernicious anemia*, spurred investigations that ultimately led to the discovery of vitamin B₁₂ and folic acid. Even today, the characteristic abnormality in red blood cell morphology is important for diagnosis and as a therapeutic guide following administration of the vitamins.

History. The discovery of vitamin B₁₂ and folic acid is a dramatic story that started >180 years ago and includes two discoveries that won the Nobel Prize. The first descriptions of what must have been megaloblastic anemias came from the work of Combe and Addison, who published a series of case reports beginning in 1824. It still is

common practice to describe megaloblastic anemia as Addisonian pernicious anemia. Although Combe suggested that the disorder might have some relationship to digestion, it was Austin Flint who in 1860 first described the severe gastric atrophy and called attention to its possible relationship to the anemia.

After the observation by Whipple in 1925 that liver is a source of a potent hematopoietic substance for iron-deficient dogs, Minot and Murphy carried out Nobel Prize-winning experiments that demonstrated the effectiveness of the feeding of liver to reverse pernicious anemia. Soon thereafter, Castle defined the need for both intrinsic factor, a substance secreted by the parietal cells of the gastric mucosa, and extrinsic factor, the vitamin-like material provided by crude liver extracts. Nearly 20 years passed before Rickes and coworkers and Smith and Parker isolated and crystallized vitamin B₁₂; Dorothy Hodgkin received the Nobel Prize for determining its x-ray crystal structure.

As attempts were being made to purify extrinsic factor, Wills and her associates described a macrocytic anemia in women in India that responded to a factor present in crude liver extracts but not in the purified fractions known to be effective in pernicious anemia. This factor, first called Wills' factor and later vitamin M, is now known to be folic acid. The term *folic acid* was coined by Mitchell and coworkers in 1941, after its isolation from leafy vegetables.

More recent work has shown that neither vitamin B₁₂ nor folic acid as purified from foodstuffs is the active coenzyme in humans. During extraction, active labile forms are converted to stable congeners of vitamin B₁₂ and folic acid, cyanocobalamin and pteroylglutamic acid, respectively. These congeners must then be modified *in vivo* to be effective. Although a great deal has been learned about the intracellular metabolic pathways in which these vitamins function as required cofactors, many questions remain, among them: what is the relationship of vitamin B₁₂ deficiency to the neurological abnormalities that occur with this disorder?

Relationships Between Vitamin B₁₂ and Folic Acid. The major roles of vitamin B₁₂ and folic acid in intracellular metabolism are summarized in Figure 37–6. Intracellular vitamin B₁₂ is maintained as two active coenzymes: methylcobalamin and deoxyadenosylcobalamin. Deoxyadenosylcobalamin (deoxyadenosyl B₁₂) is a cofactor for the mitochondrial mutase enzyme that catalyzes the isomerization of l-methylmalonyl CoA to succinyl CoA, an important reaction in carbohydrate and lipid metabolism. This reaction has no direct relationship to the metabolic pathways that involve folate. In contrast, methylcobalamin (CH₃B₁₂) supports the methionine synthetase reaction, which is essential for normal metabolism of folate (Weissbach, 2008). Methyl groups contributed by methyltetrahydrofolate (CH₃H₄PteGlu₁) are used to form methylcobalamin, which then acts as a methyl group donor for the conversion of homocysteine to methionine. This folate-cobalamin interaction is pivotal for normal synthesis of purines and pyrimidines, and therefore of DNA. The methionine synthetase reaction is largely responsible for the control of the recycling of folate cofactors; the maintenance of intracellular concentrations of folylpolyglutamates; and, through the synthesis of methionine and its product, S-adenosylmethionine, the maintenance of a number of methylation reactions.

Because methyltetrahydrofolate is the principal folate congener supplied to cells, the transfer of the

Figure 37–6. Interrelationships and metabolic roles of vitamin B₁₂ and folic acid. See text for explanation and Figure 37–7 for structures of the various folate coenzymes. FIGLU, formiminoglutamic acid, which arises from the catabolism of histidine; TcII, transcobalamin II; CH₃H₄PteGlu₁, methyltetrahydrofolate.

methyl group to cobalamin is essential for the adequate supply of tetrahydrofolate ($H_4PteGlu_1$), the substrate for a number of metabolic steps. Tetrahydrofolate is a precursor for the formation of intracellular folylpolyglutamates; it also acts as the acceptor of a one-carbon unit in the conversion of serine to glycine, with the resultant formation of 5,10-methylenetetrahydrofolate (5,10- $CH_2H_4PteGlu$). The latter derivative donates the methylene group to deoxyuridylate (dUMP) for the synthesis of thymidylate (dTMP)—an extremely important reaction in DNA synthesis. In the process, the 5,10- $CH_2H_4PteGlu$ is converted to dihydrofolate ($H_2PteGlu$). The cycle then is completed by the reduction of the $H_2PteGlu$ to $H_4PteGlu$ by dihydrofolate reductase, the step that is blocked by folate antagonists such as methotrexate (Chapter 61). As shown in Figure 37–6, other pathways also lead to the synthesis of 5,10-methylenetetrahydrofolate. These pathways are important in the metabolism of formiminoglutamic acid (FIGLU) and purines and pyrimidines.

In the presence of a deficiency of either vitamin B_{12} or folate, the decreased synthesis of methionine and S-adenosylmethionine interferes with protein biosynthesis, a number of methylation reactions, and the synthesis of polyamines. In addition, the cell responds to the deficiency by redirecting folate metabolic pathways to supply increasing amounts of methyltetrahydrofolate; this tends to preserve essential methylation reactions at the expense of nucleic acid synthesis. With vitamin B_{12} deficiency, methylenetetrahydrofolate reductase activity increases, directing available intracellular folates into the methyltetrahydrofolate pool (not shown in Figure 37–6). The methyltetrahydrofolate then is trapped by the lack of sufficient vitamin B_{12} to accept and transfer methyl groups, and subsequent steps in folate metabolism that require tetrahydrofolate are deprived of substrate. This process provides a common basis for the development of megaloblastic anemia with deficiency of either vitamin B_{12} or folic acid.

The mechanisms responsible for the neurological lesions of vitamin B_{12} deficiency are less well understood (Solomon, 2007). Damage to the myelin sheath is the most obvious lesion in this neuropathy. This observation led to the early suggestion that the deoxyadenosyl B_{12} -dependent methylmalonyl CoA mutase reaction, a step in propionate metabolism, is related to the abnormality. However, other evidence suggests that the deficiency of methionine synthetase and the block of the conversion of methionine to S-adenosylmethionine are more likely to be responsible.

Nitrous oxide (N_2O), used for anesthesia (Chapter 19), can cause megaloblastic changes in the marrow and a neuropathy that resemble those of vitamin B_{12} deficiency. Studies with N_2O have demonstrated a reduction in methionine synthetase and reduced concentrations of methionine and S-adenosylmethionine. The latter is necessary for methylation reactions, including those required for the synthesis of phospholipids and myelin. Significantly, the neuropathy induced with N_2O can be prevented partially by feeding methionine. A neuropathy similar to that occurring with vitamin B_{12} deficiency has been reported in dentists who are exposed to N_2O used as an anesthetic.

Vitamin B_{12}

Chemistry. The structural formula of vitamin B_{12} is shown in Figure 37–7. These are the three major portions of the molecule:

1. A planar group or corrin nucleus—a porphyrin-like ring structure with four reduced pyrrole rings (A-D in Figure 37–7)

Vitamin B_{12} Congeners	
Permissive Name	R Group
Cyanocobalamin (Vitamin B_{12})	-CN
Hydroxocobalamin	-OH
Methylcobalamin	- CH_3
5'-Deoxyadenosylcobalamin	-5'-Deoxyadenosyl

Figure 37–7. The structures and nomenclature of vitamin B_{12} congeners.

linked to a central cobalt atom and extensively substituted with methyl, acetamide, and propionamide residues.

2. A 5,6-dimethylbenzimidazolyl nucleotide, which links almost at right angles to the corrin nucleus with bonds to the cobalt atom and to the propionate side chain of the C pyrrole ring.
3. A variable R group—the most important of which are found in the stable compounds cyanocobalamin and hydroxocobalamin and the active coenzymes methylcobalamin and 5-deoxyadenosylcobalamin.

The terms *vitamin B₁₂* and *cyanocobalamin* are used interchangeably as generic terms for all of the cobamides active in humans. Preparations of vitamin B₁₂ for therapeutic use contain either cyanocobalamin or hydroxocobalamin because only these derivatives remain active after storage.

Metabolic Functions. The active coenzymes methylcobalamin and 5-deoxyadenosylcobalamin are essential for cell growth and replication. Methylcobalamin is required for the conversion of homocysteine to methionine and its derivative S-adenosylmethionine. In addition, when concentrations of vitamin B₁₂ are inadequate, folate becomes “trapped” as methyltetrahydrofolate to cause a functional deficiency of other required intracellular forms of folic acid (see Figures 37–6 and 37–7 and preceding discussion). The hematologic abnormalities in vitamin B₁₂-deficient patients result from this process. 5-Deoxyadenosylcobalamin is required for the re-arrangement of methylmalonyl CoA to succinyl CoA (Figure 37–6).

Sources in Nature. Humans depend on exogenous sources of vitamin B₁₂. In nature, the primary sources are certain microorganisms that grow in soil, sewage, water, or the intestinal lumen of animals that synthesize the vitamin. Vegetable products are free of vitamin B₁₂ unless they are contaminated with such microorganisms, so that animals are dependent on synthesis in their own alimentary tract or the ingestion of animal products containing vitamin B₁₂. The daily nutritional requirement of 3–5 μg must be obtained from animal by-products in the diet. Despite this, strict vegetarians rarely develop vitamin B₁₂ deficiency. Some vitamin B₁₂ is available from legumes, which are contaminated with bacteria capable of synthesizing vitamin B₁₂, and vegetarians often fortify their diets with a wide range of vitamins and minerals.

Absorption, Distribution, Elimination, and Daily Requirements. In the presence of gastric acid and pancreatic proteases, dietary vitamin B₁₂ is released from food and salivary binding protein and bound to gastric intrinsic factor. When the vitamin B₁₂-intrinsic factor complex reaches the ileum, it interacts with a receptor

on the mucosal cell surface and is actively transported into circulation. Adequate intrinsic factor, bile, and sodium bicarbonate (to provide a suitable pH) all are required for ileal transport of vitamin B₁₂. Vitamin B₁₂ deficiency in adults is rarely the result of a deficient diet per se; rather, it usually reflects a defect in one or another aspect of this complex sequence of absorption (Figure 37–8). Achlorhydria and decreased secretion of intrinsic factor by parietal cells secondary to gastric atrophy or gastric surgery is a common cause of vitamin B₁₂ deficiency in adults. Antibodies to parietal cells or intrinsic factor complex also can play a prominent role in producing a deficiency. A number of intestinal diseases can interfere with absorption, including pancreatic disorders (loss of pancreatic protease secretion), bacterial overgrowth, intestinal parasites, sprue, and localized damage to ileal mucosal cells by disease or as a result of surgery.

Once absorbed, vitamin B₁₂ binds to transcobalamin II, a plasma β-globulin, for transport to tissues. Two other transcobalamins (I and III) also are present in plasma; their concentrations are related to the rate of turnover of granulocytes. They may represent

Figure 37–8. The absorption and distribution of vitamin B₁₂. Deficiency of vitamin B₁₂ can result from a congenital or acquired defect in any one of the following: (1) inadequate dietary supply; (2) inadequate secretion of intrinsic factor (classical pernicious anemia); (3) ileal disease; (4) congenital absence of transcobalamin II (TcII); or (5) rapid depletion of hepatic stores by interference with reabsorption of vitamin B₁₂ excreted in bile. The utility of measurements of the concentration of vitamin B₁₂ in plasma to estimate supply available to tissues can be compromised by liver disease and (6) the appearance of abnormal amounts of transcobalamins I and III (TcI and III) in plasma. Finally, the formation of methylcobalamin requires (7) normal transport into cells and an adequate supply of folic acid as CH₃H₄PteGlu₁.

intracellular storage proteins that are released with cell death. Vitamin B₁₂ bound to transcobalamin II is rapidly cleared from plasma and preferentially distributed to hepatic parenchymal cells. The liver is a storage depot for other tissues. In normal adults, as much as 90% of the body's stores of vitamin B₁₂, from 1-10 mg, is in the liver. Vitamin B₁₂ is stored as the active coenzyme with a turnover rate of 0.5-8 µg per day, depending on the size of the body stores. The recommended daily intake of the vitamin in adults is 2.4 µg.

Approximately 3 µg of cobalamins are secreted into bile each day, 50-60% of which is not destined for reabsorption. This enterohepatic cycle is important because interference with reabsorption by intestinal disease can progressively deplete hepatic stores of the vitamin. This process may help explain why patients can develop vitamin B₁₂ deficiency within 3-4 years of major gastric surgery, even though a daily requirement of 1-2 µg would not be expected to deplete hepatic stores of more than 2 to 3 mg during this time.

The supply of vitamin B₁₂ available for tissues is directly related to the size of the hepatic storage pool and the amount of vitamin B₁₂ bound to transcobalamin II (Figure 37-8). The plasma concentration of vitamin B₁₂ is the best routine measure of B₁₂ deficiency, and normally ranges from 150-660 pmol (~200-900 pg/mL). Deficiency should be suspected whenever the concentration falls below 150 pmol. The correlation is excellent except when the plasma concentrations of transcobalamin I and III are increased, as occurs with hepatic disease or a myeloproliferative disorder. Inasmuch as the vitamin B₁₂ bound to these transport proteins is relatively unavailable to cells, tissues can become deficient when the concentration of vitamin B₁₂ in plasma is normal or even high. In subjects with congenital absence of transcobalamin II, megaloblastic anemia occurs despite relatively normal plasma concentrations of vitamin B₁₂; the anemia will respond to parenteral doses of vitamin B₁₂ that exceed the renal clearance (Hakami et al., 1971).

Defects in intracellular metabolism of vitamin B₁₂ have been reported in children with methylmalonic aciduria and homocystinuria. Potential mechanisms include an incapacity of cells to transport vitamin B₁₂ or accumulate the vitamin because of a failure to synthesize an intracellular acceptor, a defect in the formation of deoxyadenosylcobalamin, or a congenital lack of methylmalonyl CoA isomerase.

Vitamin B₁₂ Deficiency. Vitamin B₁₂ deficiency is recognized clinically by its impact on the hematopoietic and nervous systems. The sensitivity of the hematopoietic system relates to its high rate of cell turnover. Other tissues with high rates of cell turnover (e.g., mucosa and cervical epithelium) also have high requirements for the vitamin.

As a result of an inadequate supply of vitamin B₁₂, DNA replication becomes highly abnormal. Once a hematopoietic stem cell is committed to enter a programmed series of cell divisions, the defect in

chromosomal replication results in an inability of maturing cells to complete nuclear divisions while cytoplasmic maturation continues at a relatively normal rate. This results in the production of morphologically abnormal cells and death of cells during maturation, a phenomenon referred to as *ineffective hematopoiesis*. These abnormalities are readily identified by examination of the marrow and peripheral blood. Maturation of red-cell precursors is highly abnormal (megaloblastic erythropoiesis). Those cells that do leave the marrow also are abnormal, and many cell fragments, poikilocytes, and macrocytes appear in the peripheral blood. The mean red-cell volume increases to values >110 fL. Severe deficiency affects all cell lines, and a pronounced pancytopenia results.

The diagnosis of a vitamin B₁₂ deficiency usually can be made using measurements of the serum vitamin B₁₂ and/or serum methylmalonic acid. The latter is somewhat more sensitive and has been used to identify metabolic deficiency in patients with normal serum vitamin B₁₂ levels. As part of the clinical management of a patient with severe megaloblastic anemia, a therapeutic trial using very small doses of the vitamin can be used to confirm the diagnosis. Serial measurements of the reticulocyte count, serum iron, and hematocrit are performed to define the characteristic recovery of normal red-cell production. The Schilling test can be used to measure the absorption of the vitamin and delineate the mechanism of the disease. By performing the Schilling test with and without added intrinsic factor, it is possible to discriminate between intrinsic factor deficiency by itself and primary ileal cell disease.

Vitamin B₁₂ deficiency can irreversibly damage the nervous system. Progressive swelling of myelinated neurons, demyelination, and neuronal cell death are seen in the spinal column and cerebral cortex. This causes a wide range of neurological signs and symptoms, including paresthesias of the hands and feet, decreased vibration and position senses with resultant unsteadiness, decreased deep tendon reflexes, and in the later stages, confusion, moodiness, loss of memory, and even a loss of central vision. The patient may exhibit delusions, hallucinations, or even overt psychosis. Because the neurological damage can be dissociated from the changes in the hematopoietic system, vitamin B₁₂ deficiency must be considered in elderly patients with dementia or psychiatric disorders, even if they are not anemic.

Vitamin B₁₂ Therapy. Vitamin B₁₂ is available for injection or oral administration; combinations with other

vitamins and minerals also can be given orally or parenterally. The choice of a preparation always depends on the cause of the deficiency. Although oral preparations may be used to supplement deficient diets, they are of limited value in the treatment of patients with deficiency of intrinsic factor or ileal disease. Even though small amounts of vitamin B₁₂ may be absorbed by simple diffusion, the oral administration cannot be relied on for effective therapy in the patient with a marked deficiency of vitamin B₁₂ and abnormal hematopoiesis or neurological deficits. Therefore, the preparation of choice for treatment of a vitamin B₁₂ deficiency state is cyanocobalamin, and it should be administered by intramuscular or subcutaneous injection.

Cyanocobalamin injection is safe when given by the intramuscular or deep subcutaneous route, but it should never be given intravenously. There have been rare reports of transitory exanthema and anaphylaxis after injection. If a patient reports a previous sensitivity to injections of vitamin B₁₂, an intradermal skin test should be performed before the full dose is administered.

Cyanocobalamin is administered in doses of 1-1000 µg. Tissue uptake, storage, and utilization depend on the availability of transcobalamin II (discussed earlier). Doses >100 µg are cleared rapidly from plasma into the urine, and administration of larger amounts of vitamin B₁₂ will not result in greater retention of the vitamin. Administration of 1000 µg is of value in the performance of the Schilling test. After isotopically labeled vitamin B₁₂ is administered orally, the compound that is absorbed can be quantitatively recovered in the urine if 1000 µg of cyanocobalamin is administered intramuscularly. This unlabeled material saturates the transport system and tissue binding sites, so >90% of the labeled and unlabeled vitamin is excreted during the next 24 hours.

A number of multivitamin preparations are marketed either as nutritional supplements or for the treatment of anemia. Many of these contain up to 80 µg of cyanocobalamin without or with intrinsic factor concentrate prepared from the stomachs of hogs or other domestic animals. One oral unit of intrinsic factor is defined as that amount of material that will bind and transport 15 µg of cyanocobalamin. Most multivitamin preparations supplemented with intrinsic factor contain 0.5 oral unit per tablet. Although the combination of oral vitamin B₁₂ and intrinsic factor would appear to be ideal for patients with an intrinsic factor deficiency, such preparations are not reliable. With prolonged therapy, some patients become refractory to oral intrinsic factor, perhaps related to production of an intraluminal antibody against the hog protein. Patients taking such preparations must be reevaluated at periodic intervals for recurrence of pernicious anemia.

Hydroxocobalamin given in doses of 100 µg intramuscularly has been reported to have a more sustained effect than cyanocobalamin, with a single dose maintaining plasma vitamin B₁₂ concentrations in the normal range for up to 3 months. However, some patients show reductions of the concentration of vitamin B₁₂ in plasma within 30 days, similar to that seen after cyanocobalamin. Furthermore, the administration of hydroxocobalamin has resulted in the formation of antibodies to the transcobalamin II-vitamin B₁₂ complex.

Vitamin B₁₂ has an undeserved reputation as a health tonic and has been used for a number of disease states. Effective use of the vitamin depends on accurate diagnosis and an understanding of the following general principles of therapy:

1. Vitamin B₁₂ should be given prophylactically only when there is a reasonable probability that a deficiency exists or will exist. Dietary deficiency in the strict vegetarian, the predictable malabsorption of vitamin B₁₂ in patients who have had a gastrectomy, and certain diseases of the small intestine constitute such indications. When GI function is normal, an oral prophylactic supplement of vitamins and minerals, including vitamin B₁₂, may be indicated. Otherwise, the patient should receive monthly injections of cyanocobalamin.
2. The relative ease of treatment with vitamin B₁₂ should not prevent a full investigation of the etiology of the deficiency. The initial diagnosis usually is suggested by a macrocytic anemia or an unexplained neuropsychiatric disorder. Full understanding of the etiology of vitamin B₁₂ deficiency involves studies of dietary supply, GI absorption, and transport.
3. Therapy always should be as specific as possible. Although a large number of multivitamin preparations are available, the use of shotgun vitamin therapy in the treatment of vitamin B₁₂ deficiency can be dangerous. With such therapy, there is the danger that sufficient folic acid will be given to result in a hematologic recovery that can mask continued vitamin B₁₂ deficiency and permit neurological damage to develop or progress.
4. Although a classical therapeutic trial with small amounts of vitamin B₁₂ can help confirm the diagnosis, acutely ill elderly patients may not be able to tolerate the delay in the correction of a severe anemia. Such patients require supplemental blood transfusions and immediate therapy with folic acid and vitamin B₁₂ to guarantee rapid recovery.
5. Long-term therapy with vitamin B₁₂ must be evaluated at intervals of 6-12 months in patients who are otherwise well. If there is an additional illness or a condition that may increase the requirement for the vitamin (e.g., pregnancy), reassessment should be performed more frequently.

Treatment of the Acutely Ill Patient. The therapeutic approach depends on the severity of the patient's illness. In uncomplicated pernicious anemia, in which the abnormality is restricted to a mild or moderate anemia without leukopenia, thrombocytopenia, or

neurological signs or symptoms, the administration of vitamin B₁₂ alone will suffice. Moreover, therapy may be delayed until other causes of megaloblastic anemia have been excluded and sufficient studies of GI function have been performed to reveal the underlying cause of the disease. In this situation, a therapeutic trial with small amounts of parenteral vitamin B₁₂ (1–10 µg per day) can confirm the presence of an uncomplicated vitamin B₁₂ deficiency.

In contrast, patients with neurological changes or severe leukopenia or thrombocytopenia associated with infection or bleeding require emergency treatment. The older individual with a severe anemia (hematocrit <20%) is likely to have tissue hypoxia, cerebrovascular insufficiency, and congestive heart failure. Effective therapy must not wait for detailed diagnostic tests. Once the megaloblastic erythropoiesis has been confirmed and sufficient blood collected for later measurements of vitamin B₁₂ and folic acid, the patient should receive intramuscular injections of 100 µg of cyanocobalamin and 1–5 mg of folic acid. For the next 1–2 weeks the patient should receive daily intramuscular injections of 100 µg of cyanocobalamin, together with a daily oral supplement of 1 to 2 mg of folic acid. Because an effective increase in red-cell mass will not occur for 10–20 days, the patient with a markedly depressed hematocrit and tissue hypoxia also should receive a transfusion of 2–3 units of packed red blood cells. If congestive heart failure is present, diuretics can be administered to prevent volume overload.

Patients usually report an increased sense of well-being within the first 24 hours of the initiation of therapy. Objectively, memory and orientation can improve dramatically, although full recovery of mental function may take months, or it may never occur. In addition, even before an obvious hematologic response is apparent, the patient may report an increase in strength, a better appetite, and reduced soreness of the mouth and tongue.

The first objective hematologic change is the disappearance of the megaloblastic morphology of the bone marrow. As the ineffective erythropoiesis is corrected, the concentration of iron in plasma falls dramatically as the metal is used in the formation of hemoglobin. This usually occurs within the first 48 hours. Full correction of precursor maturation in marrow with production of an increased number of reticulocytes begins about the second or third day and peaks 3–5 days later. When the anemia is moderate to severe, the maximal reticulocyte index will be between three and five times the normal value (i.e., a reticulocyte count of 20–40%). The ability of the marrow to sustain a high rate of production determines the rate of recovery of the hematocrit. Patients with complicating iron deficiency, an infection or other inflammatory state, or renal disease may be unable to correct their anemia. Therefore it is important to monitor the reticulocyte index over the first several weeks. If it does not continue at elevated levels while the hematocrit is <35%, plasma concentrations of iron and folic acid should again be determined and the patient reevaluated for an illness that could inhibit the response of the marrow.

The degree and rate of improvement of neurological signs and symptoms depend on the severity and the duration of the abnormalities. Those that have been present for only a few months usually disappear relatively rapidly. When a defect has been present for many months or years, full return to normal function may never occur.

Long-Term Therapy with Vitamin B₁₂. Once begun, vitamin B₁₂ therapy must be maintained for life. This fact must be impressed on the

patient and family, and a system must be established to guarantee continued monthly injections of cyanocobalamin.

Intramuscular injection of 100 µg of cyanocobalamin every 4 weeks is sufficient to maintain a normal concentration of vitamin B₁₂ in plasma and an adequate supply for tissues. Patients with severe neurological symptoms and signs may be treated with larger doses of vitamin B₁₂ in the period immediately after the diagnosis. Doses of 100 µg per day or several times per week may be given for several months with the hope of encouraging faster and more complete recovery. It is important to monitor vitamin B₁₂ concentrations in plasma and to obtain peripheral blood counts at intervals of 3–6 months to confirm the adequacy of therapy. Because refractoriness to therapy can develop at any time, evaluation must continue throughout the patient's life. Intranasal preparations are available for maintenance following normalization of vitamin B₁₂-deficient patients without nervous system involvement (CALOMIST, NASCOBAL) or as a supplement for vitamin B₁₂ deficiencies of various etiologies (NASCOBAL).

Other Therapeutic Uses of Vitamin B₁₂. Vitamin B₁₂ has been used in the therapy of a number of conditions, including trigeminal neuralgia, multiple sclerosis and other neuropathies, various psychiatric disorders, poor growth or nutrition, and as a "tonic" for patients complaining of tiredness or easy fatigue. There is no evidence for the validity of such therapy in any of these conditions. Maintenance therapy with vitamin B₁₂ has been used with some apparent success in the treatment of children with methylmalonic aciduria.

Folic Acid

Chemistry and Metabolic Functions. The structural formula of pteroylglutamic acid (PteGlu) is shown in Figure 37–9. Major portions of the molecule include a pteridine ring linked by a methylene bridge to para-aminobenzoic acid, which is joined by an amide linkage to glutamic acid. Although pteroylglutamic acid is the common pharmaceutical form of folic acid, it is neither the principal folate congener in food nor the active coenzyme for intracellular metabolism. After absorption, PteGlu is rapidly reduced at the 5, 6, 7, and 8 positions to tetrahydrofolic acid (H₄PteGlu), which then acts as an acceptor of a number of one-carbon units. These are attached at either the 5 or the 10 position of the pteridine ring or may bridge these atoms to form a new five-membered ring. The most important forms of the coenzyme that are synthesized by these reactions are listed in Figure 37–9. Each plays a specific role in intracellular metabolism, summarized as follows (see "Relationships Between Vitamin B₁₂ and Folic Acid," as well as Figure 37–6).

Conversion of Homocysteine to Methionine. This reaction requires CH₃H₄PteGlu as a methyl donor and uses vitamin B₁₂ as a cofactor.

Conversion of Serine to Glycine. This reaction requires tetrahydrofolate as an acceptor of a methylene group from serine and uses pyridoxal phosphate as a cofactor. It results in the formation of 5,10-CH₂H₄PteGlu, an essential coenzyme for the synthesis of thymidylate.

Synthesis Of thymidylate. 5,10-CH₂H₄PteGlu donates a methylene group and reducing equivalents to deoxyuridylylate for the synthesis of thymidylate—a rate-limiting step in DNA synthesis.

Histidine Metabolism. H₄PteGlu also acts as an acceptor of a formimino group in the conversion of formiminoglutamic acid to glutamic acid.

Synthesis of Purines. Two steps in the synthesis of purine nucleotides require the participation of 10-CHOH₄PteGlu as a formyl donor in

Figure 37–9. The structures and nomenclature of pteroylglutamic acid (folic acid) and its congeners. X represents additional residues of glutamate; polyglutamates are the storage and active forms of the vitamin. The subscript that designates the number of residues of glutamate is frequently omitted because this number is variable.

reactions catalyzed by ribotide transformylases: the formylation of glycinamide ribonucleotide and the formylation of 5-aminoimidazole-4-carboxamide ribonucleotide. By these reactions, carbon atoms at positions 8 and 2, respectively, are incorporated into the growing purine ring.

Utilization or generation of formate. This reversible reaction uses H₄PteGlu and 10-CHOH₄PteGlu.

Daily Requirements. Many food sources are rich in folates, especially fresh green vegetables, liver, yeast, and some fruits. However, lengthy cooking can destroy up to 90% of the folate content of such food.

Generally, a standard U.S. diet provides 50-500 µg of absorbable folate per day, although individuals with high intakes of fresh vegetables and meats will ingest as much as 2 mg per day. In the normal adult, the recommended daily intake is 400 µg; pregnant or lactating women and patients with high rates of cell turnover (such as patients with a hemolytic anemia) may require 500-600 µg or more per day. For the prevention of neural tube defects, a daily intake of at least 400 µg of folate in food or in supplements beginning a month before pregnancy and continued for at least the first trimester is recommended. Folate supplementation also is being considered in patients with elevated levels of plasma homocysteine.

Absorption, Distribution, and Elimination. As with vitamin B₁₂, the diagnosis and management of deficiencies of folic acid depend on an understanding of the transport pathways and intracellular metabolism of the vitamin (Figure 37–10). Folates present in food are largely in the form of reduced polyglutamates, and absorption requires transport and the action of a pteroylglutamyl carboxypeptidase associated with

mucosal cell membranes. The mucosae of the duodenum and upper part of the jejunum are rich in dihydrofolate reductase and can methylate most or all of the reduced folate that is absorbed. Because most absorption occurs in the proximal portion of the small intestine, it is not unusual for folate deficiency to occur when the jejunum is diseased. Both nontropical and tropical sprue are common causes of folate deficiency and megaloblastic anemia.

Once absorbed, folate is transported rapidly to tissues as CH₃H₄PteGlu. Although certain plasma proteins do bind folate derivatives, they have a greater affinity for nonmethylated analogs. The role of such binding proteins in folate homeostasis is not well understood. An increase in binding capacity is detectable in folate deficiency and in certain disease states, such as uremia, cancer, and alcoholism, but how binding affects transport and tissue supply requires further investigation.

A constant supply of CH₃H₄PteGlu is maintained by food and by an enterohepatic cycle of the vitamin. The liver actively reduces and methylates PteGlu (and H₂ or H₄PteGlu) and then transports the CH₃H₄PteGlu into bile for reabsorption by the gut and subsequent delivery to tissues. This pathway may provide ≥200 µg of folate each day for recirculation to tissues. The importance of the enterohepatic cycle is suggested by animal studies that show a rapid reduction of the plasma folate concentration after either drainage of bile or ingestion of alcohol, which apparently blocks the release of CH₃H₄PteGlu from hepatic parenchymal cells.

Folate Deficiency. Folate deficiency is a common complication of diseases of the small intestine that interferes with the absorption of folate from food and the recirculation of folate through the enterohepatic cycle. In acute

Figure 37–10. Absorption and distribution of folate derivatives. Dietary sources of folate polyglutamates are hydrolyzed to the monoglutamate, reduced, and methylated to $\text{CH}_3\text{H}_4\text{PteGlu}_1$ during gastrointestinal transport. Folate deficiency commonly results from (1) inadequate dietary supply and (2) small intestinal disease. In patients with uremia, alcoholism, or hepatic disease there may be defects in (3) the concentration of folate binding proteins in plasma and (4) the flow of $\text{CH}_3\text{H}_4\text{PteGlu}_1$ into bile for reabsorption and transport to tissue (the folate enterohepatic cycle). Finally, vitamin B_{12} deficiency will (5) “trap” folate as $\text{CH}_3\text{H}_4\text{PteGlu}_1$, thereby reducing the availability of $\text{H}_4\text{PteGlu}_1$ for its essential roles in purine and pyrimidine synthesis.

or chronic alcoholism, daily intake of folate in food may be severely restricted, and the enterohepatic cycle of the vitamin may be impaired by toxic effects of alcohol on hepatic parenchymal cells; this is the most common cause of folate-deficient megaloblastic erythropoiesis. However, it also is the most amenable to therapy, inasmuch as the reinstatement of a normal diet is sufficient to overcome the effect of alcohol. Disease states characterized by a high rate of cell turnover, such as hemolytic anemias, also may be complicated by folate deficiency. Additionally, drugs that inhibit dihydrofolate reductase (e.g., methotrexate and trimethoprim) or that interfere with the absorption and storage of folate in tissues (e.g., certain anticonvulsants and oral contraceptives) can lower the concentration of folate in plasma and may cause a megaloblastic anemia (Scott and Weir, 1980).

Folate deficiency has been implicated in the incidence of neural tube defects, including spina bifida, encephaloceles, and anencephaly. This is true even in the absence of folate-deficient anemia or alcoholism. A less-than-adequate intake of folate also can result in elevations in plasma homocysteine (Green and Miller, 1999). Because even moderate hyperhomocysteinemia is considered an independent risk factor for coronary artery and peripheral vascular

disease and for venous thrombosis, the role of folate as a methyl donor in the homocysteine-to-methionine conversion is getting increased attention. Patients who are heterozygous for one or another enzymatic defect and have high normal to moderate elevations of plasma homocysteine may improve with folic acid therapy.

Folate deficiency is recognized by its impact on the hematopoietic system. As with vitamin B_{12} , this fact reflects the increased requirement associated with high rates of cell turnover. The megaloblastic anemia that results from folate deficiency cannot be distinguished from that caused by vitamin B_{12} deficiency. This finding is to be expected because of the final common pathway of the major intracellular metabolic roles of the two vitamins. At the same time, folate deficiency is rarely if ever associated with neurological abnormalities. Thus the observation of characteristic abnormalities in vibratory and position sense and in motor and sensory pathways is incompatible with an isolated deficiency of folic acid.

After deprivation of folate, megaloblastic anemia develops much more rapidly than it does following interruption of vitamin B_{12} absorption (e.g., gastric surgery). This observation reflects the fact that body stores of folate are limited. Although the rate of induction of megaloblastic erythropoiesis may vary, a folate-deficiency state may appear in 1-4 weeks, depending on the individual's dietary habits and stores of the vitamin.

Folate deficiency is best diagnosed from measurements of folate in plasma and in red cells. However, an empirical trial of folate in cases of suspected deficiency has been proposed as more cost effective (Robinson and Mladenovic, 2001). Indeed, the concentration of folate in plasma is extremely sensitive to changes in dietary intake of the vitamin and the influence of inhibitors of folate metabolism or transport, such as alcohol. Normal folate concentrations in plasma range from 9-45 nmol (4-20 ng/mL); <9 nmol is considered folate deficient. The plasma folate concentration rapidly falls to values indicative of deficiency within 24-48 hours of steady ingestion of alcohol (Eichner and Hillman 1973). The plasma folate concentration will revert quickly to normal once such ingestion is stopped, even while the marrow is still megaloblastic. Such rapid fluctuations detract from the clinical usefulness of the plasma folate concentration. The amount of folate in red cells or the adequacy of stores in lymphocytes (as measured by the deoxyuridine suppression test) may be used to diagnose a longstanding deficiency of folic acid. A positive result on either test shows that the deficiency must have existed for a sufficient time to allow the production of a population of cells with deficient folate stores.

Folic acid is marketed as oral tablets containing pteroylglutamic acid or L-methylfolate, as an aqueous solution for injection (5 mg/mL), and in combination with other vitamins and minerals.

Folinic acid (leucovorin calcium, citrovorum factor) is the 5-formyl derivative of tetrahydrofolic acid. The principal therapeutic uses of folinic acid are to circumvent the inhibition of dihydrofolate reductase as a part of high-dose methotrexate therapy and to potentiate fluorouracil in the treatment of colorectal cancer (Chapter 61). It also has been used as an antidote to counteract the toxicity of folate antagonists such as pyrimethamine or trimethoprim. Although it can be used to treat any folate-deficient state, folinic acid provides no advantage over folic acid, is more expensive, and therefore is not recommended. A single exception is the megaloblastic anemia associated with congenital dihydrofolate reductase deficiency.

Leucovorin should never be used for the treatment of pernicious anemia or other megaloblastic anemias secondary to a deficiency of vitamin B₁₂. Just as is seen with folic acid, its use can result in an apparent response of the hematopoietic system, but neurological damage may occur or progress if already present. Leucovorin is marketed as oral tablets and as products for intravenous infusion.

Untoward Effects. There have been rare reports of reactions to parenteral injections of folic acid and leucovorin. If a patient describes a history of a reaction before the drug is given, caution should be exercised. Oral folic acid usually is not toxic. Even with doses as high as 15 mg/day, there have been no substantiated reports of side effects. Folic acid in large amounts may counteract the antiepileptic effect of phenobarbital, phenytoin, and primidone, and increase the frequency of seizures in susceptible children (Reynolds, 1968). Although some studies have not supported these contentions, the FDA recommends that oral tablets of folic acid be limited to strengths of ≤1 mg.

General Principles of Therapy. The therapeutic use of folic acid is limited to the prevention and treatment of deficiencies of the vitamin. As with vitamin B₁₂ therapy, effective use of the vitamin depends on accurate diagnosis and an understanding of the mechanisms that are operative in a specific disease state. The following general principles of therapy should be respected:

1. Prophylactic administration of folic acid should be undertaken for clear indications. Dietary supplementation is necessary when there is a requirement that may not be met by a “normal” diet. The daily ingestion of a multivitamin preparation containing 400-500 µg of folic acid has become standard practice before and during pregnancy to reduce the incidence of neural tube defects and for as long as a woman is breast-feeding. In women with a history of a pregnancy complicated by a neural tube defect, an even larger dose of 4 mg/day has been recommended (MRC Vitamin Study Research Group, 1991). Patients on total parenteral nutrition should receive folic acid supplements as part of their fluid regimen because liver folate stores are limited. Adult patients with a disease state characterized by high cell turnover (e.g., hemolytic anemia) generally require larger doses, 1 mg of folic acid given once or twice a day. The 1-mg dose also has been used in the treatment of patients with elevated levels of homocysteine.
2. As with vitamin B₁₂ deficiency, any patient with folate deficiency and a megaloblastic anemia should be evaluated carefully to determine the underlying cause of the deficiency state. This should include evaluation of the effects of medications, the amount of alcohol intake, the patient’s history of travel, and the function of the GI tract.

3. Therapy always should be as specific as possible. Multivitamin preparations should be avoided unless there is good reason to suspect deficiency of several vitamins.
4. The potential danger of mistreating a patient who has vitamin B₁₂ deficiency with folic acid must be kept in mind. The administration of large doses of folic acid can result in an apparent improvement of the megaloblastic anemia, inasmuch as PteGlu is converted by dihydrofolate reductase to H₄PteGlu; this circumvents the methylfolate “trap.” However, folate therapy does not prevent or alleviate the neurological defects of vitamin B₁₂ deficiency, and these may progress and become irreversible.

Treatment of the Acutely Ill Patient. As described in detail in the section on vitamin B₁₂, treatment of the patient who is acutely ill with megaloblastic anemia should begin with intramuscular injections of vitamin B₁₂ and folic acid. Inasmuch as the patient requires therapy before the exact cause of the disease has been defined, it is important to avoid the potential problem of a combined deficiency of vitamin B₁₂ and folic acid. When the patient is deficient in both, therapy with only one vitamin will not provide an optimal response. Longstanding nontropical sprue is one example of a disease in which combined deficiency of B₁₂ and folate is common. When indicated, vitamin B₁₂ (100 µg) and folic acid (1-5 mg) should be administered intramuscularly, and the patient should then be maintained on daily oral supplements of 1-2 mg of folic acid for the next 1-2 weeks.

Oral administration of folate generally is satisfactory for patients who are not acutely ill, regardless of the cause of the deficiency state. Even the patient with tropical or nontropical sprue and a demonstrable defect in absorption of folic acid will respond adequately to such therapy. Abnormalities in the activity of pteroyl-γ-glutamyl carboxypeptidase and the function of mucosal cells will not prevent passive diffusion of sufficient amounts of PteGlu across the mucosal barrier if the dosage is adequate, and continued ingestion of alcohol or other drugs also will not prevent an adequate therapeutic response. The effects of most inhibitors of folate transport or dihydrofolate reductase are overcome easily by administration of pharmacological doses of the vitamin. Folinic acid is the appropriate form of the vitamin for use in chemotherapeutic protocols, including “rescue” from methotrexate (Chapter 61). Perhaps the only situation in which oral administration of folate will be ineffective is when vitamin C is severely deficient. Patients with scurvy may suffer from a megaloblastic anemia despite increased intake of folate and normal or high concentrations of the vitamin in plasma and cells.

The therapeutic response may be monitored by study of the hematopoietic system in a fashion identical to that described for vitamin B₁₂. Within 48 hours of the initiation of appropriate therapy, megaloblastic erythropoiesis disappears, and as efficient erythropoiesis begins, the concentration of iron in plasma falls to normal or below-normal values. The reticulocyte count begins to rise on the second or third day and reaches a peak by the fifth to

seventh days; the reticulocyte index reflects the proliferative state of the marrow. Finally, the hematocrit begins to rise during the second week.

It is possible to use the pattern of recovery as the basis for a therapeutic trial. For this purpose, the patient should receive a daily parenteral injection of 50-100 µg of folic acid. Administration of doses >100 µg/day entails the risk of inducing a hematopoietic response in patients who are deficient in vitamin B₁₂, and oral administration of the vitamin may be unreliable because of intestinal malabsorption. A number of other complications also may interfere with the therapeutic trial. The patient with sprue and deficiencies of other vitamins or iron may fail to respond because of these inadequacies. In cases of alcoholism, the presence of hepatic disease, inflammation, or iron deficiency can blunt the proliferative response of the marrow and prevent the correction of the anemia. For these reasons, the therapeutic trial for the evaluation of the patient with a potential deficiency of folic acid has not gained great popularity.

CLINICAL SUMMARY

Several hematopoietic growth factors are available for clinical use. Recombinant erythropoietin routinely is used for patients with the anemia of renal insufficiency, inflammation, and associated with cancer or the therapy of cancer. Longer-acting growth factors that permit less frequent dosing schedules are coming into increased use. One of the first of these is novel erythropoiesis-stimulating protein (NESP), produced by the insertion of two extra N-linked sialic acid side chains into the erythropoietin molecule. Myeloid growth factors (e.g., GM-CSF and G-CSF) are used to hasten the recovery of granulocytes after myelosuppressive therapy, to help mobilize hematopoietic stem cells into the peripheral blood to allow their harvest for transplantation, and to augment the number of mature leukocytes in the peripheral blood so that they can be used in patients with overwhelming infection. Finally, the development of IL-11 for use in thrombocytopenia and the investigational use of thrombopoietin or mimics of the molecule may provide many of the same therapeutic advances.

Introduction To Endocrinology: The Hypothalamic-Pituitary Axis

Keith L. Parker
and Bernard P. Schimmer

ENDOCRINOLOGY AND HORMONES: GENERAL CONCEPTS

Endocrinology analyzes the biosynthesis of hormones, their sites of production, and the sites and mechanisms of their action and interaction. The term *hormone* is of Greek origin and classically refers to chemical messengers that circulate in body fluids and produce specific effects on cells distant from their point of origin. The major functions of hormones include the regulation of energy storage, production, and utilization; the adaptation to new environments or conditions of stress; the facilitation of growth and development; and the maturation and function of the reproductive system. Although hormones were originally defined as products of ductless glands, we now appreciate that many organs that were not classically considered as “endocrine” (e.g., the heart, kidneys, GI tract, adipocytes, and brain) synthesize and secrete hormones that play key physiological roles; many of these hormones are now employed either diagnostically or therapeutically in clinical medicine. In addition, the field of endocrinology has expanded to include the actions of growth factors acting by means of autocrine and paracrine mechanisms, the influence of neurons—particularly those in the hypothalamus—that regulate endocrine function, and the reciprocal interactions of cytokines and other components of the immune system with the endocrine system.

As discussed in Chapter 3, hormones generally exert their actions on target cells via a plenitude of receptors, including heptaspanning GPCRs, monospanning membrane tyrosine kinases and guanylyl cyclases, cytokine receptors, ligand-activated ion channels, and nuclear transcription factors. Conceptually, it is useful to

divide hormones into two classes: those that act predominantly via nuclear receptors to modulate transcription in target cells and those that typically act via membrane receptors to exert rapid effects on signal transduction pathways. Steroid hormones, thyroid hormone, and vitamin D belong to the first class, whereas peptide and amino acid hormones are generally assigned to the second class. The receptors for both classes of hormones provide tractable targets for a diverse group of compounds that are among the most widely used drugs in clinical medicine.

DISORDERS OF ENDOCRINE REGULATION

Because of their potent effects, circulating levels of hormones generally are tightly regulated within a normal range. The physiological strategies used to maintain the appropriate levels of hormones range from relatively simple ones involving direct feedback or feed-forward mechanisms (e.g., the secretion of parathyroid hormone by the parathyroid glands is inversely related to the serum Ca^{2+} concentration, which is sensed by a GPCR termed the Ca^{2+} -sensing receptor; Chapter 44) to more complex ones involving reciprocal interactions among the hypothalamus, anterior pituitary, and endocrine glands (see the section “The Hypothalamic-Pituitary-Endocrine Axis”).

Regardless of the mechanism, normal regulation can be perturbed in disease states when a given hormone is either over or underproduced or when its signaling mechanisms are impaired. Understanding the normal regulation and actions of the various hormones is critical to both diagnosis and treatment of these endocrine

disorders. Chapters 38 through 44 describe the different endocrine organs and the drugs that are employed to affect their function or to mimic or block their hormonal products.

THE HYPOTHALAMIC-PITUITARY-ENDOCRINE AXIS

Many of the classic endocrine hormones (e.g., cortisol, thyroid hormone, sex steroids, growth hormone) are regulated by complex reciprocal interactions among the hypothalamus, anterior pituitary, and endocrine glands (Table 38–1). These interactions permit precise control over the levels of circulating hormones and also provide a means to alter hormone levels under special physiological or pathological circumstances.

The basic organization of the hypothalamic-pituitary-endocrine axis is summarized in Figure 38–1. Discrete sets of hypothalamic neurons produce different releasing hormones, which are axonally transported to the median eminence. Upon stimulation, these neurons secrete their respective hypothalamic releasing hormones into the hypothalamic-adenohypophyseal plexus, which flows to the anterior pituitary gland. The hypothalamic releasing hormones bind to membrane receptors on specific subsets of pituitary cells and stimulate the secretion of the corresponding pituitary hormones. The pituitary hormones, which can be thought of as the master signals, then circulate to the target endocrine glands, where they again activate specific receptors to stimulate the synthesis and secretion of the target endocrine hormones. These interactions thus represent

feed-forward regulation in which the master (signal) hormones stimulate the production of target hormones by the endocrine organs.

Superimposed on this positive feed-forward regulation is negative feedback regulation, which permits precise control of hormone levels. Figures 38–2 and 38–7 show examples of this negative feedback regulation. Typically, the endocrine target hormone circulates to both the hypothalamus and pituitary, where it acts via specific receptors to inhibit the production and secretion of both its hypothalamic releasing hormone and the regulatory pituitary hormone, thereby tightly regulating target hormone levels. In addition, other brain regions have inputs to the hypothalamic releasing neurons, further integrating the regulation of hormone levels in response to diverse stimuli.

An understanding of this regulation facilitates the diagnosis and management of a number of endocrine diseases. Endocrine deficiency states can be divided into those with impaired function at the level of the target endocrine gland (primary disease; as is the case in the autoimmune destruction of the adrenal or thyroid glands) and those with defects at the level of the pituitary gland and/or hypothalamus that impair delivery of the pituitary trophic hormone to its target gland (secondary/tertiary disease). In *primary hypofunction*, the production of the target endocrine hormone will be impaired; however, the hypothalamus and pituitary will sense the diminished feedback inhibition and the anterior pituitary gland will secrete higher than normal levels of the signal hormone. In *secondary hypofunction*, both the signal hormone and the target hormone will be below the normal range.

Table 38–1

Hormones that Integrate the Hypothalamic-Pituitary-Endocrine Axis

HYPOTHALAMIC RELEASING HORMONE	PITUITARY TROPHIC (SIGNAL) HORMONE	TARGET HORMONE(S)
Growth hormone-releasing hormone (GHRH)	Growth hormone (GH)	IGF-1
Somatostatin (SST) ^a	Growth hormone	
Dopamine (DA) ^b	Prolactin	—
Corticotropin-releasing hormone (CRH)	Corticotropin	Cortisol/DHEA
Thyrotropin-releasing hormone (TRH)	Thyroid-stimulating hormone (TSH)	Thyroid hormone
Gonadotropin-releasing hormone (GnRH)	Follicle-stimulating hormone (FSH)	Estrogen
	Luteinizing hormone (LH)	Progesterone/Estrogen (f) Testosterone (m)

^aSomatostatin inhibits growth hormone release.

^bDopamine inhibits prolactin release.

IGF-1, insulin-like growth factor-1; DHEA, dehydroepiandrosterone; f, female; m, male.

Figure 38–1. Organization of the anterior and posterior pituitary gland. Hypothalamic neurons in the supraoptic (SON) and paraventricular (PVN) nuclei synthesize arginine vasopressin (AVP) or oxytocin (OXY). Most of their axons project directly to the posterior pituitary, from which AVP and OXY are secreted into the systemic circulation to regulate their target tissues. Neurons that regulate the anterior lobe cluster in the mediobasal hypothalamus, including the PVH and the arcuate (ARC) nuclei. They secrete hypothalamic releasing hormones, which reach the anterior pituitary via the hypothalamic-adenohypophyseal portal system and stimulate distinct populations of pituitary cells. These cells, in turn, secrete the trophic (signal) hormones, which regulate endocrine organs and other tissues. See Table 38-1 for abbreviations.

Hormone excess similarly can result either from primary disorders at the level of the target endocrine glands (e.g., a hyperfunctioning tumor of the adrenal cortex that oversecretes cortisol) or from secondary disorders at the level of the pituitary gland (e.g., a pituitary corticotrope adenoma that oversecretes corticotropin, the predominant stimulator of adrenal glucocorticoid biosynthesis). Again, knowledge of the levels of the pituitary signal hormone and the target hormone allows the clinician to identify the site of the endocrine disorder.

PITUITARY HORMONES AND THEIR HYPOTHALAMIC RELEASING FACTORS

The peptide hormones of the anterior pituitary are essential for the regulation of growth and development, reproduction, response to stress, and intermediary metabolism. Their synthesis and secretion are controlled by hypothalamic hormones and by hormones from the peripheral endocrine organs. A large number of disease states, as well as a diverse group of drugs, also affect their secretion. The complex interactions among the hypothalamus, pituitary, and target endocrine glands provide elegant examples of the integrated feedback regulation described earlier. Clinically, an improved understanding of the mechanisms that underlie these interactions provides the rationale for diagnosing and treating endocrine disorders and for predicting certain side effects of drugs that affect the endocrine system. Moreover, the elucidation of the structures of the anterior pituitary hormones and hypothalamic releasing hormones and advances in protein chemistry and molecular biology have made it possible to produce synthetic peptide agonists and antagonists that have important diagnostic and therapeutic applications.

The anterior pituitary hormones can be classified into three different groups based on their structural features (Table 38–2). *Corticotropin* (adrenocorticotrophic hormone, ACTH) and *α -melanocyte-stimulating hormone* (α -MSH) are part of a family of peptides derived from *pro-opiomelanocortin* (POMC) by proteolytic processing (Chapters 18 and 42). *Growth hormone* (GH) and *prolactin* belong to the somatotrophic family of hormones, which in humans also includes placental lactogen. The glycoprotein hormones—*thyroid-stimulating hormone* (TSH; also called thyrotropin), *luteinizing hormone* (LH; also called lutropin), and *follicle-stimulating hormone* (FSH; also called follitropin)—share a common α -subunit but have different β -subunits that determine their distinct biological activities. In humans, the glycoprotein hormone family also includes *human chorionic gonadotropin* (hCG).

The synthesis and release of anterior pituitary hormones are influenced by the central nervous system (CNS). Their secretion is positively regulated by a group of peptides referred to as *hypothalamic releasing hormones*, which are released from hypothalamic neurons in the region of the median eminence and reach the anterior pituitary through the hypothalamic-adenohypophyseal portal system (Figure 38–1). The hypothalamic-releasing hormones include *corticotropin-releasing hormone* (CRH), *growth hormone-releasing*

hormone (GHRH), gonadotropin-releasing hormone (GnRH), and thyrotropin-releasing hormone (TRH). Somatostatin (SST), another hypothalamic peptide, negatively regulates secretion of pituitary GH and TSH. The neurotransmitter dopamine inhibits the secretion of prolactin by lactotropes.

The posterior pituitary gland, also known as the neurohypophysis, contains the endings of nerve axons arising from distinct populations of neurons in the supraoptic and paraventricular nuclei of the hypothalamus that synthesize either arginine vasopressin or oxytocin (Figure 38–1). Arginine vasopressin plays an important role in water homeostasis (Chapter 25); oxytocin plays important roles in labor and parturition and in milk letdown, as discussed in the following sections and in Chapter 66.

SOMATOTROPIC HORMONES: GROWTH HORMONE AND PROLACTIN

GH and prolactin are structurally related members of the somatotropic hormone family and share many

biological features, thus providing a rationale for discussing them together. The somatotropes and lactotropes, the pituitary cells that produce GH and prolactin, respectively, derive during pituitary development from a common precursor and are eosinophilic in histological sections. Consistent with their common origin, defects in certain transcription factors affect both cell lineages. In addition to their structural similarities, GH and prolactin act via membrane receptors that belong to the cytokine receptor family and modulate target cell function via very similar signal transduction pathways (Chapter 3). The secretion of both hormones is subject to strong inhibitory input from hypothalamic neurons; for prolactin, this negative dopaminergic input clearly is the predominant regulator of secretion. Finally, several drugs that are used to treat excessive secretion of these hormones are effective to varying degrees for both GH and prolactin.

Physiology of the Somatotropic Hormones

Structures of the Somatotropic Hormones. The gene encoding human GH resides on the long arm of

chromosome 17 (17q22), which also contains three different variants of placental lactogen and a GH variant, chorionic somatotropin, expressed in the syncytiotrophoblast. GH is secreted by somatotropes as a heterogeneous mixture of peptides; the principal form is a single polypeptide chain of 22 kDa that has two disulfide bonds and is not glycosylated. Alternative splicing deletes residues 32 to 46 of the larger form to produce a smaller form (~20 kDa) with equal bioactivity that makes up 5-10% of circulating GH. Recombinant human GH consists entirely of the 22 kDa form, which provides a way to detect GH abuse for sports performance enhancement.

Additional GH species, differing in size or charge, are found in serum, but their physiological significance is unclear. In the circulation, a 55 kDa protein binds approximately 45% of the 22 kDa and 25% of the 20 kDa forms; this binding protein contains the extracellular domain of the GH receptor and apparently arises from proteolytic cleavage. A second protein unrelated to the GH receptor also binds approximately 5-10% of circulating GH with lower affinity. Bound GH is cleared more slowly and has a biological $t_{1/2}$ ~10 times that of unbound GH, suggesting that the bound hormone may provide a GH reservoir that dampens acute fluctuations in GH levels associated with its pulsatile secretion. Alternatively, the binding protein may decrease GH bioactivity by preventing it from binding to its receptor in target tissues. Obesity increases circulating levels of GH binding proteins and thus may affect the clinical response to exogenous GH.

Human prolactin is a 23 kDa protein with three intramolecular disulfide bonds. It is synthesized by lactotropes, and a portion of the secreted hormone is glycosylated at a single Asn residue. In circulation, dimeric and polymeric forms of prolactin also are found, as are degradation products of 16 kDa and 18 kDa. As with GH, the biological significance of these different forms is not known.

Regulation of Secretion of the Somatotrophic Hormones. Daily GH secretion varies throughout life; secretion is high in children, peaks during puberty, and then decreases in an age-related manner in adulthood. GH is secreted in discrete but irregular pulses. Between these pulses, circulating GH falls to levels that are undetectable with most assays. The amplitude of secretory pulses is greatest at night, and the most consistent period of GH secretion is shortly after the onset of deep sleep.

GH secretion, as illustrated in Figure 38–2, incorporates many of the classic features of endocrine regulation. GHRH, produced by hypothalamic neurons found predominantly in the arcuate nucleus, stimulates GH secretion by binding to a specific GPCR on

Figure 38–2. Growth hormone secretion and actions. Two hypothalamic factors, growth hormone–releasing hormone (GHRH) and somatostatin (SST) stimulate or inhibit the release of growth hormone (GH) from the pituitary, respectively. Insulin-like growth factor-1 (IGF-1), a product of GH action on peripheral tissues, causes negative feedback inhibition of GH release by acting at the hypothalamus and the pituitary. The actions of GH can be direct or indirect (mediated by IGF-1). See text for discussion of the other agents that modulate GH secretion and of the effects of locally produced IGF-1. Inhibition, –; stimulation, +.

somatotropes that resembles most closely the receptors for secretin, vasoactive intestinal polypeptide (VIP), pituitary adenylyl cyclase-activating peptide (PACAP), glucagon, glucagon-like peptide-1 (GLP-1), calcitonin, and parathyroid hormone (PTH). Upon binding GHRH, the GHRH receptor couples to G_s to raise intracellular levels of cyclic AMP and Ca^{2+} , thereby stimulating GH synthesis and secretion. Loss-of-function mutations of the GHRH receptor cause a rare form of short stature in humans, thereby demonstrating its essential role in normal GH secretion (Wajnrajch et al., 1996).

Typical of endocrine systems, GH and its major peripheral effector, insulin-like growth factor 1 (IGF-1), act in negative feedback loops to suppress GH secretion. The negative effect of IGF-1 is predominantly through direct effects on the anterior pituitary gland. In contrast, the negative feedback action of GH is mediated in part by SST, which is synthesized in more widely distributed neurons.

Figure 38–3. Structures of somatostatin-14 and selected synthetic analogs. The amino acid sequence of somatostatin (SST)-14 is shown. Residues that play key roles in receptor binding, as discussed in the text, are shown in red. Also shown are the structures of the two clinically available synthetic analogs of somatostatin, octreotide and lanreotide, and three other analogs that have been used in clinical trials, seglitide, vapreotide, and pasireotide. APro, [(2-aminoethyl) aminocarboxyl oxy]-L-proline; D-Nal, (3-(2-naphthyl)-D-alanyl; PGly, phenylglycine; BTyr, benzylytyrosine.

Somatostatin is synthesized as a 92-amino acid precursor and processed by proteolytic cleavage to generate two peptides: SST-28 and SST-14. SST-14 consists of the carboxy-terminal 14 amino acids of SST-28, which form an intrapeptide disulfide bond (Figure 38–3). SST exerts its effects by binding to and activating a family of five related GPCRs that signal through G_i to inhibit cyclic AMP accumulation and to activate K^+ channels and protein phosphotyrosine phosphatases.

Each of the SST receptor subtypes (abbreviated SSTRs) binds SST with nanomolar affinity; whereas receptor types 1–4 (SSTR1–4) bind the two SSTs with approximately equal affinity, type 5 (SSTR5) has a 10- to 15-fold greater affinity for SST-28. SSTR2 and SSTR5 are the most important for regulation of GH secretion, and recent studies suggest that these two SSTRs form functional heterodimers

with distinctive signaling behavior (Grant et al., 2008). SST exerts direct effects on somatotropes in the pituitary and indirect effects mediated via GHRH neurons in the arcuate nucleus. As discussed later, SST analogs play a key role in the pharmacotherapy of syndromes of GH excess and certain cancers.

Ghrelin, a 28-amino acid peptide that is octanoylated at Ser3, also stimulates GH secretion. Ghrelin is synthesized predominantly in endocrine cells in the fundus of the stomach but also is produced at lower levels at a number of other sites. Both fasting and hypoglycemia stimulate circulating ghrelin levels.

Ghrelin acts primarily through a GPCR called the GH secretagogue receptor. Although the interaction of ghrelin with this receptor directly stimulates GH release by isolated somatotropes, the major action on GH secretion apparently is through actions on the GHRH neurons in the arcuate nucleus. Apart from its effects on GH secretion, ghrelin also stimulates appetite and increases food intake, apparently by central actions on NPY and agouti-related peptide neurons in the hypothalamus. Thus, ghrelin and its receptor act in a complex manner to integrate the functions of the GI tract, the hypothalamus, and the anterior pituitary (Ghigo et al., 2005). Peptide and nonpeptide agonists (termed GH secretagogues) and antagonists of the GH secretagogue receptor are undergoing evaluation as possible modulators of neuroendocrine function.

Several neurotransmitters, drugs, metabolites, and other stimuli modulate the release of GHRH and/or SST and thereby affect GH secretion. DA, 5-HT, and α_2 adrenergic receptor agonists stimulate GH release, as do hypoglycemia, exercise, stress, emotional excitement, and ingestion of protein-rich meals. In contrast, β adrenergic receptor agonists, free fatty acids, IGF-1, and GH itself inhibit release, as does the administration of glucose to normal subjects in an oral glucose-tolerance test.

Many of the physiological factors that influence prolactin secretion also affect GH secretion. Thus sleep, stress, hypoglycemia, exercise, and estrogen increase the secretion of both hormones.

Prolactin is unique among the anterior pituitary hormones in that hypothalamic regulation of its secretion is predominantly inhibitory. The major regulator of prolactin secretion is DA, which is released by tuberoinfundibular neurons and interacts with the D_2 receptor, a GPCR on lactotropes, to inhibit prolactin secretion (Figure 38–4). Recent reports have suggested that the D_2 receptor and the SST_2 receptor can form heterodimers (Baragli et al., 2007), which may have implications for therapy (see following discussion).

A number of putative prolactin-releasing factors have been described, including TRH, VIP, prolactin-releasing peptide, and PACAP, but their physiological roles are unclear. Under certain

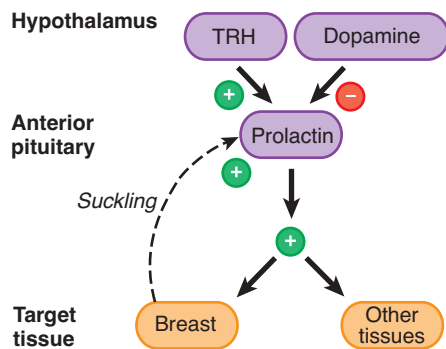

Figure 38–4. Prolactin secretion and actions. Prolactin is the only anterior pituitary hormone for which a unique stimulatory releasing factor has not been identified. Thyrotropin-releasing hormone (TRH), however, can stimulate prolactin release and dopamine can inhibit it. Suckling induces prolactin secretion, and prolactin affects lactation and reproductive functions but also has varied effects on many other tissues. Prolactin is not under feedback control by peripheral hormones.

pathological conditions, such as severe primary hypothyroidism, persistently elevated levels of TRH can induce hyperprolactinemia.

Unlike GH, which plays important roles throughout life in both sexes, prolactin acts predominantly in women, both during pregnancy and in the postpartum period in women who breast-feed. Serum prolactin levels remain low in men but are elevated somewhat in normal cycling females. During pregnancy, the maternal serum prolactin level starts to increase at 8 weeks of gestation, increases to peak levels of 250 ng/mL at term, and declines thereafter to prepregnancy levels unless the mother breast-feeds the infant. Suckling or breast manipulation in nursing mothers transmits signals from the breast to the hypothalamus via the spinal cord and the median fore-brain bundle, which, in turn, stimulate circulating prolactin levels. Prolactin levels can rise 10- to 100-fold within 30 minutes of stimulation. This response is distinct from milk letdown, which is mediated by oxytocin release from the posterior pituitary gland. The suckling-induced prolactin secretion involves both decreased secretion of dopamine by tuberoinfundibular neurons and possibly increased release of factors that stimulate prolactin secretion. The suckling response becomes less pronounced after several months of breast-feeding, and prolactin concentrations eventually decline to prepregnancy levels.

Prolactin also is synthesized in lactotropes near the end of the luteal phase of the menstrual cycle and by decidual cells early in pregnancy; the latter source is responsible for the very high levels of prolactin in amniotic fluid during the first trimester of human pregnancy. The function of this prolactin and what regulates its expression are not known.

Molecular and Cellular Bases of Somatotrophic Hormone Action. All of the effects of GH and prolactin result from their interactions with specific membrane receptors on target tissues (Figure 38–5). Both the GH and prolactin receptors are widely distributed cell surface

receptors that belong to the cytokine receptor superfamily and thus share structural similarity with the receptors for leptin, erythropoietin, granulocyte-macrophage colony-stimulating factor, and several of the interleukins. Like other members of the cytokine receptor family, these receptors contain an extracellular hormone-binding domain, a single membrane-spanning region, and an intracellular domain that mediates signal transduction.

The mature human GH receptor contains 620 amino acids, approximately 250 of which are extracellular, 24 of which are transmembrane, and ~350 of which are cytoplasmic. It exists as a preformed homodimer that forms a ternary complex with one molecule of GH. The formation of the GH-GH receptor ternary complex is initiated by high-affinity interaction of GH with one monomer of the GH receptor dimer (mediated by GH site 1), followed by a second, lower affinity interaction of GH with the GH receptor mediated by GH site 2; these interactions induce a conformational change that activates downstream signaling. As discussed later, pegvisomant is a GH analog with amino acid substitutions that disrupt site 2; it binds the receptor and causes its internalization but cannot trigger the conformational change that stimulates downstream events in the signal transduction pathway. Amino acid-substituted versions of human prolactin that act as antagonists at the prolactin receptor are also under development (Goffin et al., 2006).

The ligand-occupied GH receptor dimer lacks inherent tyrosine kinase activity. Rather, it provides docking sites for two molecules of JAK2, a cytoplasmic tyrosine kinase of the Janus kinase family. The juxtaposition of two JAK2 molecules leads to *trans*-phosphorylation and autoactivation of JAK2, with consequent tyrosine phosphorylation of cytoplasmic proteins that mediate downstream signaling events (Lanning and Carter-Su, 2006). These include STAT proteins (Signal Transducers and Activators of Transcription), Shc (an adapter protein that regulates the Ras/MAPK signaling pathway), and IRS-1 and IRS-2 (insulin-receptor substrate proteins that activate the PI3K pathway). One critical target of STAT5 is the gene encoding IGF-1 (Figure 38–5). The fine control of GH action also involves feedback regulatory events that subsequently turn off the GH signal. As part of its action, GH induces the expression of a family of SOCS (suppressor of cytokine signaling) proteins and a group of protein tyrosine phosphatases that, by different mechanisms, disrupt the communication of the activated GH receptor with JAK2 (Flores-Morales et al., 2006).

Some studies have shown that the GH receptor can translocate to the nucleus and act as a coregulator to activate transcription and cell proliferation (Swanson and Kopchick, 2007). The precise role of this signal transduction pathway in GH physiology and pathophysiology remains to be defined.

The effects of prolactin on target cells also result from interactions with a cytokine receptor that is widely distributed and signals through many of the same pathways as the GH receptor. Alternative splicing of the prolactin receptor gene on chromosome 5 gives rise to multiple forms of the receptor that are identical in the extracellular domain but differ in their cytoplasmic domains. In addition, soluble forms that correspond to the extracellular domain of the receptor are found in circulation. Unlike human GH and placental

Figure 38–5. Mechanisms of growth hormone and prolactin action and of GH receptor antagonism. **Left (A):** The binding of GH to a homodimer of the growth hormone receptor (GHR) induces autophosphorylation of JAK2. JAK2 then phosphorylates cytoplasmic proteins that activate downstream signaling pathways, including STAT5 and mediators upstream of MAPK, which ultimately modulate gene expression. The structurally related prolactin receptor also is a ligand activated homodimer that recruits the JAK-STAT signaling pathway (see text for further details). The GHR also activates IRS-1, which may mediate the increased expression of glucose transporters on the plasma membrane. The diagram does not reflect the localization of the intracellular molecules, which presumably exist in multicomponent signaling complexes. JAK2, janus kinase 2; IRS-1, insulin receptor substrate-1; PI3K, phosphatidylinositol-3 kinase; STAT, signal transducer and activator of transcription; MAPK, mitogen-activated protein kinase; SHC, Src homology containing. **Right (B):** Pegvisomant, a recombinant pegylated variant of human GH, contains amino acid substitutions that increase the affinity for one site of the GHR but do not activate its downstream signaling cascade. It thus interferes with GH signaling in target tissues.

lactogen, which also bind to the prolactin receptor and thus are lactogenic, prolactin binds specifically to the prolactin receptor and has no somatotropic (GH-like) activity.

Physiological Effects of the Somatotrophic Hormones.

The most striking physiological effect of GH—and the basis for its name—is the stimulation of the longitudinal growth of bones (Giustina et al., 2008). GH also increases bone mineral density after the epiphyses have closed and longitudinal growth ceases. These effects of GH involve the differentiation of prechondrocytes to chondrocytes and stimulation of osteoclast and osteoblast proliferation. Other effects of GH include the stimulation of myoblast differentiation (in experimental animals) and increased muscle mass (in human subjects with GH deficiency), increased glomerular filtration rate, and stimulation of preadipocyte differentiation into adipocytes. GH has potent anti-insulin actions in both the liver and peripheral sites (e.g., adipocytes and muscle) that decrease glucose utilization and increase lipolysis.

Finally, GH has been implicated in the development and function of the immune system.

Growth hormone acts directly on adipocytes to increase lipolysis and on hepatocytes to stimulate gluconeogenesis, but its anabolic and growth-promoting effects are mediated indirectly through the induction of IGF-1. Although most circulating IGF-1 is made in the liver, IGF-1 produced locally in many tissues is critical for growth, as revealed by normal growth in mice that have a hepatocyte-specific inactivation of IGF-1. Circulating IGF-1 is associated with a family of binding proteins, designated the IGF-binding proteins (IGFBPs), that serve as transport proteins and also may mediate certain aspects of IGF-1 signaling. Most IGF-1 in circulation is bound to IGFBP-3 and another protein called the acid-labile subunit.

The essential role of IGF-1 in growth is evidenced by patients with loss-of-function mutations in both alleles of the *IGF1* gene, whose severe intrauterine and

postnatal growth retardation is unresponsive to GH but responsive to recombinant human IGF-1, and by the association of mutations in the IGF-1 receptor with intrauterine growth retardation (Walenkamp and Wit, 2008).

After its synthesis and release, IGF-1 interacts with receptors on the cell surface that mediate its biological activities. The type 1 IGF receptor is closely related to the insulin receptor and consists of a heterotetramer with intrinsic tyrosine kinase activity. This receptor is present in essentially all tissues and binds IGF-1 and the related growth factor, IGF-2, with high affinity; insulin also can activate the type 1 IGF receptor but with an affinity approximately two orders of magnitude less than that of the IGFs. The signal transduction pathway for the insulin receptor is described in detail in Chapter 43.

Unlike GH, prolactin does not induce the synthesis of a second hormone that then mediates many of its effects in an indirect manner. Rather, prolactin effects are limited to tissues that express the prolactin receptor, particularly the mammary gland. A number of hormones—including estrogens, progesterone, placental lactogen, and GH—stimulate development of the breast and prepare it for lactation. Prolactin, acting via prolactin receptors, plays an important role in inducing growth and differentiation of the ductal and lobuloalveolar epithelia and is essential for lactation. Target genes, by which prolactin induces mammary development, include those encoding milk proteins (e.g., caseins), genes important for intracellular structure (e.g., keratins), genes important for cell-cell communication (e.g., amphiregulin and Wnt4), and components of the extracellular matrix (e.g., laminin and collagen).

Prolactin receptors are present in many other sites, including the hypothalamus, liver, adrenal, testes, ovaries, prostate, and immune system, suggesting that prolactin may play multiple roles outside of the breast. The physiological effects of prolactin at these sites remain poorly characterized, and specific defects in their function that result from prolactin deficiency have not been defined.

Pathophysiology of the Somatotrophic Hormones

Distinct endocrine disorders result from either excessive or deficient GH production. In contrast, prolactin predominantly impacts endocrine function when produced in excess.

Excess Production of Somatotrophic Hormones. Syndromes of excess secretion of GH and prolactin typically are caused by somatotrope or lactotrope adenomas that oversecrete the respective hormones. These adenomas often retain some features of the normal

regulation described earlier, thus permitting pharmacological modulation of secretion—an important modality in therapy.

Clinical Manifestations. GH excess causes distinct clinical syndromes depending on the age of the patient. If the epiphyses are unfused, GH excess causes increased longitudinal growth, resulting in gigantism. In adults, GH excess causes acromegaly. The symptoms and signs of acromegaly (e.g., arthropathy, carpal tunnel syndrome, generalized visceromegaly, macroglossia, hypertension, glucose intolerance, headache, lethargy, excess perspiration, and sleep apnea) progress slowly, and diagnosis often is delayed. Mortality is increased at least 2-fold relative to age-matched controls, predominantly due to increased death from cardiovascular disease.

Hyperprolactinemia is a relatively common endocrine abnormality that can result from hypothalamic or pituitary diseases that interfere with the delivery of inhibitory dopaminergic signals, from renal failure, from primary hypothyroidism associated with increased TRH levels, or from treatment with dopamine receptor antagonists. Most often, hyperprolactinemia is caused by prolactin-secreting pituitary adenomas—either microadenomas (≤ 1 cm in diameter) or macroadenomas (> 1 cm in diameter). Manifestations of prolactin excess in women include galactorrhea, amenorrhea, and infertility. In men, hyperprolactinemia causes loss of libido, erectile dysfunction, and infertility.

Diagnosis of Somatotropin Hormone Excess. Although acromegaly should be suspected in patients with the appropriate symptoms and signs, diagnostic confirmation requires the demonstration of increased circulating GH or IGF-1. The “gold standard” diagnostic test for acromegaly is the oral glucose tolerance test. Whereas normal subjects suppress their GH level to < 1 ng/mL in response to an oral glucose challenge (the absolute value may vary depending on the sensitivity of the assay), patients with acromegaly either fail to suppress or show a paradoxical increase in GH level.

In patients with hyperprolactinemia, the major question is whether conditions other than a prolactin-producing adenoma are responsible for the elevated prolactin level. A number of medications that inhibit DA signaling can cause moderate elevations in prolactin (e.g., antipsychotics, metoclopramide), as can primary hypothyroidism, pituitary mass lesions that interfere with dopamine delivery to the lactotropes, and pregnancy. Thus thyroid function and pregnancy tests are indicated, as is magnetic resonance imaging (MRI) to look for a pituitary adenoma or other defect that might elevate serum prolactin.

Impaired Production of the Somatotrophic Hormones. Prolactin deficiency may result from conditions that damage the pituitary gland, but prolactin is not given as part of endocrine replacement therapy.

1112 *Clinical Manifestations of Growth Hormone Deficiency.* Clinically, children with GH deficiency present with short stature, delayed bone age, and a low age-adjusted growth velocity. Specific etiologies associated with GH deficiency in children include genetic disorders that affect pituitary development and can cause deficiencies of multiple pituitary hormones, pituitary or hypothalamic tumors, previous CNS irradiation, and infiltrative processes such as histiocytosis. In most patients, however, the deficiency is idiopathic, with normal production of other pituitary hormones and no obvious structural abnormalities.

GH deficiency in adults does not impair linear growth, which ceases with closure of the epiphyses. Rather, GH deficiency in adults is associated with decreased muscle mass and exercise capacity, decreased bone density, impaired psychosocial function, and increased mortality from cardiovascular causes, probably secondary to deleterious changes in fat distribution, increases in circulating lipids, and increased inflammation (Molitch et al., 2006).

Diagnosis of Growth Hormone Deficiency. Because GH secretion is highly pulsatile, random sampling of serum GH is insufficient to diagnose GH deficiency. Whereas tests for substances that provide an estimate of integrated GH levels over time (e.g., IGF-1 and IGFBP-3) are more useful, provocative tests usually are required. After excluding other causes of poor growth, the diagnosis of GH deficiency should be entertained in children with height >2 to 2.5 standard deviations below normal, delayed bone age, a decreased growth velocity, and a predicted adult height substantially below the mean parental height. In this setting, a serum GH level <10 ng/mL following provocative testing (e.g., insulin-induced hypoglycemia, arginine, levodopa, clonidine, or glucagon) indicates GH deficiency; a stimulated value <5 ng/mL reflects severe deficiency.

In adults, overt GH deficiency usually results from pituitary lesions caused by a functioning or nonfunctioning pituitary adenoma, secondary to trauma, or related to surgery or radiotherapy for a pituitary or suprasellar mass (Molitch et al., 2006). Almost all patients with multiple deficits in other pituitary hormones also have deficient GH secretion, and some experts incorporate the number of other pituitary deficiencies into a diagnostic algorithm for diagnosing GH deficiency. Others accept a serum IGF-1 level below the age- and sex-adjusted normal range as indicative of GH deficiency in a patient with known pituitary disease. The converse is not true because an IGF-1 level within the normal range does not exclude adult GH deficiency. Some experts require an inadequate GH response to provocative testing (i.e., a value <5 ng/mL), with either insulin-induced hypoglycemia or a combination of Arg and GHRH as the preferred stimulus for GH secretion. Finally, in patients with known hypothalamic/pituitary disease of recent onset, Arg alone can be used as the stimulus, with the hGH cutoff set at 1.4 ng/mL. The risk of false-positive provocative tests (i.e., a subnormal GH response) is increased in obese subjects.

Pharmacotherapy of Disorders of the Somatotropin Hormones

Pharmacotherapy of Growth Hormone Excess. Treatment options in gigantism/acromegaly include transphenoidal surgery, radiation, and drugs that inhibit GH secretion or action. Pituitary surgery traditionally has been the

treatment of choice. In patients with microadenomas, skilled neurosurgeons can achieve cure rates of 65-85%; however, the long-term success rate for patients with macroadenomas typically is <50%. In addition, there is increasing appreciation that acromegalic patients previously considered cured by pituitary surgery actually have persistent GH excess, with its attendant complications. Pituitary irradiation may be associated with significant long-term complications, including visual deterioration and pituitary dysfunction. Thus, increased attention has been given to the pharmacological management of acromegaly, either as primary treatment or for the treatment of persistent GH excess after transphenoidal surgery or irradiation. Another area receiving increased investigation is the potential role of medical therapy before surgery to improve outcome (Carlsen et al., 2008). The favored therapy has been with SST analogs, although the GH receptor antagonist pegvisomant increasingly is used. In patients who refuse these injected treatments, DA agonists may be used, although they are much less effective.

Somatostatin Analogs. The development of synthetic analogs of SST (Figure 38–3) revolutionized the medical treatment of acromegaly. The goal of treatment is to decrease GH levels to <2.5 ng/mL after an oral glucose-tolerance test and to bring IGF-1 levels to within the normal range for age and sex. Some have argued that a basal GH level of <1 ng/mL indicates cure, whereas a basal level of >2 ng/mL is highly suggestive of persistent disease.

Chemistry. Structure-function studies of SST and its derivatives established that the amino acid residues in positions 7-10 of the SST-14 peptide (Phe-Trp-Lys-Thr) are the major determinants of biological activity. Residues Trp⁸ and Lys⁹ appear to be essential, whereas conservative substitutions at Phe⁷ and Thr¹⁰ are permissible. Active SST analogs retain this core segment constrained in a cyclic structure, formed either by a disulfide bond (octreotide, lanreotide, vapreotide) or an amide linkage (seglitide, pasireotide) that stabilizes the optimal conformation (Pawlikowski and Melen-Mucha, 2004). The endogenous peptides, SST-14 and SST-28, do not show specificity for SST receptor subtypes except for SST₅, which preferentially binds SST-28. Some SST analogs exhibit greater selectivity. For example, the octapeptides octreotide and lanreotide bind to the SST subtypes with the following order of selectivity: SST₂ > SST₅ > SST₃ >> SST₁ and SST₄. The cyclohexapeptide, pasireotide (SOM230), binds with high affinity to all but the SST₄ receptor. Small nonpeptide agonists that exhibit high selectivity for SST receptor subtypes have been isolated from combinatorial chemical libraries; these compounds may lead to a new class of highly selective, orally active SST mimetics (Weckbecker et al., 2003).

A chimeric compound that activates SST receptors and the D₂ receptor (BIM-23A387) is now in clinical trials for therapy of

mixed GH- and prolactin-secreting adenomas and for nonfunctioning pituitary adenomas (Pawlikowski and Melen-Mucha, 2004). Based on the apparent formation of heterodimers between the SST₂ and D₂ receptors, such chimeric compounds may have efficacy for certain tumors that do not respond to either classic SST analogs or DA agonists (Florio et al., 2008).

Therapeutic Uses

Currently, the two somatostatin analogs used widely are *octreotide* and *lanreotide*, synthetic derivatives that have longer half-lives and bind preferentially to SST₂ and SST₅ receptors. Octreotide (100 µg) administered subcutaneously three times daily is virtually 100% bioactive, peak effects are seen within 30 min, serum t_{1/2} is ~90 min, and duration of action is ~12 hour. This formulation successfully controls the biochemical parameters of acromegaly in 50-60% of patients.

The need to inject octreotide three times daily poses a significant obstacle to patient compliance. A long-acting, slow-release form (SANDOSTATIN-LAR DEPOT) in which the active species is incorporated into microspheres of a biodegradable polymer greatly reduces the injection frequency. Administered intramuscularly in a dose of 20 or 30 mg once every 4 week, typically to patients who have tolerated and responded to the shorter-acting formulation, octreotide LAR is at least as effective as the regular formulation (Murray and Melmed, 2008). Like the shorter-acting formulation, the longer-acting formulation of octreotide generally is well tolerated with a similar incidence of side effects (see following discussion). A lower dose of 10 mg per injection should be used in patients requiring hemodialysis or with hepatic cirrhosis.

In addition to its effect on GH secretion, octreotide can decrease tumor size, although tumor growth generally resumes after octreotide treatment is stopped.

Lanreotide is another long-acting octapeptide SST analog that causes prolonged suppression of GH secretion when administered in a 30-mg dose intramuscularly. Although its efficacy appears comparable to that of the long-acting formulation of octreotide, its duration of action is shorter; thus, it is administered at 10- or 14-day intervals.

A supersaturated aqueous formulation of lanreotide, *lanreotide autogel* (SOMATULINE DEPOT), has recently been approved for use in the U.S. It is supplied in prefilled syringes containing 60, 90, or 120 mg lanreotide and administered by deep subcutaneous injection. Administered once every 4 weeks, lanreotide autogel provides more uniform drug levels than the depot formulation of octreotide. Results of current clinical trials are at least comparable to those with the slow-release octreotide formulation (Murray and Melmed, 2008).

Adverse Effects. GI side effects—including diarrhea, nausea, and abdominal pain—occur in up to 50% of patients receiving octreotide. In most patients, these symptoms diminish over time and do not require cessation of therapy. Approximately 25% of patients receiving octreotide develop gallbladder sludge or even gallstones, presumably due to decreased gallbladder contraction and bile secretion. In the absence of symptoms, gallstones are not a contraindication to continued use of octreotide. Compared with SST, octreotide reduces insulin secretion to a lesser extent and only infrequently affects glycemic control. Inhibitory effects on TSH secretion may lead to hypothyroidism, and thyroid function tests should be evaluated

periodically. The incidence and severity of side effects associated with lanreotide are similar to those of octreotide. Perhaps related to its more global inhibition of SST receptors, pasireotide has exhibited a relatively greater impairment in glycemic control than octreotide or lanreotide. The degree to which this may limit its clinical utility is not yet established.

Other Therapeutic Uses. Somatostatin blocks not only GH secretion but also the secretion of other hormones, growth factors, and cytokines. Thus octreotide and the slow-release formulations of SST analogs have been used to treat symptoms associated with metastatic carcinoid tumors (e.g., flushing and diarrhea) and adenomas secreting vasoactive intestinal peptide (e.g., watery diarrhea). Octreotide also is used for treatment of acute variceal bleeding and for perioperative prophylaxis in pancreatic surgery (see Chapter 46 for discussion of the uses of SST analogs in GI disease). Octreotide also has significant inhibitory effects on TSH secretion, and it is the treatment of choice for patients who have thyrotrope adenomas that oversecrete TSH who are not good candidates for surgery. Finally, modified forms of octreotide labeled with indium or technetium have been used for diagnostic imaging of neuroendocrine tumors such as pituitary adenomas and carcinoids (OCTREOSCAN); modified forms labeled with β emitters such as ⁹⁰Y have been used in selective destruction of SST₂ receptor-positive tumors.

Novel uses under evaluation include the treatment of eye diseases associated with excessive proliferation and inflammation (e.g., Graves' orbitopathy and diabetic retinopathy), diabetic nephropathy, and various diseases associated with inflammation (e.g., rheumatoid arthritis, inflammatory bowel disease, pulmonary fibrosis, and psoriasis).

Growth Hormone Antagonists. Pegvisomant (SOMAVERT) is a GH receptor antagonist that is FDA-approved for the treatment of acromegaly. Pegvisomant binds to the GH receptor but does not activate JAK-STAT signaling or stimulate IGF-1 secretion (Figure 38–5).

Pegvisomant is administered subcutaneously as a 40-mg loading dose under physician supervision, followed by self-administration of 10 mg per day. Based on serum IGF-1 levels, the dose is titrated at 4- to 6-week intervals to a maximum of 40 mg per day. Pegvisomant should not be used in patients with an unexplained elevation of hepatic transaminases, and liver function tests should be monitored in all patients. In addition, lipohypertrophy has occurred at injection sites, sometimes requiring cessation of therapy; this is believed to reflect the inhibition of direct actions of GH on adipocytes. Because of concerns that loss of negative feedback by GH and IGF-1 may increase the growth of GH-secreting adenomas, careful follow-up by pituitary MRI is strongly recommended, although this may change as more data become available (Jimenez et al., 2008). Pegvisomant differs structurally from native GH and induces the formation of specific antibodies in ~15% of patients despite the covalent coupling of Lys residues to 4-5 molecules of a polyethylene glycol polymer per modified GH molecule. Nevertheless, the development of tachyphylaxis due to these antibodies has not been reported.

In clinical trials, pegvisomant at higher doses decreased serum IGF-1 to normal age- and sex-adjusted levels in >90% of patients and significantly improved clinical parameters such as ring size, soft-tissue swelling, excessive perspiration, and fatigue. Thus pegvisomant

1114 provides a highly effective alternative for use in patients who have not responded to SST analogs, either as sole therapy or as a temporizing measure while waiting for radiation therapy to achieve its full effect; it also is receiving increased scrutiny as first-line therapy.

Therapy of Prolactin Excess. The therapeutic options for patients with prolactinomas include transphenoidal surgery, radiation, and treatment with DA receptor agonists that suppress prolactin production via activation of D₂ receptors. The surgical success rates are 75% for microadenomas and 33% for macroadenomas. Given these results, D₂ receptor agonists are widely recognized as the treatment of choice for most patients (Gillam et al., 2006).

Dopamine Receptor Agonists

These agents generally decrease both prolactin secretion and the size of the adenoma, thereby improving both the endocrine abnormalities and neurological symptoms caused directly by the adenoma (including visual field deficits). Over time, especially with cabergoline, the prolactinoma may decrease in size to the extent that the drug can be discontinued without recurrence of the hyperprolactinemia. Some experts therefore recommend treatment with a dopamine receptor agonist for a minimum of 2 years, followed by a trial of dopamine agonist withdrawal in patients who have responded to dopamine agonist therapy with normalization of prolactin and disappearance of the tumor on MRI scanning (Gillam et al., 2006).

Patients with prolactinomas who wish to become pregnant comprise a special subset of hyperprolactinemic patients because drug safety during pregnancy becomes an important consideration. The dopamine agonists described here relieve the inhibitory effect of prolactin on ovulation and permit most patients with prolactinomas to become pregnant. Clinical experience also indicates that many patients can discontinue the dopaminergic agonist during pregnancy without clinically significant tumor growth. Although drug therapy ideally is discontinued before pregnancy to avoid any fetal exposure, most experts discontinue therapy after pregnancy is confirmed and carefully follow for symptoms or signs of pituitary mass effect throughout gestation. Because of its greater track record, bromocriptine generally is recommended for fertility induction in patients with hyperprolactinemia. Substantial clinical use with cabergoline has not revealed adverse maternal or fetal effects (Colao et al., 2008a), but most endocrinologists still prefer bromocriptine in this setting. Although not definitive, there are data linking

quinagolide with fetal abnormalities (reviewed by Gillam et al., 2006), and it should not be used when pregnancy is intended.

Bromocriptine. Bromocriptine (PARLODEL) is the dopamine receptor agonist against which newer agents are compared.

Chemistry. Bromocriptine is a semisynthetic ergot alkaloid (Figure 38–6) that interacts with D₂ receptors to inhibit spontaneous and TRH-induced release of prolactin; to a lesser extent, it also activates D₁ receptors.

Absorption, Distribution, and Elimination. Although a large fraction of the oral dose of bromocriptine is absorbed, only 7% of the dose reaches the systemic circulation because of a high extraction rate and extensive first-pass metabolism in the liver. Bromocriptine has a relatively short elimination t_{1/2} (between 2 and 8 hours) and thus is usually administered in divided doses (see Adverse Effects). To avoid the need for frequent dosing, a slow release oral form is available outside of the U.S. Bromocriptine may be administered vaginally (2.5 mg once daily), reportedly with fewer gastrointestinal side effects.

Therapeutic Uses. Bromocriptine normalizes serum prolactin levels in 70–80% of patients with prolactinomas and decreases tumor size in >50% of patients, including those with macroadenomas. Typically, bromocriptine does not cure the underlying adenoma, and hyperprolactinemia and tumor growth recur upon cessation of therapy.

Adverse Effects. Frequent side effects of bromocriptine include nausea and vomiting, headache, and postural hypotension, particularly on initial use. Less frequently, nasal congestion, digital vasospasm, and CNS effects such as psychosis, hallucinations, nightmares, or insomnia are observed. These adverse effects can be diminished by starting at a low dose (1.25 mg) administered at bedtime with a snack. After 1 week, a morning dose of 1.25 mg can be added. If clinical symptoms persist or serum prolactin levels remain elevated, the dose can be increased gradually, every 3–7 days, to 5 mg two or three times a day as tolerated. Patients often develop tolerance to the adverse effects of bromocriptine. Those who do not respond to bromocriptine or who develop intractable side effects often respond better to cabergoline. At higher concentrations, bromocriptine is used in the management of acromegaly, as noted earlier, and at still higher concentrations is used in the management of Parkinson's disease (Chapter 22).

Cabergoline. Cabergoline (DOSTINEX) is an ergot derivative with a longer t_{1/2} (~65 hours), higher affinity, and greater selectivity for the D₂ receptor (approximately four times more potent) than bromocriptine. It undergoes significant first-pass metabolism in the liver, and the precise oral availability is not known.

Therapeutic Uses. Cabergoline is FDA-approved for the treatment of hyperprolactinemia and has become the preferred drug in most settings for this disorder. Its greater efficacy in decreasing serum prolactin in patients with hyperprolactinemia may reflect

Figure 38–6. Dopamine receptor agonists used in the treatment of prolactinomas. The structures of dopamine, the predominant regulator of prolactin secretion, and of dopaminergic agonists that are used to inhibit prolactin secretion are shown. Bromocriptine and cabergoline are ergot derivatives, whereas quinagolide is not. The β -phenylethylamine region of structural similarity between dopamine and the agonists is shown in red.

improved adherence to therapy due to decreased side effects. Therapy is initiated at a dose of 0.25 mg twice a week or 0.5 mg once a week. If the serum prolactin remains elevated, the dose can be increased to a maximum of 1.5–2 mg two or three times a week as tolerated; the dose should not be increased more often than once every 4 weeks.

Cabergoline induces remission in a significant number of patients with prolactinomas, and a trial of drug discontinuation is advocated for the subset of patients with normalization of prolactin and disappearance of a detectable pituitary lesion on MRI scanning.

At higher doses, cabergoline is used in some patients with acromegaly and is now under investigation for patients with Cushing's disease due to corticotrope adenomas (Chapter 42).

Adverse Effects. Compared to bromocriptine, cabergoline has a much lower tendency to induce nausea, although it still may cause hypotension and dizziness. Cabergoline has been linked to valvular heart disease, an effect proposed to reflect agonist activity at the serotonin 5-HT_{2B} receptor. A similar effect has been seen with pergolide (see later). Thus echocardiographic assessment seems appropriate for patients receiving chronic therapy with cabergoline, particularly those on higher doses (Colao et al., 2008b).

Quinagolide. Quinagolide (NORPROLAC) is a non-ergot D₂ agonist (Figure 38–6) with a $t_{1/2}$ (22 hours) between those of bromocriptine and cabergoline. Quinagolide is administered once daily at doses of 0.1–0.5 mg/day. It is not approved by the FDA but has been used extensively in Europe and Canada.

Pergolide. Pergolide (PERMAX), an ergot derivative FDA-approved for treatment of Parkinson disease, also was used off label to treat hyperprolactinemia. In part due to concerns of valvular heart disease, pergolide has been withdrawn from the market.

Therapy of Growth Hormone Deficiency

The pharmacology of somatotrophic hormone deficiency is focused on GH because prolactin is not used clinically. Replacement therapy is well established in GH-deficient children and is gaining wider acceptance for GH-deficient adults. Several other indications are also approved, as described later. More recently, recombinant human IGF-1 has been approved for use in patients with mutations in the GH receptor that impair its action, as well as in GH-deficient children who develop antibodies against the recombinant hGH preparation. Although once marketed, a synthetic GHRH analog is no longer available.

Recombinant Human Growth Hormone. Humans do not respond to GH from nonprimate species. In earlier times, GH for therapeutic use was purified from human cadaver pituitaries; it thus was available in very limited quantities and in the mid-1980s was linked to the transmission of Creutzfeldt-Jakob disease. Currently, human GH is produced by recombinant DNA technology, thereby providing virtually unlimited amounts of the hormone while eliminating the risk of disease transmission associated with the pituitary-derived preparations.

Somatropin refers to the many GH preparations whose sequences match that of native GH (ACCRETROPIN, GENOTROPIN, HUMATROPE, NORDITROPIN, NUTROPIN, OMNITROPE, SAIZEN, SEROSTIM, TEV-TROPIN, VALTROPIN, and

1116 ZORBTIVE); *somatrem* refers to a derivative of GH with an additional methionine at the amino terminus that is no longer available in the U.S.

Chemistry. Although the bacterial or yeast systems used to express the recombinant GH subtly affect the structures of these preparations, they all have similar biological actions and potencies (3 IU/mg). An FDA-approved, encapsulated form of somatotropin (NUTROPIN DEPOT) injected intramuscularly, either monthly (1.5 mg/kg body weight) or every 2 weeks (0.75 mg/kg body weight), has been discontinued by the manufacturer.

Pharmacokinetics. As a peptide hormone, GH is administered subcutaneously, with a bioavailability of 70%. Although the circulating $t_{1/2}$ of GH is only 20 minutes, its biological $t_{1/2}$ is considerably longer, and once-daily administration is sufficient. To match the usual pattern of secretion, GH typically is administered at bedtime, although this is not essential.

Indications for Growth Hormone Treatment. GH deficiency in children is a well-accepted cause of short stature, and replacement therapy has been used for half a century to treat children with severe GH deficiency. With the advent of essentially unlimited supplies of recombinant GH, therapy has been extended to children with other conditions associated with short stature despite adequate GH production, including Turner's syndrome, Noonan's syndrome, Prader-Willi syndrome, chronic renal insufficiency, children born small for gestational age, and children with idiopathic short stature (i.e., >2.25 standard deviations below mean height for age and sex but with normal laboratory indices of growth hormone levels).

Attention also has shifted to the proper role of GH therapy in GH-deficient adults. The consensus of experts is that at least the most severely affected GH-deficient adults may benefit from GH replacement therapy (Molitch et al., 2006). The FDA also has approved GH therapy for AIDS-associated wasting and for malabsorption associated with the short bowel syndrome. The latter indication is based on the finding that GH stimulates the adaptation of gastrointestinal epithelial cells.

Contraindications. Based on controlled clinical trials showing increased mortality, GH should not be used in patients with acute critical illness due to complications after open heart or abdominal surgery, multiple accidental trauma, or acute respiratory failure. GH also should not be used in patients who have any evidence of neoplasia, and antitumor therapy should be completed before GH therapy is initiated. Other contraindications include proliferative retinopathy or severe nonproliferative diabetic retinopathy. In Prader-Willi syndrome, sudden death has been observed when GH was given to children who were severely obese or who had severe respiratory impairment.

Therapeutic Uses. In GH-deficient children, somatotropin typically is administered in a dose of 25-50 $\mu\text{g}/\text{kg}$ per day subcutaneously in the evening; higher daily doses (e.g., 50-67 $\mu\text{g}/\text{kg}$) are employed for patients with Noonan's syndrome or Turner's syndrome, who have partial GH resistance. In children with overt GH deficiency, measurement of serum IGF-1 levels sometimes is used to monitor initial response and compliance; long-term response is monitored by close evaluation of height, sometimes in conjunction with measurements of

serum IGF-1 levels (Cohen et al., 2007). Although the most pronounced increase in growth velocity occurs during the first 2 years of therapy, GH is continued until the epiphyses are fused and also may be extended into the transition period from childhood to adulthood.

In view of the effects of GH on bone density and visceral adiposity and the manifestations of GH deficiency in adults, many experts now continue therapy into adulthood for children with GH deficiency (Radovick and DiVall, 2007). However, many patients who were GH deficient in childhood based on provocative testing, especially those with idiopathic, isolated GH deficiency, respond normally to provocative tests as adults. Thus, it is essential to confirm GH deficiency after full growth has been achieved, ideally after discontinuation of GH replacement for at least 1 month, to identify patients who will benefit from continuing GH treatment.

For adults, weight-based dosing largely has been supplanted by initiation with relatively low doses irrespective of weight, followed by dose titration as tolerated to raise IGF-1 levels to the mid-normal range adjusted for age and sex. A typical starting dose is 150-300 μg per day, with higher doses used in younger patients transitioning from pediatric therapy; lower doses are used in older patients (e.g., >60 years of age). Either an elevated serum IGF-1 level or persistent side effects mandates a decrease in dose; conversely, the dose can be increased (typically by 100-200 μg per day) if serum IGF-1 has not reached the normal range after 2 months of GH therapy. Because estrogen inhibits GH action, women taking oral—but not transdermal—estrogen may require larger GH doses to achieve the target IGF-1 level. In the setting of AIDS-related wasting, considerably higher doses (e.g., 100 $\mu\text{g}/\text{kg}$) have been used. Studies are also underway to assess the effect of GH therapy on reducing visceral adiposity and increasing lean body mass in HIV-infected patients with the adipose redistribution syndrome (Grunfeld et al., 2007; Lo et al., 2008).

Based on the known age-related decline in GH levels, the use of GH therapy to ameliorate or even reverse the consequences of aging has been widely promoted. Many of the studies supporting this use were not placebo controlled and involved small numbers of subjects. Moreover, one review concluded that there was no significant improvement in strength or aerobic performance with GH therapy in elderly subjects (Liu et al., 2007). Thus, this remains an area of considerable debate. In violation of regulations and standard medical practice, some athletes also use injected GH preparations as anabolic agents to enhance performance (Gibney et al., 2007). In addition to the parenteral GH preparations, oral preparations containing "stacked" amino acids that reputedly stimulate GH release have been marketed as nutritional supplements. Despite the absence of validation in controlled trials, these formulations are part of multibillion dollar anti-aging and performance-enhancing programs (Olshansky and Perls, 2008).

Adverse Effects of Growth Hormone Therapy. In children, GH therapy is associated with remarkably few side effects. Rarely, generally within the first 8 weeks of therapy, patients develop intracranial hypertension, with papilledema, visual changes, headache, nausea, and/or vomiting. Because of this, funduscopic examination is recommended at the initiation of therapy and at periodic intervals thereafter. Leukemia has been reported in some children receiving GH therapy; a causal relationship has not been established, and conditions associated with GH deficiency (e.g., Down's syndrome, cranial irradiation for CNS tumors) probably explain the apparent increased

incidence of leukemia. Despite this, the consensus is that GH should not be administered in the first year after treatment of pediatric tumors, including leukemia, or during the first 2 years after therapy for medulloblastomas or ependymomas. Because an increased incidence of type 2 diabetes mellitus has been reported, fasting glucose levels should be followed periodically during therapy. Finally, too-rapid growth may be associated with slipped epiphyses or scoliosis, although a causal link with GH has not been proven.

Side effects associated with the initiation of GH therapy in adults include peripheral edema, carpal tunnel syndrome, arthralgias, and myalgias, which occur most frequently in patients who are older or obese and generally respond to a decrease in dose. These volume-related adverse effects occur less frequently with standard-dose rather than weight-based regimens. Although there are potential concerns about impaired glucose tolerance secondary to anti-insulin actions of GH, this generally has not been a major problem at the recommended doses. In fact, changes in visceral fat composition associated with GH replacement may improve insulin sensitivity in some patients.

Drug Interactions. The effects of estrogen on GH therapy were noted earlier. This effect is much less marked with transdermal estrogen preparations. Recent studies suggest that GH therapy can increase the metabolic inactivation of glucocorticoids in the liver. Thus, GH may precipitate adrenal insufficiency in patients with occult secondary adrenal insufficiency or in patients receiving replacement doses of glucocorticoids. This has been attributed to the inhibition of the type 1 isozyme of steroid 11 β -hydroxysteroid dehydrogenase, which normally converts inactive cortisone into the active 11-hydroxy derivative cortisol (Chapter 42).

Insulin-like Growth Factor 1 (IGF-1)

Based on the hypothesis that GH predominantly acts via increases in IGF-1, there has been a longstanding interest in developing IGF-1 preparations for therapeutic use. To this end, recombinant human IGF-1 (mecasermin, INCRELEX) and a combination of recombinant human IGF-1 with its binding protein, IGFBP-3 (mecasermin rinfabate; IPLEX), are FDA-approved. The latter formulation was subsequently discontinued for use in short stature due to patent issues, although it remains available for other conditions such as severe insulin resistance, muscular dystrophy, and HIV-related adipose redistribution syndrome.

Absorption, Distribution, and Elimination. Mecasermin is administered by subcutaneous injection and absorption is virtually complete. As discussed earlier, IGF-1 in circulation is bound by six proteins; a ternary complex that includes IGFBP-3 and the acid labile subunit accounts for >80% of the circulating IGF-1. This protein binding prolongs the $t_{1/2}$ of IGF-1 to ~6 hours. Both the liver and kidney have been shown to metabolize IGF-1.

Therapeutic Uses. Mecasermin is FDA-approved for patients with impaired growth secondary to mutations in the GH receptor or postreceptor signaling pathway, patients with GH deficiency who develop antibodies against GH that interfere with its action, and the

very rare patients with IGF-1 gene defects that lead to primary IGF-1 deficiency (Collet-Solberg and Misra, 2008). Typically the starting dose is 40–80 $\mu\text{g}/\text{kg}$ per dose twice daily by subcutaneous injection, with a maximum of 120 $\mu\text{g}/\text{kg}$ per dose twice daily.

Clinical trials also have examined the efficacy of mecasermin in the much larger cohort of patients with impaired growth secondary to GH deficiency or with idiopathic short stature. In these settings, mecasermin stimulates linear growth but is less effective than conventional therapy using recombinant GH, suggesting direct effects of GH on linear growth independent of IGF-1. Although further study is needed, mecasermin should be reserved for therapy in patients with FDA-approved indications and is unlikely to replace GH as preferred therapy for most patients with GH deficiency or short stature.

Adverse Effects. Side effects of mecasermin include hypoglycemia and lipohypertrophy, both presumably secondary to activation of the insulin receptor. To diminish the frequency of hypoglycemia, mecasermin should be administered shortly before or after a meal or snack. Lymphoid tissue hypertrophy, including enlarged tonsils, also is seen and may require surgical intervention. Other adverse effects are similar to those associated with GH therapy and include intracranial hypertension, slipped epiphyses, and scoliosis.

Contraindications. Mecasermin should not be used for growth promotion in patients with closed epiphyses. It should not be given to patients with active or suspected neoplasia and should be stopped if evidence of neoplasia develops.

Sermorelin. *Sermorelin* (GEREF) is a synthetic form of human GHRH that corresponds in sequence to the first 29 amino acids of human GHRH (a 44–amino acid peptide) and has full biological activity. Although sermorelin is FDA-approved for treatment of GH deficiency and as a diagnostic agent to differentiate between hypothalamic and pituitary disease, the drug was withdrawn from the U.S. market in late 2008.

THE GYCOPROTEIN HORMONES: TSH AND THE GONADOTROPINS

The gonadotropins include LH, FSH, and hCG. They are referred to as the gonadotropins because of their actions on the gonads (Table 38–2). Together with TSH, they constitute the glycoprotein family of pituitary hormones. Each hormone is a glycosylated heterodimer containing a common α -subunit and a distinct β -subunit that confers specificity of action.

LH and FSH were named initially based on their actions on the ovary; appreciation of their roles in male reproductive function came later. LH and FSH are synthesized and secreted by gonadotropes, which make up ~10% of the hormone-secreting cells in the anterior pituitary. hCG, which is produced only in primates and horses, is synthesized by the syncytiotrophoblast of the placenta. Pituitary gonadotropin production is stimulated by GnRH and further

Figure 38–7. *The hypothalamic-pituitary-gonadal axis.* A single hypothalamic releasing factor, gonadotropin-releasing hormone (GnRH), controls the synthesis and release of both gonadotropins (LH and FSH) in males and females. Gonadal steroid hormones (androgens, estrogens, and progesterone) exert feedback inhibition at the level of the pituitary and the hypothalamus. The pre-ovulatory surge of estrogen also can exert a stimulatory effect at the level of the pituitary and the hypothalamus. Inhibins, a family of polypeptide hormones produced by the gonads, specifically inhibit FSH secretion by the pituitary.

regulated by feedback effects of the gonadal hormones (Figures 38–7 and 40–2). Chapters 40 and 41 provide more detailed descriptions of gonadotropin regulation.

TSH is measured in the diagnosis of thyroid disorders, and recombinant TSH is used in the evaluation and treatment of well-differentiated thyroid cancer, as discussed in Chapter 39.

Physiology of the Gonadotropins

Structure-Function Aspects of the Gonadotropins. The carbohydrate residues on the gonadotropins influence their rates of clearance from the circulation, and thus their serum half-lives, and also play a role in activating the gonadotropin receptors. Among the gonadotropin β -subunits, that of hCG is most divergent because it contains a carboxy-terminal extension of 30 amino acids and extra carbohydrate residues that prolong its $t_{1/2}$. The longer $t_{1/2}$ of hCG has some clinical relevance for its use in assisted reproduction technologies (Chapter 66).

Regulation of Gonadotropin Synthesis and Secretion.

The predominant regulator of gonadotropin synthesis and secretion is the hypothalamic peptide GnRH. It is a decapeptide with blocked amino and carboxyl termini (Table 38–3) derived by proteolytic cleavage of a 92-amino acid precursor peptide. A separate gene encodes a related GnRH peptide, termed GnRH-II (Millar et al., 2004); its potential functions in reproduction remain to be defined. GnRH release is pulsatile and is governed by a neural pulse generator in the hypothalamus, primarily in the arcuate nucleus, that controls the frequency and amplitude of GnRH release. The GnRH pulse generator is active late in fetal life and for ~1 year after birth but decreases considerably thereafter, presumably secondarily to CNS inhibition. Shortly before puberty, CNS inhibition decreases and the amplitude and frequency of GnRH pulses increase, particularly during sleep. As puberty progresses, the GnRH pulses increase further in amplitude and frequency until the normal adult pattern is established. The intermittent release of GnRH is crucial for the proper synthesis and release of the gonadotropins; the continuous administration of GnRH leads to desensitization and down-regulation of GnRH receptors on pituitary gonadotropes and forms the basis for the clinical use of long-acting GnRH agonists to suppress gonadotropin secretion, as discussed later.

Molecular and Cellular Bases of GnRH Action.

GnRH signals through a specific GPCR on gonadotropes that activates $G_{q/11}$ and stimulates the PLC-IP₃-Ca²⁺ pathway (Chapter 3), resulting in increased synthesis and secretion of LH and FSH. Although cyclic AMP is not the major mediator of GnRH action, binding of GnRH to its receptor also increases adenylyl cyclase activity. GnRH receptors also are present in the ovary, testis, and other sites, where their physiological significance remains to be determined. The presence of these receptors on certain tumors has led to investigation of the role of GnRH analogs in cancer therapy (Engel and Schally, 2007).

Other Regulators of Gonadotropin Production. Gonadal steroids regulate gonadotropin production at the level of the pituitary and the hypothalamus, but effects on the hypothalamus predominate. The feedback effects of gonadal steroids are dependent on sex, concentration, and time. In women, low levels of estradiol and progesterone inhibit gonadotropin production, largely through opioid action on the neural pulse generator. Higher and more sustained levels of estradiol have positive feedback effects that ultimately result in the gonadotropin surge that triggers ovulation. In men, testosterone inhibits gonadotropin production, in part through direct actions and in part via its conversion by aromatase to estradiol.

Table 38-3

Structures of Gonadotropin-Releasing Hormone (GnRH) and GnRH Analogs

GnRH CONGENER (TRADE NAME)	AMINO ACID RESIDUE										DOSAGE FORMS

Ac, acetyl; Bzl, benzyl; EtNH₂, N-ethylamide; tBu, t butyl; D-Nal, 3-(2-naphthyl)-D-alanyl; Cpa, chlorophenylalanyl; Lys(iPr), isopropyl-lysyl; Pal, 3-pyridylalanyl; AzGly, azaglycyl; hArg(Et)₂, ethyl homoarginine; IV, intravenous; SC, subcutaneous; IN, intranasal; IM, intramuscular. A dash (—) denotes amino acid identity with GnRH.

Gonadotropin production also is regulated by the *inhibins*, which are members of the bone morphogenetic protein family of secreted signaling proteins. Inhibin A and B are made by granulosa cells in the ovary and Sertoli cells in the testis in response to the gonadotropins and local growth factors (Bilezikjian et al., 2006). They act directly in the pituitary to inhibit FSH secretion without affecting that of LH. Inhibin A exhibits variation during the menstrual cycle, suggesting that it acts as a dynamic regulator of FSH secretion.

Molecular and Cellular Bases of Gonadotropin Action.

The actions of LH and hCG on target tissues are mediated by the LH receptor; those of FSH are mediated by the FSH receptor. Both of these GPCRs have large glycosylated extracellular domains that contribute to their affinity and specificity for their ligands. The FSH and LH receptors couple to G_{sa} to activate the adenylyl cyclase/cyclic AMP pathway. At higher ligand concentrations, the agonist-occupied gonadotropin receptors also activate PKC and Ca^{2+} signaling pathways via G_q -mediated effects on $PLC\beta$. Because most, if not all, actions of the gonadotropins can be mimicked by cyclic AMP analogs, the precise physiological role of Ca^{2+} and PKC in gonadotropin action remains to be determined.

Physiological Effects of Gonadotropins. In men, LH acts on testicular Leydig cells to stimulate the *de novo* synthesis of androgens, primarily testosterone, from cholesterol. Testosterone is required for gametogenesis within the seminiferous tubules and for maintenance of libido and secondary sexual characteristics (Chapter 41). FSH acts on the Sertoli cells to stimulate the production of proteins and nutrients required for sperm maturation.

In women, the actions of FSH and LH are more complicated. FSH stimulates the growth of developing ovarian follicles and induces the expression of LH receptors on theca and granulosa cells. FSH also regulates the expression of aromatase in granulosa cells, thereby stimulating the production of estradiol. LH acts on the theca cells to stimulate the *de novo* synthesis of androstenedione, the major precursor of ovarian estrogens in premenopausal women (Figure 40-1). LH also is required for the rupture of the dominant follicle during ovulation and for the synthesis of progesterone by the corpus luteum.

CLINICAL DISORDERS OF THE HYPOTHALAMIC-PITUITARY-GONADAL AXIS

Clinical disorders of the hypothalamic-pituitary-gonadal axis can manifest either as alterations in levels and

effects of sex steroids (hyper- or hypogonadism) or as impaired reproduction. This section focuses on those conditions that specifically affect the hypothalamic-pituitary components of the axis and those for which gonadotropins are used diagnostically or therapeutically.

Deficient sex steroid production resulting from hypothalamic or pituitary defects is termed hypogonadotropic hypogonadism because circulating levels of gonadotropins are either low or undetectable (Layman, 2007). Hypogonadotropic hypogonadism in some patients results from GnRH receptor mutations; some of these mutations impair targeting of the GnRH receptor to the plasma membrane of gonadotropes, prompting efforts to develop pharmacological strategies to correct receptor trafficking and restore function (Conn et al., 2007). Many other disorders can impair gonadotropin secretion, including pituitary tumors, other genetic disorders such as Kallmann's syndrome, infiltrative processes such as sarcoidosis, and functional disorders such as exercise-induced amenorrhea.

In contrast, reproductive disorders caused by processes that directly impair gonadal function are termed hypergonadotropic because the impaired production of sex steroids leads to a loss of negative feedback inhibition, thereby increasing the synthesis and secretion of gonadotropins.

Precocious Puberty. Puberty normally is a sequential process requiring several years over which the GnRH neurons escape CNS inhibition and initiate pulsatile secretion of GnRH. This stimulates the secretion of gonadotropins and gonadal steroids, thus directing the development of secondary sexual characteristics appropriate for sex. Normally, the initial signs of puberty (breast development in girls and testes enlargement in boys) do not occur before age 8 in girls or age 9 in boys; the initiation of sexual maturation before this time is termed "precocious."

Precocious puberty can be divided into processes that lead to the premature activation of the normal hypothalamic-pituitary-gonadal axis, termed central or GnRH-dependent precocious puberty, and processes that lead to peripheral production of sex steroids in a GnRH-independent manner (Carel and Léger, 2008). Specific etiologies of GnRH-dependent precocious puberty include CNS tumors (including hypothalamic hamartomas), developmental abnormalities of the CNS, and encephalitis or other infectious processes; in most patients and especially in girls, a specific etiology is never defined, and patients are deemed to have an idiopathic process. GnRH-independent precocious puberty

results from peripheral production of sex steroids in a manner not driven by pituitary gonadotropins; etiologies include adrenal or gonadal tumors, activating mutations of the LH receptor in boys, and congenital adrenal hyperplasia. As discussed later, synthetic GnRH analogs play important roles in the diagnosis and treatment of GnRH-dependent precocious puberty. In contrast, drugs that interfere with the production of sex steroids, including ketoconazole and aromatase inhibitors, are used in patients with GnRH-independent precocious puberty (Shulman et al., 2008), with varying success.

Sexual Infantilism. The converse of precocious puberty is a failure to initiate the processes of pubertal development at the normal time. This can reflect defects in the GnRH neurons or gonadotropes (secondary hypogonadism) or primary dysfunction in the gonads. In either case, induction of sexual maturation using sex steroids (estrogen followed by estrogen/progesterone in females, testosterone in males) is standard therapy. This suffices to direct sex differentiation in the normal manner. If fertility is the goal, then therapy with either GnRH or gonadotropins is needed to stimulate appropriate germ cell maturation.

Infertility. Infertility, or a failure to conceive after 12 months of unprotected intercourse, is seen in up to 10-15% of couples and is increasing in frequency as women choose to delay childbearing. The rising incidences of obesity, sexually transmitted diseases that disrupt the reproductive tract, and reduced sperm count to due environmental pollution also are contributing factors. When the infertility is due to impaired synthesis or secretion of gonadotropins (hypogonadotropic hypogonadism), various pharmacological approaches are employed. In contrast, when infertility results from intrinsic processes affecting the gonads, pharmacotherapy generally is less effective. Therapeutic approaches to male infertility are described later in this chapter; strategies for female infertility are described in Chapter 66.

Clinical Uses of GnRH and Its Synthetic Analogs

A synthetic peptide comprising the native sequence of GnRH has been used both diagnostically and therapeutically in human reproductive disorders. In addition, as illustrated in Table 38–3, a number of GnRH analogs with structural modifications have been synthesized and brought to market.

Synthetic GnRH. Synthetic GnRH (gonadorelin; FACTEREL, LUTREPULSE) is FDA-approved, but ongoing problems with availability have limited its clinical use in the U.S. to a few specialized centers; synthetic analogs have largely supplanted gonadorelin.

Chemistry. The structure of gonadorelin (Table 38–3) corresponds to that of native GnRH; it is a decapeptide with blocked amino and carboxyl termini.

Absorption, Distribution, and Elimination. As a peptide, gonadorelin is administered either subcutaneously or intravenously. It is well-absorbed following subcutaneous injection and has a circulating $t_{1/2}$ of ~2-4 minutes. For therapeutic uses, it must be administered in a pulsatile manner to avoid down-regulation of the GnRH receptor.

Diagnostic and Therapeutic Uses. Because of the limited availability of GnRH, many of its diagnostic and therapeutic uses have been discontinued. For diagnostic purposes, gonadorelin was used in the GnRH stimulation test in patients with hypogonadotropic hypogonadism in an effort to differentiate between hypothalamic and pituitary defects. A blood sample was obtained for a baseline LH value, a single 100- μ g dose of GnRH was administered subcutaneously or intravenously, and serum LH levels were measured at various times after injection. A normal LH response to >10 mIU/mL indicated the presence of functional pituitary gonadotropes and prior exposure to GnRH. Inasmuch as the long-term absence of GnRH can impair the responsiveness of otherwise normal gonadotropes, the absence of a response did not always indicate intrinsic pituitary disease. Thus some experts had advocated use of multiple doses of GnRH in an effort to restore gonadotrope responsiveness.

GnRH-stimulation testing also was used to determine whether a child with precocious puberty had a GnRH-dependent (central) or GnRH-independent (peripheral) disorder. A GnRH-induced increase in plasma LH to >10 mIU/mL in boys or >7 mIU/mL in girls indicated true precocious puberty rather than a GnRH-independent process. Currently, some experts in the U.S. and elsewhere have used long-lasting GnRH agonists off label as the stimulating agent for diagnostic assessment (see section on Gonadotropin-Releasing Hormone Agonists).

To treat female infertility secondary to impaired GnRH secretion, gonadorelin was administered by infusion in pulses that promoted a physiological cycle. Advantages over gonadotropin therapy included a lower risk of multifetal pregnancies and a decreased need to monitor plasma estradiol levels or follicle size by ovarian ultrasonography. Side effects usually were minimal; the most common was local irritation due to the infusion device. In women, normal cycling levels of ovarian steroids could be achieved, leading to ovulation and menstruation. The manufacturer has discontinued production for this indication, and gonadorelin is no longer generally available in the U.S.

GnRHA. Synthetic agonists have longer half-lives than native GnRH. After a transient stimulation of gonadotropin secretion, they down-regulate the GnRH receptor and inhibit gonadotropin secretion; this is used

1122 to therapeutic advantage in a number of conditions, as outlined in the following discussion and in Chapter 66.

Chemistry. The sequences of the available GnRH agonists are listed in Table 38–3. They contain substitutions of the native sequence at position 6 that protect against proteolysis and substitutions at the carboxyl terminus that improve receptor-binding affinity. Compared to GnRH, these analogs exhibit enhanced potency and prolonged duration of action.

Pharmacokinetics. The GnRH agonists are available in a variety of formulations for diverse applications, including relatively short-term effects (e.g., assisted reproduction technology) and more prolonged action (e.g., depot forms that inhibit gonadotropin secretion in GnRH-dependent precocious puberty). The rates and extents of absorption thus vary considerably. The intranasal formulations are noteworthy because their bioavailability (~4%) is considerably lower than those of the parenteral formulations.

Clinical Uses. Based on the intermittent supply of gonadorelin, the depot form of the GnRH agonist leuprolide (LUPRON) has been used diagnostically to differentiate between GnRH-dependent and GnRH-independent precocious puberty (Brito et al., 2004). Leuprolide depot (3.75 mg) is injected subcutaneously, and serum LH is measured 2 hours later. A plasma LH level of >6.6 mIU/mL is diagnostic of GnRH-dependent (central) disease.

Clinically, the various GnRH agonists are used to achieve pharmacological castration in disorders that respond to reduction in gonadal steroids. A clear indication is in children with GnRH-dependent precocious puberty, whose premature sexual maturation can be arrested with minimal side effects by chronic administration of a depot form of a GnRH agonist.

Long-acting GnRH agonists are used for palliative therapy of hormone responsive tumors (e.g., prostate or breast cancer), generally in conjunction with agents that block steroid biosynthesis or action to avoid transient increases in hormone levels (Chapters 40–42). The GnRH agonists also are used to suppress steroid-responsive conditions such as endometriosis, uterine fibroids, acute intermittent porphyria, and priapism. They also have been evaluated off label for their potential to preserve follicles in women undergoing therapy with cytotoxic drugs for cancer treatment, although efficacy in this setting has not been established. Depot preparations can be administered subcutaneously or intramuscularly monthly or every 3 months in these settings and may be particularly useful for pharmacological castration in disorders such as paraphilia (an off-label use), where strict patient compliance is problematic.

Finally, the long-lasting GnRH agonists have been used to avoid a premature LH surge, and thus ovulation, in various ovarian stimulation protocols for *in vitro* fertilization. The specifics of this use are outlined in Chapter 66.

Adverse Effects. The long-acting agonists generally are well tolerated, and side effects are those that would be predicted to occur when gonadal steroidogenesis is inhibited (e.g., hot flashes and decreased bone density in both sexes, vaginal dryness and atrophy in women, and erectile dysfunction in men). Because of these effects, therapy in non-life-threatening diseases such as endometriosis or uterine fibroids generally is limited to 6 months unless add-back therapy with sex steroids is incorporated into the regimen. Postmarketing surveillance noted an apparent increase in the incidence of pituitary

apoplexy, a syndrome of headache, neurological manifestations, and impaired pituitary function that usually results from infarction of a pituitary adenoma (Davis et al., 2006); the product labeling for the GnRH agonists has been updated to include this risk. Although definitive evidence of an increased risk of congenital abnormalities is lacking (Elizur and Tulundi, 2008), the GnRH agonists interfered with pregnancy in animal models and thus are considered as contraindicated in pregnant women (FDA Category X). Thus caution should be exercised to avoid the exposure of pregnant women to GnRH agonists.

Specific Drug Formulations and Approved Indications

Leuprolide (LUPRON, ELIGARD) is formulated in multiple doses for injection: subcutaneous (500 mg/day), subcutaneous depot (7.5 mg/month; 22.5 mg/3 months; 30 mg/4 months; 45 mg/6 months), and intramuscular depot (3.75 mg/month; 11.25 mg/3 months). It is approved for endometriosis, uterine fibroids, advanced prostate cancer, and central precocious puberty.

Goserelin (ZOLADEX) is formulated as a subcutaneous implant (3.6 mg/month; 10.8 mg/12 weeks). It is approved for endometriosis and advanced prostate and breast cancer.

Histrelin (VANTAS, SUPPRELIN LA) is formulated as a subcutaneous implant (50 mg/12 months). It is approved for central precocious puberty and advanced prostate cancer.

Nafarelin (SYNAREL) is formulated as a nasal spray (200 µg/spray). It is approved for endometriosis (400 µg/day) and central precocious puberty (1600 µg/day).

Triptorelin (TRELSTAR DEPOT, TRELSTAR LA) is formulated for depot intramuscular injection (3.75 mg/month; 11.25 mg/12 weeks) and approved for advanced prostate cancer.

Buserelin and *Deslorelin* are not available in the U.S.

GnRH Antagonist Analogs. Two GnRH antagonists, ganirelix (ANTAGON) and cetrorelix (CETROTIDE; Table 38–3), are FDA approved to suppress the LH surge and thus prevent premature ovulation in ovarian-stimulation protocols as part of assisted reproduction technology. Specifics of use in that setting are given in Chapter 66. Cetrorelix is also used off label for endometriosis and uterine fibroids, both of which are estrogen dependent. As antagonists rather than agonists, these drugs do not transiently increase gonadotropin secretion and sex steroid biosynthesis. A depot form of a third GnRH antagonist, abarelix (PLENAXIS) was FDA approved for androgen suppression in men with advanced prostate cancer but has since been withdrawn from market for economic reasons.

Chemistry. The GnRH antagonists are synthetic peptides with modifications of certain residues found in the native GnRH sequence. In addition to a D-amino acid at position 6 and a D-Ala amide at position 10, the antagonists each contain D-chlorophenylalanyl and 3-pyridylalanyl substitutions at positions 2 and 3, respectively, which affect receptor activation and increase inhibitory potency and solubility. The additional substitution at position 8, along with that at position 10, reduces the induction of histamine release and the tendency to trigger immediate hypersensitivity reactions (Reissmann et al., 1995).

Absorption, Distribution, and Elimination. Both available GnRH antagonists are formulated for subcutaneous administration. Bioavailability exceeds 90% within 1-2 hours, and the $t_{1/2}$ varies depending on the dose. Once-daily administration suffices for therapeutic effect.

Adverse Effects. In contrast to older antagonists, the FDA-approved drugs did not manifest potent histamine release in preclinical or clinical trials. However, hypersensitivity reactions, including anaphylaxis, have been noted in postmarketing surveillance, some with the initial dose. When used in conjunction with gonadotropin injections for assisted reproduction, the effects of estrogen withdrawal (e.g., hot flashes) are not seen. The product labeling indicates that the GnRH antagonists are contraindicated in pregnant women (FDA Category X), although definitive data linking them to an increased risk of congenital abnormalities is lacking (Elizur and Tulandi, 2008).

NATURAL AND RECOMBINANT GONADOTROPINS

The gonadotropins are used for both diagnosis and therapy in reproductive endocrinology. The therapeutic uses of the gonadotropins are briefly presented here; further discussion of the uses of gonadotropins in female reproduction is provided in Chapter 66.

The original gonadotropin preparations for clinical therapy were prepared from human urine and included *chorionic gonadotropin*, obtained from the urine of pregnant women, and *menotropins*, obtained from the urine of postmenopausal women. Because of their relatively low purity, these gonadotropins were administered intramuscularly to decrease the incidence of hypersensitivity reactions. Subsequently, urine-derived preparations of sufficient purity to be administered subcutaneously were developed. Highly purified preparations of human gonadotropins now are prepared using recombinant DNA technology that exhibit less batch-to-batch variation; this same technology is likely to lead to improved forms of gonadotropins with increased half-lives or higher clinical efficacy. One such “designer” gonadotropin, FSH-CTP, contains the β -subunit of FSH fused to the carboxy-terminal extension of hCG, thereby increasing considerably the $t_{1/2}$ of the recombinant protein. In clinical trials, FSH-CTP has been shown to stimulate follicle maturation *in vivo* when injected weekly (reviewed by Macklin et al., 2006).

Preparations

Follicle-Stimulating Hormone. Follicle-stimulating hormone has long been a mainstay of regimens for either ovarian stimulation or *in vitro* fertilization. The original *menotropin* formulations (REPRONEX) contained roughly equal amounts of FSH and LH, as well as a number of other urinary proteins, and were administered intramuscularly to diminish local reactions. *Urofollitropin* (uFSH; BRAVELLE, MENOPUR), prepared by immunoneutralization of FSH with monoclonal antibodies, is pure

enough to be administered subcutaneously. The amount of LH contained in such preparations is diminished considerably, prompting (unproven) speculation that the lack of LH activity might impair follicle maturation to some degree.

Recombinant FSH (rFSH) is prepared by expressing cDNAs encoding the α and β subunits of human FSH in mammalian cell lines, yielding products whose glycosylation pattern mimics that of FSH produced by gonadotropes. The two available rFSH preparations (*follitropin α* [GONAL-F] and *follitropin β* [FOLLISTIM, PUREGON]) differ slightly in their carbohydrate structures; both exhibit less interbatch variability than do preparations purified from urine and can be administered subcutaneously because they are considerably purer. The relative advantages (i.e., efficacy, lower frequency of side effects such as ovarian hyperstimulation) of recombinant FSH versus urine-derived gonadotropins have not been definitively established despite much debate in the published literature (see Chapter 66 for further discussion).

Human Chorionic Gonadotropin. The hCG used clinically originally came from the urine of pregnant women. Several urine-derived preparations are available (NOVAREL, PREGNYL, PROFASI); all of them are administered intramuscularly due to local reactions. Recombinant hCG (choriogonadotropin alfa; OVIDREL) also has reached clinical use. Again, it is likely that recombinant hCG preparations will have an increasing role in the future, possibly replacing the urinary preparations entirely.

Recombinant Human LH. Menotropins contain considerable LH activity, thereby providing any LH that is needed to promote follicle maturation. Traditionally, LH was not used for ovulation induction because hCG produced identical effects via the LH receptor and had a longer $t_{1/2}$. Human LH produced using recombinant DNA technology and designated lutropin alfa (LUVERIS, LHADI) now is available. Again, advantages or disadvantages relative to hCG remain to be established, although LH appears to be less likely to induce ovarian hyperstimulation when used to induce ovulation in IVF protocols (Chapter 66).

Diagnostic Uses of Gonadotropins

Pregnancy Testing. During pregnancy, the placenta produces significant amounts of hCG, which can be detected in maternal urine. Over-the-counter pregnancy kits containing antibodies specific for the unique β -subunit of hCG qualitatively assay for the presence of hCG and can detect pregnancy within a few days after a woman’s first missed menstrual period.

Quantitative measurements of plasma hCG concentration by radioimmunoassay can indicate whether pregnancy is proceeding normally and can help to

1124 detect the presence of an ectopic pregnancy, hydatidiform mole, or choriocarcinoma. Such assays also are used to follow the therapeutic response of malignancies that secrete hCG, such as germ cell tumors.

Timing of Ovulation. Ovulation occurs ~36 hours after the onset of the LH surge. Therefore urinary concentrations of LH, as measured with an over-the-counter radioimmunoassay kit, can be used to predict the time of ovulation. Urine LH levels are measured every 12-24 hours, beginning on day 10-12 of the menstrual cycle (assuming a 28-day cycle), to detect the rise in LH and estimate the time of ovulation. This estimate facilitates the timing of sexual intercourse to optimize the chance of achieving pregnancy.

Localization of Endocrine Disease. Measurements of plasma LH and FSH levels with β subunit-specific radioimmunoassays are useful in the diagnosis of several reproductive disorders. Low or undetectable levels of LH and FSH are indicative of hypogonadotropic hypogonadism and suggest hypothalamic or pituitary disease, whereas high levels of gonadotropins suggest primary gonadal diseases. A plasma FSH level of ≥ 10 -12 mIU/mL on day 3 of the menstrual cycle, indicative of decreased ovarian reserve, is associated with reduced fertility, even if a woman is menstruating normally, and predicts a lower likelihood of success in assisted reproduction techniques such as *in vitro* fertilization.

The administration of hCG can be used to stimulate testosterone production and thus to assess Leydig cell function in males suspected of having primary hypogonadism (e.g., in delayed puberty). Serum testosterone levels are assayed after multiple injections of hCG. A diminished testosterone response to hCG indicates Leydig cell failure; a normal testosterone response suggests a hypothalamic-pituitary disorder and normal Leydig cells.

Therapeutic Uses of the Gonadotropins

Male Infertility. In men with impaired fertility secondary to gonadotropin deficiency (hypogonadotropic hypogonadism), gonadotropins can establish or restore fertility. Due to expense and to the occasional development of antibody-mediated resistance to gonadotropins with prolonged use, standard treatment has been to induce sexual development with androgens, reserving gonadotropins until fertility is desired.

Treatment typically is initiated with hCG (1500-2000 IUs intramuscularly or subcutaneously) three times per week until clinical parameters and the plasma testosterone level indicate full induction of steroidogenesis. Thereafter, the dose of hCG is reduced to

2000 IU twice a week or 1000 IU three times a week, and menopins (FSH + LH) or recombinant FSH is injected three times a week (typical dose of 150 IU) to fully induce spermatogenesis.

Based on the observation that the normal male infant is exposed to high levels of gonadotropins during the first year of life, it has been proposed that therapy with LH and FSH during infancy may be associated with increased spermatogenesis later in life (Grumbach, 2005), and studies addressing this question are in progress.

The most common side effect of gonadotropin therapy in males is gynecomastia, which occurs in up to a third of patients and presumably reflects increased production of estrogens due to the induction of aromatase. Maturation of the prepubertal testes typically requires treatment for >6 months, and optimal spermatogenesis in some patients may require treatment for up to 2 years. Once spermatogenesis has been initiated, either by this combined therapy in patients with prepubertal disease or in patients who developed hypogonadotropic hypogonadism after sexual maturation, ongoing treatment with hCG alone usually is sufficient to support sperm production.

Cryptorchidism. Cryptorchidism, the failure of one or both testes to descend into the scrotum, affects up to 3% of full-term male infants and becomes less prevalent with advancing postnatal age. Cryptorchid testes have defective spermatogenesis and are at increased risk for developing germ cell tumors. Hence the current approach is to reposition the testes as early as possible, typically at 1 year of age but definitely before 2 years of age. The local actions of androgens stimulate descent of the testes; thus hCG has been used by some to induce testicular descent if the cryptorchidism is not secondary to anatomical blockage.

Therapy usually consists of injections of hCG (3000 IU/m² body surface area) intramuscularly every other day for six doses. If this does not induce testicular descent, orchiopexy should be performed. Some experts prefer surgery as the initial approach based on the association of hCG treatment with germ cell apoptosis in certain experimental settings (Ritzen, 2008).

POSTERIOR PITUITARY HORMONES: OXYTOCIN AND VASOPRESSIN

The structures of the neurohypophyseal hormones oxytocin and arginine vasopressin (also called antidiuretic hormone, or ADH) and the physiology and pharmacology of vasopressin are presented in Chapter 25. The following discussion emphasizes the physiology of oxytocin. Therapeutic uses of synthetic oxytocin as a uterine-stimulating agent to induce or augment labor in selected pregnant women and to decrease postpartum hemorrhage are described in Chapter 66.

Physiology of Oxytocin

Biosynthesis of Oxytocin. *Oxytocin* is a cyclic nonapeptide that differs from vasopressin by only two amino

acids. It is synthesized as a larger precursor in neurons whose cell bodies reside in the paraventricular nucleus and, to a lesser extent, the supraoptic nucleus in the hypothalamus. The precursor peptide is rapidly cleaved to the active hormone and its neurophysin, packaged into secretory granules as an oxytocin-neurophysin complex, and secreted from nerve endings that terminate primarily in the posterior pituitary gland (neurohypophysis). In addition, oxytocinergic neurons that regulate the autonomic nervous system project to regions of the hypothalamus, brainstem, and spinal cord. Other sites of oxytocin synthesis include the luteal cells of the ovary, the endometrium, and the placenta.

Secretion of Oxytocin. Stimuli for oxytocin secretion include sensory stimuli arising from dilation of the cervix and vagina and from suckling at the breast. Increases in circulating oxytocin in women in labor are difficult to detect, partly because of the pulsatile nature of oxytocin secretion and partly because of the activity of circulating oxytocinase. Nevertheless, increased oxytocin in maternal circulation is detected in the second stage of labor, likely triggered by sustained distension of the uterine cervix and vagina.

Estradiol stimulates oxytocin secretion, whereas the ovarian polypeptide relaxin inhibits its release. The inhibitory effect of relaxin appears to be the net result of a direct effect on oxytocin-producing cells and an inhibitory action mediated indirectly by endogenous opiates. Other factors that primarily affect vasopressin secretion also have some impact on oxytocin release; for example, ethanol inhibits release, whereas pain, dehydration, hemorrhage, and hypovolemia stimulate release. Although peripheral actions of oxytocin appear to play no significant role in the response to dehydration, hemorrhage, or hypovolemia, oxytocin may participate in the central regulation of blood pressure.

Pharmacological doses of oxytocin can inhibit free water clearance by the kidney through arginine vasopressin-like activity at vasopressin V_2 receptors, occasionally causing water intoxication if administered with large volumes of hypotonic fluid. Based on the behavior of intravenously administered oxytocin during labor induction, the plasma $t_{1/2}$ of oxytocin is approximately 12–15 minutes.

Mechanism of Action. Oxytocin acts via a specific GPCR (OXT) closely related to the V_{1a} and V_2 vasopressin receptors. In the human myometrium, OXT couples to G_q/G_{11} , activating the PLC_{β} - IP_3 - Ca^{2+} pathway and enhancing activation of voltage-sensitive Ca^{2+} channels. Oxytocin also increases local prostaglandin production, which further stimulates uterine contractions. Figure 66–2 summarizes the interactions of signaling pathways affecting myometrial contractility.

Effects of Oxytocin

Uterus. The human uterus has a very low level of motor activity during the first two trimesters of pregnancy. During the third trimester, spontaneous motor activity

increases progressively until the sharp rise that constitutes the initiation of labor. Oxytocin stimulates the frequency and force of uterine contractions. Uterine responsiveness to oxytocin roughly parallels this increase in spontaneous activity and is highly dependent on estrogen, which increases the expression of the oxytocin receptors. Progesterone antagonizes the stimulatory effect of oxytocin *in vitro*, and refractoriness to progesterone in late pregnancy may contribute to the normal initiation of human parturition.

Because of difficulties associated with the measurement of oxytocin levels and because loss of pituitary oxytocin apparently does not compromise labor and delivery, the physiological role of oxytocin in pregnancy has been highly debated. Exogenous oxytocin can initiate or enhance rhythmic contractions at any time, but a considerably higher dose is required in early pregnancy. An eight-fold increase in uterine sensitivity to oxytocin occurs in the last half of pregnancy, mostly in the last 9 weeks, and is accompanied by a 30-fold increase in oxytocin receptor numbers between week 32 and term. The finding that the oxytocin antagonist atosiban is effective in suppressing preterm labor further supports the physiological importance of oxytocin in this setting.

Breast. Oxytocin plays an important physiological role in milk ejection. Stimulation of the breast through suckling or mechanical manipulation induces oxytocin secretion, causing contraction of the myoepithelium that surrounds alveolar channels in the mammary gland. This action forces milk from the alveolar channels into large collecting sinuses, where it is available to the suckling infant.

Brain. As noted earlier, oxytocin is synthesized by hypothalamic neurons, predominantly located in the paraventricular and supraoptic nuclei. Studies in rodents and humans have implicated oxytocin as an important CNS regulator of trust and of autonomic systems linked to anxiety and fear (Leng et al., 2008).

Brain regions proposed to be critical in the response to fearful stimuli, including the amygdala, midbrain, and striatum, showed decreased activation in response to stressful stimuli following oxytocin treatment (Baumgartner et al., 2008; Huber et al., 2005). The role of perturbations of oxytocin signaling in mental conditions such as social phobia and autism and the possible therapeutic benefit of drugs that manipulate CNS oxytocin effects are exciting areas of ongoing investigation.

Clinical Therapeutics of Oxytocin

Deficiencies of oxytocin associated with disorders of the posterior pituitary impair milk letdown after delivery and may be one of the earliest signs of pituitary insufficiency secondary to postpartum hemorrhage (Sheehan's syndrome); oxytocin is not used clinically in this setting. Rather, oxytocin is used therapeutically to induce or augment labor and to treat or prevent postpartum hemorrhage, as described in Chapter 66.

Progress continues to be made in the pharmacotherapy of endocrine and reproductive disorders related to the anterior pituitary gland. In children, the indications for therapy with recombinant human GH have been expanded beyond patients with classic, unequivocal GH deficiency, and the drug increasingly is used in conditions such as Turner's syndrome, Noonan's syndrome, chronic renal failure, cystic fibrosis, and other conditions associated with short stature, including idiopathic short stature. Recombinant human GH also is used increasingly to treat adults with GH deficiency, with proposed benefits that include increased muscle mass, decreased adiposity, increased bone mineral density, and improved subjective well-being. Adverse effects occur more commonly in adults, and the dose should be adjusted so that the serum IGF-1 level is in the mid-normal range.

Pharmacotherapy also plays an important role in the treatment of functional tumors that produce GH (gigantism/acromegaly) or prolactin (prolactinomas). For acromegaly, sustained-release preparations of somatostatin analogs (e.g., octreotide and lanreotide) normalize GH and IGF-1 levels in ~65% of patients. Pegvisomant, a GH receptor antagonist, is even more effective, normalizing these parameters in up to 90% of patients. For prolactinomas, dopamine receptor agonists remain the mainstay of treatment. Cabergoline generally is used because of its lower incidence of side effects; when pregnancy is desired, bromocriptine is preferred.

Pituitary hormones also have a role in reproductive medicine. Both GnRH receptor agonists and antagonists are used to down-regulate gonadotropin levels and block endogenous production of sex steroids. Indications include interruption of central precocious puberty, therapy of cancers whose growth is stimulated by sex steroids (e.g., breast and prostate), and suppression of endogenous gonadotropins in assisted reproduction technologies. Gonadotropins are frequently used in assisted reproduction technologies to stimulate follicular maturation and to induce ovulation. Recombinant gonadotropins largely are replacing gonadotropins purified from human urine in clinical use.

chapter

Thyroid and Anti-Thyroid Drugs

Gregory A. Brent
and Ronald J. Koenig

Thyroid hormone is essential for normal development, especially of the central nervous system (CNS). In the adult, thyroid hormone maintains metabolic homeostasis and influences the function of virtually all organ systems. Thyroid hormone contains iodine that must be supplied by nutritional intake. The thyroid gland contains large stores of thyroid hormone in the form of thyroglobulin. These stores maintain systemic concentrations of thyroid hormone despite variations in iodine availability and nutritional intake. The thyroidal secretion is predominantly the prohormone thyroxine, which is converted in the liver and other tissues to the active form, triiodothyronine. Local activation of thyroxine also occurs in target tissues (e.g., brain and pituitary) and is increasingly recognized as an important regulatory step in thyroid hormone action. Serum concentrations of thyroid hormones are precisely regulated by the pituitary hormone, thyrotropin (TSH), in a classic negative-feedback system. The predominant actions of thyroid hormone are mediated through binding to nuclear thyroid hormone receptors (TRs) and modulating transcription of specific genes. Thyroid hormones share a common mechanism of action with steroid and steroid-like hormones, such as vitamin D and the retinoids, whose receptors are members of a superfamily of nuclear receptors (Chapter 3). Although the predominant actions of thyroid hormone are nuclear, actions of thyroid hormone outside the nucleus have been reported.

Disorders of the thyroid are common. Thyroid nodules and goiter, thyroid enlargement, are the most common abnormalities and can be either benign or malignant processes. In most of these patients, circulating thyroid hormone levels are normal. Overt hyperthyroidism and hypothyroidism, thyroid hormone excess or deficiency, are usually associated with dramatic clinical manifestations. Milder disease often has

a more subtle clinical presentation and is identified based on abnormal biochemical tests of thyroid function. Screening of the newborn population for congenital hypothyroidism occurs in all developed countries, and when followed by the prompt institution of appropriate thyroid hormone replacement therapy, has dramatically decreased the incidence of mental retardation and cretinism. Maternal and neonatal hypothyroidism, due to iodine deficiency, remains the major preventable cause of mental retardation worldwide, although much progress has been made in eradicating iodine deficiency.

Effective treatment of most thyroid disorders is readily available. Treatment of the hypothyroid patient consists of thyroid hormone replacement. Treatment options for the hyperthyroid patient include anti-thyroid drugs to decrease hormone synthesis and secretion, destruction of the gland by the administration of radioactive iodine, or surgical removal. In most patients, disorders of thyroid function can be either cured or have their diseases controlled. Likewise, thyroid malignancies are most often localized and resectable. Metastatic disease often responds to radioiodide treatment but may become highly aggressive and unresponsive to conventional treatment. Newer therapies that target specific genetic mutations in malignancies have shown significant activity in both medullary and papillary thyroid cancers.

THYROID

The thyroid gland is the source of two fundamentally different types of hormones. The thyroid follicle produces the iodothyronine hormones *thyroxine* (T_4) and *3,5,3'-triiodothyronine* (T_3). These hormones are essential for normal growth and development and play an

1130 important role in energy metabolism. The thyroid also contains parafollicular cells (C-cells) that produce calcitonin (Chapter 44).

History. The thyroid is named for the Greek word for “shield shaped,” from the shape of the nearby tracheal cartilage. It was first recognized as an organ of importance when thyroid enlargement was observed to be associated with changes in the eyes and the heart in the condition we now call *hyperthyroidism*. Parry saw his first patient in 1786 but did not publish his findings until 1825. Graves reported the disorder in 1835 and Basedow in 1840. Hypothyroidism was described later, in 1874, when Gull associated atrophy of the gland with the symptoms characteristic of *hypothyroidism*. The term *myxedema* was applied to the clinical syndrome in 1878 by Ord in the belief that the characteristic thickening of the subcutaneous tissues was due to excessive formation of mucus. In 1891, Murray first treated a case of hypothyroidism by injecting an extract of sheep thyroid gland, later shown to be fully effective when given by mouth. The successful treatment of thyroid deficiency by administering thyroid extract was an important step toward modern endocrinology.

Extirpation experiments to elucidate the function of the thyroid were at first misinterpreted because of the simultaneous removal of the parathyroids. However, Gley’s research on the parathyroid glands in the late 19th century allowed the functional differentiation of these two endocrine glands. The structure of parathyroid hormone, however, was not reported until the early 1970s. Calcitonin was discovered in 1961, demonstrating that the thyroid gland produced a hormone in addition to thyroxine.

Chemistry of Thyroid Hormones. The principal hormones of the thyroid gland are the iodine-containing amino acid derivatives of thyronine (T_4 and T_3 ; Figure 39–1). Following the isolation and the chemical identification of thyroxine, it was generally thought that all the hormonal activity of thyroid tissue could be accounted for by its content of thyroxine. However, careful studies revealed that crude thyroid preparations possessed greater calorogenic activity than could be accounted for by their thyroxine content. The presence of a “second” thyroid hormone was debated, but triiodothyronine was finally detected, isolated, and synthesized by Gross and Pitt-Rivers (1952). Triiodothyronine has a much higher affinity for the nuclear thyroid hormone receptor compared with thyroxine and is much more potent biologically on a molar basis. The subsequent demonstration of T_3 production from T_4 in athyreotic humans led to the practice of effective replacement in hypothyroidism with levothyroxine only (Braverman et al., 1970).

Structure–Activity Relationships. The structural requirements for a significant degree of thyroid hormone activity have been defined (Baxter and Webb, 2009; Yoshihara et al., 2003). The 3′-monosubstituted compounds are more active than the 3′,5′-disubstituted molecules. Thus, triiodothyronine is five times more potent than thyroxine, and 3′-isopropyl-3,5-diiiodothyronine has seven times the activity. Substitutions at the 3,5,3′, and 5′ sites influence the conformation of the molecule. In thyronine, the two rings are angulated at $\sim 120^\circ$ at the ether oxygen and are free to rotate on their axes. As depicted schematically in Figure 39–2, the 3,5 iodines restrict rotation of the two rings, which tend to take up positions perpendicular to one

Figure 39–1. Thyronine, thyroid hormones, and precursors.

another. In general, the affinity of iodothyronines for the thyroid hormone receptors (TRs) parallels their biological potency (Yen, 2001), but additional factors can affect therapeutic potency, including affinity for plasma proteins, rate of metabolism, and rate of entry into cell nuclei. Specific thyroid hormone transporters, such as MCT8, are likely to be important in specific tissues.

The stereochemical nature of the thyroid hormones plays an important role in defining hormone activity. Many structural analogs of thyroxine have been synthesized to define the structure–activity relationship, to detect antagonists of thyroid hormones, and to find compounds exhibiting a desirable activity while not showing unwanted effects. Introduction of specific arylmethyl groups at the 3′ position of triiodothyronine results in analogs that are liver-selective, cardiac-sparing thyromimetics (Brenta et al., 2007). Solving the x-ray crystallographic structure of the ligand binding domains of the nuclear thyroid hormone receptors α and β has resulted in the rapid development of a range of TR isoform-selective compounds. The difference in the ligand binding domain pocket between TR α and TR β is only a single amino acid (Ser 277 in TR α

Figure 39–2. Structural formula of 3,5-diiodothyronine, drawn to show the conformation in which the planes of the aromatic rings are perpendicular to each other. (Adapted from Jorgensen, 1964.)

and Asn 331 in TR β). GC-1, a TR β -specific agonist, stabilizes the ligand binding domain by promoting hydrogen bonding between Asn331 and Arg282. GC-1 has a 10-fold greater affinity for TR β , the predominant TR isoform in the liver, than TR α , the predominant TR isoform in the heart, and lowers cholesterol without stimulating the heart. Cholesterol lowering with cardiac sparing by GC-1 and other TR β -selective agonists, however, is also the result of much higher distribution in the liver and less in the heart compared with T $_3$. Similar compounds, such as KB-141, lower cholesterol in clinical studies (Baxter and Webb, 2009). Interestingly, none of these newer thyroid hormone analogs contains iodine or any halogen.

Biosynthesis of Thyroid Hormones. The synthesis of the thyroid hormones is unique, complex, and seemingly inefficient. The thyroid hormones are synthesized and stored as amino acid residues of thyroglobulin, a protein constituting the vast majority of the thyroid follicular colloid (Rubio and Medeiros-Neto, 2009). The thyroid gland is unique in storing great quantities of potential hormone in this way, and extracellular thyroglobulin can represent a large portion of the thyroid mass. Thyroglobulin is a complex glycoprotein made up of two apparently identical subunits, each of 330,000 Da. Interestingly, molecular cloning has revealed that thyroglobulin belongs to a superfamily of serine hydrolases, including acetylcholinesterase (Chapter 10).

The major steps in the synthesis, storage, release, and interconversion of thyroid hormones are as follows:

1. uptake of iodide ion (I $^-$) by the gland
2. oxidation of iodide and the iodination of tyrosyl groups of thyroglobulin
3. coupling of iodotyrosine residues by ether linkage to generate the iodothyronines
4. resorption of the thyroglobulin colloid from the lumen into the cell
5. proteolysis of thyroglobulin and the release of thyroxine and triiodothyronine into the blood

6. recycling of the iodine within the thyroid cell via de-iodination of mono- and diiodotyrosines and reuse of the I $^-$
7. conversion of thyroxine (T $_4$) to triiodothyronine (T $_3$) in peripheral tissues as well as in the thyroid

These processes are summarized in Figure 39–3 and described in the correspondingly labeled sections that follow.

1. Uptake of Iodide. Iodine ingested in the diet reaches the circulation in the form of iodide ion (I $^-$). Under normal circumstances, the I $^-$ concentration in the blood is very low (0.2–0.4 $\mu\text{g/dL}$; ~ 15 –30 nM), but the thyroid efficiently and actively transports the ion via a specific membrane-bound protein, termed the *sodium-iodide symporter* (NIS) (Dohan et al., 2003). As a result, the ratio of thyroid to plasma iodide concentration is usually between 20 and 50 and can exceed 100 when the gland is stimulated. The iodide transport mechanism is inhibited by a number of ions such as thiocyanate and perchlorate (Figure 39–3). Thyrotropin (thyroid-stimulating hormone [TSH]) stimulates NIS gene expression and promotes insertion of NIS protein into the membrane in a functional configuration. Thus decreased stores of thyroid iodine enhance iodide uptake, and the administration of iodide can reverse this situation by decreasing NIS protein expression (Eng et al., 1999).

NIS has been identified in many other tissues, including the salivary glands, gastric mucosa, midportion of the small intestine, choroid plexus, skin, mammary gland, and perhaps the placenta, all of which maintain a concentration of iodide greater than that of the blood. Iodide accumulation by the placenta and mammary gland may provide adequate supplies for the fetus and infant. Iodine accumulation throughout the body is mediated by a single NIS gene. Individuals with congenital NIS gene mutations have absent or defective iodine concentration in all tissues known to concentrate iodine.

2. Oxidation and Iodination. Consistent with the conditions generally necessary for halogenation of aromatic rings, the iodination of tyrosine residues requires the iodinating species to be in a higher state of oxidation than is the anion. The iodinating species is hypoiodite, either as hypoiodous acid or as an enzyme-linked species (Magnusson et al., 1984).

The oxidation of iodide to its active form is accomplished by thyroid peroxidase, a heme-containing enzyme that uses hydrogen peroxide (H $_2$ O $_2$) as the oxidant (Dunn and Dunn, 2001). The peroxidase is membrane bound and appears to be concentrated at or near the apical surface of the thyroid cell. The reaction results in the formation of monoiodotyrosyl and diiodotyrosyl residues in

Figure 39–3. Major pathways of thyroid hormone biosynthesis and release. Abbreviations: Tg, thyroglobulin; DIT, diiodotyrosine; MIT, monoiodotyrosine; TPO, thyroid peroxidase; HOI, hypiodous acid; EOI, enzyme-linked species; D1 and D2, deiodinases (see Table 39–1); PTU, propylthiouracil; MMI, methimazole.

thyroglobulin just prior to its extracellular storage in the lumen of the thyroid follicle. The formation of the H_2O_2 that serves as a substrate for the peroxidase probably occurs near its site of utilization and is stimulated by a rise in cytosolic Ca^{2+} (Takasu et al., 1987). The TSH receptor is notably promiscuous in its coupling, stimulating members of four G protein families including G_q , which couples to the $\text{PLC-IP}_3\text{-Ca}^{2+}$ pathway (Laugwitz et al., 1996); thus, a Ca^{2+} -dependent effect on H_2O_2 production may be a means by which TSH stimulates the organification of iodide in thyroid cells (Figure 39–3).

3. Formation of Thyroxine and Triiodothyronine from Iodotyrosines. The remaining synthetic step is the coupling of two diiodotyrosyl residues to form thyroxine or of monoiodotyrosyl and diiodotyrosyl residues to form triiodothyronine. These oxidative reactions apparently are catalyzed by the same thyroid peroxidase. The mechanism involves the enzymatic transfer of groups, perhaps as iodotyrosyl free radicals or positively charged ions, within thyroglobulin.

Although many other proteins can serve as substrates for the peroxidase, none is as efficient as thyroglobulin in yielding thyroxine. Presumably, conformation of thyroglobulin facilitates this coupling reaction. Thyroxine formation primarily occurs near the amino terminus of the protein, whereas most of the triiodotyrosine is synthesized near the carboxy terminus (Dunn and Dunn, 2001). The relative rates of synthetic activity at the various sites depend on the concentration of TSH and the availability of iodide. Iodine

deficiency is associated with an increase in thyroidal T_3 relative to T_4 content (Zimmerman, 2009). Because triiodothyronine is the transcriptionally active iodothyronine and contains only three-fourths as much iodine, a decrease in the quantity of available iodine need have little impact on the effective amount of thyroid hormone elaborated by the gland. Although a decrease in the availability of iodide and the associated increase in the proportion of monoiodotyrosine favor the formation of triiodothyronine over thyroxine, a deficiency in diiodotyrosine ultimately can impair the formation of both compounds. Intrathyroidal and secreted T_3 are also generated by the 5'-deiodination of thyroxine.

4. Resorption; 5. Proteolysis of Colloid; and, 6. Secretion of Thyroid Hormones. Because T_4 and T_3 are synthesized and stored within thyroglobulin, proteolysis is an important part of the secretory process. This process is initiated by endocytosis of colloid from the follicular lumen at the apical surface of the cell, with the participation of a thyroglobulin receptor, megalin. This “ingested” thyroglobulin appears as intracellular colloid droplets, which apparently fuse with lysosomes containing the requisite proteolytic enzymes. It is generally believed that thyroglobulin must be completely broken down into its constituent amino acids for the hormones to be released. The molecular mass of thyroglobulin is 660,000 Da, and the protein is made up of ~300 carbohydrate residues and 5500 amino acid

residues, only two to five of which are thyroxine; thus this is an extravagant process.

TSH enhances the degradation of thyroglobulin by increasing the activity of several thiol endopeptidases of the lysosomes. Endopeptidases selectively cleave thyroglobulin, yielding hormone-containing intermediates that subsequently are processed by exopeptidases (Dunn and Dunn, 2001). The liberated hormones then exit the cell, presumably at its basal membrane. When thyroglobulin is hydrolyzed, monoiodotyrosine and diiodotyrosine also are liberated but usually do not leave the thyroid; rather, they are selectively metabolized and the iodine, liberated as I^- , is reincorporated into protein. The iodotyrosine deiodinase enzyme, DHAL1, is essential for conserving iodine and mutations of this gene identified in several kindreds are associated with goitrous hypothyroidism and cognitive deficit (Moreno et al., 2008). Normally, all this iodide is reused; however, when proteolysis is activated intensely by TSH, some of the iodide reaches the circulation, at times accompanied by trace amounts of the iodotyrosines.

7. Thyroid Hormone Metabolism and the Conversion of Thyroxine to Triiodothyronine in Peripheral Tissues. The normal daily production of thyroxine is estimated to range between 80 and 100 μg ; that of triiodothyronine is between 30 and 40 μg . Although triiodothyronine is secreted by the thyroid, metabolism of thyroxine by 5', or

outer ring, deiodination in the peripheral tissues accounts for ~80% of circulating triiodothyronine (Figure 39–4). In contrast, removal of the iodine on position 5 of the inner ring produces the metabolically inactive 3,3',5'-triiodothyronine (reverse T_3 , rT_3 ; Figure 39–1). Under normal conditions, ~40% of T_4 is converted to each of T_3 and rT_3 , and ~20% is metabolized *via* other pathways, such as glucuronidation in the liver and excretion in the bile. Normal circulating concentrations of T_4 in plasma range from 4.5–11 $\mu\text{g/dL}$; those of T_3 are ~1/100 of that (60–180 ng/dL).

Key properties of the three iodothyronine deiodinases are summarized in Table 39–1. The types 1 and 2 deiodinases (D1, D2) convert thyroxine to triiodothyronine (St. Germain et al., 2009). These enzymes contribute approximately equally to the plasma T_3 in rats, but it has not been possible to determine their relative contributions in humans. D1 is expressed primarily in the liver and kidney, and also in the thyroid and pituitary (Figure 39–5). It is upregulated in hyperthyroidism and downregulated in hypothyroidism. A clinically important feature of D1 is its inhibition by the anti-thyroid drug *propylthiouracil*. D1 is localized to the plasma membrane, and the T_3 it produces equilibrates rapidly with the plasma. D2 is expressed primarily in the CNS (including the pituitary and hypothalamus) and brown adipose tissue, also in the thyroid, and at very low levels in other organs such as skeletal muscle. The activity of D2 is unaffected

Figure 39–4. Pathways of iodothyronine deiodination.

Table 39–1

Properties of Iodothyronine Deiodinases

	TYPE 1 (D1)	TYPE 2 (D2)	TYPE 3 (D3)
Outer ring deiodinase	Yes	Yes	No
Inner ring deiodinase	Yes	No	Yes
Inhibited by PTU	Yes	No	No
Inhibited by amiodarone	Yes	Yes	Unknown
Regulation by thyroid hormone	T ₃ induces D1 gene expression	Substrate (T ₄) causes D2 protein degradation	T ₃ induces D3 gene expression
Location	Liver, kidney, thyroid, pituitary	Brain, pituitary, hypothalamus, thyroid, brown fat, skeletal muscle (very low levels)	Brain, placenta, some sites of inflammation
Selenocysteine in active site	Yes	Yes	Yes

by propylthiouracil. D2 localizes to the endoplasmic reticulum, which facilitates access of D2-generated T₃ to the nucleus. Hence organs that express D2 tend to use the locally generated T₃ to increase the occupancy of nuclear T₃ receptors, and D2-generated T₃ equilibrates slowly with the plasma. D2 is dynamically regulated by its substrate, thyroxine, such that elevated levels of the enzyme are found in hypothyroidism and suppressed levels are found in hyperthyroidism. Thus, D2 autoregulates the intracellular supply of triiodothyronine in organs in which it is expressed.

Inner ring- or 5-deiodination, the main inactivating pathway of T₃ metabolism, is catalyzed mainly by the type 3 deiodinase (D3), and to some extent also by D1. D3 is found at highest levels in the CNS and placenta, and it also is expressed in skin and uterus (St. Germain et al., 2009). It is highly expressed in hemangiomas.

D3 can be induced at sites of inflammation, and at least in an animal model this can result in local hypothyroidism (Peeters et al., 2003; Simonides et al., 2008).

D2 and D3 also play important roles in regulating local T3 levels during development, during which thyroid hormone tends to promote differentiation and decrease proliferation. Examples include chondrocyte development and bone differentiation, and auditory (cochlea) development. In the brain, D2 is expressed in glial cells and D3 in neurons. Because T₃ receptors are enriched in neurons, the current model is that glial cells convert T₄ to T₃, which is then exported and taken up by neurons where it activates T₃ receptors, with subsequent degradation by D3 and termination of the T₃ effect. There is a growing recognition of circumstances where D2 and D3 regulate local thyroid hormone levels independent of the plasma T₄ and T₃ concentrations.

The three deiodinases contain the rare amino acid selenocysteine in their active sites. Incorporation of selenocysteine into the growing peptide chain is a complex process involving multiple proteins. Mutations in one such protein, SECIS binding protein 2, are associated with abnormal circulating thyroid hormone levels (Dumitrescu et al., 2005).

Transport of Thyroid Hormones in the Blood. Iodine in the circulation is normally present in several forms, with 95% as organic iodine and ~5% as iodide. Most organic iodine is thyroxine (90–95%); triiodothyronine represents a relatively minor fraction (~5%). The thyroid hormones are transported in the blood in strong but noncovalent association with certain plasma proteins (Schussler, 2000).

Figure 39–5. Deiodinase isozymes.

D1, type I iodothyronine 5'-deiodinase; D2, type II iodothyronine 5'-deiodinase; D3, type III iodothyronine 5-deiodinase; BAT, brown adipose tissue.

Thyroxine-binding globulin (TBG) is the major carrier of thyroid hormones. It is an acidic glycoprotein with a molecular mass of ~63,000 Da that binds one molecule of T₄ per molecule of protein

with a very high affinity (the equilibration dissociation constant, K_d , is $\sim 10^{-10}$ M). T_3 is bound less avidly. Thyroxine, but not triiodothyronine, also is bound by transthyretin (thyroxine-binding prealbumin), a retinol-binding protein. This protein is present in higher concentration than is TBG and primarily binds thyroxine with an equilibrium dissociation constant $\sim 10^{-7}$ M. Transthyretin has four apparently identical subunits but only a single high-affinity binding site. Albumin also can bind thyroxine when the more avid carriers are saturated, but it is difficult to estimate its quantitative or physiological importance except in *familial dysalbuminemic hyperthyroxinemia*. This syndrome is an autosomal dominant disorder characterized by the increased affinity of albumin for thyroxine due to a point mutation in the albumin gene. There are a number of genetic defects of thyroid-binding globulin (Refetoff, 1989), but these individuals generally have normal circulating free thyroid hormones and serum TSH, and they are euthyroid.

Binding of thyroid hormones to plasma proteins protects the hormones from metabolism and excretion, resulting in their long half-lives in the circulation. The free (unbound) hormone is a small percentage ($\sim 0.03\%$ of thyroxine and $\sim 0.3\%$ of triiodothyronine) of the total hormone in plasma. The differential binding affinities for serum proteins also contribute to establishing the 10- to 100-fold differences in circulating hormone concentrations and half-lives of T_4 and T_3 .

Essential to understanding the regulation of thyroid function is the “free hormone” concept: Only the unbound hormone has metabolic activity. Thus, because of the high degree of binding of thyroid hormones to plasma proteins, changes in either the concentrations of these proteins or the binding affinity of the hormones for the proteins has major effects on the total serum hormone levels. Certain drugs and a variety of pathological and physiological conditions, such as the changes in circulating concentrations of estrogens during pregnancy or during the administration of oral estrogens, can alter both the binding of thyroid hormones to plasma proteins and the amounts of these proteins (Table 39–2). However, because the pituitary responds to and regulates circulating free hormone levels, minimal changes in free hormone concentrations are seen. Therefore, laboratory tests that measure only total hormone levels can be misleading. Appropriate tests of thyroid function are discussed later in this chapter.

Degradation and Excretion (Figure 39–6). Thyroxine is eliminated slowly from the body, with a $t_{1/2}$ of 6–8 days. In hyperthyroidism, the $t_{1/2}$ is shortened to 3–4 days, whereas in hypothyroidism it may be 9–10 days. These changes presumably reflect altered rates of metabolism of the hormone. In conditions associated with increased binding to TBG, such as pregnancy, clearance is retarded. The increase in TBG is due to the estrogen-induced

Table 39–2

Factors that Alter Binding of Thyroxine to Thyroxine-Binding Globulin

INCREASE BINDING	DECREASE BINDING
Drugs	
Estrogens	Glucocorticoids
Methadone	Androgens
Clofibrate	L-Asparaginase
5-Fluorouracil	Salicylates
Heroin	Mefenamic acid
Tamoxifen	Antiseizure medications (phenytoin, carbamazepine)
Selective estrogen receptor modulators	Furosemide
Systemic Factors	
Liver disease	Inheritance
Porphyria	Acute and chronic illness
HIV infection	
Inheritance	

increase in the sialic acid content of the synthesized TBG, resulting in decreased TBG clearance. The opposite effect is observed when there is reduced protein binding of thyroid hormones or when binding to protein is inhibited by certain drugs (Table 39–2). T_3 , which is less avidly bound to protein, has a $t_{1/2}$ of ~ 1 day.

DIT, diiodotyrosine; MIT, monoiodotyrosine; T_4S , T_4 sulfate; T_4G , T_4 glucuronide; T_3S , T_3 sulfate; T_3G , T_3 glucuronide; T_4K , T_4 pyruvic acid; T_3K , T_3 pyruvic acid; Tetrac, tetraiodothyroacetic acid; Triac, triiodothyroacetic acid.

Table 39–3

Factors Influencing Oral Levothyroxine Therapy**Drugs and other factors that may increase levothyroxine dosage requirements***Impaired levothyroxine absorption*

- Aluminum-containing antacids
- Bile acid sequestrants (cholestyramine, colestipol, colesevelam)
- Calcium carbonate (effect generally small)
- Chromium picolinate
- Food
- Iron salts
- Lactose intolerance (single case report)
- Phosphate binders (lanthanum carbonate, sevelamer)
- Proton pump inhibitors
- Raloxifene
- Soy products (effect generally very small)
- Sucralfate

Increased thyroxine metabolism, CYP3A4 induction of hepatic

- Bexarotene
- Carbamazepine
- Phenytoin
- Rifampin
- Sertraline

Impaired $T_4 \rightarrow T_3$ conversion

- Amiodarone

Mechanisms uncertain or multifactorial

- Estrogen pregnancy
- Ethionamide
- Tyrosine kinase inhibitors (imatinib, sunitinib)
- Lovastatin, simvastatin

Drugs and other factors that may decrease levothyroxine dosage requirements

- Advancing age (>65 years)
- Androgen therapy in women

Drugs that may decrease TSH without changing free T_4 in levothyroxine-treated patients

- Metformin

The liver is the major site of non-deiodinative degradation of thyroid hormones; T_4 and T_3 are conjugated with glucuronic and sulfuric acids through the phenolic hydroxyl group and excreted in the bile. Some thyroid hormone is liberated by hydrolysis of the conjugates in the intestine and reabsorbed. A portion of the conjugated material reaches the colon unchanged, where it is hydrolyzed and eliminated in feces as the free compounds.

As discussed earlier, the major route of metabolism of T_4 is deiodination to either T_3 or reverse T_3 . Triiodothyronine and reverse

T_3 are deiodinated to three different diiodothyronines, which are further deiodinated to two monoiodothyronines (Figure 39–4), inactive metabolites that are normal constituents of human plasma. Additional metabolites (monoiodotyrosine and diiodotyrosine) in which the diphenyl ether linkage is cleaved have been detected both *in vitro* and *in vivo*.

Regulation of Thyroid Function. Thyrotropin or TSH is a glycoprotein hormone with α and β subunits analogous to those of the gonadotropins. Its structure is discussed with those of the other glycoprotein hormones in Chapter 38. TSH is secreted in a pulsatile manner and circadian pattern; its levels in the circulation are highest during sleep at night. TSH secretion is precisely controlled by the hypothalamic peptide *thyrotropin-releasing hormone* (TRH) and by the concentration of free thyroid hormones in the circulation. Extra thyroid hormone inhibits transcription of both the TRH gene and the genes encoding the α and β subunit of thyrotropin, which suppresses the secretion of TSH and causes the thyroid to become inactive and regress (Chiamolera and Wondisford, 2009). Any decrease in the normal rate of thyroid hormone secretion by the thyroid evokes an enhanced secretion of TSH in the absence of exogenous hormone in an attempt to stimulate the thyroid to secrete more hormone. Additional mechanisms mediating the effect of thyroid hormone on TSH secretion appear to be a reduction in TRH secretion by the hypothalamus and a reduction in the number of TRH receptors on pituitary cells. Figure 39–7 summarizes the regulation of thyroid hormone secretion.

Thyrotropin-Releasing Hormone. TRH stimulates the release of preformed TSH from secretory granules and also stimulates the subsequent synthesis of both α and β subunits of TSH. Somatostatin, dopamine, and pharmacological doses of glucocorticoids inhibit TRH-stimulated TSH secretion.

TRH is a tripeptide with both terminal amino and carboxyl groups blocked (L-pyroglutamyl-L-histidyl-L-proline amide). The mature hormone is derived from a precursor protein that contains six copies of the tripeptide flanked by dibasic residues. TRH is synthesized by the hypothalamus and released into the hypophyseal-portal circulation, where it interacts with TRH receptors on thyrotropes. The binding of TRH to its receptor, a GPCR, stimulates the G_q -PLC-IP₃-Ca²⁺ pathway and activates PKC, ultimately stimulating the synthesis and release of TSH by the thyrotropes (Monga et al., 2008).

TRH also has been localized in the CNS in the cerebral cortex, circumventricular structures, neurohypophysis, pineal gland, and

Figure 39–7. Regulation of thyroid hormone secretion. Myriad neural inputs influence hypothalamic secretion of thyrotropin-releasing hormone (TRH). TRH stimulates release of thyrotropin (TSH, thyroid-stimulating hormone) from the anterior pituitary; TSH stimulates the synthesis and release of the thyroid hormones T₃ and T₄. T₃ and T₄ feed back to inhibit the synthesis and release of TRH and TSH. Somatostatin (SST) can inhibit TRH action, as can dopamine and high concentrations of glucocorticoids. Low levels of I⁻ are required for thyroxine synthesis, but high levels inhibit thyroxine synthesis and release.

spinal cord. These findings, as well as its localization in nerve endings, suggest that TRH may act as a neurotransmitter or neuromodulator outside of the hypothalamus. Administration of TRH to animals produces CNS-mediated effects on behavior, thermoregulation, autonomic tone, and cardiovascular function, including increases in blood pressure and heart rate. TRH also has been identified in pancreatic islets, heart, testis, and parts of the gastrointestinal tract. Its physiological role in these sites is not known. Two TRH receptors have now been identified, TRH-R1 and TRH-R2, as well as selective analogs for these receptors (Monga et al., 2008). TRH analogs with CNS activity, but without other hormonal actions, are being developed for therapeutic applications. TRH is no longer available in the U.S.

Actions of Thyroid-Stimulating Hormone on the Thyroid. When TSH is given to experimental animals, the first measurable effect on thyroid hormone metabolism is increased secretion, which is detectable within minutes. All phases of hormone synthesis and release are

eventually stimulated: iodide uptake and organification, hormone synthesis, endocytosis, and proteolysis of colloid. There is increased vascularity of the gland and hypertrophy and hyperplasia of thyroid cells.

These effects follow the binding of TSH to its receptor on the plasma membrane of thyroid cells. The TSH receptor is a GPCR that is structurally similar to the receptors for luteinizing hormone and follicle-stimulating hormone (Chapter 38) (Kleinau and Krause, 2009). These receptors share significant amino acid homology and have large extracellular domains that are involved in hormone binding. Binding of TSH to its receptor stimulates the G_s-adenylyl cyclase–cyclic AMP pathway. Higher concentrations of TSH activate the G_q-PLC pathway. Both the adenylyl cyclase and the phospholipase C signaling pathways appear to mediate effects of TSH on thyroid function in humans (Kogai et al., 2006).

Multiple mutations of the TSH receptor result in clinical thyroid dysfunction (Latif et al., 2009). Germline mutations can present as congenital, nonautoimmune hypothyroidism or as autosomal dominant toxic thyroid hyperplasia. Germline mutations of the TSH receptor can cause gestational hyperthyroidism due to a hypersensitivity of the receptor to HCG (Rodien et al., 1998). Somatic mutations that result in constitutive activation of the receptor are associated with hyperfunctioning thyroid adenomas (Krohn and Paschke, 2001). Finally, resistance to TSH has been described, both in families with mutant TSH receptors (Sunthornthepvarakul et al., 1995) and in those with no apparent mutations in either the TSH receptor or in TSH itself (Xie et al., 1997).

Relation of Iodine to Thyroid Function. Normal thyroid function obviously requires an adequate intake of iodine; without it, normal amounts of hormone cannot be made, TSH is secreted in excess, and the thyroid becomes hyperplastic and hypertrophic. The enlarged and stimulated thyroid becomes remarkably efficient at extracting the residual traces of iodide from the blood, developing an iodine gradient that may be 10 times normal; in mild-to-moderate iodine deficiency, the thyroid usually succeeds in producing sufficient hormone and preferentially secreting T₃. In more severe iodine deficiency, adult hypothyroidism and cretinism may occur.

In some areas of the world, simple or nontoxic goiter is prevalent because of insufficient dietary iodine (Zimmerman, 2009). Regions of iodine deficiency exist in Central and South America, Africa, Europe, Southeast Asia, and China. In the U.S., recommended daily allowances for iodine range from 90–120 μg for children, 150 μg for adults, 220 μg for pregnancy, and 290 μg for lactation (Becker et al., 2006). Vegetables, meat, and poultry contain minimal amounts of iodine,

1138 whereas dairy products and fish are relatively high in iodine.

Iodine has been used empirically for the treatment of iodine-deficiency goiter for 150 years; however, its modern use evolved from extensive studies using iodine to prevent goiter in school children in Akron, Ohio, where endemic iodine-deficiency goiter was prevalent. The success of these experiments led to the adoption of iodine prophylaxis and therapy in many regions throughout the world where iodine-deficiency goiter was endemic.

The most practical method for providing small supplements of iodine for large segments of the population is the addition of iodide or iodate to table salt; iodate is now preferred. The use of iodized salt is required by law in some countries, but in others such as the U.S., the use is optional. In the U.S., iodized salt provides 100 μg of iodine per gram. Although the U.S. population remains iodine sufficient, iodine intake has steadily decreased over the last 20 years (Hollowell et al., 1998). The most recent data indicate that iodine intake has stabilized, although pregnant women remain a susceptible population for iodine insufficiency (Haddow et al., 2007; Hollowell and Haddow, 2007). Other vehicles for supplying iodine to large populations who are iodine deficient include oral or intramuscular injection of iodized oil (Elnagar et al., 1995), iodized drinking water supplies, iodized irrigation systems, and iodized animal feed.

Thyroid Hormone Transport Into and Out of Cells. Thyroid hormone crosses the cell membrane primarily via specific transporter proteins (Visser et al., 2008). Multiple such transporters likely exist, each expressed in overlapping but different subsets of tissues. To date, the only transporter of proven importance in humans is monocarboxylic acid transporter 8 (MCT8, SLC16A2). Ectopic expression in cultured cells demonstrates that MCT8 transports T_4 and T_3 bidirectionally across the cell membrane. MCT8 is widely expressed, including in liver, heart, and brain. MCT8 mutations cause Allan-Herndon-Dudley syndrome, characterized by a severe neurological phenotype and abnormal circulating thyroid hormone levels. The serum T_3 typically is about 2-fold elevated, associated with a slight increase in TSH and slight decrease in T_4 .

MCT10 also transports T_4 and T_3 and is widely expressed, but there are no mutation studies to demonstrate its importance for thyroid hormone transport *in vivo*. The organic anion transporter OATP1C1 preferentially transports T_4 rather than T_3 , is highly expressed in brain capillaries, and has been hypothesized to be responsible for the transport of T_4 across the blood-brain barrier (Chapter 5).

Actions of Thyroid Hormones

Classical Nuclear-Mediated Effects. Thyroid hormone action is mediated largely by the binding of T_3 to thyroid hormone receptors (TRs), which are members of the nuclear receptor superfamily of transcription factors (Bassett et al., 2003; Yen et al., 2006). This superfamily includes the receptors for steroid hormones, vitamin D, retinoic acid, and a variety of small molecule metabolites such as certain fatty acids and bile acids. The nuclear receptor superfamily also includes a number of “orphan receptors” that have no known ligands and may be regulated by posttranslational modifications or other events. The TRs have the classic nuclear receptor structure consisting of an amino terminal domain, a centrally located zinc finger DNA binding domain, and a ligand binding domain that occupies the carboxyl terminal half of the protein (Figure 39–8).

T_3 binds to TRs with ~ 10 -fold greater affinity than does T_4 , and T_4 is not thought to be biologically active in normal physiology. TRs bind to specific DNA sequences (thyroid hormone response elements, TREs) in the promoter/regulatory regions of target genes. The transcription of most target genes is repressed by unliganded TRs and induced following the binding of T_3 . The mechanisms of these effects have been well studied (Yen, 2001; Yen et al., 2006). In the unliganded state, the TR ligand binding domain interacts with a co-repressor complex that includes

Figure 39–8. Thyroid hormone receptor isoforms. The percent amino acid identities of the amino terminal, DNA binding, and ligand binding domains relative to TR β 1 are shown. TR α 2 does not bind T_3 or any other known ligand.

histone deacetylases and other proteins. The binding of T_3 causes replacement of the co-repressor complex by a co-activator complex that includes histone acetyltransferases, methyltransferases, and other proteins. The actual situation is very complex and probably involves cyclical recruitment of multiple protein complexes to the target gene, leading to cyclical transcription despite the constant presence of T_3 (Liu et al., 2006). Other thyroid hormone target genes, such as those encoding TRH and the TSH subunits, are negatively regulated by T_3 . The mechanism is not well defined, but these genes tend to be induced by the unliganded TR in addition to being repressed by T_3 .

The TRs are the cellular homologs of the avian retroviral oncoprotein *c-erbA*. There are two genes that encode TRs, *THRA* and *THRB*. *THRA* encodes the receptor TR α 1. The biological function of TR α 1 is inferred largely through studies of genetically modified mice and cell culture experiments because human mutations in *THRA* have not been described. Although TR α 1 is expressed in most cell types, studies in knockout mice demonstrate that the major specific roles for this isoform are in the regulation of heart rate, body temperature, skeletal muscle function, and the development of bone and small intestine (O'Shea and Williams, 2002). Alternative splicing of the TR α primary transcript results in the production of TR α 2, which does not bind T_3 because it lacks part of the ligand-binding domain (LBD). TR α 2 is expressed ubiquitously and its function is unknown, although there is some evidence that it may inhibit T_3 action. A cryptic promoter within intron 7 of *THRA* drives the production of small proteins that contain only a portion of the TR α LBD. These non-hormone-binding proteins appear to play a role, along with TR α 1, in GI development.

The *THRB* gene has two promoters that lead to the production of TR β 1 and TR β 2. These receptors have unique amino terminal domains but otherwise are identical. TR β 1 is ubiquitous, whereas TR β 2 has a highly restricted pattern of expression. Mutations in *THRB* cause the syndrome of resistance to thyroid hormone (Refetoff and Dumitrescu, 2007). Studies in these patients, as well as in genetically modified mice and in cell culture, demonstrate a specific role for TR β 1 in liver metabolism (including the hypocholesterolemic effect of T_3), and for TR β 2 in the negative feedback by T_3 on hypothalamic TRH and pituitary TSH (O'Shea and Williams, 2002). TR β 2 also is important in the development of cones in the retina and in inner ear development.

Non-genomic Effects of Thyroid Hormone. Although nuclear receptors were classically described as being DNA-binding transcription factors, it is now clear that these proteins also can be found outside the nucleus where they can exert biological effects via rapid nongenomic mechanisms (Davis et al., 2008). TRs associate in a T_3 -dependent manner with the p85 α subunit of phosphatidylinositol 3-kinase (PI3K), which results in the phosphorylation and activation of

PKB/Akt (Hiroi et al., 2006). The PI3K/Akt pathway has broad effects on cellular metabolism. For example, it stimulates NO production by endothelial cells, which leads to vasodilation. Hence, T_3 administration causes rapid vasodilation.

There also is evidence for non-genomic actions of thyroid hormone via a plasma membrane receptor within integrin α V β 3 (Davis et al., 2008). This putative receptor binds extracellular T_4 in preference to T_3 , resulting in activation of MAP kinase. However, the importance of non-genomic actions in thyroid hormone physiology and pathophysiology remains uncertain.

Effects of Thyroid Hormone Metabolites. 3-Iodothyronamine and thyronamine, naturally occurring metabolites of T_4 , are ligands for the GPCR trace amine-associated receptor 1 (TAAR1) (Scanlan et al., 2004). Administration of 3-iodothyronamine or thyronamine to mice causes hypothermia and bradycardia, presumably through activation of TAAR1 and G $_s$. 3-Iodothyronamine activation of TAAR1 also induces insulin secretion in the MIN6 cell line (Regard et al., 2007). Interestingly, 3-iodothyronamine also binds to the α_{2A} adrenergic receptor, leading to decreased insulin secretion from mouse islets via a G $_i$ protein-coupled mechanism (Regard et al., 2007). The importance of these effects in human physiology and disease remains to be determined.

MAJOR CLINICAL EFFECTS OF THYROID HORMONES

Growth and Development. Perhaps the most dramatic example of thyroid hormone action is amphibian metamorphosis, in which the tadpole is almost magically transformed into a frog by triiodothyronine. Not only does the animal grow limbs, lungs, and other terrestrial accoutrements, but T_3 also causes the tail to regress.

Thyroid hormone plays a critical role in brain development (Anderson et al., 2003, Bernal, 2007). The absence of thyroid hormone during the period of active neurogenesis (up to 6 months postpartum) leads to irreversible mental retardation (cretinism) and is accompanied by multiple morphological alterations in the brain. These severe morphological alterations result from disturbed neuronal migration, deranged axonal projections, and decreased synaptogenesis. Thyroid hormone supplementation during the first 2 weeks of postnatal life prevents the development of these disturbed morphological changes.

The mechanisms by which thyroid hormone promotes brain development are incompletely understood. Surprisingly, mice with genetic deletions of TR α , TR β , or both have essentially normal brain development (Gothe et al., 1999). Equally surprisingly, genetic deletion of TR α 1 protects mice from the toxic effects of hypothyroidism on brain development (Morte et al., 2002). Perhaps

it is the effects of unliganded TRs that result in impaired brain development, such that either T_3 or the absence of TRs is protective. T_3 induces the expression of a number of genes that could plausibly be important in normal brain development, but the exact roles of these specific gene inductions are not known (Anderson et al., 2003). The T_3 -dependent expression of many proteins appears to be merely delayed in the hypothyroid animal; normal levels are eventually achieved. Myelin basic protein, a major component of myelin, is induced by T_3 during development. Decreased expression of myelin basic protein in the hypothyroid brain impairs myelination. RC3/neurogranin, a protein involved in synaptic plasticity, also is induced by T_3 . Through its induction of the transcription factor BTEB (basic transcription element binding protein), T_3 expands a network of secondary genes in brain development.

The actions of thyroid hormones on protein synthesis and enzymatic activity are not limited to the brain, and in fact most tissues are affected by the administration of thyroid hormone or by its deficiency. The extensive defects in growth and development in cretins vividly illustrate the pervasive effects of thyroid hormones in normal individuals.

Cretinism is usually classified as endemic or sporadic. *Endemic cretinism* occurs in regions of endemic goiter and usually is caused by extreme iodine deficiency. Goiter may or may not be present. *Sporadic cretinism* is a consequence of failure of the thyroid to develop normally or the result of a defect in the synthesis of thyroid hormone. Goiter is present if a synthetic defect is at fault. While detectable at birth, cretinism often is not recognized until 3-5 months of age. When untreated, the condition eventually leads to such gross changes as to be unmistakable: The child is dwarfed, with short extremities, mentally retarded, inactive, uncomplaining, and listless. The face is puffy and expressionless, and the enlarged tongue may protrude through the thickened lips of the half-opened mouth. The skin may have a yellowish hue and feel doughy, dry, and cool to the touch. The heart rate is slow, the body temperature may be low, closure of the fontanels is delayed, and the teeth erupt late. Appetite is poor, feeding is slow and interrupted by choking, constipation is frequent, and there may be an umbilical hernia.

For treatment to be fully effective, the diagnosis must be made long before these changes are obvious. In regions of endemic cretinism due to iodine deficiency, iodine replacement is best instituted before pregnancy. However, iodine replacement given to pregnant women up to the end of the second trimester has been shown to enhance the neurological and psychological development of the children (Cao et al., 1994). Screening of newborn infants for deficient thyroid function is carried out in the U.S. and in most industrialized countries. Concentrations of TSH and thyroxine are measured in blood from the umbilical cord or from a heel stick. The incidence of congenital dysfunction of the thyroid is ~1 per 4000 births.

Thermogenic Effects. Thyroid hormone is necessary for both obligatory thermogenesis (the heat resulting from vital processes) as well as for facultative or adaptive thermogenesis (Silva, 2006). Only a few organs, including the brain, gonads, and spleen, are unresponsive to

the thermogenic effects of T_3 . Obligatory thermogenesis is the result of T_3 making most biological processes thermodynamically less efficient for the sake of producing heat. Multiple mechanisms underlie the stimulation of obligatory thermogenesis, but the pathways involved and their quantitative contributions have yet to be fully defined. The ability of T_3 to induce the skeletal muscle Ca^{++} -dependent ATPase (SERCA1) contributes to thermogenesis by stimulating the cycling of calcium between cytosol and sarcoplasmic reticulum. Metabolic “futile cycling” (e.g., lipogenesis-lipolysis) has been considered a mechanism to produce heat, but best estimates indicate the contribution is minor. Other than in brown adipose tissue, there is no evidence that a major thermogenic mechanism is uncoupling of phosphorylation, although some groups still believe that T_3 can increase the proton leak through the inner mitochondrial membrane. Regardless of the mechanism, thermogenesis is highly sensitive to thyroid hormone around the physiological range because small changes in L-thyroxine replacement doses may significantly alter resting energy expenditure in the hypothyroid patient. The discovery of type 2 deiodinase in brown fat and its activation by the sympathetic nervous system showed that thyroid hormone also is important for facultative thermogenesis. The ability of T_3 to stimulate thermogenesis has evolved along with ancillary effects to support this thermogenic action, such as the stimulation of appetite and lipogenesis.

Cardiovascular Effects. Changes in the cardiovascular system are prominent in both hyper- and hypothyroidism (Kahaly and Dillmann, 2005). Hyperthyroid patients have tachycardia, increased stroke volume, increased cardiac index, cardiac hypertrophy, decreased peripheral vascular resistance, and increased pulse pressure. Hyperthyroidism is a relatively common cause of atrial fibrillation. Hypothyroid patients have bradycardia, decreased cardiac index, pericardial effusion, increased peripheral vascular resistance, decreased pulse pressure, and elevation of mean arterial pressure.

Triiodothyronine directly regulates myocardial gene expression primarily through $TR\alpha_1$, which is expressed at a higher level in cardiomyocytes than $TR\beta$. T_3 shortens diastolic relaxation (lusitropic effect) by inducing expression of the sarcoplasmic reticulum ATPase SERCA2 and decreasing phospholamban, a SERCA2 inhibitor. T_3 increases the force of myocardial contraction (inotropic effect) in part by inducing expression of the ryanodine channel, the calcium channel of the sarcoplasmic reticulum. T_3 induces the gene encoding the myosin heavy chain (MHC) α isoform and decreases expression of the MHC β gene. Because MHC α endows the myosin holoenzyme with greater ATPase activity, this is one mechanism by

which T_3 enhances the velocity of contraction. The chronotropic effect of T_3 is mediated by increases in the pacemaker ion current I_f in the sinoatrial node. Several proteins that comprise the I_f channel are induced by T_3 , including HCN2 and HCN4. Interestingly, T_3 also appears to have a direct non-genomic vasodilating effect on vascular smooth muscle (Hiroi et al., 2006), which may contribute to the decreased systemic vascular resistance and increased cardiac output of hyperthyroidism.

Metabolic Effects. Thyroid hormone stimulates the expression of hepatic low-density lipoprotein (LDL) receptors and the metabolism of cholesterol to bile acids, such that hypercholesterolemia is a characteristic feature of hypothyroidism.

Thyroid hormone has complex effects on carbohydrate metabolism (Crunkhorn and Patti, 2008). Thyrotoxicosis is an insulin-resistant state. Post-receptor defects in the liver and peripheral tissues are manifested by depleted glycogen stores and enhanced gluconeogenesis. In addition, the rate of glucose absorption from the gut is increased. Compensatory increases in insulin secretion result in hyperinsulinemia. There may be impaired glucose tolerance or even clinical diabetes, but most hyperthyroid patients are euglycemic. However, diabetic patients already on insulin may have increased insulin requirements in the setting of hyperthyroidism. Conversely, hypothyroidism results in decreased absorption of glucose from the gut, decreased insulin secretion, and a reduced rate of peripheral glucose uptake. Glucose metabolism generally is not affected in a clinically significant manner in nondiabetic patients, although insulin requirements decrease in the hypothyroid patient with diabetes.

Thyroid Hypofunction. Hypothyroidism, known as myxedema when severe, is the most common disorder of thyroid function. Worldwide, hypothyroidism resulting from iodine deficiency remains an all-too-common problem. In non-endemic areas where iodine is sufficient, chronic autoimmune thyroiditis (Hashimoto's thyroiditis) accounts for most cases. This disorder is characterized by high levels of circulating antibodies directed against thyroid peroxidase and, less commonly, against thyroglobulin. In addition, blocking antibodies directed at the TSH receptor may be present, exacerbating the hypothyroidism. The conditions just described are examples of *primary hypothyroidism*, failure of the thyroid gland itself. *Central hypothyroidism* occurs much less often and results from diminished stimulation of the thyroid by TSH because of pituitary failure (*secondary hypothyroidism*) or hypothalamic failure (*tertiary hypothyroidism*). Hypothyroidism present at birth (*congenital hypothyroidism*) is the most common preventable cause of mental

retardation in the world. Diagnosis and early intervention with thyroid hormone replacement prevent the development of cretinism, as discussed earlier.

Common symptoms of hypothyroidism include fatigue, lethargy, cold intolerance, mental slowness, depression, dry skin, constipation, mild weight gain, fluid retention, muscle aches and stiffness, irregular menses, and infertility. Common signs include goiter (primary hypothyroidism only), bradycardia, delayed relaxation phase of the deep tendon reflexes, cool and dry skin, hypertension, nonpitting edema, and facial puffiness. Deficiency of thyroid hormone during the first few months of life causes feeding problems, failure to thrive, constipation, and sleepiness. Retardation of mental development is irreversible if not treated promptly. Childhood hypothyroidism impairs linear growth and bone maturation. Because the signs and symptoms of hypothyroidism are nonspecific, diagnosis requires the finding of an elevated serum TSH or, in cases of central hypothyroidism, a decreased serum free T_4 . Because physicians maintain a high index of suspicion, the diagnosis usually is made at a relatively early stage. Thus, severe hypothyroidism and myxedema coma are uncommon, except in hypothyroid patients who are non-compliant with their thyroid hormone replacement therapy or individuals without access to medical care.

Thyroid Hyperfunction. Thyrotoxicosis is a condition caused by elevated concentrations of circulating free thyroid hormones. Increased thyroid hormone production is the most common cause, with the common link of TSH receptor stimulation and increased iodine uptake by the thyroid gland as shown by the measurement of the percentage uptake of ^{123}I or ^{131}I in a 24-hour radioactive iodine uptake (RAIU) test. TSH receptor stimulation is either the result of TSH receptor stimulating antibody in Graves' disease or somatic activating TSH receptor mutations in autonomously functioning nodules or a toxic goiter. In contrast, thyroid inflammation or destruction resulting in excess "leak" of thyroid hormones or excess exogenous thyroid hormone intake results in a low 24-hour RAIU. The term *subclinical hyperthyroidism* is defined as those with a subnormal serum TSH and normal concentrations of T_4 and T_3 . Atrial arrhythmias, excess cardiac mortality, and excessive bone loss have been associated with this profile of thyroid function tests (Biondi and Cooper, 2008).

Graves' disease is the most common cause of high RAIU thyrotoxicosis (Brent, 2008). It accounts for 60-90% of cases, depending on age and geographic region. Graves' disease is an autoimmune disorder characterized by increased thyroid hormone production, diffuse goiter, and immunoglobulin (Ig)G antibodies that bind to and activate the TSH receptor. This is a relatively common disorder, with an incidence of 0.02-0.4% in the U.S. Endemic areas of iodine deficiency have a lower incidence of autoimmune thyroid disease. As with most

1142 types of thyroid dysfunction, women are affected more than men, with a ratio ranging from 5:1-7:1. Graves' disease is more common between the ages of 20 and 50, but it may occur at any age. Major histocompatibility alleles (HLA) B₈ and DR₃ are associated with Graves' disease in whites. Graves' disease is commonly associated with other autoimmune diseases.

The characteristic exophthalmos associated with Graves' disease is an infiltrative ophthalmopathy and is considered an autoimmune-mediated inflammation of the periorbital connective tissue and extraocular muscles. This disorder is clinically evident with various degrees of severity in ~50% of patients with Graves' disease, but it is present on radiological studies, such as ultrasound or CT scan, in almost all patients. The pathogenesis of Graves' ophthalmopathy, including the role of the TSH receptor present in retro-orbital tissues, and the management of this disorder, remain controversial (Khoo and Bahn, 2007).

Toxic uninodular/multinodular goiter accounts for 10-40% of cases of hyperthyroidism and is more common in older patients. Infiltrative ophthalmopathy is absent.

A low RAIU is seen in the destructive thyroiditides and in thyrotoxicosis resulting from exogenous thyroid hormone ingestion. Low RAIU thyrotoxicosis caused by subacute (painful) and silent (painless or lymphocytic) thyroiditis represents ~5-20% of all cases. Silent thyroiditis occurs in 7-10% of postpartum women in the U.S. (Abalovich et al., 2007). Other causes of thyrotoxicosis are much less common.

Most of the signs and symptoms of thyrotoxicosis stem from the excessive production of heat, increased motor activity, and increased sensitivity to catecholamines produced by the sympathetic nervous system. The skin is flushed, warm, and moist; the muscles are weak and tremulous; the heart rate is rapid, the heartbeat is forceful, and the arterial pulses are prominent and bounding. Increased expenditure of energy gives rise to increased appetite and, if intake is insufficient, to loss of weight. There also may be insomnia, difficulty in remaining still, anxiety and apprehension, intolerance to heat, and increased frequency of bowel movements. Angina, arrhythmias, and heart failure may be present in older patients. Older patients may experience less manifestations of sympathetic nervous system stimulation, so called apathetic hyperthyroidism. Some individuals may show extensive muscular wasting as a result of thyroid myopathy. Patients with long-standing undiagnosed or undertreated thyrotoxicosis may develop osteoporosis due to increased bone turnover (Murphy and Williams, 2004).

The most severe form of hyperthyroidism is thyroid storm, which is discussed later in the discussion of therapeutic uses of anti-thyroid drugs.

Thyroid Function Tests. The development of radioimmunoassays and, more recently, chemiluminescent and enzyme-linked immunoassays for T₄, T₃, and TSH have greatly improved the laboratory diagnosis of thyroid disorders (Demers and Spencer, 2003). However, measurement of the total hormone concentration in plasma may not give an accurate picture of the activity of the thyroid gland. The total hormone concentration changes with alterations

in either the amount of TBG in plasma or the binding affinity of TBG for hormones. Although equilibrium dialysis of undiluted serum and radioimmunoassay for free thyroxine (FT₄) in the dialysate represent the gold standard for determining FT₄ concentrations, this assay is typically not available in routine clinical laboratories. The FT₄ index is an estimation of the FT₄ concentration and is calculated by multiplying the total thyroxine concentration by the thyroid hormone binding ratio, which estimates the degree of saturation of TBG. The most common assays used for estimating the free T₄ and free T₃ concentrations employ labeled analogs of these iodothyronines in chemiluminescence and enzyme-linked immunoassays. These assays correlate well with free T₄ concentrations measured by the more cumbersome equilibrium dialysis method and are easily adaptable to routine clinical laboratory use. However, the analog assays are affected by extremes of serum binding proteins as well as a wide variety of non-thyroidal disease states, including acute illness, and by certain drugs to a greater degree than are the free T₄ index and free T₄ determined by equilibrium dialysis.

In individuals with normal pituitary function, serum measurement of TSH is the thyroid function test of choice because pituitary secretion of TSH is sensitively regulated in response to circulating concentrations of thyroid hormones.

A major use of the TSH assay is to differentiate between normal and thyrotoxic patients, who should exhibit suppressed TSH values. Indeed, the sensitive TSH assay has replaced evaluation of the response of TSH to injection of synthetic TRH (TRH stimulation test) in the thyrotoxic patient. Although the serum TSH assay is extremely useful in determining the euthyroid state and titrating the replacement dose of thyroid hormone in patients with primary hypothyroidism, abnormal serum TSH concentrations may not always indicate thyroid dysfunction. In such patients, assessment of the circulating thyroid hormone levels will further determine whether or not thyroid dysfunction is truly present. Synthetic preparations of TRH (protirelin) are no longer available in the U.S. for the evaluation of pituitary or hypothalamic failure as a cause of secondary hypothyroidism.

Recombinant human TSH (*thyrotropin alfa*, THYROGEN) is available as an injectable preparation to test the ability of thyroid tissue, both normal and malignant, to take up radioactive iodine and release thyroglobulin (Duntas and Cooper, 2008; Haugen et al., 1999; Pacini and Castagna, 2008).

Therapeutic Uses of Thyroid Hormone

The major indications for the therapeutic use of thyroid hormone are for hormone replacement therapy in patients with hypothyroidism and for TSH suppression therapy in patients with thyroid cancer. Other less common uses also are discussed.

Thyroid Hormone Preparations. Synthetic preparations of the sodium salts of the natural isomers of the thyroid hormones are available and widely used for thyroid hormone therapy.

Levothyroxine. Levothyroxine sodium (L-T₄, LEVOTHROID, LEVOXYL, SYNTHROID, UNITHROID, others) is available in

tablets and as a lyophilized powder for injection. Concerns have been raised regarding variations in therapeutic effectiveness among the branded and generic levothyroxine products and the standards used to establish bioequivalence (Hennessey, 2006). More recently, the focus has been on improving uniformity among preparations in tablet content of levothyroxine and stability (Burman et al., 2008). Table 39–3 lists drugs and other factors that may influence levothyroxine dosage requirements.

The potency standards of levothyroxine have been narrowed from the previous standard of 90–110% to 95–105%, and the content must be stable at this level for the designated shelf life. Absorption of thyroxine occurs in the stomach and small intestine and is incomplete (~80% of the dose is absorbed). Absorption is slightly increased when the hormone is taken on an empty stomach, and it is associated with less variability in the TSH when taken this way regularly (Bach-Huynh et al., 2009). The serum T_4 peaks 2–4 hours after oral ingestion, but changes are barely discernable with once-daily dosing due to the 7-day plasma $t_{1/2}$ of the T_4 . Given this long $t_{1/2}$, omission of one day's dose does not materially affect the serum TSH or FT_4 , but to maintain consistent dosing the patient should be instructed to take a double dose the next day. For any given serum TSH, the serum T_4/T_3 ratio is higher in patients taking levothyroxine than in patients with endogenous thyroid function, due to the fact that ~20% of circulating T_3 normally is supplied by direct thyroidal secretion (Jonklaas et al., 2008). Occasionally this may result in a levothyroxine-treated patient having a marginally elevated free T_4 and a normal TSH, which is acceptable. Follow-up blood tests typically are done ~6 weeks after any dosage change due to the 1-week plasma $t_{1/2}$ of T_4 . Dosages are discussed subsequently under specific indications.

In situations where patients cannot take oral medications or where intestinal absorption is in question, levothyroxine may be given intravenously once a day at a dose ~80% of the patient's daily oral requirement.

Liothyronine. Liothyronine sodium ($L-T_3$) is the salt of triiodothyronine and is available in tablets (CYTOMEL) and in an injectable form (TRIOSTAT, others).

Liothyronine absorption is nearly 100% with peak serum levels 2–4 hours following oral ingestion. Liothyronine may be used occasionally when a more rapid onset of action is desired such as in the rare presentation of myxedema coma or if rapid termination of action is desired such as when preparing a thyroid cancer patient for ^{131}I therapy. Liothyronine is less desirable for chronic replacement therapy due to the requirement for more frequent dosing (plasma $t_{1/2}$ = 0.75 days), higher cost, and transient elevations of serum T_3 concentrations above the normal range. In addition, organs that express the type 2 deiodinase use the locally generated T_3 in addition to plasma T_3 , and hence there is theoretical concern that these organs will not maintain physiological intracellular T_3 levels in the absence of plasma T_4 . Ten to 15 μg of liothyronine sodium three times per day typically yields a normal serum free T_3 in an athyreotic individual. However, normalization of circulating TSH may require higher levels of free T_3 , perhaps because negative feedback normally relies in

part on the local generation of T_3 from circulating T_4 (Koutras et al., 1981, Saberi and Utiger, 1974).

Other Preparations. A mixture of thyroxine and triiodothyronine 4:1 by weight is marketed as liotrix (THYROLAR). Desiccated thyroid preparations such as (ARMOUR THYROID, others), with a similar $T_4:T_3$ ratio, also are available. A 60-mg (1 grain) desiccated thyroid tablet is approximately equivalent in activity to 80 μg of thyroxine. This conversion can be used when changing a patient from replacement therapy with desiccated thyroid to levothyroxine, but typically such patients can be dosed with levothyroxine using dosing guidelines based on age and weight.

Thyroid Hormone Replacement Therapy in Hypothyroidism. Thyroxine (levothyroxine sodium) is the hormone of choice for thyroid hormone replacement therapy due to its consistent potency and prolonged duration of action. With this therapy, one relies on the types 1 and 2 deiodinases to convert T_4 to T_3 to maintain a steady serum level of free T_3 .

The average daily adult replacement dose of levothyroxine sodium is 1.7 $\mu\text{g}/\text{kg}$ body weight (0.8 $\mu\text{g}/\text{lb}$), although the variation about this average is substantial. Dosing should generally be based on lean body mass (Santini et al., 2005). Although not ideal, once-a-week dosing can be used in situations where compliance is otherwise not possible (Grebe et al., 1997). The goal of therapy is to normalize the serum TSH (in primary hypothyroidism) or free T_4 (in secondary or tertiary hypothyroidism) and to relieve symptoms of hypothyroidism. In primary hypothyroidism, generally it is sufficient to follow TSH without free T_4 . A patient with mild primary hypothyroidism will achieve a normal TSH with substantially less than a full replacement dose, but as the endogenous thyroid function declines, the dose will need to be increased. Thus, especially in young healthy patients, it can be simpler to begin with nearly a full replacement dose. In individuals >60 years of age and those with known or suspected cardiac disease or with areas of autonomous thyroid function, institution of therapy at a lower daily dose of levothyroxine sodium (12.5–50 μg per day) is appropriate. The dose can be increased at a rate of 25 μg per day every 6–8 weeks until the TSH is normalized.

Combination therapy with levothyroxine plus liothyronine seems attractive superficially because the thyroid gland secretes T_4 and T_3 . However, the $T_4:T_3$ ratio in human thyroid secretion is ~11:1, compared with 4:1 in the currently available combination pills. Furthermore, the short plasma $t_{1/2}$ of T_3 would necessitate multiple daily dosing to achieve steady circulating T_3 levels. Importantly, randomized blinded controlled trials have failed to uncover evidence of a better therapeutic response to combination therapy with T_4 plus T_3 , versus T_4 alone (Grozinsky-Glasberg et al., 2006). Although occasional patients find that they feel better on combination therapy, this is usually short lived. The data indicate that monotherapy with levothyroxine most closely mimics normal physiology and generally is preferred.

1144 **Subclinical Hypothyroidism.** Subclinical hypothyroidism is the presence of a mildly elevated serum TSH concentration and a normal free T_4 without obvious symptoms. Population screening has shown that subclinical hypothyroidism is very common, with a prevalence of up to 15% in some populations and up to 25% in the elderly. The prevalence is strongly influenced by the definition of the upper limit of normal of serum TSH, which itself is controversial (Surks and Hollowell, 2007). The decision to use levothyroxine therapy in these patients to normalize the serum TSH must be made on an individual basis because treatment may not be appropriate for all patients.

An elevated TSH, especially common among elderly patients and among centenarians, may even be associated with longevity (Atzmon et al., 2009). Patients with subclinical hypothyroidism who may benefit from levothyroxine therapy include those with goiter, autoimmune thyroid disease, hypercholesterolemia, cognitive dysfunction, or pregnancy, and those patients who have nonspecific symptoms that could be due to hypothyroidism (Biondi and Cooper, 2008).

Hypothyroidism During Pregnancy. The dose of levothyroxine in the hypothyroid patient who becomes pregnant usually needs to be increased (Abalovich et al., 2007), perhaps due to the increased serum concentration of TBG induced by estrogen, the expression of type 3 deiodinase by the placenta, and the small amount of transplacental passage of levothyroxine from mother to fetus. In addition, pregnancy may “unmask” hypothyroidism in patients with preexisting autoimmune thyroid disease or in those who reside in a region of iodine deficiency. Overt hypothyroidism during pregnancy is associated with fetal distress and impaired psychoneural development in the progeny. In addition, studies have suggested that subclinical hypothyroidism during pregnancy is associated with mildly impaired psychomotor development in the children and preterm delivery. An increase in miscarriage rate is strongly associated with the presence of anti-thyroid peroxidase antibodies, and early treatment with thyroxine may reduce miscarriages and preterm delivery. These findings strongly suggest that any degree of hypothyroidism, as judged by an elevated serum TSH or perhaps a relatively low T_4 , should be treated during pregnancy.

The increased levothyroxine requirement averages 30-50% and can become apparent as early as the fifth week of gestation. The magnitude of thyroxine dose adjustment is greatest for women who are athyreotic from surgical thyroidectomy or radioiodine ablation (Loh et al., 2009). The optimal way to anticipate this increased dosage need and hence to avoid an elevated TSH is not known. Some experts recommend that women increase their levothyroxine dosage by ~30% as soon as pregnancy is confirmed, which can be

accomplished by taking two extra pills per week. Most measure a serum TSH in the first trimester and then adjust the thyroxine dose based on this result. Subsequent dosage adjustments would be based on serum TSH, measured 4-6 weeks after each adjustment. For non-pregnant women of reproductive age not using contraception, maintaining the TSH in the lower portion of the reference range (~0.3-2.0 mIU/L) will allow room to move within the reference range during the early part of pregnancy. For similar reasons, dosage adjustments during pregnancy should be made to bring the TSH into the lower portion of the reference range. The increased dosage requirement plateaus at about gestation week 16-20, and dosage needs fall back to prepregnancy levels immediately after delivery.

Myxedema Coma. Myxedema coma is a rare syndrome that represents the extreme expression of severe, long-standing hypothyroidism (Kwaku and Burman, 2007). *It is a medical emergency, and even with early diagnosis and treatment, the mortality rate can be as high as 60%* (Yamamoto et al., 1999). Myxedema coma occurs most often in elderly patients during the winter months. Common precipitating factors include pulmonary infections, cerebrovascular accidents, and congestive heart failure. The clinical course of lethargy proceeding to stupor and then coma is often hastened by drugs, especially sedatives, narcotics, antidepressants, and tranquilizers. Indeed, many cases of myxedema coma have occurred in hypothyroid patients who have been hospitalized for other medical problems.

Cardinal features of myxedema coma are:

- hypothermia, which may be profound
- respiratory depression
- decreased consciousness

Other clinical features include bradycardia, macroglossia, delayed reflexes, and dry, rough skin. Dilutional hyponatremia is common and may be severe. Elevated plasma creatine kinase (CK) and lactate dehydrogenase (LDH) concentrations, acidosis, and anemia are common findings. Lumbar puncture reveals increased opening pressure and high protein content. Hypothyroidism is confirmed by measuring the serum FT_4 and TSH. Ultimately, myxedema coma is a clinical diagnosis.

The mainstay of therapy is supportive care, with ventilatory support, rewarming with blankets, correction of hyponatremia, and treatment of the precipitating cause. Due to a 5-10% incidence of coexisting decreased adrenal reserve in patients with myxedema coma, intravenous steroids are indicated before initiating thyroxine therapy and should be continued until adrenal function has been proven normal (Chapter 42).

There are no randomized controlled clinical trials to evaluate the optimal form of thyroid hormone therapy in myxedema coma. Intravenous administration of thyroid hormone is advised due to uncertain absorption through the gut. Therapy with levothyroxine is

commonly begun with a loading dose of 250-500 μg followed by a daily full replacement dose, although some clinicians omit the loading dose. Some clinicians recommend adding liothyronine (10 μg intravenously every 8 hours) with the initial dose of levothyroxine, until the patient is stable and conscious. The limited studies that are available suggest that excessive treatment with either levothyroxine (>500 μg per day) or liothyronine (>75 μg) may be associated with an increased mortality rate.

Congenital Hypothyroidism. Success in the treatment of congenital hypothyroidism depends on the age at which therapy is started. Because of this, newborn screening for congenital hypothyroidism is routine in the U.S., Canada, and many other countries. In cases that do not come to the attention of physicians until retardation of development is clinically obvious, the detrimental effects of thyroid hormone deficiency on mental development will be irreversible. If, however, therapy is instituted within the first 2 weeks of life, normal physical and mental development can be achieved (Rose et al., 2006). Prognosis also depends on the severity of the hypothyroidism at birth and may be worse for infants with thyroid agenesis.

To rapidly normalize the serum thyroxine concentration in the congenitally hypothyroid infant, an initial daily dose of levothyroxine of 10-15 $\mu\text{g}/\text{kg}$ is recommended. This dose will increase the serum FT_4 concentration to the upper half of the normal range in most infants within 1-2 weeks. A dose of up to 17 $\mu\text{g}/\text{kg}$ has been suggested for the most severely hypothyroid infants, which can normalize the serum T_4 in 3 days (LaFranchi and Austin, 2007). Laboratory evaluations of TSH and FT_4 are performed 2 and 4 weeks after treatment is initiated, every 1-2 months in the first 6 months, every 3-4 months between 6 months and 3 years of age, and every 6-12 months from age 3 years until the end of growth. The goal is to maintain serum FT_4 in the upper half of the reference range and the TSH in the lower normal range during the first 3 years of life. Assessments that are important guides for appropriate hormone replacement include physical growth, motor development, bone maturation, and developmental progress.

Management of premature infants with hypothyroxinemia (~50% of those born at <30 weeks of gestation) remains a therapeutic dilemma. Despite impaired psychomotor development in these patients (Reuss et al., 1996), it is not clear whether levothyroxine therapy may be beneficial, and in some settings it may be detrimental (van Wassenaer et al., 2005).

Thyroid Nodules. Nodular thyroid disease is the most common endocrinopathy. The prevalence of clinically apparent nodules is 4-7% in the U.S., with the frequency increasing throughout adult life. When ultrasound and autopsy data are included, the prevalence of thyroid nodules approaches 50% by age 60. As with other forms of thyroid disease, nodules are more frequent in women. Exposure to ionizing radiation, especially in childhood, increases the rate of nodule

development. Approximately 5% of thyroid nodules that come to medical attention are malignant.

The evaluation of the patient with nodular thyroid disease includes a careful physical examination, biochemical analysis of thyroid function, and assessment of the malignant potential of the nodule (Cooper et al., 2006). Thyroid nodules usually are asymptomatic, although they can cause neck discomfort, dysphagia, and a choking sensation. Most patients with thyroid nodules are euthyroid, which should be confirmed by TSH measurement. The most useful diagnostic procedures generally are ultrasound imaging and a fine-needle aspiration biopsy.

TSH suppressive therapy with levothyroxine sometimes is prescribed for the patient with a benign thyroid nodule and a normal serum TSH. The rationale is that a benign nodule will either stop growing or decrease in size after TSH stimulation of the thyroid gland has been suppressed. However, a meta-analysis of randomized trials reveals the shortcomings of this approach (Sdano et al., 2005). Only 22% of nodules decrease in volume by >50% with levothyroxine versus 10% with placebo. Eight patients need to be treated to have one response, and limited data suggest that the nodule will regrow if the levothyroxine is stopped. Furthermore, a 50% decrease in volume represents only about a 20% decrease in linear dimension, a very modest change. The minimum level of TSH suppression needed to achieve this modest response is not known, and long-term exposure to excess thyroid hormone carries risks such as osteoporosis and atrial fibrillation. *Thus the use of levothyroxine to suppress TSH in euthyroid individuals with thyroid nodules cannot be recommended as a general practice. However, if the TSH is elevated, it is appropriate to administer levothyroxine to bring the TSH into the lower portion of the reference range.*

Thyroid Cancer. The mainstays of therapy for well-differentiated thyroid cancer (papillary, follicular) are surgical thyroidectomy, radioiodine, and levothyroxine to suppress TSH (Cooper et al., 2006; Tuttle et al., 2007). The rationale for TSH suppression is that TSH is a growth factor for these cancers. These interventions mainly benefit those patients with stage 2 or higher thyroid cancer (Jonklass et al., 2006).

Given the generally excellent prognosis of well-differentiated thyroid cancer, a prospective randomized controlled trial to assess which patients benefit from suppressive therapy, how low the TSH should be, or how long the suppression should be maintained has not been done. For most low-risk patients with stage 1 or 2 disease, maintaining the TSH just below the reference range for not more than 5 years is one reasonable approach. A greater degree of TSH suppression for a longer duration is recommended for higher risk patients and those with metastatic disease (Cooper et al., 2006).

Non-thyroidal Illness (Sick Euthyroid) Syndrome. Although the circulating free T_3 is low in the non-thyroidal illness syndrome, the current standard of care is not to treat with thyroid hormone because there is no convincing evidence that the low T_3 state contributes to the patient's prognosis or that thyroid hormone therapy would alter the course of the illness. However, there have been very few randomized controlled trials, and these generally involve small numbers

of patients and hence have little statistical power. Two trials suggest possible benefit of T_3 therapy in cardiac surgery patients (Klemperer et al., 1995, 1996; Mullis-Jansson et al., 1999).

Depression. Data from several small double-blind placebo-controlled studies suggest potential efficacy of thyroid hormone therapy in euthyroid individuals with major depression, when added to tricyclic antidepressants (Carvalho et al., 2007). It is unclear whether T_3 supplementation of specific serotonin reuptake inhibitor (SSRI) therapy is beneficial (Papakostas et al., 2009). One study suggests that a beneficial effect of T_3 added to the SSRI sertraline is seen primarily in subjects with a C785T polymorphism in the type 1 deiodinase gene (Cooper-Kazaz et al., 2009). The mechanism of the T_3 effect (if any) is not known.

Adverse Effects of Thyroid Hormone. Adverse effects of thyroid hormone would generally occur only upon overtreatment and would be similar to the consequences of hyperthyroidism. An excess of thyroid hormone can increase the risk of atrial fibrillation, especially in the elderly, and can increase the risk of osteoporosis, especially in postmenopausal women.

Novel Thyroid Hormone Analogs and Their Potential Therapeutic Applications

The discovery of multiple thyroid hormone receptor isoforms, combined with tissue specific differences in their levels of expression, has led to the development of isoform-specific thyroid hormone analogs with interesting properties (Baxter and Webb, 2009; Brenta et al., 2007). Additional research will be required to determine the therapeutic value of these novel compounds, but their potential merits brief discussion.

TR β Agonists. Thyroid hormone has long been known to reduce serum cholesterol via effects on hepatic metabolism, but T_4 and T_3 are not useful hypocholesterolemic drugs due to the adverse effects of thyrotoxicosis on the heart and other organs. However, the liver primarily expresses TR β , whereas the heart primarily expresses TR α . T_3 analogs that have a higher affinity for TR β than TR α and that accumulate preferentially in the liver have been shown to lower serum cholesterol without causing tachycardia in humans and animals (Erion et al., 2007). These analogs also can induce weight loss in mice with diet-induced obesity. Thyromimetics with preferential action on TR β also might be useful in the management of thyroid hormone resistance, which in most cases is caused by mutations in TR β that lower the binding affinity for T_3 (Refetoff and Dumitrescu, 2007).

Thyroid Hormone Receptor α Agonists. Because TR α 1 is expressed preferentially in the heart, specific agonists might find use in the management of heart failure or bradycardia. The design of specific agonists for TR α , however, has proven much more difficult than for TR β (Ocasio and Scanlan, 2008).

Thyromimetics with Altered Entry into Cells. Monocarboxylate transporter 8 (MCT8) transports T_3 into cells and is highly expressed in

the brain. Patients with MCT8 mutations have the Allan-Herndon-Dudley syndrome with severe neurological impairment, presumably due to intracellular thyroid hormone deficiency. A thyromimetic that can enter the brain in an MCT8-independent manner could be valuable in treating these patients. The thyroid hormone analog 3,5-diiodothyropropionic acid (DITPA) has this property in mice (Di Cosmo et al., 2009).

Thyroid Hormone Receptor Antagonists. In principle, thyroid hormone receptor antagonists could be useful therapeutics in the medical management of thyrotoxicosis, and possibly even in the management of cardiac arrhythmias. A thyroid hormone analog denoted NH3 antagonizes the cholesterol lowering, TSH lowering, and tachycardic actions of T_3 in rats, but at high doses this drug functions as a T_3 agonist (Grover et al., 2007).

Thyronamines. 3-Iodothyronamine and thyronamine are endogenous thyroid hormone metabolites that functions as agonists for the GPCR Trace Amine Associated Receptor 1 (TAAR1) and the α_{2A} adrenergic receptor. These compounds appear to have broad metabolic effects in experimental animals, such as inducing hypothermia and bradycardia (Scanlan et al., 2004), and conferring protection against brain ischemia (Doyle et al., 2007). The therapeutic potential of these agents or their analogs requires further investigation.

ANTI-THYROID DRUGS AND OTHER THYROID INHIBITORS

A number of compounds are capable of interfering, directly or indirectly, with the synthesis, release, or action of thyroid hormones (Table 39–4). Several are of great clinical value for the temporary or extended control of hyperthyroid states. The major inhibitors may be classified into four categories:

- Anti-thyroid drugs, which interfere directly with the synthesis of thyroid hormones;
- Ionic inhibitors, which block the iodide transport mechanism;
- High concentrations of iodine, which decrease release of thyroid hormones from the gland and also may decrease hormone synthesis;
- Radioactive iodine, which damages the thyroid gland with ionizing radiation.

Adjuvant therapy with drugs that have no specific effects on thyroid hormone synthesis is useful in controlling the peripheral manifestations of thyrotoxicosis. These drugs include inhibitors of the peripheral deiodination of thyroxine to the active hormone, triiodothyronine, β adrenergic receptor antagonists, and Ca^{2+} channel blockers. The anti-thyroid drugs have been reviewed by Cooper (2005). Adrenergic receptor antagonists are discussed more fully in Chapter 12 and Ca^{2+} channel blockers in Chapter 27.

Table 39–4

Anti-thyroid Compounds

PROCESS AFFECTED	EXAMPLES OF INHIBITORS
Active transport of iodide	Complex anions: perchlorate, fluoroborate, pertechnetate, thiocyanate
Iodination of thyroglobulin	Thionamides: propylthiouracil, methimazole, carbimazole Thiocyanate Aniline derivatives; sulfonamides Iodide
Coupling reaction	Thionamides Sulfonamides ?All other inhibitors of iodination
Hormone release	Lithium salts Iodide
Iodotyrosine deiodination	Nitrotyrosines
Peripheral iodothyronine deiodination	Thiouracil derivatives
Hormone excretion/inactivation	Oral cholecystographic agents Amiodarone Inducers of hepatic drug-metabolizing enzymes: phenobarbital, rifampin, carbamazepine, phenytoin
Hormone action	Thyroxine analogs Amiodarone ?Phenytoin Binding in gut: cholestyramine

Source: Data adapted from Meier C.A., Burger A.C. Effects of drugs and other substances on thyroid hormone synthesis and metabolism. In: *Werner and Ingbar's The Thyroid*, 9th ed. (Braverman L.E. and Utiger R.D. eds.) Lippincott Williams & Wilkins, Philadelphia, 2005.

Anti-Thyroid Drugs

The anti-thyroid drugs that have clinical utility are the thioureylens, which belong to the family of thionamides. Propylthiouracil may be considered as the prototype.

History. Studies on the mechanism of the development of goiter began with the observation that rabbits fed a diet composed largely of cabbage often developed goiters. This result was probably due to the presence of precursors of the thiocyanate ion in cabbage leaves. Later, two pure compounds were shown to produce goiter: sulfaguanidine, a sulfanilamide antimicrobial used to treat enteric infections, and phenylthiourea.

Investigation of the effects of thiourea derivatives revealed that rats became hypothyroid despite hyperplastic changes in their

thyroid glands that were characteristic of intense thyrotropic stimulation. After treatment was begun, no new hormone was made, and the goitrogen had no visible effect on the thyroid gland following hypophysectomy or the administration of thyroid hormone. This suggested that the goiter was a compensatory change resulting from the induced state of hypothyroidism and that the primary action of the compounds was to inhibit the formation of thyroid hormone. The therapeutic possibilities of such agents in hyperthyroidism were evident, and the substances so used became known as *anti-thyroid drugs* (Astwood, 1945).

Structure–Activity Relationship. The two goitrogens found in the early 1940s proved to be prototypes of two different classes of anti-thyroid drugs. These two, with one later addition, made up three general categories into which most of the agents can be assigned:

- *Thioureylens* include all the compounds currently used clinically (Figure 39–9);
- *Aniline derivatives*, of which the sulfonamides make up the largest number, embrace a few substances that have been found to inhibit thyroid hormone synthesis;
- *Polyhydric phenols*, such as resorcinol, which have caused goiter in humans when applied to abraded skin.

A few other compounds, mentioned briefly later, do not fit into any of these categories.

Thiourea and its simpler aliphatic derivatives and heterocyclic compounds containing a thioureylene group make up most of the known anti-thyroid agents that are effective in humans. Although most of them incorporate the entire thioureylene group, in some a nitrogen atom is replaced by oxygen or sulfur so that only the thioamide group is common to all. Among the heterocyclic compounds, active representatives are the sulfur derivatives of imidazole, oxazole, hydantoin, thiazole, thiadiazole, uracil, and barbituric acid.

L-5-Vinyl-2-thiooxazolidone (goitritin) is responsible for the goiter that results from consuming turnips or the seeds or green parts of cruciferous plants. These plants are eaten by cows, and the compound is found in cow's milk in areas of endemic goiter in Finland; it is about as active as propylthiouracil in humans.

As the result of industrial exposure, toxicological studies, or clinical trials for various purposes, several other compounds have been noted to possess anti-thyroid activity (Miller et al., 2009). Thiopental and oral hypoglycemic drugs of the sulfonylurea class

Figure 39–9. Anti-thyroid drugs of the thiamide type.

have weak anti-thyroid action in experimental animals. This is not significant at usual doses in humans. However, anti-thyroid effects in humans have been observed from dimercaprol and lithium salts. Polychlorinated biphenyls bear a striking structural resemblance to the thyroid hormones and may function as either agonists or antagonists of thyroid hormone action (Zoeller et al., 2000). Amiodarone, the iodine-rich drug used in the management of cardiac arrhythmias, has complex effects on thyroid function (Basaria and Cooper, 2005). In areas of iodine sufficiency, amiodarone-induced hypothyroidism due to the excess iodine is not uncommon, whereas in iodine-deficient regions, amiodarone-induced thyrotoxicosis predominates, whether because of the excess iodine or the thyroiditis induced by the drug. Amiodarone and its major metabolite, desethylamiodarone, are potent inhibitors of iodothyronine deiodination, resulting in decreased conversion of thyroxine to triiodothyronine. In addition, desethylamiodarone decreases binding of triiodothyronine to its nuclear receptors. Recommendations have been made as to screening methods to identify chemicals that may alter thyroid hormone action or homeostasis (Diamanti-Kandarakis et al., 2009).

Mechanism of Action. The mechanism of action of the thioureyline drugs has been thoroughly reviewed (Cooper, 2005). Anti-thyroid drugs inhibit the formation of thyroid hormones by interfering with the incorporation of iodine into tyrosyl residues of thyroglobulin; they also inhibit the coupling of these iodotyrosyl residues to form iodothyronines. This implies that they interfere with the oxidation of iodide ion and iodotyrosyl groups. The drugs are thought to inhibit the peroxidase enzyme, thereby preventing oxidation of iodide or iodotyrosyl groups to the required active state (Taurog et al., 1996). The anti-thyroid drugs bind to and inactivate the peroxidase only when the heme of the enzyme is in the oxidized state. Over a period of time, the inhibition of hormone synthesis results in the depletion of stores of iodinated thyroglobulin as the protein is hydrolyzed and the hormones are released into the circulation. Only when the preformed hormone is depleted and the concentrations of circulating thyroid hormones begin to decline do clinical effects become noticeable.

There is some evidence that the coupling reaction may be more sensitive to an anti-thyroid drug, such as propylthiouracil, than is the iodination reaction. This may explain why patients with hyperthyroidism respond well to doses of the drug that only partially suppress organification.

When Graves' disease is treated with anti-thyroid drugs, the concentration of thyroid-stimulating immunoglobulins in the circulation often decreases, prompting some to propose that these agents act as immunosuppressants. Perchlorate, which acts by an

entirely different mechanism, also decreases thyroid-stimulating immunoglobulins, suggesting that improvement in hyperthyroidism may reduce thyroid antibodies.

In addition to blocking hormone synthesis, propylthiouracil partially inhibits the peripheral deiodination of T_4 to T_3 . *Methimazole* does not have this effect; although the quantitative significance of this inhibition has not been established, it provides a rationale for the choice of propylthiouracil over other anti-thyroid drugs in the treatment of severe hyperthyroid states or of thyroid storm, where a decreased rate of $T_4 \rightarrow T_3$ conversion would be beneficial.

Absorption, Metabolism, and Excretion. The anti-thyroid compounds currently used in the U.S. are propylthiouracil (6-*n*-propylthiouracil) and methimazole (1-methyl-2-mercaptoimidazole; TAPAZOLE, others). In Great Britain and Europe, carbimazole (NEOMERCAZOLE), a carbethoxy derivative of methimazole, is available, and its anti-thyroid action is due to its conversion to methimazole after absorption. Pharmacological properties of propylthiouracil and methimazole are shown in Table 39–5.

Table 39–5

Selected Pharmacokinetic Features of Anti-thyroid Drugs

	PROPYLTHIOURACIL	METHIMAZOLE
Plasma protein binding	~75%	Nil
Plasma $t_{1/2}$	75 minutes	~4-6 hours
Volume of distribution	~20 liters	~40 liters
Concentrated in thyroid	Yes	Yes
Metabolism of drug during illness		
Severe liver disease	Normal	Decreased
Severe kidney disease	Normal	Normal
Dosing frequency	1-4 times daily	Once or twice daily
Transplacental passage	Low	Low
Levels in breast milk	Low	Low

Measurements of the course of organification of radioactive iodine by the thyroid show that absorption of effective amounts of propylthiouracil follows within 20-30 minutes of an oral dose and that the duration of action of the compounds used clinically is brief. The effect of a dose of 100 mg of propylthiouracil begins to wane in 2-3 hours, and even a 500-mg dose is completely inhibitory for only 6-8 hours. As little as 0.5 mg of methimazole similarly decreases the organification of radioactive iodine in the thyroid gland, but a single dose of 10-25 mg is needed to extend the inhibition to 24 hours.

The $t_{1/2}$ of propylthiouracil in plasma is ~75 minutes, whereas that of methimazole is 4-6 hours. The drugs are concentrated in the thyroid, and methimazole, derived from the metabolism of carbimazole, accumulates after carbimazole is administered. Drugs and metabolites appear largely in the urine.

Propylthiouracil and methimazole cross the placenta equally (Mortimer et al., 1997) and also can be found in milk. The use of these drugs during pregnancy is discussed later.

Untoward Reactions. The incidence of side effects from propylthiouracil and methimazole as currently used is relatively low. The overall incidence as compiled from published cases by early investigators was 3% for propylthiouracil and 7% for methimazole, with 0.44% and 0.12% of cases, respectively, developing the most serious reaction, agranulocytosis.

Agranulocytosis usually occurs during the first few weeks or months of therapy but may occur later. Because agranulocytosis can develop rapidly, periodic white cell counts usually are of little help, although a baseline white blood cell count and differential should be obtained before anti-thyroid drug treatment is initiated. Patients should be instructed to immediately report the development of sore throat or fever, which are often signs of the presence of leukopenia. If these signs or symptoms occur, patients should discontinue their anti-thyroid drug and obtain a granulocyte count. Agranulocytosis is reversible upon discontinuation of the offending drug, and the administration of recombinant human granulocyte colony-stimulating factor may hasten recovery (Magner and Snyder, 1994). Mild granulocytopenia, if noted, may be due to thyrotoxicosis or may be the first sign of this dangerous drug reaction. Caution and frequent leukocyte counts are then required.

The most common reaction is a mild, occasionally purpuric, urticarial papular rash. It often subsides spontaneously without interrupting treatment, but it sometimes calls for the administration of an antihistamine, corticosteroids, and changing to another drug (cross-sensitivity between propylthiouracil and methimazole is uncommon). Other less frequent complications are pain and stiffness in the joints, paresthesias, headache, nausea, skin pigmentation, and loss of hair. Drug fever, hepatitis, and nephritis are rare, although abnormal liver function tests are not infrequent with higher doses of propylthiouracil. Although vasculitis was previously thought to be a rare complication, antineutrophilic cytoplasmic antibodies (ANCA) have been reported to occur in ~50% of patients receiving propylthiouracil and rarely with methimazole (Sato et al., 2000; Sera et al., 2000).

Propylthiouracil-associated hepatic failure has been increasingly recognized, especially in children and pregnant women (Cooper and Rivkees, 2009). There are 47 published reports of propylthiouracil-associated liver failure in adults and children, and

23 liver transplants between 1990 and 2007 due to propylthiouracil-associated liver failure. Methimazole may cause cholestatic dysfunction, but it is not associated with hepatocellular necrosis, and there are no reports of liver transplants due to methimazole-associated liver toxicity. There is increasing concern about using propylthiouracil as a first-line treatment, except in severe thyrotoxicosis when the inhibition of T_4 to T_3 is desired, and possibly in the first trimester of pregnancy. *The FDA has added a "black box" warning to propylthiouracil because of liver failure, recommending close monitoring of liver function during its use. Propylthiouracil should not be used in children except in the case of methimazole allergy.*

Therapeutic Uses. The anti-thyroid drugs are used in the treatment of hyperthyroidism in the following three ways:

- as definitive treatment, to control the disorder in anticipation of a spontaneous remission in Graves' disease
- in conjunction with radioactive iodine, to hasten recovery while awaiting the effects of radiation
- to control the disorder in preparation for surgical treatment (Cooper, 2003)

Methimazole is the drug of choice for Graves' disease; it is effective when given as a single daily dose, has improved adherence, and is less toxic than propylthiouracil. Methimazole has a relatively long plasma and intrathyroidal $t_{1/2}$, as well as a long duration of action. The usual starting dose for methimazole is 15-40 mg per day. The usual starting dose of propylthiouracil is 100 mg every 8 hours. When doses >300 mg daily are needed, further subdivision of the time of administration to every 4-6 hours is occasionally helpful. Failures of response to daily treatment with 300-400 mg of propylthiouracil or 30-40 mg of methimazole are most commonly due to nonadherence but can be seen with very severe disease. Delayed responses also are noted in patients with very large goiters or those in whom iodine in any form has been given beforehand. Once euthyroidism is achieved, usually within 12 weeks, the dose of anti-thyroid drug can be reduced, but not stopped, lest an exacerbation of Graves' disease occur (see later section on remissions).

Response to Treatment. The thyrotoxic state usually improves within 3-6 weeks after the initiation of anti-thyroid drugs. The clinical response is related to the dose of anti-thyroid drug, the size of the goiter, and pretreatment serum T_3 concentrations. The rate of response is determined by the quantity of stored hormone, the rate of turnover of hormone in the thyroid, the $t_{1/2}$ of the hormone in the periphery, and the completeness of the block in synthesis imposed by the dosage given. When large doses are continued, and sometimes with the usual dose, hypothyroidism may develop as a result of overtreatment. The earliest signs of hypothyroidism call for a reduction in dose; if they have advanced to the point of discomfort, thyroid hormone in full replacement doses can be given to hasten recovery;

then the lower maintenance dose of anti-thyroid drug as discussed earlier is instituted for continued therapy. Despite initial suggestions to the contrary, there is no demonstrated benefit of combination levothyroxine and methimazole therapy on either remission rates (Rittmaster et al., 1998) or on changes in serum concentrations of thyroid-stimulating immunoglobulins.

After treatment is initiated, patients should be examined and thyroid function tests (serum FT₄ and total or free triiodothyronine concentrations) measured every 2–4 months. Serum TSH will often remain suppressed for several months after a patient has been hyperthyroid, so the circulating thyroxine and triiodothyronine concentrations are the most reliable assessment of thyroid status (Uy et al., 1995). Once euthyroidism is established, follow-up every 4–6 months is reasonable.

Control of the hyperthyroidism usually is associated with a decrease in goiter size. When this occurs, the dose of the anti-thyroid drug should be significantly decreased and/or levothyroxine can be added once hypothyroidism is confirmed by laboratory testing.

Remissions. There is no highly reliable way of predicting before treatment which patients will eventually achieve a lasting remission and which will relapse. A favorable outcome is unlikely when the disorder is of long standing, the thyroid is quite large, serum T₃ concentration is high relative to serum T₄ concentration, or various forms of treatment have failed. To complicate the issue further, remission and eventual hypothyroidism may represent the natural history of Graves' disease.

During treatment, a positive sign that a remission may have taken place is reduced size of the goiter. The persistence of goiter often indicates failure, unless the patient becomes hypothyroid. Another favorable indication is continued freedom from all signs of hyperthyroidism when the maintenance dose is small. Finally, a decrease in thyroid-stimulating immunoglobulins is associated with remission, although the clinical features and improvement in thyroid function tests are usually sufficient to make this assessment.

The Therapeutic Choice. Because anti-thyroid drug therapy, radioactive iodine, and subtotal thyroidectomy all are effective treatments for Graves' disease, there is no worldwide consensus among endocrinologists about the best therapeutic approach. Prolonged drug therapy of Graves' disease in anticipation of a remission is most successful in patients with small goiters or mild hyperthyroidism. Those with large goiters or severe disease usually require definitive therapy with either surgery or radioactive iodine (¹³¹I). Radioactive iodine remains the treatment of choice of many endocrinologists in the U.S.

Many investigators consider coexisting ophthalmopathy to be a relative contraindication for radioactive iodine therapy

because worsening of ophthalmopathy has been reported after radioactive iodine (Bartalena et al., 1998a), although this remains controversial. Others suggest that development of hypothyroidism, regardless of the treatment, is the strongest risk factor for progression of ophthalmopathy. Smoking is a risk factor for worsening ophthalmopathy (Bartalena et al., 1998b). In older patients, depleting the thyroid gland of preformed hormone by treatment with anti-thyroid drugs is advisable before therapy with radioactive iodine, thus preventing a severe exacerbation of the hyperthyroid state during the subsequent development of radiation thyroiditis. Subtotal thyroidectomy is advocated for Graves' disease in young patients with large goiters, children who are allergic to anti-thyroid drugs, pregnant women (usually in the second trimester) who are allergic to anti-thyroid drugs, and patients who prefer surgery over anti-thyroid drugs or radioactive iodine. Radioactive iodine or surgery is indicated for definitive therapy in toxic nodular goiter.

Thyrotoxicosis in Pregnancy. Thyrotoxicosis occurs in ~0.2% of pregnancies and is caused most frequently by Graves' disease (Chan and Mandel, 2007). Anti-thyroid drugs are the treatment of choice; radioactive iodine is clearly contraindicated. Historically, propylthiouracil has been preferred over methimazole because transplacental passage was thought to be lower; however, as noted earlier, both propylthiouracil and methimazole cross the placenta equally (Mortimer et al., 1997). Methimazole is also very rarely associated with aplasia cutis and an embryopathy that can include choanal atresia and other anomalies (Diav-Citrin and Ornoy, 2002). Current data suggest that either may be used safely in the pregnant patient (Momotani et al., 1997; Mortimer et al., 1997), although the concern for propylthiouracil-associated liver failure in pregnancy may favor the use of methimazole, especially after organogenesis in the first trimester (Cooper and Rivkees, 2009). Carbimazole is used in the EU during pregnancy and is rarely associated with congenital gut abnormalities (Barwell et al., 2002).

The anti-thyroid drug dosage should be minimized to keep the serum FT₄ index in the upper half of the normal range or slightly elevated. As pregnancy progresses, Graves' disease often improves, and it is not uncommon for patients either to be on very low doses or off anti-thyroid drugs completely by the end of pregnancy. Therefore the anti-thyroid drug dose should be reduced, and maternal thyroid function should be frequently monitored to decrease chances of fetal hypothyroidism. Relapse or worsening of Graves' disease is common after delivery, and patients should be monitored closely. Methimazole up to 20 mg daily in nursing mothers reportedly has no effect on thyroid function in the infant (Azizi et al., 2003), and propylthiouracil is thought to cross into breast milk even less than methimazole.

Adjuvant Therapy. Several drugs that have no intrinsic anti-thyroid activity are useful in the symptomatic treatment of thyrotoxicosis.

β Adrenergic receptor antagonists (Chapter 12) are effective in antagonizing the sympathetic/adrenergic effects of thyrotoxicosis, thereby reducing the tachycardia, tremor, and stare, and relieving palpitations, anxiety, and tension. Either propranolol, 20-40 mg four times daily, or atenolol, 50-100 mg daily, is usually given initially. Propranolol or esmolol can be given intravenously if needed. Ca^{2+} channel blockers (diltiazem, 60-120 mg four times daily) can be used to control tachycardia and decrease the incidence of supraventricular tachyarrhythmias (Chapters 27 and 29). These drugs, however, should be used as an adjunct to anti-thyroid drug therapy for more rapid improvement of adrenergic-related symptoms and not as the only treatment for hyperthyroidism. Usually only short-term treatment with β adrenergic receptor antagonists or Ca^{2+} channel blockers is required, 2-6 weeks, and it should be discontinued once the patient is euthyroid.

Other drugs that are useful in the rapid treatment of the severely thyrotoxic patient are agents that inhibit the peripheral conversion of thyroxine to triiodothyronine. Dexamethasone (0.5-1 mg, two to four times daily) and the iodinated radiological contrast agents iopanoic acid (500-1000 mg once daily) and sodium ipodate (ORAGRAFIN) (500-1000 mg once daily) are effective in preoperative preparation; neither iopanoic acid nor sodium ipodate is available in the U.S. Cholestyramine has been used in severely toxic patients to bind thyroid hormones in the gut and thus block the enterohepatic circulation of the iodothyronines (Mercado et al., 1996). Immunotherapy has been used for Graves' hyperthyroidism and ophthalmopathy. The B-lymphocyte depleting agent rituximab, when used with methimazole, prolongs remission of Graves' disease (El Fassi et al., 2009). A novel approach that has been successful only *in vitro* uses low-molecular-weight antagonists of the TSH receptor (Neumann et al., 2008). This approach has the potential to provide a rapid and targeted treatment for Graves' disease.

Preoperative Preparation. To reduce operative morbidity and mortality, patients should be rendered euthyroid before subtotal thyroidectomy as definitive treatment for hyperthyroidism. It is possible to bring almost all patients to a euthyroid state with a normal range serum T_4 and T_3 concentration. The serum TSH concentration will be suppressed below normal for several months after serum T_4 and T_3 is normalized, so it is not required that the serum TSH concentration be normal before surgery. The operative mortality in these patients in the hands of an experienced thyroid surgeon is extremely low. Prior treatment with anti-thyroid drugs usually is successful in rendering the patient euthyroid for surgery. Iodide is added to the regimen for 7-10 days before surgery to decrease the vascularity of the gland, making it less friable and decreasing the difficulties for the surgeon. In the patient who is either allergic to anti-thyroid drugs or is noncompliant, a euthyroid state usually can be achieved by treatment with iopanoic acid (not available in the U.S.), dexamethasone, and propranolol for 5-7 days before surgery. All of these drugs should be discontinued after surgery.

Thyroid Storm. Thyroid storm is an uncommon but life-threatening complication of thyrotoxicosis in which a severe form of the disease is usually precipitated by an intercurrent medical problem (Nayak and Burman, 2006). It occurs in untreated or partially treated thyrotoxic patients. Precipitating factors associated with thyrotoxic crisis include infections, stress, trauma, thyroidal or non-thyroidal surgery, diabetic ketoacidosis, labor, heart disease, and, rarely, radioactive iodine treatment.

Clinical features are similar to those of thyrotoxicosis but more exaggerated. Cardinal features include fever (temperature usually $>38.5^\circ\text{C}$) and tachycardia out of proportion to the fever. Nausea, vomiting, diarrhea, agitation, and confusion are frequent presentations. Coma and death may ensue in up to 20% of patients. Thyroid function abnormalities are similar to those found in uncomplicated hyperthyroidism. Therefore thyroid storm is primarily a clinical diagnosis.

Treatment includes supportive measures such as intravenous fluids, antipyretics, cooling blankets, and sedation. Anti-thyroid drugs are given in large doses. Propylthiouracil is preferred over methimazole because it also impairs peripheral conversion of $T_4 \rightarrow T_3$. The recommended initial dose of propylthiouracil is 200-400 mg every 6-8 hours (Nayak and Burman, 2006). Propylthiouracil and methimazole can be administered by nasogastric tube or rectally if necessary. Neither of these preparations is available for parenteral administration in the U.S.

Oral iodides are used after the first dose of an anti-thyroid drug has been administered. The agents mentioned earlier as adjuvant therapies of thyrotoxicosis may be usefully applied. Hydrocortisone (100 mg intravenously every 8 hours) can be used in the setting of hypotension both as an inhibitor of conversion of thyroxine to triiodothyronine and as supportive therapy of possible relative adrenal insufficiency (Nayak and Burman, 2006). Finally, *treatment of the underlying precipitating illness is essential.*

Ionic Inhibitors

The term *ionic inhibitors* designates substances that interfere with the concentration of iodide by the thyroid gland (Diamanti-Kandarakis et al., 2009). The effective agents are anions that resemble iodide: *thiocyanate*, *perchlorate*, and *fluoroborate*, all monovalent hydrated anions of a size similar to that of iodide.

The most studied example, *thiocyanate*, differs from the others qualitatively; it is not concentrated by the thyroid gland but in large amounts may inhibit the organification of iodine. Thiocyanate is produced following the enzymatic hydrolysis of certain plant glycosides. Thus, certain foods (e.g., cabbage) and cigarette smoking result in an increased concentration of thiocyanate in the blood and urine, as does the administration of sodium nitroprusside. Indeed,

cigarette smoking has been reported to worsen both subclinical hypothyroidism (Müller et al., 1995) and Graves' ophthalmopathy (Bartalena et al., 1998b). Dietary precursors of thiocyanate may be a contributing factor in endemic goiter in certain parts of the world, especially in Central Africa, where the intake of iodine is very low.

Among other anions, perchlorate (ClO_4^-) is 10 times as active as thiocyanate (Wolff, 1998). The various NIS inhibitors, perchlorate, thiocyanate, and nitrate, are additive in inhibiting iodine uptake (Tonacchera et al., 2004). Perchlorate blocks the entrance of iodide into the thyroid by competitively inhibiting the NIS. Perchlorate is transported by NIS using a different stoichiometry, electroneutral, compared with that seen with transport of iodine (Dohan et al., 2007). Although perchlorate can be used to control hyperthyroidism, it has caused fatal aplastic anemia when given in excessive amounts (2–3 g daily). Perchlorate in doses of 750 mg daily has been used in the treatment of Graves' disease and amiodarone-iodine-induced thyrotoxicosis (National Academy of Sciences/National Research Council [NAS/NRC], 2005). Perchlorate can be used to "discharge" inorganic iodide from the thyroid gland in a diagnostic test of iodide organification. Other ions, selected on the basis of their size, also have been found to be active; fluoroborate (BF_4^-) is as effective as perchlorate.

Ammonium perchlorate is an essential oxidizer in the production of rocket fuel, and water supplies have been contaminated with perchlorate derived from the sites of production. A National Academy of Sciences Committee recommended a reference dose of perchlorate exposure of 0.0007 mg/kg per day that would produce no adverse effect. This level of no effect is much higher than that found in most water supplies, indicating a low risk of perchlorate exposure influencing thyroid function (NAS/NRC, 2005). The reference dose was primarily derived from a 2-week study in normal volunteers that determined the daily dose of perchlorate that produced no effect on thyroid function or ^{123}I uptake (Greer et al., 2002). There remain concerns that accumulated perchlorate exposure from multiple sources and combined exposure to other iodine uptake inhibitors may impair thyroid function, especially as it might affect pregnant women and young children (Miller et al., 2009). A study in the U.S. showed a correlation between perchlorate exposure and an increase in serum TSH (still within the normal range), only among women with low iodine intake (Blount et al., 2006). Men and women with adequate iodine intake did not show any influence of perchlorate on thyroid function. Others have argued that the risk of thyroid dysfunction from perchlorate exposure is extremely low and there is little evidence to support this view (Charnley, 2008). A study among pregnant women living in areas of very high natural perchlorate contamination showed no effect on maternal thyroid function or pregnancy outcome for mother or infant (Tellez et al., 2006). Although reassuring, the high iodine content in this region may limit the effects of perchlorate. Because the primary mode of toxicity of perchlorate is inhibition of iodine uptake, the best approach to reduce susceptibility is to maintain adequate iodine intake, especially during pregnancy (Becker et al., 2006).

Lithium has a multitude of effects on thyroid function; its principal effect is decreased secretion of thyroxine and triiodothyronine (Takami, 1994), which can cause overt hypothyroidism in some patients taking Li^+ for the treatment of mania (Chapter 16).

Iodide

Iodide is the oldest remedy for disorders of the thyroid gland. Before the anti-thyroid drugs were used, it was the only substance available for control of the signs and symptoms of hyperthyroidism. Its use in this way is indeed paradoxical, and the explanation for this paradox is still incomplete.

Mechanism of Action. High concentrations of iodide appear to influence almost all important aspects of iodine metabolism by the thyroid gland. The capacity of iodide to limit its own transport was mentioned earlier. Acute inhibition of the synthesis of iodotyrosines and iodothyronines by iodide also is well known (the *Wolff-Chaikoff effect*). This transient 2-day inhibition is observed only above critical concentrations of intracellular rather than extracellular concentrations of iodide. With time, "escape" from this inhibition is associated with an adaptive decrease in iodide transport and a lowered intracellular iodide concentration, associated with a decrease in NIS mRNA and protein (Eng et al., 1999).

An important clinical effect of high $[\text{I}^-]_{\text{plasma}}$ is inhibition of the release of thyroid hormone. This action is rapid and efficacious in severe thyrotoxicosis. The effect is exerted directly on the thyroid gland and can be demonstrated in the euthyroid subject as well as in the hyperthyroid patient. Studies in a cultured thyroid cell line suggest that some of the inhibitory effects of iodide on thyrocyte proliferation may be mediated by actions of iodide on crucial regulatory points in the cell cycle (Smerdely et al., 1993).

In euthyroid individuals, the administration of doses of iodide from 1.5–150 mg daily results in small decreases in plasma thyroxine and triiodothyronine concentrations and small compensatory increases in serum TSH values, with all values remaining in the normal range. However, euthyroid patients with a history of a wide variety of underlying thyroid disorders may develop iodine-induced hypothyroidism when exposed to large amounts of iodine present in many commonly prescribed drugs (Table 39–6), and these patients do not escape from the acute Wolff-Chaikoff effect (Roti et al., 1997). Among the disorders that predispose patients to iodine-induced hypothyroidism are treated Graves' disease, Hashimoto's thyroiditis, postpartum lymphocytic thyroiditis, subacute painful thyroiditis, and lobectomy for benign nodules. The most commonly prescribed iodine-containing drugs are certain expectorants (e.g., potassium iodide), topical antiseptics (e.g., povidone iodine), and iodinated radiological contrast agents.

Response to Iodide in Hyperthyroidism. The response to iodides in patients with hyperthyroidism is often striking and rapid. The effect usually is discernible within 24 hours, and the basal metabolic rate may fall at a rate comparable to that following thyroidectomy.

Table 39-6

Commonly Used Iodine-Containing Drugs

DRUGS	IODINE CONTENT
Oral or local	
Amiodarone	75 mg/tablet
Calcium iodide syrup	26 mg/mL
Iodoquinol (diiodohydroxyquin)	134-416 mg/ tablet
Echothiophate iodide ophthalmic solution	5-41 µg/drop
Hydriodic acid syrup	13-15 mg/mL
Iodochlorhydroxyquin	104 mg/tablet
Iodine-containing vitamins	0.15 mg/tablet
Iodoxuridine ophthalmic solution	18 µg/drop
Kelp/seaweed	0.15 mg/tablet
Lugol's solution	6.3 mg/drop
PONARIS nasal emollient	5 mg/0.8 mL
KI, saturated solution (KISS)	38 mg/drop
Topical antiseptics	
Iodoquinol cream (diiodohydroxyquin)	6 mg/g
Iodine tincture	40 mg/mL
Iodochlorhydroxyquin cream	12 mg/g
Iodoform gauze	4.8 mg/100 mg gauze
Povidone-iodine	10 mg/mL
Radiology contrast agents	
Diatrizoate meglumine sodium	370 mg/mL
Propyl iodone	340 mg/mL
Iopanoic acid	333 mg/tablet
Ipodate	308 mg/capsule
Iothalamate	480 mg/mL
Metrizamide (undiluted)	483 mg/mL
Iohexol	463 mg/mL

This provides evidence that the release of hormone into the circulation is rapidly blocked. Furthermore, thyroid hormone synthesis also is mildly decreased. In the thyroid gland, vascularity is reduced, the gland becomes much firmer, the cells become smaller, colloid reaccumulates in the follicles, and the quantity of bound iodine increases, as though an excessive stimulus to the gland has been removed or antagonized. The maximal effect is attained after 10-15 days of continuous therapy

when the signs and symptoms of hyperthyroidism may have greatly improved.

Unfortunately, iodide therapy usually does not completely control the manifestations of hyperthyroidism, and after a variable period of time, the beneficial effect disappears. With continued treatment, the hyperthyroidism may return in its initial intensity or may become even more severe than it was at first.

Therapeutic Uses. The uses of iodide in the treatment of hyperthyroidism are in the preoperative period in preparation for thyroidectomy, and in conjunction with anti-thyroid drugs and propranolol, in the treatment of thyrotoxic crisis.

Before surgery, iodide is sometimes employed alone, but more frequently it is used after the hyperthyroidism has been controlled by an anti-thyroid drug. It is then given for 7-10 days immediately preceding the operation. Optimal control of hyperthyroidism is achieved if anti-thyroid drugs are first given alone. If iodine also is given from the beginning, variable responses are observed; sometimes the effect of iodide predominates, storage of hormone is promoted, and prolonged anti-thyroid treatment is required before the hyperthyroidism is controlled. These clinical observations may be explained by the capacity of iodide to prevent the inactivation of thyroid peroxidase by anti-thyroid drugs (Taurog et al., 1996).

Another use of iodide is to protect the thyroid from radioactive iodine fallout following a nuclear accident, military exposure, or large scale radioiodination procedures in laboratories. Because the uptake of radioactive iodine is inversely proportional to the serum concentration of stable iodine, the administration of 30-100 mg of iodide daily will markedly decrease the thyroid uptake of radioisotopes of iodine. Following the Chernobyl nuclear reactor accident in 1986, ~10 million children and adults in Poland were given stable iodide to block the thyroid exposure to radioactive iodine from the atmosphere and from dairy products from cows that ate contaminated grass (Nauman and Wolff, 1993).

The dosage or form in which iodide is administered bears little relationship to the response achieved in hyperthyroidism, provided that not less than the minimal effective amount is given; this dosage is 6 mg of iodide per day in most, but not all, patients.

Strong iodine solution (Lugol's solution) is widely used and consists of 5% iodine and 10% potassium iodide, which yields a dose of 8 mg of iodine per drop. The iodine is reduced to iodide in the intestine before absorption. Saturated solution of potassium iodide (SSKI) also is available, containing 50 mg per drop. Typical doses include 16-36 mg (2-6 drops) of Lugol's solution or 50-100 mg (1-2 drops) of SSKI three times a day. A potassium iodide product (THYROSHIELD) is available over the counter in the U.S. to take in the event of a radiation emergency and block the uptake of radioiodide into the thyroid gland. The adult dose is 2 mL (130 mg) every 24 hours, as directed by public health officials, with specific dose recommendations in children and infants based on age and weight.

1154 **Untoward Reactions.** Occasional individuals show marked sensitivity to iodide or to organic preparations that contain iodine when they are administered intravenously as a supplement (e.g., sodium iodine [IODOPEN]) during total parental nutrition therapy. The onset of an acute reaction may occur immediately or several hours after administration. Angioedema is the outstanding symptom, and laryngeal edema may lead to suffocation. Multiple cutaneous hemorrhages may be present. Also, manifestations of the serum-sickness type of hypersensitivity—such as fever, arthralgia, lymph node enlargement, and eosinophilia—may appear. Thrombotic thrombocytopenic purpura and fatal periarteritis nodosa attributed to hypersensitivity to iodide also have been described.

The severity of symptoms of chronic intoxication with iodide (*iodism*) is related to the dose. The symptoms start with an unpleasant brassy taste and burning in the mouth and throat as well as soreness of the teeth and gums. Increased salivation is noted. Coryza, sneezing, and irritation of the eyes with swelling of the eyelids are commonly observed. Mild iodism simulates a “head cold.” The patient often complains of a severe headache that originates in the frontal sinuses. Irritation of the mucous glands of the respiratory tract causes a productive cough. Excess transudation into the bronchial tree may lead to pulmonary edema. In addition, the parotid and submaxillary glands may become enlarged and tender, and the syndrome may be mistaken for mumps parotitis. There also may be inflammation of the pharynx, larynx, and tonsils. Skin lesions are common and vary in type and intensity. They usually are mildly acneform and distributed in the seborrheic areas. Rarely, severe and sometimes fatal eruptions (*ioderma*) may occur after the prolonged use of iodides. The lesions are bizarre; they resemble those caused by bromism, a rare problem, and as a rule involute quickly when iodide is withdrawn. Symptoms of gastric irritation are common, and diarrhea, which is sometimes bloody, may occur. Fever is occasionally observed, and anorexia and depression may be present.

Fortunately, the symptoms of iodism disappear spontaneously within a few days after stopping the administration of iodide. The renal excretion of I^- can be increased by procedures that promote Cl^- excretion (e.g., osmotic diuresis, chloruretic diuretics, and salt loading). These procedures may be useful when the symptoms of iodism are severe.

Radioactive Iodine

Chemical and Physical Properties. Iodine has several radioactive isotopes, although the primary ones used for the diagnosis and treatment of thyroid disease are ^{123}I and ^{131}I . The short-lived radionuclide of iodine, ^{123}I , is primarily a γ -emitter with a $t_{1/2}$ of only 13 hours and is used in diagnostic studies to measure 24-hour iodine uptake and for thyroid imaging. In contrast, ^{131}I has a $t_{1/2}$ of 8 days and emits both γ rays and β particles. More than 99% of its radiation is expended within 56 days. It is used therapeutically for thyroid destruction of an overactive or enlarged thyroid and in thyroid cancer for thyroid ablation and treatment of metastatic disease.

Effects on the Thyroid Gland. The chemical behavior of the radioactive isotopes of iodine is identical to that of the stable isotope, ^{127}I . ^{131}I

is rapidly and efficiently trapped by the thyroid, incorporated into the iodoamino acids, and deposited in the colloid of the follicles, from which it is slowly liberated. Thus the destructive β particles originate within the follicle and act almost exclusively on the parenchymal cells of the thyroid, with little or no damage to surrounding tissue. The γ radiation passes through the tissue and can be quantified by external detection. The effects of the radiation depend on the dosage. When small tracer doses of ^{131}I are administered, thyroid function is not disturbed. However, when large amounts of radioactive iodine gain access to the gland, the characteristic cytotoxic actions of ionizing radiation are observed. Pyknosis and necrosis of the follicular cells are followed by disappearance of colloid and fibrosis of the gland. With properly selected doses of ^{131}I , it is possible to destroy the thyroid gland completely without detectable injury to adjacent tissues. After smaller doses, some of the follicles, usually in the periphery of the gland, retain their function.

Therapeutic Uses. Radioactive iodine finds its widest use in the treatment of hyperthyroidism and in the diagnosis of disorders of thyroid function. Sodium iodide ^{131}I (HICON, others) is available as a solution or in capsules containing essentially carrier-free ^{131}I suitable for oral administration. Sodium iodide ^{123}I is available for scanning procedures. Discussion here is focused on the therapeutic uses of ^{131}I .

Hyperthyroidism. Radioactive iodine is a valuable alternative or adjunctive treatment of hyperthyroidism (Brent, 2008). Stable iodide (non-radioactive) used as treatment for hyperthyroidism, however, may preclude treatment and imaging with radioactive iodine for weeks after the stable iodide has been discontinued. A urinary iodine measurement can be performed to monitor the iodine load. In those patients exposed to stable iodide, a 24-hour radioiodine measurement of a tracer dose of ^{123}I should be performed before ^{131}I administration to ensure there is sufficient uptake to accomplish the desired ablation.

Dosage and Technique. ^{131}I , 7000-10,000 rads per gram of thyroid tissue, is administered orally. The effective dose for a given patient depends primarily on the size of the thyroid, the iodine uptake of the gland, and the rate of release of radioactive iodine from the gland subsequent to the nuclide's deposition in the colloid. Comparison studies have shown little advantage of a standard individualized dose, based on gland weight and radioactive iodine uptake, over a fixed dose (Jarlov et al., 1995). For these reasons, the optimal dose of ^{131}I , expressed in terms of microcuries taken up per gram of thyroid tissue, varies in different laboratories from 80-150 μCi . The usual total dose is 4-15 mCi.

The lower doses produce a lower incidence of hypothyroidism in the early years after treatment; however, many patients with late hypothyroidism may go undetected, and the ultimate incidence of hypothyroidism is probably no less than with the larger doses. In addition, relapse of the hyperthyroid state, or initial failure to alleviate the hyperthyroid state, is increased in patients receiving lower doses of ^{131}I . Thus, many endocrinologists recommend initial treatment with thyroid ablative doses of ^{131}I , with subsequent treatment for hypothyroidism. There also is evidence that pretreatment with an anti-thyroid drug reduces the therapeutic efficacy of ^{131}I . The medication, therefore, should be discontinued ~1 week before the therapeutic dose

of ^{131}I therapy and only resumed 3 days after ^{131}I (Walter et al., 2007). If the anti-thyroid drug cannot be discontinued, the effect can be overcome by adjusting to a higher radioiodine dose.

Course of Disease. The course of hyperthyroidism in a patient who has received an optimal dose of ^{131}I is characterized by progressive recovery. Beginning a few weeks after treatment, the symptoms of hyperthyroidism gradually abate over a period of 2-3 months. If therapy has been inadequate, the necessity for further treatment is apparent within 6-12 months. It is not uncommon, however, for the serum TSH to remain low for several months after ^{131}I therapy, especially if the patient was not rendered euthyroid before receiving the radioactive iodine. Occasionally, this delayed recovery of the hypothalamic-pituitary-thyroid axis results in a picture of central hypothyroidism, with low circulating thyroid hormones. Thus, assessing radioactive iodine failure based on TSH concentrations alone may be misleading and should always be accompanied by determination of free T_4 and usually serum T_3 concentrations. Furthermore, transient hypothyroidism, lasting up to 6 months, may occur in up to 50% of patients receiving a dose of ^{131}I calculated to result in euthyroidism (Aizawa et al., 1997). This is less of a problem if the patient receives a higher, ablative dose of ^{131}I because hypothyroidism occurs far more frequently and persists.

Depending to some extent on the dosage schedule adopted, 80% of patients are cured by a single dose, ~20% require two doses, and a very small fraction require three or more doses before the disorder is controlled. Patients treated with larger doses of ^{131}I almost always develop hypothyroidism within a few months.

β Adrenergic antagonists, anti-thyroid drugs, or both, or stable iodide, can be used to hasten the control of hyperthyroidism while awaiting the full effects of the radioactive iodine.

Advantages. The advantages of radioactive iodine in the treatment of Graves' disease are many. No death as a direct result of the use of the isotope has been reported. There have been reports of increased mortality from cardiovascular and cerebrovascular disease in the first year after radioactive iodine therapy (Franklyn et al., 1998); however, there is no evidence that the increased mortality was related to the radioactive iodine itself, and long-term follow-up of radioactive iodine therapy for Graves' disease has demonstrated no increase in overall cancer mortality in patients treated with ^{131}I (Ron et al., 1998). In the non-pregnant patient, no tissue other than the thyroid is exposed to sufficient ionizing radiation to be detectably altered. Nevertheless, continuing concern about potential effects of radiation on germ cells prompts some endocrinologists to advocate anti-thyroid drugs or surgery in younger patients who are acceptable operative risks. Hypoparathyroidism is a small risk of surgery. With radioactive iodine treatment, the patient is spared the risks and discomfort of surgery. The cost is low, hospitalization is not required in the U.S., and patients can participate in their customary activities during the entire procedure, although there are recommendations to limit exposure to young children.

Disadvantages. The chief consequence of the use of radioactive iodine is the high incidence of delayed hypothyroidism. Even when elaborate procedures are used to estimate iodine uptake and gland size, most patients become hypothyroid.

Several analyses of groups of patients treated ≥ 10 years previously suggest that the eventual rate may exceed 80%. However, it now appears that the incidence of hypothyroidism also increases progressively after subtotal thyroidectomy or after anti-thyroid drug therapy, and such failure of glandular function is probably part of the natural progression of Graves' disease, no matter what the therapy. Although cancer death rate is not increased after radioiodine therapy, there is a small but significant increase shown in specific types of cancer, including stomach, kidney, and breast (Metso et al., 2007). This finding is especially significant because these tissues all express the iodine transporter NIS and may be especially susceptible to radiation effects.

It is essential that patients treated with radioiodine understand that the resulting hypothyroidism will require lifelong treatment and monitoring. Because there are variations in the interval of time from treatment to the development of hypothyroidism, patients must have regular thyroid function testing after radioiodine. Also, once diagnosed, it is difficult to ensure that patients who need the hormone actually take it. Because the health risks of untreated subclinical hypothyroidism are becoming increasingly evident (Biondi and Cooper, 2008), hypothyroidism, either subclinical or overt, requires long-term follow-up to ensure adequate thyroid hormone status and optimal replacement therapy.

Another disadvantage of radioactive iodine therapy is the long period of time that is sometimes required before the hyperthyroidism is controlled. When a single dose is effective, the response is most satisfactory; however, when multiple doses are needed, it may be many months or a year or more before the patient is well. This disadvantage can be largely overcome if the initial dose is sufficiently large. Other disadvantages include possible worsening of ophthalmopathy after treatment (Bartalena et al., 1998a). Radioactive iodine treatment can induce a radiation thyroiditis, with release of preformed thyroxine and triiodothyronine into the circulation. In most patients, this is asymptomatic, but in some there can be worsening of symptoms of hyperthyroidism and rarely cardiac manifestations, such as atrial fibrillation or ischemic heart disease and very rarely thyroid storm. Pretreatment with anti-thyroid drugs should reduce or eliminate this complication and is indicated especially in those with underlying cardiac disease or the elderly. Finally, salivary gland dysfunction may be seen, especially after the higher doses used for the treatment of thyroid cancer (Mandel and Mandel, 2003). Sialogogic agents to hasten the transit of radioiodine through the salivary glands are used by many clinicians but have unproven efficacy. Salivary gland damage is most strongly linked to the cumulative dose of radioiodine.

Indications. The clearest indication for this form of treatment is hyperthyroidism in older patients and in those with heart disease. Radioactive iodine also is the best form of treatment when Graves' disease has persisted or recurred after subtotal thyroidectomy and

when prolonged treatment with anti-thyroid drugs has not led to remission. Finally, radioactive iodine is indicated in patients with toxic nodular goiter because the disease does not go into spontaneous remission.

The risk of inducing hypothyroidism is less in nodular goiter than in Graves' disease, perhaps because of the normal progression of the latter and the preservation of nonautonomous thyroid tissue in the former. Usually, larger doses of radioactive iodine are required in the treatment of toxic nodular goiter than in the treatment of Graves' disease. Radioactive iodine has been used to decrease the size of large nontoxic multinodular goiters that are causing compressive symptoms in patients who are otherwise poor operative risks. Although surgery remains the treatment of choice for patients with compressive multinodular goiters, radioactive iodine therapy may benefit elderly patients, especially those with cardiopulmonary disease. The uptake in multinodular goiters may be low, so some have increased radioiodine uptake by administration of exogenous recombinant human TSH (thyrotropin alfa [THYROGEN]) (Duntas and Cooper, 2008), but caution should be exercised because this treatment may induce transient elevations in serum thyroxine and triiodothyronine that could result in excessive stimulation of the heart.

Contraindications. *The main contraindication for the use of ^{131}I therapy is pregnancy.* After the first trimester, the fetal thyroid will concentrate the isotope and thus suffer damage; even during the first trimester, radioactive iodine is best avoided because there may be adverse effects of radiation on fetal tissues. The risk of causing neoplastic changes in the thyroid gland has been an ongoing concern since radioactive iodine was first introduced, and only small numbers of children have been treated in this way. Indeed, many clinics have declined to treat younger patients for fear of causing cancer and have reserved radioactive iodine for patients older than some arbitrary age, such as 25 or 30 years. Because experience with ^{131}I is now vast, these age limits are lower than they were in the past. The most recent report by the Cooperative Thyrotoxicosis Therapy Follow-up Study Group shows no increase in total cancer mortality following ^{131}I treatment for Graves' disease (Ron et al., 1998). Furthermore, there was no increase in the occurrence of leukemia following large-dose ^{131}I therapy for thyroid cancer, although there was an increase in colorectal cancers in this population (de Vathaire et al., 1997). These data strongly suggest that laxatives be given to all patients receiving ^{131}I therapy for treatment of thyroid cancer to decrease the risk of future digestive tract malignancies. Transient abnormalities in testicular function have been reported following ^{131}I therapy for treatment of thyroid cancer, but no long-term effects on fertility in either men or women have been demonstrated (Dottorini et al., 1995; Pacini et al., 1994). Patients with allergies to iodine contrast agents or to topical iodide-containing products should not have any adverse reaction to ^{131}I . The amount of elemental iodine contained in the treatment is not greater than that contained in iodized salt or flour that is part of regular dietary intake.

Diagnostic Uses. Measurement of the thyroidal accumulation of a tracer dose is helpful in the differential diagnosis of hyperthyroidism and nodular goiter. The response of the thyroid to TSH-suppressive doses of

thyroid hormone can be evaluated in this way. Following the administration of a tracer dose, the pattern of localization in the thyroid gland can be depicted by a special scanning apparatus, and this technique is sometimes useful in defining thyroid nodules as functional ("hot") or non-functional ("cold") and in finding ectopic thyroid tissue and occasionally metastatic thyroid tumors.

Thyroid Carcinoma. Because most well-differentiated thyroid carcinomas accumulate very little iodine, stimulation of iodine uptake with TSH is required to treat metastases effectively. Currently, endogenous TSH stimulation is evoked by withdrawal of thyroid hormone replacement therapy in patients previously treated with near-total thyroidectomy with or without radioactive ablation of residual thyroid tissue. Total-body ^{131}I scanning and measurement of serum thyroglobulin when the patient is hypothyroid (TSH >35 mU/L) help to identify metastatic disease or residual thyroid bed tissue. Depending on the residual uptake or the presence of metastatic disease, an ablative dose of ^{131}I ranging from 30 mCi to >150 mCi is administered, and a repeat total body scan is obtained 1 week later. The precise amount of ^{131}I needed to treat residual tissue and metastases is controversial. Thyrotropin alfa (recombinant human TSH) is now available to test the ability of thyroid tissue, both normal and malignant, to take up radioactive iodine and to secrete thyroglobulin (Haugen et al., 1999). Thyrogen allows assessment of the presence of metastatic disease, without the necessity for patients to stop their suppressive levothyroxine therapy and become clinically hypothyroid. Thyrotropin alfa is approved for diagnostic scanning and for thyroid remnant ablation after thyroidectomy in thyroid cancer patients, but not for treatment of metastatic disease. (Duntas and Cooper, 2008; Pacini and Castagna, 2008).

TSH-suppressive therapy with levothyroxine is indicated in all patients after treatment for thyroid cancer. The goal of therapy usually is to keep serum TSH levels in the subnormal range, although relaxing the degree and duration of suppression, especially for stage 1 and 2 cancers, is now recommended (Burmeister et al., 1992; Cooper et al., 2006). Follow-up evaluation every 6 months is reasonable, along with determination of serum thyroglobulin concentrations (Spencer and LoPresti, 2008). Patients with a rise in thyroglobulin but no detectable disease on whole-body scan require additional imaging and consideration of alternative treatments including surgery and external radiation (Kloos, 2008). A rise in serum thyroglobulin concentration is often the first indication of recurrent disease. The prognosis in patients with thyroid cancer depends on the pathology and size of the tumor and is generally worse in older individuals. Overall, the vast majority of patients with thyroid cancer will not die of their disease. Papillary cancer is usually not aggressive; the 10-year survival rate exceeds 80%. Follicular cancer is more aggressive and can metastasize via the bloodstream. Still, prognosis is fair and long-term survival is common. Even in patients with metastatic, differentiated thyroid cancer, ^{131}I therapy is very effective and may be even curative (Cooper et al., 2006). Anaplastic cancer is the exception: It is highly malignant with survival usually <1 year. Medullary thyroid carcinomas do not accumulate I^- and cannot be treated with ^{131}I .

Chemotherapy in Thyroid Cancer

Advanced and metastatic poorly differentiated papillary and follicular thyroid cancer often does not concentrate iodine sufficient for therapy with ^{131}I (Kloos, 2008). There have been significant advances in targeted chemotherapy for thyroid cancer (Sherman, 2009). Recent advances in the molecular genetics of thyroid cancer have resulted in the identification of oncogenic mutations in the *BRAF* and *RAS* genes, known to activate the MAPK signaling pathway. Medullary thyroid carcinoma is associated with mutations in the *RET* gene, which also enhance MAPK signaling. These findings have led to a number of successful clinical trials in poorly differentiated papillary and follicular thyroid cancer and medullary thyroid cancer. Treatment with inhibitors of receptor tyrosine kinases, vascular endothelial growth factor (VEGF), and the VEGF receptor have produced partial response rates in the range of 30%. Agents studied include axitinib, gefitinib, imatinib, motesanib, sorafenib, sunitinib, and vandetanib (Sipos and Shah, 2010). Single agents in poorly differentiated thyroid cancer have most commonly produced disease stabilization, although combining agents to target multiple growth-promoting pathways may improve the disease response.

CLINICAL SUMMARY

Replacement therapy for hypothyroidism typically uses oral L-thyroxine given once daily. The goals of therapy are to restore the serum TSH concentration to the mid-normal or low-normal range, and to relieve the signs and symptoms of hypothyroidism. In patients with central hypothyroidism, the biochemical goal is to restore the serum-free T_4 to the upper half of the normal range. Based on the long $t_{1/2}$ of thyroxine, at least 6-8 weeks are required before a new steady-state level is reached following initiation of therapy or adjustment of dose. Special cases of hypothyroidism include patients following surgical resection of differentiated thyroid carcinoma and pregnancy. In the former setting, the goal is to suppress the TSH level to below normal, thereby removing the potential effect of TSH to stimulate proliferation of the cancer cells. In pregnant patients, the standard replacement dose is usually increased. Realizing the effects of even relatively mild hypothyroidism on neurological development of the fetus and miscarriage, it is especially important to monitor thyroid function tests carefully during pregnancy.

Options available for treating hyperthyroid patients include anti-thyroid drugs (e.g., propylthiouracil and methimazole), radioactive iodine ablation, and surgery. The preferred therapy differs among endocrinologists and geographic regions as well as patient characteristics. Special circumstances, such as the presence of coexisting ophthalmopathy in patients with Graves' disease, also may influence the choice of

therapy; radioactive iodine may aggravate the ophthalmopathy. Although younger patients with hyperthyroidism often can be treated effectively with radioactive iodine, medical therapy with anti-thyroid drugs to reduce the levels of thyroid hormone has been the preferred approach. The potential for increased toxicity of anti-thyroid drugs in children and pregnant women may influence this choice. In older patients or those with cardiac disease, radioactive iodine usually is recommended after the patient has been rendered euthyroid with anti-thyroid medication. Surgery remains an option for those who cannot tolerate anti-thyroid drugs or decline radioactive iodine. Surgery is also the most rapid way to treat hyperthyroidism permanently. The initial treatment for thyroid cancer is surgical, usually a total or near-total thyroidectomy. Radioiodine treatment to ablate remnant thyroid tissue or to identify metastatic spread can be done after withdrawal of thyroxine replacement and elevation of endogenous TSH or treatment with recombinant human TSH in patients who are having a total body scan and serum thyroglobulin measurement to determine the presence of residual tissue. Treatment of metastatic disease with radioiodine is performed after thyroxine withdrawal and elevation of endogenous TSH.

Estrogens and Progestins

Ellis R. Levin
and Stephen R. Hammes

Estrogens and *progestins* are endogenous hormones that produce numerous physiological actions. In women, these include developmental effects, neuroendocrine actions involved in the control of ovulation, the cyclical preparation of the reproductive tract for fertilization and implantation, and major actions on mineral, carbohydrate, protein, and lipid metabolism. Estrogens also have important actions in males, including effects on bone, spermatogenesis, and behavior. The biosynthesis, biotransformation, and disposition of estrogens and progestins are well established. Two well-characterized receptors are present for each hormone, and there is evidence that the receptors mediate biological actions in both the unliganded and steroid hormone-liganded states.

The therapeutic use of estrogens and progestins largely reflects extensions of their physiological activities. The most common uses of these agents are menopausal hormone therapy and contraception in women, but the specific compounds and dosages used in these two settings differ substantially. Estrogen- and progesterone-receptor antagonists also are available. The main uses of anti-estrogens are treatment of hormone-responsive breast cancer and infertility. Selective estrogen receptor modulators (SERMs) that display tissue-selective agonist or antagonist activities are useful to prevent breast cancer and osteoporosis. The main use of anti-progestins has been for medical abortion, but other uses are theoretically possible.

A number of naturally occurring and synthetic environmental chemicals mimic, antagonize, or otherwise affect the actions of estrogens in experimental test systems. The precise effect of these agents on humans is unknown, but this is an area of active investigation. Cancer chemotherapeutic strategies based on blockade of estrogen- and/or progesterone-receptor functions are considered in further detail in Chapter 63.

Complementary therapeutic strategies based on suppression of gonadotropin secretion by long-acting gonadotropin-releasing hormone agonists are also discussed in Chapter 63.

History. The hormonal nature of the ovarian control of the female reproductive system was firmly established in 1900 by Knauer when he found that ovarian transplants prevented the symptoms of gonadectomy, and by Halban, who showed that normal sexual development and function occurred when glands were transplanted. In 1923, Allen and Doisy devised a bioassay for ovarian extracts based on the vaginal smear of the rat. Frank and associates in 1925 detected an active sex principle in the blood of sows in estrus, and Loewe and Lange discovered in 1926 that a female sex hormone varied in the urine of women throughout the menstrual cycle. The excretion of estrogen in the urine during pregnancy also was reported by Zondek in 1928 and enabled Butenandt and Doisy in 1929 to crystallize an active substance.

Early investigations indicated that the ovary secretes two substances. Beard had postulated in 1897 that the corpus luteum serves a necessary function during pregnancy, and Fraenkel showed in 1903 that destruction of the corpora lutea in pregnant rabbits caused abortion. Several groups then isolated progesterone from mammalian corpora lutea in the 1930s.

In the early 1960s, pioneering studies by Jensen and colleagues suggested the presence of intracellular receptors for estrogens in target tissues. This was the first demonstration of receptors of the steroid/thyroid superfamily and provided techniques to identify receptors for the other steroid hormones. A second estrogen receptor was identified in 1996 and termed *estrogen receptor β* (ER β) to distinguish it from the receptor identified by Jensen and others, termed *estrogen receptor α* (ER α). Two protein isoforms, A and B, of the progesterone receptor arise from a single gene by transcription initiation from different promoters. For the primary literature references about the history of this subject, consult the ninth and tenth editions of this text.

ESTROGENS

Chemistry. Many steroidal and nonsteroidal compounds, some of which are shown in Table 40–1 and Figure 40–1, possess estrogenic activity. The most potent naturally occurring estrogen in

Table 40–1

Structural Formulas of Selected Estrogens

STEROIDAL ESTROGENS				NONSTEROIDAL COMPOUNDS WITH ESTROGENIC ACTIVITY
<i>Derivative</i>	R_1	R_2	R_3	
Estradiol	—H	—H	—H	
Estradiol valerate	—H	—H	$-\text{C}(\text{O})\text{(CH}_2\text{)}_3\text{CH}_3$	
Ethinyl estradiol	—H	—C≡CH	—H	
Mestranol	—CH ₃	—C≡CH	—H	
Estrone sulfate	—SO ₃ H	— ^a	==O ^a	
Equilin ^b	—H	— ^a	==O ^a	

^aDesignates C17 Ketone.

^bAlso contains 7, 8 double bond.

humans, for both ER α - and ER β -mediated actions, is 17 β -estradiol, followed by *estrone* and *estriol*. Each contains a phenolic A ring with a hydroxyl group at carbon 3, and a β -OH or ketone in position 17 of ring D.

The phenolic A ring is the principal structural feature responsible for selective high-affinity binding to both receptors. Most alkyl substitutions on the A ring impair binding, but substitutions on ring C or D may be tolerated. Ethinyl substitutions at the C17 position greatly increase oral potency by inhibiting first-pass hepatic metabolism. Models for the ligand-binding sites of both estrogen receptors have been determined from structure–activity relationships (Harrington et al., 2003) and structural analysis (Pike et al., 2000).

Diethylstilbestrol (DES), which is structurally similar to *estradiol* when viewed in the *trans* conformation, binds with high affinity to both estrogen receptors and it is as potent as estradiol in most assays but has a much longer $t_{1/2}$. DES no longer has widespread use, but it was important historically as an inexpensive orally active estrogen.

Selective ligands for ER α and ER β are available for experimental studies but are not yet used therapeutically (Harrington et al., 2003).

Nonsteroidal compounds with estrogenic or anti-estrogenic activity—including flavones, isoflavones (e.g., genistein), and

coumestan derivatives—occur in plants and fungi. Synthetic agents—including pesticides (e.g., *p,p'*-DDT), plasticizers (e.g., bisphenol A), and a variety of other industrial chemicals (e.g., polychlorinated biphenyls)—also have hormonal or antihormonal activity. Although their affinity is relatively weak, their large number, bioaccumulation, and persistence in the environment have raised concerns about their potential toxicity in humans and wildlife. Over-the-counter and prescription preparations containing naturally occurring estrogenlike compounds from plants (i.e., phytoestrogens) now are available (Fitzpatrick, 2003).

Biosynthesis. Steroidal estrogens arise from androstenedione or testosterone (Figure 40–1) by aromatization of the A ring. The reaction is catalyzed by aromatase (CYP19) that uses nicotinamide adenine dinucleotide phosphate (NADPH) and molecular oxygen as co-substrates. A ubiquitous flavoprotein, NADPH–cytochrome P450 reductase, also is essential. Both proteins are localized in the endoplasmic reticulum of ovarian granulosa cells, testicular Sertoli and Leydig cells, adipose stroma, placental syncytiotrophoblasts, preimplantation blastocysts, bone, various brain regions, and many other tissues (Simpson et al., 2002).

The ovaries are the principal source of circulating estrogen in premenopausal women, with estradiol the main secretory product.

Figure 40–1. The biosynthetic pathway for the estrogens.

Gonadotropins, acting via receptors that couple to the G_s -adenylyl cyclase–cyclic AMP pathway, increase the activities of aromatase and the cholesterol side-chain cleavage enzyme and facilitate the transport of cholesterol (the precursor of all steroids) into the mitochondria of cells that synthesize steroids. The ovary contains a form of 17 β -hydroxysteroid dehydrogenase (type I) that favors the production of testosterone and estradiol from androstenedione and estrone, respectively. However, in the liver, another form of this enzyme (type II) favors oxidation of circulating estradiol to estrone (Peltoketo et al., 1999), and both of these steroids are then converted to estrone (Figure 40–1). All three of these estrogens are excreted in the urine along with their glucuronide and sulfate conjugates.

In postmenopausal women, the principal source of circulating estrogen is adipose tissue stroma, where estrone is synthesized from dehydroepiandrosterone secreted by the adrenals. In men, estrogens are produced by the testes, but extragonadal production by aromatization of circulating C19 steroids (e.g., androstenedione and dehydroepiandrosterone) accounts for most circulating estrogens. Thus, the level of estrogens is regulated in part by the availability of androgenic precursors (Simpson, 2003).

Estrogenic effects most often have been attributed to circulating hormones, but locally produced estrogens also may have important actions (Simpson et al., 2002). For example, estrogens may be produced from androgens by the actions of aromatase or from estrogen conjugates by hydrolysis. Such local production of estrogens could play a causal or promotional role in the development of certain diseases such as breast cancer because mammary tumors contain

both aromatase and hydrolytic enzymes. Estrogens also may be produced from androgens via aromatase in the central nervous system (CNS) and other tissues and exert local effects near their production site (e.g., in bone they affect bone mineral density).

The placenta uses fetal dehydroepiandrosterone and its 16 α -hydroxyl derivative to produce large amounts of estrone and estrone. Human urine during pregnancy is thus an abundant source of natural estrogens, and pregnant mare's urine is the source of *conjugated equine estrogens*, which have been widely used therapeutically for many years.

Physiological and Pharmacological Actions

Developmental Actions. Estrogens are largely responsible for pubertal changes in girls and secondary sexual characteristics. They cause growth and development of the vagina, uterus, and fallopian tubes, and contribute to breast enlargement. They also contribute to molding the body contours, shaping the skeleton, and causing the pubertal growth spurt of the long bones and epiphyseal closure. Growth of axillary and pubic hair, pigmentation of the genital region, and the regional pigmentation of the nipples and areolae that occur after the first trimester of pregnancy are also estrogenic actions. Androgens may also play a secondary role in female sexual development (Chapter 41).

Estrogens appear to play important developmental roles in males. In boys, estrogen deficiency diminishes the pubertal growth spurt and delays skeletal maturation and epiphyseal closure so that linear growth continues into adulthood. Estrogen deficiency in men leads to elevated gonadotropins, macroorchidism, and increased testosterone levels and also may affect carbohydrate and lipid metabolism and fertility in some individuals (Grumbach and Auchus, 1999).

Neuroendocrine Control of the Menstrual Cycle. A neuroendocrine cascade involving the hypothalamus,

pituitary, and ovaries controls the menstrual cycle (Figure 40–2). A neuronal oscillator, or “clock,” in the hypothalamus fires at intervals that coincide with bursts of gonadotropin-releasing hormone (GnRH) release into the hypothalamic-pituitary portal vasculature (Chapter 38). GnRH interacts with its cognate receptor on pituitary gonadotropes to cause release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). The frequency of the GnRH pulses, which varies in the different phases of the menstrual cycle, controls the relative synthesis of the unique β subunits of FSH and LH.

Figure 40–2. Neuroendocrine control of gonadotropin secretion in females. The hypothalamic pulse generator located in the arcuate nucleus of the hypothalamus functions as a neuronal “clock” that fires at regular hourly intervals (A). This results in the periodic release of gonadotropin-releasing hormone (GnRH) from GnRH-containing neurons into the hypothalamic-pituitary portal vasculature (B). GnRH neurons (B) receive inhibitory input from opioid, dopamine, and GABA neurons and stimulatory input from noradrenergic neurons (NE, norepinephrine). The pulses of GnRH trigger the intermittent release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from pituitary gonadotropes (C), resulting in the pulsatile plasma profile (D). FSH and LH regulate ovarian production of estrogen and progesterone, which exert feedback controls (E). (See text and Figure 40–3 for additional details.)

The gonadotropins (LH and FSH) regulate the growth and maturation of the graafian follicle in the ovary and the ovarian production of estrogen and progesterone, which exert feedback regulation on the pituitary and hypothalamus.

Because the release of GnRH is intermittent, LH and FSH secretion is pulsatile. The pulse *frequency* is determined by the neural “clock” (Figure 40–2), termed the *hypothalamic GnRH pulse generator* (Knobil, 1981), but the amount of gonadotropin released in each pulse (i.e., the pulse *amplitude*) is largely controlled by the actions of estrogens and progesterone on the pituitary. The intermittent, *pulsatile* nature of hormone release is essential for the maintenance of normal ovulatory menstrual cycles because constant infusion of GnRH results in a cessation of gonadotropin release and ovarian steroid production (Chapter 38). The neuropeptide kisspeptin-1, which is released from the hypothalamic anteroventral periventricular nucleus and the arcuate nucleus, may regulate GnRH pulsatility through its G protein-coupled receptor, GPR54, expressed in GnRH neurons. Inactivating mutations in GPR54 have been associated with hypogonadotropic hypogonadism (Seminara, 2006).

Although the precise mechanism that regulates the timing of GnRH release (i.e., pulse frequency) is unclear, hypothalamic cells appear to have an intrinsic ability to release GnRH episodically. The overall pattern of GnRH release likely is regulated by the interplay of intrinsic mechanism(s) and extrinsic synaptic inputs from opioid, catecholamine, and GABAergic neurons (Figure 40–2). Ovarian steroids, primarily progesterone, regulate the frequency of GnRH release, but the cellular and molecular mechanisms of this regulation are not well established. Some GnRH cells have immunoreactive steroid receptors. Some nerve cells that synapse with GnRH neurons also contain steroid receptors, and neighboring glial cells may contain estrogen and progesterone receptors. Steroids may thus directly and indirectly modulate GnRH neuronal function.

At puberty the pulse generator is activated and establishes cyclic profiles of pituitary and ovarian hormones. Although the mechanism of activation is not entirely established, it may involve increases in circulating insulin-like growth factor (IGF)-1 and leptin levels, the latter acting to inhibit neuropeptide Y (NPY) in the arcuate nucleus to relieve an inhibitory effect on GnRH neurons.

Figure 40–3 provides a schematic diagram of the profiles of gonadotropin and gonadal steroid levels in the menstrual cycle. The “average” plasma levels of LH throughout the cycle are shown in panel A of Figure 40–3; inserts illustrate the pulsatile patterns of LH during the proliferative and secretory phases in more detail. The average LH levels are similar throughout the early (follicular) and late (luteal) phases of the cycle, but the frequency and amplitude of the LH

pulses are quite different in the two phases. This characteristic pattern of hormone secretions results from complex positive and negative feedback mechanisms (Hotchkiss and Knobil, 1994).

In the early follicular phase of the cycle, (1) the pulse generator produces bursts of neuronal activity with a frequency of about one per hour that correspond with pulses of GnRH secretion, (2) these cause a corresponding pulsatile release of LH and FSH from pituitary gonadotropes, and (3) FSH in particular causes the graafian follicle to mature and secrete estrogen. The effects of estrogens on the pituitary are inhibitory at this time and cause the amount of LH and FSH released from the pituitary to decline (i.e., the amplitude of the LH pulse decreases), so gonadotropin levels gradually fall, as seen in Figure 40–3. Inhibin, produced by the ovary, also exerts a negative feedback to selectively decrease serum FSH at this time (Chapter 38). Activin and follistatin, two other peptides released from the ovary, may also regulate FSH production and secretion to a lesser extent, although their levels do not vary appreciably during the menstrual cycle.

At mid-cycle, serum estradiol rises above a threshold level of 150–200 pg/mL for ~36 hours. This sustained elevation of estrogen no longer inhibits gonadotropin release but exerts a brief positive feedback effect on the pituitary to trigger the preovulatory surge of LH and FSH. This effect primarily involves a change in pituitary responsiveness to GnRH. In some species, estrogens may also exert a positive effect on hypothalamic neurons that contributes to a mid-cycle “surge” of GnRH release; this is not yet established in humans. Progesterone may contribute to the mid-cycle LH surge.

The mid-cycle surge in gonadotropins stimulates follicular rupture and ovulation within 1–2 days. The ruptured follicle then develops into the corpus luteum, which produces large amounts of progesterone and lesser amounts of estrogen under the influence of LH during the second half of the cycle. In the absence of pregnancy, the corpus luteum ceases to function, steroid levels drop, and menstruation occurs. When steroid levels drop, the pulse generator reverts to a firing pattern characteristic of the follicular phase, the entire system then resets, and a new ovarian cycle occurs.

Regulation of the frequency and amplitude of gonadotropin secretions by steroids may be summarized as follows: Estrogens act primarily on the pituitary to control the amplitude of gonadotropin pulses, and they may also contribute to the amplitude of GnRH pulses secreted by the hypothalamus.

In the follicular phase of the cycle, estrogens inhibit gonadotropin release but then have a brief mid-cycle stimulatory action that increases the amount released and causes the LH surge. Progesterone, acting on the hypothalamus, exerts the predominant control of the frequency of LH release. It decreases the firing rate of the hypothalamic pulse generator, an action thought to be mediated largely via inhibitory opioid neurons (containing progesterone receptors) that synapse with GnRH neurons. Progesterone also exerts a direct effect on the pituitary to oppose the inhibitory actions of estrogens and thus enhance the amount of LH released (i.e., to increase the amplitude of the LH pulses). These steroid feedback effects, coupled with the intrinsic activity of the hypothalamic GnRH pulse generator, lead to relatively frequent LH pulses of small amplitude in the follicular phase of the cycle, and less frequent pulses of larger amplitude in the luteal phase. Studies in knockout mice indicate that

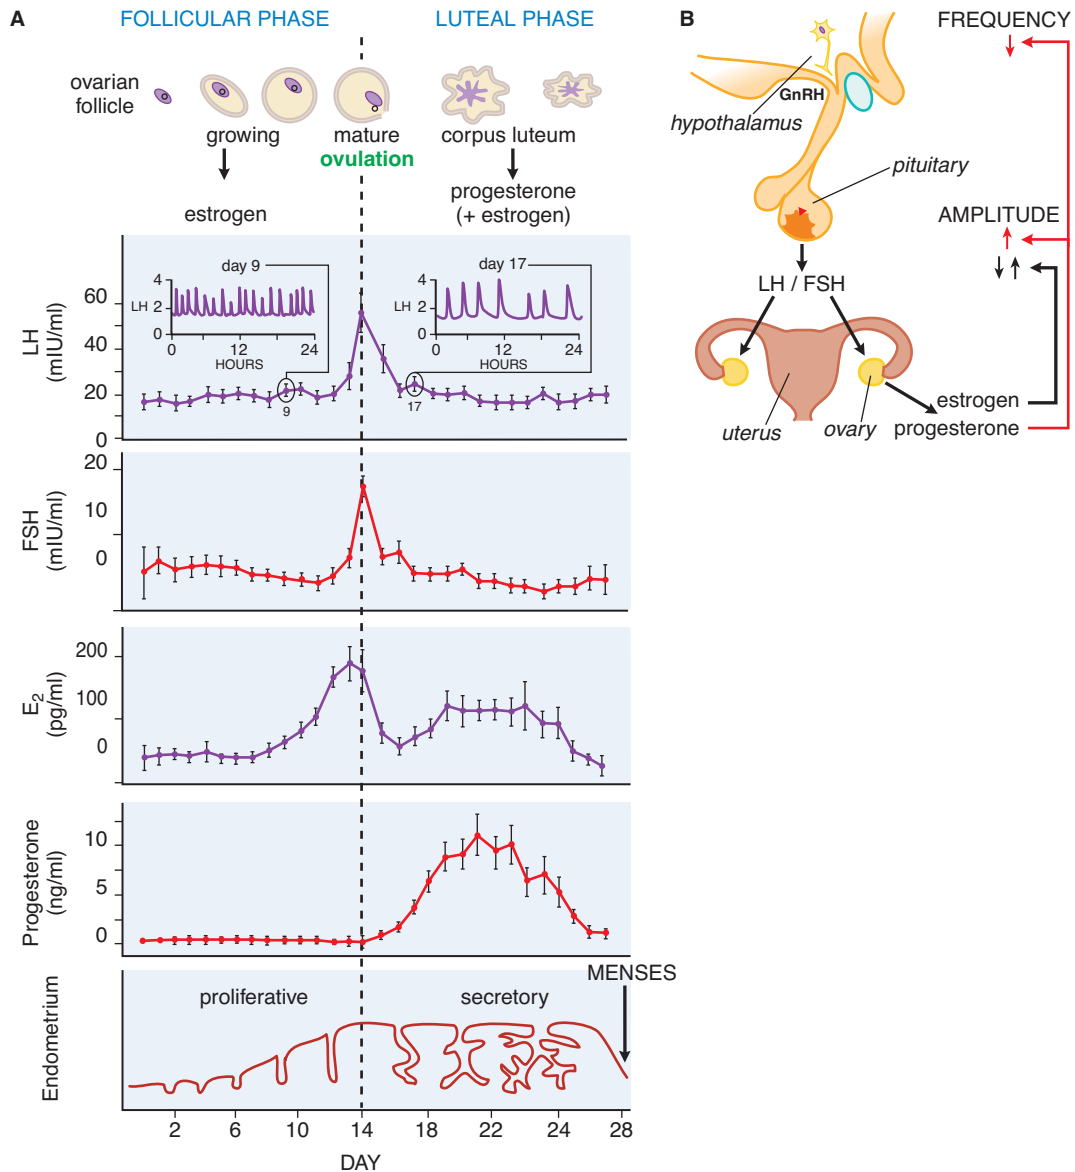

Figure 40-3. Hormonal relationships of the human menstrual cycle.

A. Average daily values of LH, FSH, estradiol (E₂), and progesterone in plasma samples from women exhibiting normal 28-day menstrual cycles. Changes in the ovarian follicle (*top*) and endometrium (*bottom*) also are illustrated schematically. Frequent plasma sampling reveals pulsatile patterns of gonadotropin release. Characteristic profiles are illustrated schematically for the follicular phase (day 9, inset on left) and luteal phase (day 17, inset on right). Both the frequency (number of pulses per hour) and amplitude (extent of change of hormone release) of pulses vary throughout the cycle. (Redrawn with permission from Thorneycroft et al., 1971. Copyright © Elsevier).

B. Major regulatory effects of ovarian steroids on hypothalamic-pituitary function. Estrogen decreases the amount of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) released (i.e., gonadotropin pulse amplitude) during most of the cycle and triggers a surge of LH release only at mid-cycle. Progesterone decreases the frequency of GnRH release from the hypothalamus and thus decreases the frequency of plasma gonadotropin pulses. Progesterone also increases the amount of LH released (i.e., the pulse amplitude) during the luteal phase of the cycle.

ER α (Hewitt and Korach, 2003) and the progesterone receptor PR-A (Conneely et al., 2002) mediate the major actions of estrogens and progestins, respectively, on the hypothalamic-pituitary axis.

In males, testosterone regulates the hypothalamic-pituitary-gonadal axis at both the hypothalamic and pituitary levels, and its negative feedback effect is mediated to a substantial degree by estrogen formed via aromatization. Thus, exogenous estrogen administration decreases LH and testosterone levels in men, and anti-estrogens such as *clomiphene* cause an elevation of serum LH, which can be used to evaluate the male reproductive axis.

When the ovaries are removed or cease to function, there is overproduction of FSH and LH, which are excreted in the urine. Measurement of urinary or plasma LH is valuable to assess pituitary function and the effectiveness of therapeutic doses of estrogen. Although FSH levels will also decline upon estrogen administration, they do not return to normal, secondary to production of inhibin by the ovary (Chapter 38). Consequently, the measurement of FSH levels as a means to monitor the effectiveness of hormone therapy is not clinically useful. Additional features of the regulation of gonadotropin secretion and actions are discussed in Chapters 38 and 66.

Effects of Cyclical Gonadal Steroids on the Reproductive Tract.

The cyclical changes in estrogen and progesterone production by the ovaries regulate corresponding events in the fallopian tubes, uterus, cervix, and vagina. Physiologically, these changes prepare the uterus for implantation, and the proper timing of events in these tissues is essential for pregnancy. If pregnancy does not occur, the endometrium is shed as the menstrual discharge.

The uterus is composed of an endometrium and a myometrium. The endometrium contains an epithelium lining the uterine cavity and an underlying stroma; the myometrium is the smooth muscle component responsible for uterine contractions. These cell layers, the fallopian tubes, cervix, and vagina display a characteristic set of responses to both estrogens and progestins. The changes typically associated with menstruation occur largely in the endometrium (Figure 40–3).

The luminal surface of the endometrium is a layer of simple columnar epithelial secretory and ciliated cells that is continuous with the openings of numerous glands that extend through the underlying stroma to the myometrial border. Fertilization normally occurs in the fallopian tubes, so ovulation, transport of the fertilized ovum through the fallopian tube, and preparation of the endometrial surface must be temporally coordinated for successful implantation.

The endometrial stroma is a highly cellular connective-tissue layer containing a variety of blood vessels that undergo cyclic changes associated with menstruation. The predominant cells are fibroblasts, but macrophages, lymphocytes, and other resident and migratory cell types also are present.

Menstruation marks the start of the menstrual cycle. During the follicular (or proliferative) phase of the cycle, estrogen begins the rebuilding of the endometrium by stimulating proliferation and differentiation. Numerous mitoses become visible, the thickness of the layer increases, and characteristic changes occur in the glands and blood vessels. In rodent models, ER α mediates the uterotrophic effects of estrogens (Hewitt and Korach, 2003). The overall endometrial response involves estrogen- and progesterone-mediated expression of peptide growth factors and receptors, cell cycle genes, and

other regulatory signals. An important response to estrogen in the endometrium and other tissues is induction of the progesterone receptor (PR), which enables cells to respond to this hormone during the second half of the cycle.

In the luteal (or secretory) phase of the cycle, elevated progesterone limits the proliferative effect of estrogens on the endometrium by stimulating differentiation. Major effects include stimulation of epithelial secretions important for implantation of the blastocyst and the characteristic growth of the endometrial blood vessels seen at this time. These effects are mediated by PR-A in animal models (Conneely et al., 2002). Progesterone is thus important in preparation for implantation and for the changes that take place in the uterus at the implantation site (i.e., the decidual response). There is a narrow “window of implantation,” spanning days 19–24 of the endometrial cycle, when the epithelial cells of the endometrium are receptive to blastocyst implantation. Because endometrial status is regulated by estrogens and progestins, the efficacy of some contraceptives may be due in part to production of an endometrial surface that is not receptive to implantation. If pregnancy does not occur, the corpus luteum regresses due to lack of continued LH secretion, estrogen and progesterone levels fall, and the endometrium is shed (Figure 40–3).

If implantation occurs, human chorionic gonadotropin (hCG) (Chapter 38), produced initially by the trophoblast and later by the placenta, interacts with the LH receptor of the corpus luteum to maintain steroid hormone synthesis during the early stages of pregnancy. In later stages the placenta itself becomes the major site of estrogen and progesterone synthesis.

Estrogens and progesterone have important effects on the fallopian tube, myometrium, and cervix. In the fallopian tube, estrogens stimulate proliferation and differentiation, whereas progesterone inhibits these processes. Also, estrogens increase and progesterone decreases tubal muscular contractility, which affects transit time of the ovum to the uterus. Estrogens increase the amount of cervical mucus and its water content to facilitate sperm penetration of the cervix, whereas progesterone generally has opposite effects. Estrogens favor rhythmic contractions of the uterine myometrium, and progesterone diminishes contractions. These effects are physiologically important and may also play a role in the action of some contraceptives.

Metabolic Effects. Estrogens affect many tissues and have many metabolic actions in humans and animals. It is not clear in all cases if effects result directly from hormone actions on the tissue in question or secondarily from actions at other sites. Many nonreproductive tissues, including bone, vascular endothelium, liver, CNS, immune system, gastrointestinal (GI) tract, and heart, express low levels of both estrogen receptors, and the ratio of ER α to ER β varies in a cell-specific manner. Many metabolic effects of estrogens result directly from receptor-mediated events in affected organs. The effects of estrogens on selected aspects of mineral, lipid, carbohydrate, and protein metabolism are particularly important for understanding their pharmacological actions.

Estrogens have positive effects on bone mass (reviewed by Riggs et al., 2002). Bone is continuously remodeled at sites called *bone-remodeling units* by the resorptive action of osteoclasts and the bone-forming action of osteoblasts (Chapter 61). Maintenance of total bone mass requires equal rates of formation and resorption as occurs in early adulthood (ages 18-40 years); thereafter resorption predominates. Osteoclasts and osteoblasts express both $ER\alpha$ and $ER\beta$, with the former apparently playing a greater role. Bone also expresses both androgen and progesterone receptors. Based on animal models, the actions of $ER\alpha$ predominate in bone. Estrogens directly regulate osteoblasts and increase the synthesis of type I collagen, osteocalcin, osteopontin, osteonectin, alkaline phosphatase, and other markers of differentiated osteoblasts. Estrogens also increase osteocyte survival by inhibiting apoptosis. However, the major effect of estrogens is to decrease the number and activity of osteoclasts. Much of the action of estrogens on osteoclasts appears to be mediated by altering cytokine (both paracrine and autocrine) signals from osteoblasts. Estrogens decrease osteoblast and stromal cell production of the osteoclast-stimulating cytokines interleukin (IL)-1, IL-6, and tumor necrosis factor (TNF)- α and increase the production of IGF-1, bone morphogenic protein (BMP)-6, and transforming growth factor (TGF)- β , which are anti-resorptive (reviewed by Spelsberg et al., 1999). Estrogens also increase osteoblast production of the cytokine osteoprotegerin (OPG), a soluble non-membrane-bound member of the TNF superfamily (Chapter 44). OPG acts as a “decoy” receptor that antagonizes the binding of OPG-ligand (OPG-L) to its receptor (termed RANK, or receptor activator of NF- κ B) and prevents the differentiation of osteoclast precursors to mature osteoclasts. Estrogens increase osteoclast apoptosis, either directly or by increasing OPG. Estrogens have anti-apoptotic effects on both osteoblasts and osteocytes in animal models, and this action may be mediated by rapid signal transduction mechanisms (Kousteni et al., 2002; Levin, 2008). Estrogens affect bone growth and epiphyseal closure in both sexes. The importance of estrogen in the male skeleton is illustrated by a man with a completely defective ER who had osteoporosis, unfused epiphyses, increased bone turnover, and delayed bone age (Smith et al., 1994), and by the observation that male idiopathic osteoporosis is associated with reduced $ER\alpha$ expression in both osteocytes and osteoblasts (Braidman et al., 2000).

Estrogens have many effects on lipid metabolism; of major interest are their effects on serum lipoprotein and triglyceride levels (Walsh et al., 1994). In general,

estrogens slightly elevate serum triglycerides and slightly reduce total serum cholesterol levels. More important, they increase high-density lipoprotein (HDL) levels and decrease the levels of low-density lipoprotein (LDL) and lipoprotein A (LPA) (Chapter 31). This beneficial alteration of the ratio of HDL to LDL is an attractive effect of estrogen therapy in postmenopausal women. The initial conclusions from two large clinical trials—the Heart and Estrogen/Progestin Replacement Study, or HERS (Hulley et al., 1998), and the Women’s Health Initiative, or WHI (Anderson et al., 2004; Rossouw et al., 2002)—were that estrogen-progestin or estrogen-only regimens *do not provide any protection from cardiovascular disease*. However, re-examination of the data in women who took hormone replacement within 10 years of the menopause showed a 32% reduction in myocardial infarction (heart attack).

At relatively high concentrations, estrogens have antioxidant activity and may inhibit the oxidation of LDL by affecting superoxide dismutase. Long-term administration of estrogen is associated with decreased plasma renin, angiotensin-converting enzyme, and endothelin-1; expression of the AT_1 receptor for angiotensin II is also decreased. Estrogen actions on the vascular wall include increased production of nitric oxide (NO), which occurs within minutes via a mechanism involving activation of Akt (protein kinase B) (Simoncini et al., 2000), induction of NO synthase, and increased production of prostacyclin. All of these changes promote vasodilation and retard atherogenesis. Estrogens also promote endothelial cell growth while inhibiting the proliferation of vascular smooth muscle cells.

The presence of estrogen receptors in the liver suggests that the beneficial effects of estrogen on lipoprotein metabolism are due partly to direct hepatic actions, but other sites of action cannot be excluded. Estrogens also alter bile composition by increasing cholesterol secretion and decreasing bile acid secretion. This leads to increased saturation of bile with cholesterol and appears to be the basis for increased gallstone formation in some women receiving estrogens. The decline in bile acid biosynthesis may contribute to the decreased incidence of colon cancer in women receiving combined estrogen-progestin treatment. In general, estrogens increase plasma levels of cortisol-binding globulin, thyroxine-binding globulin, and sex hormone-binding globulin (SHBG), which binds both androgens and estrogens. $ER\alpha$ deficiency or aromatase enzyme deficiency in mice is associated with impaired glucose tolerance and other elements of the metabolic syndrome due to increased insulin resistance (Simpson, 2003).

Estrogens alter a number of metabolic pathways that affect the clotting cascade (Mendelsohn and Karas, 1999). Systemic effects include changes in hepatic production of plasma proteins. Estrogens cause a small increase in coagulation factors II, VII, IX, X, and XII, and they decrease the anticoagulation factors protein C, protein S, and antithrombin III (Chapter 30). Fibrinolytic pathways also are affected, and several studies of women treated with estrogen alone or estrogen with a progestin have demonstrated decreased levels of plasminogen-activator inhibitor 1 (PAI-1) protein with a concomitant increase in fibrinolysis (Koh et al., 1997). Thus, estrogens increase

both coagulation and fibrinolytic pathways, and imbalance in these two opposing activities may cause adverse effects.

Estrogen Receptors

Estrogens exert their effects by interaction with receptors that are members of the superfamily of nuclear receptors. The two estrogen receptor genes are located on separate chromosomes: *ESR1* encodes $ER\alpha$, and *ESR2* encodes $ER\beta$. Both ERs are estrogen-dependent nuclear transcription factors that have different tissue distributions and transcriptional regulatory effects on a wide number of target genes (reviewed by Hanstein et al., 2004). Ligands that discriminate between $ER\alpha$ and $ER\beta$ have been developed (Harrington et al., 2003) but are not yet in clinical use. Both $ER\alpha$ and $ER\beta$ exist as multiple mRNA isoforms due to differential promoter use and alternative splicing (reviewed by Kos et al., 2001; Lewandowski et al., 2002). The two human ERs are 44% identical in overall amino acid sequence and share the domain structure common to members of this family. The estrogen receptor is divided into six functional domains: The NH_2 -terminal A/B domain contains the activation function-1 (AF-1) segment, which can activate transcription independently of ligand; the highly conserved C domain comprises the DNA-binding domain, which contains four cysteines arranged in two zinc fingers; the D domain, frequently called the “hinge region,” contains the nuclear localization signal; and the E/F domain has multiple functions, including ligand binding, dimerization, and ligand-dependent transactivation, mediated by the AF-2 domain. There are significant differences between the two receptor isoforms in the ligand-binding domains and in both transactivation domains. Human $ER\beta$ does not appear to contain a functional AF-1 domain. The receptors appear to have different biological functions and respond differently to various estrogenic compounds (Kuiper et al., 1997). However, their high homology in the DNA-binding domains suggests that both receptors recognize similar DNA sequences and hence regulate many of the same target genes.

$ER\alpha$, the first discovered, is expressed most abundantly in the female reproductive tract—especially the uterus, vagina, and ovaries—as well as in the mammary gland, the hypothalamus, endothelial cells, and vascular smooth muscle. $ER\beta$ is expressed most highly in the prostate and ovaries, with lower expression in lung, brain, bone, and vasculature. Many cells express both $ER\alpha$ and $ER\beta$, which can form either homo- or heterodimers. Both forms of ER are expressed on breast cancers, although $ER\alpha$ is believed to be the predominant form responsible for growth regulation (Chapter 63). When co-expressed with $ER\alpha$, $ER\beta$ can inhibit $ER\alpha$ -mediated

transcriptional activation in many cases (Hall and McDonnell, 1999). Polymorphic variants of ER have been identified, but attempts to correlate specific polymorphisms with the frequency of breast cancer (Han et al., 2003), bone mass (Kurabayashi et al., 2004), endometrial cancer (Weiderpass et al., 2000), or cardiovascular disease (Herrington and Howard, 2003) have led to contradictory results.

A cloned G protein-coupled receptor, GPR30, also appears to interact with estrogens in some cell systems, and its participation in the rapid effects of estrogen is an attractive idea. However, four GPR30 knockout (KO) mice strains show inconsistent data with few stress or developmental phenotypes, and there is no consistent overlap of these models with $ER\alpha$ and $ER\beta$ KO phenotypes. There may be interaction/cross-talk between membrane-associated $ER\alpha$ and membrane-localized GPR30 in some cancer cells, but *in vivo* confirmation is lacking (Levin, 2008; Olde et al. 2009).

Mechanism of Action

Both estrogen receptors (ERs) are ligand-activated transcription factors that increase or decrease the transcription of target genes (Figure 40–4). After entering the cell by passive diffusion through the plasma membrane, the hormone binds to an ER in the nucleus. In the nucleus, the ER is present as an inactive monomer bound to heat-shock protein 90 (HSP90), and upon binding estrogen, a change in ER conformation dissociates the heat-shock proteins and causes receptor dimerization, which increases the affinity and the rate of receptor binding to DNA (Cheskis et al., 1997). Homodimers of $ER\alpha$ or $ER\beta$ and $ER\alpha/ER\beta$ heterodimers can be produced depending on the receptor complement in a given cell. The concept of ligand-mediated changes in ER conformation is central to understanding the mechanism of action of estrogen agonists and antagonists. The ER dimer binds to estrogen response elements (EREs), typically located in the promoter region of target genes with the consensus sequence GGTCANNNTGACC, but several similar sequences can act as estrogen response elements in a promoter-specific context. The type of ERE with which ERs interact also regulates the three-dimensional structure of the activated receptor (Hall et al., 2002).

The ER/DNA complex recruits a cascade of co-activator and other proteins to the promoter region of target genes (Figure 40–4B). Three families of proteins interact with ERs. The first of these has the ability to modify nucleosome structure either in an ATP-dependent manner, like SWI/Snf, or by histone methyltransferase (HMT) activity, as in proteins such as PRMT1. The second family comprises the p160/SRC proteins and includes SRC-1 (steroid-receptor co-activator 1), SRC-2, and SRC-3. The third family includes p300/CBP (cyclic AMP response-element binding protein), co-activators

Figure 40-4. Molecular mechanism of action of nuclear estrogen receptor. **A.** Unliganded estrogen receptor (ER) exists as a monomer within the nucleus. **B.** Agonists such as 17 β -estradiol () bind to the ER and cause a ligand-directed change in conformation that facilitates dimerization and interaction with specific estrogen response element (ERE) sequences in DNA. The ER-DNA complex recruits co-activators such as SWI/SNF that modify chromatin structure, and co-activators such as steroid-receptor co-activator-1 (SRC-1) that has histone acetyltransferase (HAT) activity that further alters chromatin structure. This remodeling facilitates the exchange of the recruited proteins such that other co-activators (e.g., p300 and the TRAP complex) associate on the target gene promoter and proteins that comprise the general transcription apparatus (GTA) are recruited, with subsequent synthesis of mRNA. **C.** Antagonists such as tamoxifen (T) also bind to the ER but produce a different receptor conformation. The antagonist-induced conformation also facilitates dimerization and interaction with DNA, but a different set of proteins called co-repressors, such as nuclear-hormone receptor co-repressor (NcoR), are recruited to the complex. NcoR further recruits proteins such as histone deacetylase I (HDAC1) that act on histone proteins to stabilize nucleosome structure and prevent interaction with the GTA.

that are targets of several signal transduction cascades and may integrate function among diverse pathways and the basal transcriptional apparatus. Agonist-bound ERs appear initially to recruit SWI/Snf and HMT members that modify nucleosome structure and facilitate the subsequent recruitment of p160 members and p300 proteins (Metivier et al., 2003). The co-activators and p300 proteins have histone acetyltransferase (HAT) activity. Acetylation of histones further alters chromatin structure in the promoter region of target genes and allows the proteins that make up the general transcription apparatus to assemble and initiate transcription.

Interaction of ERs with antagonists also promotes dimerization and DNA binding. However, an antagonist produces a conformation of ER that is different from the agonist-occupied receptor (Smith and O'Malley, 2004; Wijayarathne et al., 1999). The antagonist-induced conformation facilitates binding of co-repressors such as NCoR/SMRT (nuclear hormone receptor co-repressor/silencing mediator of retinoid and thyroid receptors) (Figure 40-4C). The co-repressor/ER complex then further recruits other proteins with histone deacetylase activity such as HDAC1. Deacetylation of histones alters chromatin conformation and reduces the ability of the general transcription apparatus to form initiation complexes.

Besides co-activators and co-repressors, both ER α and ER β can interact physically with other transcription factors such as Sp1 (Saville et al., 2000) or AP-1 (Paech et al., 1997), and these protein-protein interactions provide an alternate mechanism of action. In these circumstances, ER-ligand complexes interact with Sp1 or AP-1 that is already bound to its specific regulatory element, such that the ER complex does not interact directly with an ERE. This may explain how estrogens are able to regulate genes that lack a consensus ERE. Responses to agonists and antagonists mediated by these protein-protein interactions also are ER isoform- and promoter-specific. For example, 17 β -estradiol induces transcription of a target gene controlled by an AP-1 site in the presence of an ER α /AP-1 complex but inhibits transcription in the presence of an ER β /AP-1 complex. Conversely, anti-estrogens are potent activators of ER β /AP-1 but not of ER α /AP-1 complexes.

Other signaling systems may activate nuclear ER by ligand-independent mechanisms. Phosphorylation of ER α at serine 118 by MAP kinase activates the receptor (Kato et al., 1995). Similarly, PI-3-kinase-activated Akt directly phosphorylates ER α , causing ligand-independent activation of estrogen-target genes (Simoncini et al., 2000). This provides a means of cross-talk between membrane-bound receptor pathways (i.e., EGF/IGF-1) that activate MAPK and the nuclear ER. In a reciprocal fashion ER may interact directly with members of the Src-Shc/Erk signaling pathway. Activation of Erk by an estrogen that is a novel ER and androgen receptor (AR) agonist is thought to be responsible for the anti-apoptotic action of this drug in bone (reviewed in Manolagas et al., 2002).

Numerous studies indicate that some estrogen receptors are located on the plasma membrane of cells. This cellular pool form of the ER is encoded by the same genes that encode ER α and ER β (Pedram, 2006) but are transported to the plasma membrane and reside mainly in caveolae. Translocation to the membrane by all sex steroid receptors is mediated by palmitoylation of a nine-amino acid motif in the respective E domains of the receptors (reviewed in Levin, 2008). These membrane-localized ERs mediate the rapid activation of some proteins such as MAPK (phosphorylated in several cell types) and the rapid increase in cyclic AMP caused by the hormone (Aronica and Katzenellenbogen, 1993). The finding that MAPK is activated by estradiol provides an additional level of cross-talk with growth factor receptors for IGF-1 and EGF, which can activate multiple kinase pathways.

Absorption, Fate, and Elimination

Various estrogens are available for oral, parenteral, transdermal, or topical administration. Given the lipophilic nature of estrogens, absorption generally is good with the appropriate preparation. Aqueous or oil-based esters of estradiol are available for intramuscular injection, ranging in frequency from every week to once per month. Conjugated estrogens are available for IV or IM administration. Transdermal patches that are changed once or twice weekly deliver estradiol continuously through the skin. Preparations are available for topical use in the vagina or for application to the skin. For many therapeutic uses, estrogen preparations are available in combination with a progestin. All estrogens

are labeled with precautionary statements urging the prescribing of the lowest effective dose and for the shortest duration consistent with the treatment goals and risks for each individual patient.

Oral administration is common and may use estradiol, conjugated estrogens, esters of estrone and other estrogens, and *ethinyl estradiol (in combination with a progestin)*. Estradiol is available in nonmicronized (FEMTRACE) and micronized preparations (ESTRACE, others). The micronized formulations yield a large surface for rapid absorption to partially overcome low absolute oral bioavailability due to first-pass metabolism (Fotherby, 1996). Addition of the ethinyl substituent at C17 (ethinyl estradiol) inhibits first-pass hepatic metabolism. Other common oral preparations contain conjugated equine estrogens (PREMARIN), which are primarily the sulfate esters of estrone, equilin, and other naturally occurring compounds; *esterified esters* (MENEST); or mixtures of synthetic conjugated estrogens prepared from plant-derived sources (CENESTIN; ENJUVIA). These are hydrolyzed by enzymes present in the lower gut that remove the charged sulfate groups and allow absorption of estrogen across the intestinal epithelium. In another oral preparation, *estropipate* (ORTHO-EST, OGEN, others), estrone is solubilized as the sulfate and stabilized with piperazine. Due largely to differences in metabolism, the potencies of various oral preparations differ widely; ethinyl estradiol, e.g., is much more potent than conjugated estrogens.

A number of foodstuffs and plant-derived products, largely from soy, are available as nonprescription items and often are touted as providing benefits similar to those from compounds with established estrogenic activity. These products may contain flavonoids such as genistein (Table 40-1), which display estrogenic activity in laboratory tests, albeit generally much less than that of estradiol. In theory, these preparations could produce appreciable estrogenic effects, but their efficacy at relevant doses has not been established in human trials (Fitzpatrick, 2003).

Administration of estradiol via transdermal patches (ALORA, CLIMARA, ESTRADERM, VIVELLE, others) provides slow, sustained release of the hormone, systemic distribution, and more constant blood levels than oral dosing. Estradiol is also available as a topical emulsion (ESTRASORB), applied to the upper thigh and calf, or as a gel (ESTROGEL), applied once daily to the arm. The transdermal route does not lead to the high level of the drug that occur in the portal circulation after oral administration, and it is thus expected to minimize hepatic effects of estrogens (e.g., effects on hepatic protein synthesis, lipoprotein profiles, and triglyceride levels).

Other preparations are available for intramuscular injection. When dissolved in oil and injected, esters of estradiol are well absorbed. The aryl and alkyl esters of estradiol become less polar as the size of the substituents increases; correspondingly, the rate of absorption of oily preparations is progressively slowed, and the duration of action can be prolonged. A single therapeutic dose of compounds such as *estradiol valerate* (DELESTROGEN, others) or *estradiol cypionate* (DEPO-ESTRADIOL, others) may be absorbed over several weeks following a single intramuscular injection.

Preparations of estradiol (ESTRACE) and conjugated estrogen (PREMARIN) creams are available for topical administration to the vagina. These are effective locally, but systemic effects also are possible due to significant absorption. A 3-month vaginal ring (ESTRING,

FEMRING) may be used for slow release of estradiol, and tablets are also available for vaginal use (VAGIFEM).

Estradiol, ethinyl estradiol, and other estrogens are extensively bound to plasma proteins. Estradiol and other naturally occurring estrogens are bound mainly to SHBG and to a lesser degree to serum albumin. In contrast, ethinyl estradiol is bound extensively to serum albumin but not SHBG. Due to their size and lipophilic nature, unbound estrogens distribute rapidly and extensively.

Variations in estradiol metabolism occur and depend on the stage of the menstrual cycle, menopausal status, and several genetic polymorphisms (Herrington and Klein, 2001). In general, the hormone undergoes rapid hepatic biotransformation, with a plasma $t_{1/2}$ measured in minutes. Estradiol is converted primarily by 17 β -hydroxysteroid dehydrogenase to estrone, which undergoes conversion by 16 α -hydroxylation and 17-keto reduction to estriol, the major urinary metabolite. A variety of sulfate and glucuronide conjugates also are excreted in the urine. Lesser amounts of estrone or estradiol are oxidized to the 2-hydroxycatechols by CYP3A4 in the liver and by CYP1A in extrahepatic tissues or to 4-hydroxycatechols by CYP1B1 in extrahepatic sites, with the 2-hydroxycatechol being formed to a greater extent. The 2- and 4-hydroxycatechols are largely inactivated by catechol-*O*-methyl transferases (COMTs). However, smaller amounts may be converted by CYP- or peroxidase-catalyzed reactions to yield semiquinones or quinones that are capable of forming DNA adducts or of generating (via redox cycling) reactive oxygen species that could oxidize DNA bases (Yue et al., 2003).

Estrogens also undergo enterohepatic recirculation via (1) sulfate and glucuronide conjugation in the liver, (2) biliary secretion of the conjugates into the intestine, and (3) hydrolysis in the gut (largely by bacterial enzymes) followed by reabsorption.

Many other drugs and environmental agents (e.g., cigarette smoke) act as inducers or inhibitors of the various enzymes that metabolize estrogens, and thus have the potential to alter their clearance. Consideration of the impact of these factors on efficacy and untoward effects is increasingly important with the decreased doses of estrogens currently employed for both menopausal hormone therapy and contraception.

Ethinyl estradiol is cleared much more slowly than estradiol due to decreased hepatic metabolism, and the elimination-phase $t_{1/2}$ in various studies ranges from 13 to 27 hours. Unlike estradiol, the primary route of biotransformation of ethinyl estradiol is via 2-hydroxylation and subsequent formation of the corresponding 2- and 3-methyl ethers. *Mestranol*, another semisynthetic estrogen and a component of some combination oral contraceptives, is the 3-methyl ether of ethinyl estradiol. In the body it undergoes rapid hepatic demethylation to ethinyl estradiol, which is its active form (Fotherby, 1996).

Untoward Responses

Estrogens are highly efficacious, but they do carry a number of risks. Many concerns arose initially from studies of early oral contraceptives, which contained high doses of estrogens. Oral contraceptives now contain much lower amounts of both estrogen and progestins, and this has significantly diminished the risks associated with their use. Nevertheless, major concerns about the use of estrogens remain today, especially regarding cancer, thromboembolic disease, and gallbladder disease.

Concern About Carcinogenic Actions. The risk of developing breast, endometrial, cervical, and vaginal cancer is probably the major concern for the use of estrogens and oral contraceptives. Landmark studies (Greenwald et al., 1971; Herbst et al., 1971) reported an increased incidence of vaginal and cervical adenocarcinoma in female offspring of mothers who had taken diethylstilbestrol (DES) during the first trimester of pregnancy. The incidence of clear cell vaginal and cervical adenocarcinoma in women who were exposed to DES *in utero* was 0.01-0.1% (Food and Drug Administration, 1985); these findings established for the first time that developmental exposure to estrogens was associated with an increase in a human cancer. Estrogen use during pregnancy also can increase the incidence of nonmalignant genital abnormalities in both male and female offspring. Thus, pregnant patients should not be given estrogens because of the possibility of such reproductive tract toxicities.

The use of unopposed estrogen for hormone treatment in postmenopausal women increases the risk of endometrial carcinoma by 5- to 15-fold (Shapiro et al., 1985). This increased risk can be prevented if a progestin is co-administered with the estrogen (Pike et al., 1997), and this is now standard practice.

The association between estrogen and/or estrogen-progestin use and breast cancer is of great concern. The results of two large randomized clinical trials of estrogen/progestin and estrogen-only (i.e., the two arms of WHI) in postmenopausal women clearly established a small but significant increase in the risk of breast cancer, apparently due to the medroxyprogesterone (Anderson et al., 2004; Rossouw et al., 2002). In the WHI study, an estrogen-progestin combination increased the total risk of breast cancer by 25%; the absolute increase in attributable cases of disease was 6 per 1000 women and required 3 or more years of treatment. In women without a uterus who received estrogen alone, the relative risk of breast cancer was actually decreased by 23%, and the decrease only narrowly missed reaching statistical significance. Interestingly, the incidence of colon cancer was reduced by 26% in the WHI trial.

The Million Women Study (MWS) in the U.K. was a cohort study rather than a clinical trial (Beral et al., 2003). It surveyed >1 million women; about half had received some type of hormone treatment and half had never used them. Those receiving an estrogen-progestin combination had an increased relative risk of invasive breast cancer of 2, and those receiving estrogen alone had an increased relative risk of 1.3, but the increase in actual attributable cases of the disease was again small.

Both the WHI and MWS data are thus consistent with earlier studies indicating that the progestin component (e.g., medroxyprogesterone) in combined hormone-replacement therapy plays a major role in this increased risk of breast cancer (Ross et al., 2000; Schairer et al., 2000). Importantly, although long-term data have not accumulated for the WHI trials, the available data suggest that the excess risk of breast cancer associated with menopausal hormone use appears to abate 5 years after discontinuing therapy. Thus, hormone replacement therapy for ≤ 5 years is often prescribed to mitigate hot flashes and likely has a minimal effect on the risk of breast cancer.

Historically, the carcinogenic actions of estrogens were thought to be related to their trophic effects. An increase in cell proliferation would be expected to cause an increase in spontaneous errors associated with DNA replication, and estrogens would then enhance the growth of clones with mutations introduced by this or other mechanisms (e.g., chemical carcinogens). More recently, another mechanism has been proposed. If catechol estrogens, especially the

4-hydroxycatechols, are converted to semiquinones or quinones prior to “inactivation” by COMT, these products, or reactive oxygen species generated during subsequent biotransformations, may cause direct chemical damage to DNA bases (Yue et al., 2003). In this regard, CYP1B1, which has specific estrogen-4-hydroxylase activity, is present in tissues such as uterus, breast, ovary, and prostate, which often give rise to hormone-responsive cancers (Yue et al., 2003).

Metabolic and Cardiovascular Effects. Although they may slightly elevate plasma triglycerides, estrogens themselves generally have favorable overall effects on plasma lipoprotein profiles. However, as noted in a later section dealing with hormone-replacement regimens, progestins may reduce the favorable actions of estrogens. In contrast, estrogens do increase cholesterol levels in bile and cause a relative 2- to 3-fold increase in gallbladder disease. Currently prescribed doses of estrogens generally do not increase the risk of hypertension, and estrogen engaging the ER β receptor typically reduces blood pressure.

A number of observational studies, clinical trials using intermediate markers of cardiovascular disease, and numerous animal studies suggested that estrogen therapy in postmenopausal women would reduce the risk of cardiovascular disease by 35-50% (Manson and Martin, 2001). However, two recent randomized clinical trials have not found such protection. HERS (Hulley et al., 1998) followed women with established coronary heart disease (CHD) and found that estrogen plus a progestin increased the relative risk of nonfatal myocardial infarction or CHD death within 1 year of treatment, and found no overall change in 5 years. The HERS II follow-up (Grady et al., 2002) found no overall change in the incidence of CHD after 6.8 years of the treatment. These results indicate no role for hormone replacement in the secondary prevention of atherosclerotic heart disease. In the WHI trials, women *without* existing CHD were treated with an estrogen plus progestin (Rossouw et al., 2002); protective effects were seen but only when hormone replacement was initiated within 10 years of menopause.

It is clear, however, that oral estrogens increase the risk of thromboembolic disease in healthy women and in women with pre-existing cardiovascular disease (Grady et al., 2000). The increase in absolute risk is small but significant. In the WHI, e.g., an estrogen-progestin combination led to an increase in eight attributable cases of stroke per 10,000 older women and a similar increase in pulmonary embolism (Rossouw et al., 2002). The latter was seen mainly in women who concomitantly smoked cigarettes.

Effects on Cognition. Several retrospective studies had suggested that estrogens had beneficial effects on cognition and delayed the onset of Alzheimer’s disease (Green and Simpkins, 2000). However, the Women’s Health Initiative Memory Study (WHIMS) of a group of women ≥ 65 years of age (Shumaker et al., 2003) found that estrogen-progestin therapy was associated with a doubling in the number of women diagnosed with probable dementia, and no benefit of hormone treatment on global cognitive function was observed (Rapp et al., 2003). Women in the estrogen-only arm also showed a comparable decrease in cognitive function (Espeland et al., 2004), implicating estrogens in these cognitive changes.

Other Potential Untoward Effects. Nausea and vomiting are an initial reaction to estrogen therapy in some women, but these effects may disappear with time and may be minimized by taking estrogens with food or just before sleep. Fullness and tenderness of the breasts

and edema may occur but sometimes can be diminished by lowering the dose. A more serious concern is that estrogens may cause severe migraine in some women. Estrogens also may reactivate or exacerbate endometriosis.

Therapeutic Uses

The two major uses of estrogens are for menopausal hormone therapy (MHT) and as components of combination oral contraceptives (see final section of chapter), and the pharmacological considerations for their use and the specific drugs and doses used differ in these settings. Historically, conjugated estrogens have been the most common agents for postmenopausal use (0.625 mg/day most often used). In contrast, most combination oral contraceptives in current use employ 20-35 μg /day of ethinyl estradiol. These preparations differ widely in their oral potencies (e.g., a dose of 0.625 mg of conjugated estrogens generally is considered equivalent to 5-10 μg of ethinyl estradiol). Thus, the “effective” dose of estrogen used for MHT is less than that in oral contraceptives when one considers potency. Furthermore, in the last two decades the doses of estrogens employed in both settings have decreased substantially. The untoward effects of the 20- to 35- μg doses now commonly used thus have a lower incidence and severity than those reported in older studies (e.g., with oral contraceptives that contained 50-150 μg of ethinyl estradiol or mestranol).

Menopausal Hormone Therapy. The established benefits of estrogen therapy in postmenopausal women include amelioration of vasomotor symptoms and the prevention of bone fractures and urogenital atrophy.

Vasomotor Symptoms. The decline in ovarian function at menopause is associated with vasomotor symptoms in most women. The characteristic hot flashes may alternate with chilly sensations, inappropriate sweating, and (less commonly) paresthesias. Treatment with estrogen is specific and is the most efficacious pharmacotherapy for these symptoms (Belchetz, 1994). If estrogen is contraindicated or otherwise undesirable, other options may be considered. Medroxyprogesterone acetate (discussed in the later section on progestins) may provide some relief of vasomotor symptoms for certain patients, and the α_2 adrenergic agonist clonidine diminishes vasomotor symptoms in some women, presumably by blocking the CNS outflow that regulates blood flow to cutaneous vessels. In many women, hot flashes diminish within several years; when prescribed for this purpose the dose and duration of estrogen use should thus be the minimum necessary to provide relief.

Osteoporosis. Osteoporosis is a disorder of the skeleton associated with the loss of bone mass (Chapter 44). The result is thinning and weakening of the bones and an increased incidence of fractures, particularly compression fractures of the vertebrae and minimal-trauma fractures of the hip and wrist. The frequency and severity of these fractures and their associated complications (e.g., death and permanent disability) are a major public health problem, especially as the

population continues to age. Osteoporosis is an indication for estrogen therapy, which clearly is efficacious in decreasing the incidence of fractures. However, because of the risks associated with estrogen use, first-line use of other drugs, such as bisphosphonates, should be considered (Chapter 44). Nevertheless, it is important to note that most fractures in the postmenopausal period occur in women without a prior history of osteoporosis, and estrogens are the most efficacious agents available for prevention of fractures at all sites in such women (Anderson et al., 2004; Rossouw et al., 2002).

The primary mechanism by which estrogens act is to decrease bone resorption; consequently, estrogens are more effective at preventing rather than restoring bone loss (Belchetz, 1994; Prince et al., 1991). Estrogens are most effective if treatment is initiated before significant bone loss occurs, and their maximal beneficial effects require continuous use; bone loss resumes when treatment is discontinued. Other options for treatment of osteoporosis are presented in Chapter 44. An appropriate diet with adequate intake of Ca^{2+} and vitamin D and weight-bearing exercise enhance the effects of estrogen treatment. Public health efforts to improve diet and exercise patterns in girls and young women also are rational approaches to increase bone mass.

Vaginal Dryness and Urogenital Atrophy. Loss of tissue lining the vagina or bladder leads to a variety of symptoms in many postmenopausal women (Robinson and Cardozo, 2003). These include dryness and itching of the vagina, dyspareunia, swelling of tissues in the genital region, pain during urination, a need to urinate urgently or often, and sudden or unexpected urinary incontinence. When estrogens are being used solely for relief of vulvar and vaginal atrophy, local administration as a vaginal cream, ring device, or tablets may be considered.

Cardiovascular Disease. The incidence of cardiovascular disease is low in premenopausal women, rising rapidly after menopause, and epidemiological studies consistently showed an association between estrogen use and reduced cardiovascular disease in postmenopausal women. Furthermore, estrogens produce a favorable lipoprotein profile, promote vasodilation, inhibit the response to vascular injury, and reduce atherosclerosis. Studies such as these led to the widespread use of estrogen for prevention of cardiovascular disease in postmenopausal women (Mendelsohn and Karas, 1999). As discussed earlier, estrogens promote coagulation and thromboembolic events. Randomized prospective studies (Grady et al., 2002; Rossouw et al., 2002) unexpectedly have indicated that the incidence of heart disease and stroke in older postmenopausal women treated with conjugated estrogens and a progestin was initially increased, although the trend reversed with time. However, as mentioned, combined estrogen-progestin therapy is associated with a decrease in heart attacks in younger women.

Other Therapeutic Effects. Many other changes occur in postmenopausal women, including a general thinning of the skin; changes in the urethra, vulva, and external genitalia; and a variety of changes including headache, fatigue, and difficulty concentrating. Chronic lack of sleep created by hot flashes and other vasomotor symptoms may be contributing factors. Estrogen replacement may help alleviate or lessen some of these via direct actions (e.g., improvement of vasomotor symptoms) or secondary effects resulting in an improved feeling of well-being (Belchetz, 1994). The WHI demonstrated that a conjugated estrogen in combination with a progestin reduces the risk of colon cancer by roughly one-half in postmenopausal women (Rossouw et al., 2002).

Menopausal Hormone Regimens. In the 1960s and 1970s, there was an increase in *estrogen-replacement therapy*, or ERT (i.e., estrogens alone), in postmenopausal women, primarily to reduce vasomotor symptoms, vaginitis, and osteoporosis. About 1980, epidemiological studies indicated that this treatment increased the incidence of endometrial carcinoma. This led to the use of *hormone-replacement therapy*, or HRT, that includes a progestin to limit estrogen-related endometrial hyperplasia. Although the actions of progesterone on the endometrium are complex, its effects on estrogen-induced hyperplasia may involve a decrease in estrogen-receptor content, increased local conversion of estradiol to the less potent estrone via the induction of 17β hydroxysteroid dehydrogenase in the tissue and/or the conversion of the endometrium from a proliferative to a secretory state. Postmenopausal HRT, when indicated, should include both an estrogen and progestin for women with a uterus (Belchetz, 1994). For women who have undergone a hysterectomy, endometrial carcinoma is not a concern, and estrogen alone avoids the possible deleterious effects of progestins.

Conjugated estrogens and medroxyprogesterone acetate (MPA) historically have been used most commonly in menopausal hormone regimens, although estradiol, estrone, and estriol have been used as estrogens, and *norethindrone*, *norgestimate*, *levonorgestrel*, *norethisterone*, and *progesterone* also have been widely used (especially in Europe). Various “continuous” or “cyclic” regimens have been used; the latter regimens include drug-free days. An example of a cyclic regimen is as follows: (1) administration of an estrogen for 25 days; (2) the addition of MPA for the last 12–14 days of estrogen treatment; and (3) 5–6 days with no hormone treatment, during which withdrawal bleeding normally occurs due to breakdown and shedding of the endometrium. Continuous administration of combined estrogen plus progestin does not lead to regular, recurrent endometrial shedding but may cause intermittent spotting or bleeding, especially in the first year of use. Other regimens include a progestin intermittently (e.g., every third month), but the long-term endometrial safety of these regimens remains to be firmly established. PREMPRO (conjugated estrogens plus MPA given as a fixed dose daily) and PREMPHASE (conjugated estrogens given for 28 days plus MPA given for 14 of 28 days) are widely used combination formulations. Other combination products available in the U.S. are FEMHRT (ethinyl estradiol plus norethindrone acetate), ACTIVELLA (estradiol plus norethindrone), PREFEST (estradiol and norgestimate), and ANGIQ (estradiol and drospirenone). Doses and regimens are usually adjusted empirically based on control of symptoms, patient acceptance of bleeding patterns, and/or other untoward effects.

Another pharmacological consideration is the route of estrogen administration. Oral administration exposes the liver to higher concentrations of estrogens than does transdermal administration. Either route effectively relieves vasomotor symptoms and protects against bone loss. Oral but not transdermal estrogen may increase SHBG, other binding globulins, and angiotensinogen; the oral route might be expected to cause greater increases in the cholesterol

content of the bile. Transdermal estrogen appears to cause smaller beneficial changes in LDL and HDL profiles (~50% of those seen with the oral route) (Walsh et al., 1994) but may be preferred in women with hypertriglyceridemia.

Tibolone (LIVIAL) is widely used in the E.U. for treatment of vasomotor symptoms and prevention of osteoporosis but is not currently approved in the U.S. The parent compound itself is devoid of activity, but it is metabolized in a tissue-selective manner to three metabolites that have predominantly estrogenic, progestogenic, and androgenic activities. The drug appears to increase bone mineral density and decrease vasomotor symptoms without stimulating the endometrium, but its effects on fractures, breast cancer, and long-term outcomes remain to be established (Modelska and Cummings, 2002).

Regardless of the specific agent or regimen, menopausal hormone therapy with estrogens should use the lowest dose and shortest duration necessary to achieve an appropriate therapeutic goal.

Estrogen Treatment in the Failure of Ovarian Development. In several conditions (e.g., Turner's syndrome), the ovaries do not develop and puberty does not occur. Therapy with estrogen at the appropriate time replicates the events of puberty, and androgens (Chapter 41) and/or growth hormone (Chapter 38) may be used concomitantly to promote normal growth. Although estrogens and androgens promote bone growth, they also accelerate epiphyseal fusion, and their premature use can thus result in a shorter ultimate height.

SELECTIVE ESTROGEN RECEPTOR MODULATORS AND ANTI-ESTROGENS

In the past, estrogen pharmacology was based on a simple model of an agonist binding to a single ER that subsequently affected transcription by the same molecular mechanism in all target tissues and of antagonists that acted by simple competition with agonists for binding. This simple concept is no longer valid. By altering the conformation of the two different ERs and thereby changing interactions with co-activators and co-repressors in a cell-specific and promoter-specific contexts, ligands may have a broad spectrum of activities from purely anti-estrogenic in all tissues, to partially estrogenic in some tissues with anti-estrogenic or no activities in others, to purely estrogenic activities in all tissues. The elucidation of these concepts has been a major breakthrough in estrogen pharmacology and should permit the rational design of drugs with very selective patterns of estrogenic activity (Smith and O'Malley, 2004).

Selective Estrogen Receptor Modulators: Tamoxifen, Raloxifene, and Toremifene. Selective estrogen receptor modulators, or SERMs, are compounds with tissue-selective actions. The pharmacological goal of these drugs is to produce beneficial estrogenic actions in certain tissues (e.g., bone, brain, and liver) during

postmenopausal hormone therapy but antagonist activity in tissues such as breast and endometrium, where estrogenic actions (e.g., carcinogenesis) might be deleterious. Currently approved drugs in the U.S. in this class are tamoxifen citrate, raloxifene hydrochloride (EVISTA), and toremifene (FARESTON), which is chemically related and has similar actions to tamoxifen. Tamoxifen and toremifene are used for the treatment of breast cancer, and raloxifene is used primarily for the prevention and treatment of osteoporosis and to reduce the risk of invasive breast cancer in high-risk postmenopausal women. They are considered in detail in Chapter 63.

Anti-Estrogens: Clomiphene and Fulvestrant. These compounds are distinguished from the SERMs in that they are pure antagonists in all tissues studied. Clomiphene (CLOMID, SEROPHENE, others) is approved for the treatment of infertility in anovulatory women, and fulvestrant (FASLODEX) is used for the treatment of breast cancer in women with disease progression after tamoxifen.

Chemistry. The structures of the *trans*-isomer of tamoxifen, and of raloxifene, *trans*-clomiphene (enclomiphene), and fulvestrant are:

Tamoxifen is a triphenylethylene with the same stilbene nucleus as DES; compounds of this class display a variety of estrogenic and anti-estrogenic activities. In general, the *trans* conformations have anti-estrogenic activity, whereas the *cis* conformations display estrogenic activity. However, the pharmacological activity of the *trans* compound depends on the species, target tissue, and gene. Hepatic metabolism produces primarily *N*-desmethyltamoxifen, which has affinity for ER comparable to that of tamoxifen, and lesser amounts of the highly active 4-hydroxy metabolite, which has a 25-50 times higher affinity for both ER α and ER β than does tamoxifen (Kuiper et al., 1997). Tamoxifen is marketed as the pure *trans*-isomer. Toremifene is a triphenylethylene with a chlorine substitution at the R2 position.

Raloxifene is a polyhydroxylated nonsteroidal compound with a benzothiophene core. Raloxifene binds with high affinity for both ER α and ER β (Kuiper et al., 1997).

Clomiphene citrate is a triphenylethylene; its two isomers, zuclophene (*cis*-clomiphene) and enclomiphene (*trans*-clomiphene), are a weak estrogen agonist and a potent antagonist, respectively. Clomiphene binds to both ER α and ER β , but the individual isomers have not been examined (Kuiper et al., 1997).

Fulvestrant is a 7 α -alkylamide derivative of estradiol that interacts with both ER α and ER β (Van Den Bemd et al., 1999).

Pharmacological Effects

Tamoxifen exhibits anti-estrogenic, estrogenic, or mixed activity depending on the species and target gene measured. In clinical tests or laboratory studies with human cells, the drug's activity depends on the tissue and end point measured. For example, tamoxifen inhibits the proliferation of cultured human breast cancer cells and reduces tumor size and number in women (reviewed in Jaiyesimi et al., 1995), and yet it stimulates proliferation of endometrial cells and causes endometrial thickening (Lahti et al., 1993). The drug has an antiresorptive effect on bone, and in humans it decreases total cholesterol, LDL, and LPA but does not increase HDL and triglycerides (Love et al., 1994). Tamoxifen treatment causes a 2- to 3-fold increase in the relative risk of deep vein thrombosis and pulmonary embolism and a roughly 2-fold increase in endometrial carcinoma (Smith, 2003). Tamoxifen produces hot flashes and other adverse effects, including cataracts and nausea. Due to its agonist activity in bone, it does not increase the incidence of fractures when used in this setting.

Raloxifene is an estrogen agonist in bone, where it exerts an antiresorptive effect. It reduces the number of vertebral fractures by up to 50% in a dose-dependent manner (Delmas et al., 1997; Ettinger et al., 1999). The drug also acts as an estrogen agonist in reducing total cholesterol and LDL, but it does not increase HDL or normalize plasminogen-activator inhibitor 1 in

postmenopausal women (Walsh et al., 1998). Raloxifene does not cause proliferation or thickening of the endometrium. Preclinical studies indicate that raloxifene has an antiproliferative effect on ER-positive breast tumors and on proliferation of ER-positive breast cancer cell lines (Hol et al., 1997) and significantly reduces the risk of ER-positive but not ER-negative breast cancer (Cummings et al., 1999). Raloxifene does not alleviate the vasomotor symptoms associated with menopause. Adverse effects include hot flashes and leg cramps and a 3-fold increase in deep vein thrombosis and pulmonary embolism (Cummings et al., 1999).

Initial animal studies with clomiphene showed slight estrogenic activity and moderate anti-estrogenic activity, but the most striking effect was the inhibition of pituitary gonadotropes. In contrast, the most prominent effect in women was enlargement of the ovaries and the drug-induced ovulation in many patients with amenorrhea, polycystic ovarian syndrome, and dysfunctional bleeding with anovulatory cycles. This is the basis for clomiphene's major pharmacological use: to induce ovulation in women with a functional hypothalamic-hypophyseal-ovarian system and adequate endogenous estrogen production. In some cases, clomiphene is used in conjunction with human gonadotropins (Chapter 38) to induce ovulation.

Fulvestrant and its less potent forerunner ICI 164,384 have been purely anti-estrogenic in studies to date. *In vitro*, fulvestrant was more potent than 4-hydroxytamoxifen (DeFriend et al., 1994) in inhibiting proliferation of breast cancer cells, and in clinical trials it is efficacious in treating tamoxifen-resistant breast cancers (Robertson et al., 2003).

All of these agents bind to the ligand-binding pocket of both ER α and ER β and competitively block estradiol binding. However, the conformation of the ligand-bound ERs is different with different ligands (Smith and O'Malley, 2004), and this has two important mechanistic consequences. The distinct ER-ligand conformations recruit different co-activators and co-repressors onto the promoter of a target gene by differential protein-protein interactions at the receptor surface. The tissue-specific actions of SERMs thus can be explained in part by the distinct conformation of the ER when occupied by different ligands, in combination with different co-activator and co-repressor levels in different cell types that together affect the nature of ER complexes formed in a tissue-selective fashion.

The conformation of ERs, especially in the AF-2 domain, determines whether a co-activator or a co-repressor will be recruited to the ER-DNA complex (Smith and O'Malley, 2004). Whereas 17 β -estradiol induces a conformation that recruits co-activators to the receptor, tamoxifen induces a conformation that permits the recruitment of the co-repressor to both ER α and ER β . The agonist activity of tamoxifen seen in tissues such as the endometrium is mediated by the ligand-independent AF-1 transactivation domain of ER α ; because ER β does not contain a functional AF-1 domain, tamoxifen does not activate ER β (McInerney et al., 1998).

Raloxifene acts as a partial agonist in bone but does not stimulate endometrial proliferation in postmenopausal women. Presumably this is due to some combination of differential expression

of transcription factors in the two tissues and the effects of this SERM on ER conformation. Raloxifene induces a configuration in ER α that is distinct from that of tamoxifen-ER β (Tamrazi et al., 2003), suggesting that a different set of co-activators/co-repressors may interact with ER-raloxifene compared with ER-tamoxifen.

Clomiphene increases gonadotropin secretion and stimulates ovulation. It increases the amplitude of LH and FSH pulses without changing pulse frequency (Kettel et al., 1993). This suggests that the drug is acting largely at the pituitary level to block inhibitory actions of estrogen on gonadotropin release from the gland and/or is somehow causing the hypothalamus to release larger amounts of GnRH per pulse.

Fulvestrant binds to ER α and ER β with a high affinity comparable to estradiol but represses transactivation. It also increases dramatically the intracellular proteolytic degradation of ER α while apparently protecting ER β from degradation (Van Den Bemd et al., 1999). This effect on ER α protein levels may explain fulvestrant's efficacy in tamoxifen-resistant breast cancer.

Absorption, Fate, and Excretion

Tamoxifen is given orally, and peak plasma levels are reached within 4-7 hours after treatment. This drug displays two elimination phases with half-lives of 7-14 hours and 4-11 days. Due to the prolonged $t_{1/2}$, 3-4 weeks of treatment are required to reach steady-state plasma levels. The parent drug is converted largely to metabolites within 4-6 hours after oral administration. Tamoxifen is metabolized in humans by multiple hepatic CYPs, some of which it also induces (Sridar et al., 2002). In humans and other species, 4-hydroxytamoxifen is produced via hepatic metabolism, and this compound is considerably more potent than the parent drug as an anti-estrogen. The major route of elimination from the body involves *N*-demethylation and deamination. The drug undergoes enterohepatic circulation, and excretion is primarily in the feces as conjugates of the deaminated metabolite. Polymorphisms affect the rate of tamoxifen metabolism to its more potent 4-hydroxy metabolite and may impact its therapeutic activity in breast cancer (Chapter 63).

Raloxifene is adsorbed rapidly after oral administration and has an absolute bioavailability of ~2%. The drug has a $t_{1/2}$ of ~28 hours and is eliminated primarily in the feces after hepatic glucuronidation; it does not appear to undergo significant biotransformation by CYPs.

Clomiphene is well absorbed following oral administration, and the drug and its metabolites are eliminated primarily in the feces and to a lesser extent in the urine. The long plasma $t_{1/2}$ (5-7 days) is due largely to plasma-protein binding, enterohepatic circulation, and accumulation in fatty tissues. Other active metabolites with long half-lives also may be produced.

Fulvestrant is administered monthly by intramuscular depot injections. Plasma concentrations reach maximal levels in 7 days and are maintained for a month. Numerous metabolites are formed *in vivo*, possibly by pathways similar to endogenous estrogen metabolism, but the drug is eliminated primarily (90%) via the feces in humans.

Therapeutic Uses

Breast Cancer. Tamoxifen is highly efficacious in the treatment of breast cancer. It is used alone for palliation of advanced breast cancer in women with ER-positive

tumors, and it is now indicated as the hormonal treatment of choice for both early and advanced breast cancer in women of all ages (Jaiyesimi et al., 1995). Response rates are ~50% in women with ER-positive tumors. Tamoxifen increases disease-free survival and overall survival; treatment for 5 years reduces cancer recurrence by 50% and death by 27% and is more efficacious than shorter 1- to 2-year treatment periods. Tamoxifen reduces the risk of developing contralateral breast cancer and is approved for primary prevention of breast cancer in women at high risk, in whom it causes a 50% decrease in the development of new tumors. Prophylactic treatment should be limited to 5 years because effectiveness decreases thereafter. The most frequent side effect is hot flashes. Tamoxifen has estrogenic activity in the uterus, increases the risk of endometrial cancer by 2- to 3-fold, and also causes a comparable increase in the risk of thromboembolic disease that leads to serious risks for women receiving anticoagulant therapy (Smith, 2003) and women with a history of deep vein thrombosis or stroke.

Toremifene has therapeutic actions similar to tamoxifen, and fulvestrant may be efficacious in women who become resistant to tamoxifen. Untoward effects of fulvestrant include hot flashes, GI symptoms, headache, back pain, and pharyngitis.

Osteoporosis. Raloxifene reduces the rate of bone loss and may increase bone mass at certain sites. In a large clinical trial, raloxifene increased spinal bone mineral density by >2% and reduced the rate of vertebral fractures by 30-50% but did not significantly reduce non-vertebral fractures (Delmas et al., 2002; Ettinger et al., 1999). Raloxifene does not appear to increase the risk of developing endometrial cancer. The drug has beneficial actions on lipoprotein metabolism, reducing both total cholesterol and LDL; however, HDL is not increased. Adverse effects include hot flashes, deep vein thrombosis, and leg cramps.

Infertility. Clomiphene is used primarily for treatment of female infertility due to anovulation. By increasing gonadotropin levels, primarily FSH, it enhances follicular recruitment. It is relatively inexpensive, orally active, and requires less extensive monitoring than other treatment protocols. However, the drug may exhibit untoward effects, including ovarian hyperstimulation, increased incidence of multiple births, ovarian cysts, hot flashes, and blurred vision. In addition, clomiphene-induced cycles have a relatively high incidence of luteal phase dysfunction due to inadequate progesterone production, and prolonged use (e.g., ≥ 12 cycles) may

increase the risk of ovarian cancer. The drug should not be administered to pregnant women due to reports of teratogenicity in animals, but there is no evidence of this when the drug has been used to induce ovulation. Clomiphene also may be used to evaluate the male reproductive system because testosterone feedback on the hypothalamus and pituitary is mediated to a large degree by estrogens formed from aromatization of the androgen.

Experimental SERM-Estrogen Combinations. There is considerable interest in menopausal hormone therapy using combinations of a pure estrogen agonist (e.g., estradiol) with a SERM that has predominantly antagonist activity in the breast and endometrium but does not distribute to the CNS. The strategy is to obtain the beneficial actions of the agonist (e.g., prevention of hot flashes and bone loss) while the SERM blocks unwanted agonist action at peripheral sites (e.g., proliferative effects in breast and endometrium) but does not enter the brain to cause hot flashes. Animal studies have been encouraging (Labrie et al., 2003), but clinical efficacy and safety of this approach remain to be established.

Estrogen-Synthesis Inhibitors

Several agents can be used to block estrogen biosynthesis. Continual administration of GnRH agonists prevents ovarian synthesis of estrogens but not their peripheral synthesis from adrenal androgens (Chapter 38). *Aminoglutethimide* inhibits aromatase activity, but its use is limited by its lack of selectivity and its side effects (sedation). It was discontinued in the U.S. in 2008.

The recognition that locally produced as well as circulating estrogens may play a significant role in breast cancer has greatly stimulated interest in the use of aromatase inhibitors to selectively block production of estrogens (Chapter 63). Both steroidal (e.g., formestane and exemestane [AROMASIN]) and nonsteroidal agents (e.g., anastrozole [ARIMIDEX], letrozole [FEMARA], and vorozole) are available. Steroidal, or type I, agents are substrate analogs that act as suicide inhibitors to irreversibly inactivate aromatase, whereas the nonsteroidal, or type II, agents interact reversibly with the heme groups of CYPs (Haynes et al., 2003). Exemestane, letrozole, and anastrozole are currently approved in the U.S. for the treatment of breast cancer.

As discussed in Chapter 62, these agents may be used as first-line treatment of breast cancer or as second-line drugs after tamoxifen. They are highly efficacious and actually superior to tamoxifen in adjuvant use for postmenopausal women (Coombs et al., 2004), and are indicated either following tamoxifen for 2-5 years or as initial agents. They have the added advantage of not increasing the risk of uterine cancer or venous thromboembolism. Because they dramatically reduce circulating as well as local levels of estrogens, they produce hot flashes. They lack the beneficial effect of tamoxifen to maintain bone density and thus are usually administered with bisphosphonates. Their effects on plasma lipids remain to be established.

PROGESTINS

Compounds with biological activities similar to those of progesterone have been variously referred to in the literature as progestins, progestational agents, progestagens, progestogens, gestagens, or gestogens. The progestins (Figure 40–5) include the naturally occurring hormone progesterone, 17 α -acetoxyprogesterone derivatives in the pregnane series, 19-nortestosterone derivatives in the estrane series, and norgestrel and related compounds in the gonane series. Medroxyprogesterone acetate (MPA) and megestrol acetate are C21 steroids in the pregnane family with selective activity very similar to that of progesterone itself. MPA and oral micronized progesterone are widely used with estrogens for MHT and other situations in which a selective progestational effect is desired. Furthermore, depot MPA is used as a long-acting injectable contraceptive. The 19-nortestosterone derivatives (estrans) were developed for use as progestins in oral contraceptives, and although their predominant activity is progestational, they exhibit androgenic and other activities. The gonanes are another family of “19-nor” compounds, containing an ethyl rather than a methyl substituent in the 13-position. They have diminished androgenic activity relative to the estranes. These two classes of 19-nortestosterone derivatives are the progestational components of most oral and some long-acting injectable contraceptives. The remaining oral contraceptives contain a class of progestins derived from

Agents Similar to Progesterone (Pregnanes)

Agents Similar to 19-Norgestrel (Gonanes)

Figure 40–5. Structural features of various progestins.

spironolactone (e.g., drospirenone) that have anti-mineralocorticoid and anti-androgenic properties.

History. Corner and Allen originally isolated a hormone in 1933 from the corpora lutea of sows and named it “progestin.” The next year, several European groups independently isolated the crystalline compound and called it “luteo-sterone,” unaware of the previous name. This difference in nomenclature was resolved in 1935 at a garden party in London given by Sir Henry Dale, who helped persuade all parties that the name “progesterone” was a suitable compromise.

Two major advances overcame the early difficulties and expense of obtaining progesterone from animal sources. The first was the synthesis of progesterone by Russel Marker from the plant product diosgenin in the 1940s, which provided a relatively inexpensive and highly pure product. The second was the synthesis of 19-nor compounds, the first orally active progestins, in the early 1950s by Carl Djerassi, who synthesized norethindrone at Syntex, and Frank Colton, who synthesized the isomer *norethynodrel* at Searle. These advances led to the development of effective oral contraceptives.

Chemistry. The structural features of several progestins are shown in Figure 40–5. Unlike the ER, which requires a phenolic A ring for

high-affinity binding, the progesterone receptor (PR) favors a Δ^4 -3-one A-ring structure in an inverted 1β , 2α -conformation (Duax et al., 1988). Other steroid hormone receptors also bind this nonphenolic A-ring structure, although the optimal conformation differs from that for the PR. Thus, some synthetic progestins (especially the 19-nor compounds) display limited binding to glucocorticoid, androgen, and mineralocorticoid receptors, a property that probably accounts for some of their nonprogestational activities. The spectrum of activities of these compounds is highly dependent on specific substituent groups, especially the nature of the C17 substituent in the D ring, the presence of a C19 methyl group, and the presence of an ethyl group at position C13.

One major class of agents is similar to progesterone and its metabolite 17α -hydroxyprogesterone (Figure 40–5). Compounds such as hydroxyprogesterone caproate have progestational activity but must be used parenterally due to first-pass hepatic metabolism. However, further substitutions at the 6-position of the B ring yield orally active compounds such as medroxyprogesterone acetate and megestrol acetate with selective progestational activity.

The second major class of agents is 19-nor testosterone derivatives. These testosterone derivatives, lacking the C19 methyl group, display primarily progestational rather than androgenic activity. An ethynyl substituent at C17 decreases hepatic metabolism and yields orally active 19-nortestosterone analogs such as norethindrone, norethindrone acetate, norethynodrel, and ethynodiol diacetate. The activity of the latter three compounds is due primarily to their rapid *in vivo* conversion to norethindrone. These compounds are less selective than the 17α -hydroxyprogesterone derivatives just mentioned and have varying degrees of androgenic activity and, to a lesser extent, estrogenic and anti-estrogenic activities.

Replacement of the 13-methyl group of norethindrone with a 13-ethyl substituent yields the gonane norgestrel, which is a more potent progestin than the parent compound but has less androgenic activity. Norgestrel is a racemic mixture of an inactive dextrorotatory isomer and the active levorotatory isomer, levonorgestrel. Preparations containing half as much levonorgestrel as norgestrel thus have equivalent pharmacological activity. Other gonanes—including norgestimate, desogestrel, and gestodene (not available in the U.S.)—have very little if any androgenic activity at therapeutic doses.

Other steroidal progestins include the gonane dienogest; 19-nor-progestin derivatives (e.g., nomegestrol, Nestorone, and trimegestone), which have increased selectivity for the progesterone receptor and less androgenic activity than estranes; and the spironolactone derivative drospirenone, which is used in combination with oral contraceptives. Like spironolactone, drospirenone is also a mineralocorticoid and androgen receptor antagonist.

Biosynthesis and Secretion. Progesterone is secreted by the ovary, mainly from the corpus luteum, during the second half of the menstrual cycle (Figure 40–3). LH, acting via its G protein-coupled receptor, stimulates progesterone secretion during the normal cycle.

After fertilization, the trophoblast secretes hCG into the maternal circulation, which then stimulates the LH receptor to sustain the corpus luteum and maintain progesterone production. During the second or third month of pregnancy, the developing placenta begins to secrete estrogen and progesterone in collaboration

with the fetal adrenal glands, and thereafter the corpus luteum is not essential to continued gestation. Estrogen and progesterone continue to be secreted in large amounts by the placenta up to the time of delivery.

PHYSIOLOGICAL AND PHARMACOLOGICAL ACTIONS

Neuroendocrine Actions. As discussed earlier in this chapter, progesterone produced in the luteal phase of the cycle has several physiological effects including decreasing the frequency of GnRH pulses. This progesterone-mediated decrease in GnRH pulse frequency is critical for suppressing gonadotropin release and resetting the hypothalamic-pituitary-gonadal axis to transition from the luteal back to the follicular phase. Furthermore, GnRH suppression is the major mechanism of action of progestin-containing contraceptives.

Reproductive Tract. Progesterone decreases estrogen-driven endometrial proliferation and leads to the development of a secretory endometrium (Figure 40–3), and the abrupt decline in progesterone at the end of the cycle is the main determinant of the onset of menstruation. If the duration of the luteal phase is artificially lengthened, either by sustaining luteal function or by treatment with progesterone, decidual changes in the endometrial stroma similar to those seen in early pregnancy can be induced. Under normal circumstances, estrogen antecedes and accompanies progesterone in its action on the endometrium and is essential to the development of the normal menstrual pattern.

Progesterone also influences the endocervical glands, and the abundant watery secretion of the estrogen-stimulated structures is changed to a scant viscid material. As noted previously, these and other effects of progestins decrease penetration of the cervix by sperm.

The estrogen-induced maturation of the human vaginal epithelium is modified toward the condition of pregnancy by the action of progesterone, a change that can be detected in cytological alterations in the vaginal smear. If the quantity of estrogen concurrently acting is known to be adequate, or if it is assured by giving estrogen, the cytological response to a progestin can be used to evaluate its progestational potency.

Progesterone is very important for the maintenance of pregnancy. Progesterone suppresses menstruation and uterine contractility, but other effects also may be important. These effects to maintain pregnancy led to the historical use of progestins to prevent threatened abortion. However, such treatment is of questionable benefit, probably because spontaneous abortion infrequently results from diminished progesterone.

Mammary Gland. Development of the mammary gland requires both estrogen and progesterone. During

pregnancy and to a minor degree during the luteal phase of the cycle, progesterone, acting with estrogen, brings about a proliferation of the acini of the mammary gland. Toward the end of pregnancy, the acini fill with secretions and the vasculature of the gland notably increases; however, only after the levels of estrogen and progesterone decrease at parturition does lactation begin.

During the normal menstrual cycle, mitotic activity in the breast epithelium is very low in the follicular phase and then peaks in the luteal phase. This pattern is due to progesterone, which triggers a *single* round of mitotic activity in the mammary epithelium. This effect is transient because continued exposure to the hormone is rapidly followed by arrest of growth of the epithelial cells. Importantly, progesterone may be responsible for the increased risk of breast cancer associated with estrogen-progestin use in postmenopausal women, although controlled studies with only progestin have not been performed (Anderson et al., 2004; Rossouw et al., 2002).

Central Nervous System Effects. During a normal menstrual cycle, an increase in basal body temperature of $\sim 0.6^{\circ}\text{C}$ (1°F) may be noted at mid-cycle; this correlates with ovulation. This increase is due to progesterone, but the exact mechanism of this effect is unknown. Progesterone also increases the ventilatory response of the respiratory centers to carbon dioxide and leads to reduced arterial and alveolar PCO_2 in the luteal phase of the menstrual cycle and during pregnancy. Progesterone also may have depressant and hypnotic actions in the CNS, possibly accounting for reports of drowsiness after hormone administration. This potential untoward effect may be abrogated by giving progesterone preparations at bedtime, which may even help some patients sleep.

Metabolic Effects. Progestins have numerous metabolic actions. Progesterone itself increases basal insulin levels and the rise in insulin after carbohydrate ingestion, but it does not normally alter glucose tolerance. However, long-term administration of more potent progestins, such as norgestrel, may decrease glucose tolerance. Progesterone stimulates lipoprotein lipase activity and seems to enhance fat deposition. Progesterone and analogs such as MPA have been reported to increase LDL and cause either no effects or modest reductions in serum HDL levels. The 19-norprogestins may have more pronounced effects on plasma lipids because of their androgenic activity.

In this regard, a large prospective study has shown that MPA decreases the favorable HDL increase caused by conjugated estrogens during postmenopausal hormone replacement, but it does not significantly affect the beneficial effect of estrogens to lower LDL. In contrast, micronized progesterone does not significantly alter beneficial estrogen effects on either HDL or LDL profiles (Writing

Group for the PEPI Trial, 1995); the spironolactone derivative drospirenone may actually have advantageous effects on the cardiovascular system due to its anti-androgenic and anti-mineralocorticoid activities. Progesterone also may diminish the effects of aldosterone in the renal tubule and cause a decrease in sodium reabsorption that may increase mineralocorticoid secretion from the adrenal cortex.

Mechanism of Action

A single gene that encodes two isoforms of the progesterone receptor, PR-A and PR-B. The first 164 N-terminal amino acids of PR-B are missing from PR-A; this occurs by use of two distinct estrogen-dependent promoters in the PR gene (Giangrande and McDonnell, 1999). The ratios of the individual isoforms vary in reproductive tissues as a consequence of tissue type, developmental status, and hormone levels. Both PR-A and PR-B have AF-1 and AF-2 transactivation domains, but the longer PR-B also contains an additional AF-3 that contributes to its cell- and promoter-specific activity. Because the ligand-binding domains of the two PR isoforms are identical, there is no difference in ligand binding. In the absence of ligand, PR is present primarily in the nucleus in an inactive monomeric state bound to heat-shock proteins (HSP-90, HSP-70, and p59). When receptors bind progesterone, the heat-shock proteins dissociate, and the receptors are phosphorylated and subsequently form dimers (homo- and heterodimers) that bind with high selectivity to PREs (progesterone response elements) located on target genes (Giangrande and McDonnell, 1999). Transcriptional activation by PR occurs primarily via recruitment of co-activators such as SRC-1, NcoA-1, or NcoA-2 (Collingwood et al., 1999). The receptor-co-activator complex then favors further interactions with additional proteins such as CBP and p300, which mediate other processes including histone acetylase activity. Histone acetylation causes a remodeling of chromatin that increases the accessibility of general transcriptional proteins, including RNA polymerase II, to the target promoter. Progesterone antagonists also facilitate receptor dimerization and DNA binding, but, as with ER, the conformation of antagonist-bound PR is different from that of agonist-bound PR. This different conformation favors PR interaction with co-repressors such as NCoR/SMRT, which recruit histone deacetylases. Histone deacetylation increases DNA interaction with nucleosomes and renders a target promoter inaccessible to the general transcription apparatus.

The biological activities of PR-A and PR-B are distinct and depend on the target gene in question. In most cells, PR-B mediates the stimulatory activities of progesterone; PR-A strongly inhibits this

action of PR-B and is also a transcriptional inhibitor of other steroid receptors (McDonnell and Goldman, 1994). Current data suggest that co-activators and co-repressors interact differentially with PR-A and PR-B (e.g., the co-repressor SMRT binds much more tightly to PR-A than to PR-B) (Giangrande et al., 2000), and this may account, at least in part, for the differential activities of the two isoforms. Female PR-A knockout mice are infertile, with impaired ovulation and defective decidualization and implantation. Several uterine genes appear to be regulated exclusively by PR-A, including calcitonin and amphiregulin (Mulac-Jericevic et al., 2000), and the antiproliferative effect of progesterone on the estrogen-stimulated endometrium is lost in PR-A knockout mice. In contrast, knockout studies suggest that PR-B is largely responsible for mediating hormone effects in the mammary gland (Mulac-Jericevic et al., 2003).

Certain effects of progesterone, such as increased Ca^{2+} mobilization in sperm, can be seen in as little as 3 minutes (Blackmore, 1999) and are therefore considered transcription independent. Similarly, progesterone can promote oocyte maturation (meiotic resumption) independent of transcription (Hammes, 2004). There is debate regarding the identity of the receptors mediating these progestin-induced processes, as well as their physiological importance in humans.

Absorption, Fate, and Excretion

Progesterone undergoes rapid first-pass metabolism, but high-dose (e.g., 100-200 mg) preparations of micronized progesterone (PROMETRIUM) are available for oral use. Although the absolute bioavailability of these preparations is low (Fotherby, 1996), efficacious plasma levels nevertheless may be obtained. Progesterone also is available in oil solution for injection, as a vaginal gel (CRINONE, PROCHIEVE), as a slow-release intrauterine device (PROGESTASERT) for contraception, and as a vaginal insert (ENDOMETRIN) for assisted reproductive technology.

Esters such as MPA (DEPO-PROVERA) are available for intramuscular administration, and MPA (PROVERA, others) and megestrol acetate (MEGACE, others) may be used orally. The 19-nor steroids have good oral activity because the ethinyl substituent at C17 significantly slows hepatic metabolism. Implants and depot preparations of synthetic progestins are available in many countries for release over very long periods of time (see later section on contraceptives).

In the plasma, progesterone is bound by albumin and corticosteroid-binding globulin but is not appreciably bound to SHBG. 19-Nor compounds, such as norethindrone, norgestrel, and desogestrel, bind to SHBG and albumin, and esters such as MPA bind primarily to albumin. Total binding of all these synthetic compounds to plasma proteins is extensive, $\leq 90\%$, but the proteins involved are compound specific.

The elimination $t_{1/2}$ of progesterone is ~ 5 minutes, and the hormone is metabolized primarily in the liver to hydroxylated metabolites and their sulfate and glucuronide conjugates, which are eliminated in the urine. A major metabolite specific for progesterone is pregnane-3 α , 20 α -diol; its measurement in urine and plasma is used as an index of endogenous progesterone secretion. The synthetic progestins have much longer half-lives (e.g., ~ 7 hours for norethindrone, 16 hours for norgestrel, 12 hours for gestodene, and 24 hours for MPA). The metabolism of synthetic progestins is thought to be primarily hepatic, and elimination is generally via the urine as conjugates and various polar metabolites, although their metabolism is not as clearly defined as that of progesterone.

The two most frequent uses of progestins are for contraception, either alone or with an estrogen (Chapter 66; see also later in this chapter), and in combination with estrogen for hormone therapy of postmenopausal women.

Progestins also are used diagnostically for secondary amenorrhea. An oral progestin is given to an amenorrheic woman for 5-7 days. If endogenous estrogens are present, withdrawal bleeding will occur. Combinations of estrogens and progestins can also be given to test for endometrial responsiveness in patients with amenorrhea.

In addition, progestins are highly efficacious in decreasing the occurrence of endometrial hyperplasia and carcinoma caused by unopposed estrogens; when used in this setting, there appears to be less irregular uterine bleeding with sequential rather than continuous administration. Local intrauterine application via a hormone-releasing intrauterine device (IUD) containing levonorgestrel can be used to decrease estrogen-induced endometrial hyperplasia while reducing untoward effects (e.g., unfavorable lipid profiles and incidence of breast cancer) of systemically administered progestins.

Finally, levonorgestrel is used as so-called emergency contraception after known or suspected unprotected intercourse. The medication is given orally within 72 hours after intercourse as either a single 1.5-mg dose (PLAN B ONE STEP) or as two 0.75-mg doses (PLAN B) separated by 12 hours. The mechanism of action may involve several factors, including the prevention of ovulation, fertilization, and implantation.

ANTI-PROGESTINS AND PROGESTERONE-RECEPTOR MODULATORS

The first report of an anti-progestin, RU 38486 (often referred to as RU-486) or *mifepristone*, appeared in 1981; this drug is available for the termination of pregnancy (Christin-Maitre et al., 2000). In 2010, the FDA approved ulipristal acetate [ella (U.S.), ellaOne (E.U.)], a partial agonist at the progesterone receptor, for emergency contraception. Anti-progestins also have several other potential applications, including to prevent conception, to induce labor, and to treat uterine leiomyomas, endometriosis, meningiomas, and breast cancer (Spitz and Chwalisz, 2000).

Mifepristone

Chemistry. Mifepristone is a derivative of the 19-norprogesterone norethindrone containing a dimethyl-aminophenol substituent at the 11β-position. It effectively competes with both progesterone and glucocorticoids for binding to their respective receptors. Mifepristone was initially thought to be a pure anti-progestin, although it is now considered a progesterone-receptor modulator (PRM) due to its context-dependent activity.

Other PRMs and pure progesterone antagonists now have been synthesized, and most contain an 11β-aromatic group. Another widely studied anti-progestin is onapristone (or ZK 98299), which is similar in structure to mifepristone but contains a methyl substituent in the 13α rather than 13β orientation. More selective progesterone-receptor modulators, such as asoprisnil, are being studied experimentally (DeManno et al., 2003).

Pharmacological Actions. Mifepristone acts primarily as a competitive receptor antagonist for both progesterone receptors, although it may have some agonist activity in certain contexts. In contrast, onapristone appears to be a pure progesterone antagonist. PR complexes of both compounds antagonize the actions of progesterone-PR complexes and also appear to preferentially recruit corepressors (Leonhardt and Edwards, 2002).

When administered in the early stages of pregnancy, mifepristone causes decidual breakdown by blockade of uterine progesterone receptors. This leads to detachment of the blastocyst, which decreases hCG production. This in turn causes a decrease in progesterone secretion from the corpus luteum, which further accentuates decidual breakdown. Decreased endogenous progesterone coupled with blockade of progesterone receptors in the uterus increases uterine prostaglandin levels and sensitizes the myometrium to their contractile actions. Mifepristone also causes cervical softening, which facilitates expulsion of the detached blastocyst.

Mifepristone can delay or prevent ovulation depending on the timing and manner of administration. These effects are due largely to actions on the hypothalamus and pituitary rather than the ovary, although the mechanisms are unclear.

If administered for one or several days in the mid- to late luteal phase, mifepristone impairs the development of a secretory endometrium and produces menses. Progesterone-receptor blockade at this time is the pharmacological equivalent of progesterone withdrawal, and bleeding normally ensues within several days and lasts for 1-2 weeks after anti-progestin treatment.

Mifepristone also binds to glucocorticoid and androgen receptors and exerts anti-glucocorticoid and anti-androgenic actions. A predominant effect in humans is blockade of the feedback inhibition by cortisol of adrenocorticotropic hormone secretion from the pituitary, thus increasing both corticotropin and adrenal steroid levels in the plasma.

Absorption, Fate, and Excretion. Mifepristone is orally active with good bioavailability. Peak plasma levels occur within several hours, and the drug is slowly cleared with a plasma $t_{1/2}$ of 20-40 hours. In plasma, it is bound by α_1 -acid glycoprotein, which contributes to the drug's long $t_{1/2}$. Metabolites are primarily the mono- and di-demethylated products (thought to have pharmacological activity) formed via CYP3A4-catalyzed reactions and, to a lesser extent, hydroxylated compounds. The drug undergoes hepatic metabolism and enterohepatic circulation; metabolic products are found predominantly in the feces (Jang and Benet, 1997).

Therapeutic Uses and Prospects. Mifepristone (MIFEPREX), in combination with misoprostol or other prostaglandins, is available for the termination of early pregnancy.

When mifepristone is used to produce a medical abortion, a prostaglandin is given 48 hours after the anti-progestin to further increase myometrial contractions and ensure expulsion of the detached blastocyst. Intramuscular *sulprostone*, intravaginal *gemeprost*, and oral misoprostol have been used. The success rate with such regimens is >90% among women with pregnancies of ≤ 49 days' duration. The most severe untoward effect is vaginal bleeding, which most often lasts 8-17 days but is only rarely (0.1% of patients) severe enough to require blood transfusions. High percentages of women also have experienced abdominal pain and uterine cramps, nausea, vomiting, and diarrhea due to the prostaglandin. Women receiving chronic glucocorticoid therapy should not be given mifepristone because of its anti-glucocorticoid activity. In fact, due to its high affinity for the glucocorticoid receptor, high doses of mifepristone can result in adrenal insufficiency; thus mifepristone is being considered as a chemical treatment for diseases of excess adrenal cortisol secretion.

Ulipristal

Chemistry. Ulipristal, a derivative of 19-norprogesterone, functions as a selective progesterone receptor modulator (SPRM), acting as a partial agonist at progesterone receptors. It has a dimethylaminophenol group at the 11 β position, as does mifepristone, with an additional acetoxy group at the C17. Unlike mifepristone, ulipristal appears to be a relatively weak glucocorticoid antagonist.

Pharmacological Actions. In high doses, ulipristal has anti-proliferative effects in the uterus; however, its most relevant actions to date involve its capacity to inhibit

ovulation. Ulipristal's anti-ovulatory actions likely occur due to progesterone regulation at many levels, including inhibition of LH release through the hypothalamus and pituitary, and inhibition of LH-induced follicular rupture within the ovary.

A 30-mg dose of ulipristal can inhibit ovulation when taken up to five days after intercourse. Ulipristal can block ovarian rupture at or even just after the time of the LH surge, confirming that at least some of its effects are directly in the ovary. Ulipristal may also block endometrial implantation of the fertilized egg, although whether this contributes to its effects as an emergency contraceptive (see below) is not clear.

Therapeutic Uses. Ulipristal acetate [ella, ellaOne] has recently been licensed in the E.U. and the U.S. as an emergency contraceptive. Studies comparing ulipristal to levonorgestrel (progesterone-only emergency contraception, or POEC) demonstrate that ulipristal is at least as effective when taken up to 72 hours after unprotected sexual intercourse. In addition, ulipristal remains effective up to 120 hours (5 days) after intercourse, making ulipristal a more versatile emergency contraceptive than levonorgestrel, which does not work well beyond 72 hours after unprotected intercourse. The most severe side effect in clinical trials using ulipristal has been a self-limited headache and some abdominal pain.

HORMONAL CONTRACEPTIVES

The incredible growth of the earth's human population stands out as one of the fundamental events of the last two centuries. The Old Testament dictum "Be fruitful and multiply" (Genesis 9:1) has been followed too religiously by readers and nonreaders of the Bible alike. In 1798, Malthus started a great controversy by opposing the prevailing view of unlimited progress for humankind by making two postulates and a conclusion. Malthus postulated "that food is necessary for the existence of man" and that sexual attraction between female and male is necessary and likely to persist, since "toward the extinction of the passion between the sexes, no progress whatever has hitherto been made," barring "individual exceptions." Malthus concluded that "the power of populations is infinitely greater than the power of the earth to produce subsistence for man," producing a "natural inequality" that would someday loom "insurmountable in the way to perfectibility of society."

Malthus was right: The passion between the sexes has persisted, and the power of populations is very great indeed, so much so that our sheer numbers have increased to the point that they are straining the earth's

capacity to supply food, energy, and raw materials, and to absorb the detritus of its human burden. Marine fisheries are being depleted, forests and aquifers are disappearing, and the atmosphere is accumulating greenhouse gases from combustion of the fossil fuels that provide the energy needs of almost 7 billion people. Perhaps some of the blame can be laid at the feet of medical science: Advances in public health and medicine have led to a significant decline in mortality and an increased life expectancy. However, medical science has also begun to assume a portion of the responsibility for overpopulation and its adverse effects. To this end, drugs in the form of hormones and their analogs have been developed to control human fertility.

History. Around the beginning of the 20th century, a number of European scientists, including Beard, Prenant, and Loeb, developed the concept that secretions of the corpus luteum suppressed ovulation during pregnancy. The Austrian physiologist Haberlandt then produced temporary sterility in rodents in 1927 by feeding ovarian and placental extracts—a clear example of an oral contraceptive! In 1937, Makepeace and colleagues demonstrated that pure progesterone blocked ovulation in rabbits, and Astwood and Fevold found a similar effect in rats in 1939.

In the 1950s, Pincus, Garcia, and Rock found that progesterone and 19-norprogestins prevented ovulation in women. Ironically, this finding grew out of their attempts to treat infertility with progestins or estrogen-progestin combinations. The initial findings were that either treatment effectively blocked ovulation in most women. However, concern about cancer and other possible side effects of the estrogen they used (i.e., DES) led to the use of a progestin alone in their studies. One of the compounds used was norethynodrel, and early batches of this compound were contaminated with a small amount of mestranol. When mestranol was removed, it was noted that treatment with pure norethynodrel led to increased breakthrough bleeding and less consistent inhibition of ovulation. Mestranol was thus reincorporated into the preparation, and this combination was employed in the first large-scale clinical trial of combination oral contraceptives.

Clinical studies in the 1950s in Puerto Rico and Haiti established the virtually complete contraceptive success of the norethynodrel/mestranol combination. In early 1961, ENOVID (norethynodrel plus mestranol; no longer marketed in the U.S.) was the first “Pill” approved by the FDA for use as a contraceptive agent in the U.S.; this was followed in 1962 by approval for ORTHO-NOVUM (norethindrone plus mestranol). By 1966, numerous preparations using either mestranol or ethinyl estradiol with a 19-norprogesterone were available. In the 1960s, the progestin-only minipill and long-acting injectable preparations were developed and introduced.

Millions of women began using oral contraceptives, and frequent reports of untoward effects began appearing in the 1970s. The recognition that these side effects were dose-dependent and the realization that estrogens and progestins synergistically inhibited ovulation led to the reduction of doses and the development of so-called low-dose or second-generation contraceptives. The increasing use of biphasic and triphasic preparations throughout the 1980s further

reduced steroid dosages; it may be that currently used doses are the lowest that will provide reliable contraception. In the 1990s, the “third-generation” oral contraceptives, containing progestins with reduced androgenic activity (e.g., norgestimate [ORTHO-CYCLEN, ORTHO TRI-CYCLEN LO, others] and desogestrel [DESOGEN, others]), became available in the U.S. after being used in Europe. A variety of contraceptive formulations are currently available, including pills, injections, skin patches, subdermal implants, vaginal rings, and IUDs that release hormones.

Types of Hormonal Contraceptives

Combination Oral Contraceptives. The most frequently used agents in the U.S. are combination oral contraceptives containing both an estrogen and a progestin. Their theoretical efficacy generally is considered to be 99.9%. Combination oral contraceptives are available in many formulations. Monophasic, biphasic, or triphasic pills are generally provided in 21-day packs. (Virtually all preparations come as 28-day packs, with the pills for the last 7 days containing only inert ingredients.) For the monophasic agents, fixed amounts of the estrogen and progestin are present in each pill, which is taken daily for 21 days, followed by a 7-day “pill-free” period. The biphasic and triphasic preparations provide two or three different pills containing varying amounts of active ingredients, to be taken at different times during the 21-day cycle. This reduces the total amount of steroids administered and more closely approximates the estrogen-to-progestin ratios that occur during the menstrual cycle. With these preparations, predictable menstrual bleeding generally occurs during the 7-day “off” period each month. However, several oral contraceptions are now available whereby progestin withdrawal is only induced every 3 months.

The estrogen content of current preparations ranges from 20 to 50 μg ; most contain 30–35 μg . Preparations containing $\leq 35 \mu\text{g}$ of an estrogen are generally referred to as “low-dose” or “modern” pills. The dose of progestin is more variable because of differences in potency of the compounds used. For example, monophasic pills currently available in the U.S. contain 0.4–1.5 mg of norethindrone, 0.09–0.15 mg of levonorgestrel, 0.3–0.5 mg of norgestrel, 1 mg of ethynodiol diacetate, 0.25 mg of norgestimate, or 0.15 mg of desogestrel, with slightly different dose ranges in biphasic and triphasic preparations. In contrast, most first-generation preparations (circa 1966) contained 50–100 μg of an estrogen and 2–10 mg of a progestin. These large differences in doses complicate extrapolation of data from early epidemiological studies on the side effects of “high-dose” oral contraceptives to the “low-dose” preparations now used.

A transdermal preparation of norelgestromin and ethinyl estradiol (ORTHO EVRA) is marketed for weekly application to the buttock, abdomen, upper arm, or torso for the first 3 consecutive weeks followed by a patch-free week for each 28-day cycle. A similar 3-week on/1-week off cycle is employed for the intravaginal ring containing ethinyl estradiol and etonogestrel (NUVARING).

Progestin-Only Contraceptives. Several agents are available for progestin-only contraception, with theoretical efficacies of 99%. Specific preparations include the “minipill”; low doses of progestins (e.g., 350 µg of norethindrone [NOR-QD, ORTHO MICRONOR, others]) taken daily without interruption; subdermal implants of 216 mg of norgestrel (NORPLANT II, JADELLE) for long-term contraceptive action (e.g., up to 5 years) or 68 mg of etonogestrel (IMPLANON) for contraception lasting 3 years; and crystalline suspensions of medroxyprogesterone acetate for intramuscular injection of 104 mg (DEPO-SUBQ PROVERA 104) or 150 mg (DEPO-PROVERA, others) of drug; each provides effective contraception for 3 months.

An IUD (PROGESTASERT) that releases low amounts of progesterone locally is available for insertion on a yearly basis. Its effectiveness is considered to be 97-98%, and contraceptive action probably is due to local effects on the endometrium. An intrauterine device (MIRENA) releases levonorgestrel for up to 5 years. It inhibits ovulation in some women but is thought to act primarily by producing local effects.

Mechanism of Action

Combination Oral Contraceptives. Combination oral contraceptives act by preventing ovulation (Lobo and Stanczyk, 1994). Direct measurements of plasma hormone levels indicate that LH and FSH levels are suppressed, a mid-cycle surge of LH is absent, endogenous steroid levels are diminished, and ovulation does not occur. Although either component alone can be shown to exert these effects in certain situations, the combination synergistically decreases plasma gonadotropin levels and suppresses ovulation more consistently than either alone.

Given the multiple actions of estrogens and progestins on the hypothalamic-pituitary-ovarian axis during the menstrual cycle and the extraordinary efficacy of these agents, several effects probably contribute to the blockade of ovulation.

Hypothalamic actions of steroids play a major role in the mechanism of oral contraceptive action. Progesterone diminishes the frequency of GnRH pulses. Because the proper frequency of LH pulses is essential for ovulation, this effect of progesterone likely plays a major role in the contraceptive action of these agents. In monkeys and women with normal menstrual cycles, estrogens do not affect the frequency of the pulse generator. However, in the prolonged absence of a menstrual cycle (e.g., in ovariectomized monkeys and postmenopausal women; Hotchkiss and Knobil, 1994), estrogens markedly diminish pulse-generator frequency, and progesterone enhances this effect. In theory, this hypothalamic effect of estrogens could come into play when oral contraceptives are used for extended time periods.

Multiple pituitary effects of both estrogen and progestin components are thus likely to contribute to oral contraceptive

action. Oral contraceptives seem likely to decrease pituitary responsiveness to GnRH. Estrogens also suppress FSH release from the pituitary during the follicular phase of the menstrual cycle, and this effect seems likely to contribute to the lack of follicular development in oral contraceptive users. The progestin component may also inhibit the estrogen-induced LH surge at mid-cycle. Other effects may contribute to a minor extent to the extraordinary efficacy of oral contraceptives. Transit of sperm, the egg, and fertilized ovum are important to establish pregnancy, and steroids are likely to affect transport in the fallopian tube. In the cervix, progestin effects also are likely to produce a thick viscous mucus to reduce sperm penetration and in the endometrium to produce a state that is not receptive to implantation. However, it is difficult to assess quantitatively the contributions of these effects because the drugs block ovulation so effectively.

Progestin-Only Contraceptives. Progestin-only pills and levonorgestrel implants are highly efficacious but block ovulation in only 60-80% of cycles. Their effectiveness is thus thought to be due largely to a thickening of cervical mucus, which decreases sperm penetration, and to endometrial alterations that impair implantation; such local effects account for the efficacy of IUDs that release progestins. Depot injections of MPA are thought to exert similar effects, but they also yield plasma levels of drug high enough to prevent ovulation in virtually all patients, presumably by decreasing the frequency of GnRH pulses.

Untoward Effects

Combination Oral Contraceptives. Shortly after the introduction of oral contraceptives, reports of adverse side effects associated with their use began to appear. Many of the side effects were found to be dose dependent, and this led to the development of current low-dose preparations. Untoward effects of early hormonal contraceptives fell into several major categories: adverse cardiovascular effects, including hypertension, myocardial infarction, hemorrhagic or ischemic stroke, and venous thrombosis and embolism; breast, hepatocellular, and cervical cancers; and a number of endocrine and metabolic effects. The current consensus is that low-dose preparations pose minimal health risks in women who have no predisposing risk factors, and these drugs also provide many beneficial health effects (Burkman et al., 2004).

Cardiovascular Effects. The question of cardiovascular side effects has been reexamined for the newer low-dose oral contraceptives (Burkman et al., 2004; Sherif, 1999). For nonsmokers without other risk factors such as hypertension or diabetes, there is no significant increase in the risk of myocardial infarction or stroke. There is a 28% increase in relative risk for venous thromboembolism, but the estimated absolute increase is very small because the incidence of these

events in women without other predisposing factors is low (e.g., roughly half that associated with the risk of venous thromboembolism in pregnancy). Nevertheless, the risk is significantly increased in women who smoke or have other factors that predispose to thrombosis or thromboembolism (Castelli, 1999). Of note, postmarketing epidemiologic studies indicate that women using transdermal contraceptives have a higher than expected exposure to estrogen and are at increased risk for the development of venous thromboembolism. Early high-dose combination oral contraceptives caused hypertension in 4-5% of normotensive women and increased blood pressure in 10-15% of those with preexisting hypertension. This incidence is much lower with newer low-dose preparations, and most reported changes in blood pressure are not significant. The cardiovascular risk associated with oral contraceptive use does not appear to persist after use is discontinued. As noted previously, estrogens increase serum HDL and decrease LDL levels, and progestins tend to have the opposite effect. Recent studies of several low-dose preparations have not found significant changes in total serum cholesterol or lipoprotein profiles, although slight increases in triglycerides have been reported.

Cancer. Given the growth-promoting effects of estrogens, there has been a long-standing concern that oral contraceptives might increase the incidence of endometrial, cervical, ovarian, breast, and other cancers. These concerns were further heightened in the late 1960s by reports of endometrial changes caused by sequential oral contraceptives, which have since been removed from the market in the U.S. However, it is now clear that there is *not* a widespread association between oral contraceptive use and cancer (Burkman et al., 2004; Westhoff, 1999).

Epidemiological evidence suggests that combined oral contraceptive use may increase the risk of cervical cancer by about 2-fold but only in long-term users (>5 years) with persistent human papilloma virus infection (Moodley, 2004).

There have been reports of increases in the incidence of hepatic adenoma and hepatocellular carcinoma in oral contraceptive users. Current estimates indicate there is about a doubling in the risk of liver cancer after 4-8 years of use. However, these are rare cancers, and the absolute increases are small.

The major present concern about the carcinogenic effects of oral contraceptives is focused on breast cancer. Numerous studies have dealt with this issue, and the following general picture has emerged. The risk of breast cancer in women of childbearing age is very low, and current oral contraceptive users in this group have only a very small increase in relative risk of 1.1-1.2, depending on other variables. This small increase is not substantially affected by duration of use, dose or type of component, age at first use, or parity. Importantly, 10 years after discontinuation of oral contraceptive use, there is no difference in breast cancer incidence between past users and never users. In addition, breast cancers diagnosed in women who have ever used oral contraceptives are more likely to be localized to the breast and thus easier to treat (i.e., are less likely to have spread to other sites) (Westhoff, 1999). Thus overall there is no significant difference in the cumulative risk of breast cancer between those who have ever used oral contraceptives and those who have never used them.

Combination oral contraceptives do *not* increase the incidence of endometrial cancer but actually cause a 50% decrease in the incidence of this disease, which lasts 15 years after the pills are

stopped. This is thought to be due to the inclusion of a progestin, which opposes estrogen-induced proliferation, throughout the entire 21-day cycle of administration. These agents also decrease the incidence of ovarian cancer, and decreased ovarian stimulation by gonadotropins provides a logical basis for this effect. There are accumulating data that oral contraceptive use decreases the risk of colorectal cancer (Fernandez et al., 2001).

Metabolic and Endocrine Effects. The effects of sex steroids on glucose metabolism and insulin sensitivity are complex (Godsland, 1996) and may differ among agents in the same class (e.g., the 19-nor progestins). Early studies with high-dose oral contraceptives generally reported impaired glucose tolerance as demonstrated by increases in fasting glucose and insulin levels and responses to glucose challenge. These effects have decreased as steroid dosages have been lowered, and current low-dose combination contraceptives may even improve insulin sensitivity. Similarly, the high-dose progestins in early oral contraceptives did raise LDL and reduce HDL levels, but modern low-dose preparations do not produce unfavorable lipid profiles (Sherif, 1999). There also have been periodic reports that oral contraceptives increase the incidence of gallbladder disease, but any such effect appears to be weak and limited to current or very long-term users (Burkman et al., 2004).

The estrogenic component of oral contraceptives may increase hepatic synthesis of a number of serum proteins, including those that bind thyroid hormones, glucocorticoids, and sex steroids. Although physiological feedback mechanisms generally adjust hormone synthesis to maintain normal "free" hormone levels, these changes can affect the interpretation of endocrine function tests that measure *total* plasma hormone levels, and may necessitate dose adjustment in patients receiving thyroid-hormone replacement.

The ethinyl estradiol present in oral contraceptives appears to cause a dose-dependent increase in several serum factors known to increase coagulation. However, in healthy women who do not smoke, there also is an increase in fibrinolytic activity, which exerts a counter effect so that overall there is a minimal effect on hemostatic balance. In women who smoke, however, this compensatory effect is diminished, which may shift the hemostatic profile toward a hypercoagulable condition (Fruzzetti, 1999).

Miscellaneous Effects. Nausea, edema, and mild headache occur in some individuals, and more severe migraine headaches may be precipitated by oral contraceptive use in a smaller fraction of women. Some patients may experience breakthrough bleeding during the 21-day cycle when the active pills are being taken. Withdrawal bleeding may fail to occur in a small fraction of women during the 7-day "off" period, thus causing confusion about a possible pregnancy. Acne and hirsutism are thought to be mediated by the androgenic activity of the 19-nor progestins.

Progestin-Only Contraceptives. Episodes of irregular, unpredictable spotting and breakthrough bleeding are the most frequently encountered untoward effect and the major reason women discontinue use of all three types of progestin-only contraceptives. With time, the incidence of these bleeding episodes decreases, especially

with the long-acting preparations, and amenorrhea becomes common after a year or more of use.

No evidence indicates that the progestin-only minipill preparations increase thromboembolic events, which are thought to be related to the estrogenic component of combination preparations; blood pressure does not appear to be elevated, and nausea and breast tenderness do not occur. Acne may be a problem, however, because of the androgenic activity of norethindrone-containing preparations. These preparations may be attractive for nursing mothers because they do not decrease lactation as do products containing estrogens.

Aside from bleeding irregularities, headache is the most commonly reported untoward effect of depot MPA. Mood changes and weight gain also have been reported, but controlled clinical studies of these effects are not available. It is of more concern that many studies have found decreases in HDL levels and increases in LDL levels, and there have been several reports of decreased bone density. These effects may be due to reduced endogenous estrogens because depot MPA is particularly effective in lowering gonadotropin levels. Numerous human studies have not found any increases in breast, endometrial, cervical, or ovarian cancer in women receiving MPA (Westhoff, 2003). Because of the time required to completely eliminate the drug, the contraceptive effect of this agent may remain for 6-12 months after the last injection.

Implants of norethindrone may be associated with infection, local irritation, pain at the insertion site, and, rarely, expulsion of the inserts. Headache, weight gain, and mood changes have been reported, and acne is seen in some patients. A number of metabolic studies have been performed in users of norplant (no longer marketed in the U.S.), and in most cases only minimal changes have been observed in lipid, carbohydrate, and protein metabolism. In women desiring pregnancy, ovulation occurs fairly soon after implant removal, reaching 50% in 3 months and almost 90% within 1 year.

Contraindications

Although the use of modern oral contraceptives is considered generally safe in most healthy women, *these agents can contribute to the incidence and severity of cardiovascular, thromboembolic, or malignant disease, particularly if other risk factors are present.* The following conditions are thus considered absolute contraindications for combination oral contraceptive use: the presence or history of thromboembolic disease, cerebrovascular disease, myocardial infarction, coronary artery disease, or congenital hyperlipidemia; known or suspected carcinoma of the breast, carcinoma of the female reproductive tract; abnormal undiagnosed vaginal bleeding; known or suspected pregnancy; and past or present liver tumors or impaired liver function. *The risk of serious cardiovascular side effects is particularly marked in women >35 years of age who smoke heavily* (e.g., >15 cigarettes per day); even low-dose oral contraceptives are contraindicated in such patients.

Several other conditions are relative contraindications and should be considered on an individual basis. These include migraine headaches, hypertension, diabetes mellitus, obstructive jaundice of pregnancy or prior oral contraceptive use, and gallbladder disease. If elective surgery is planned, many physicians recommend discontinuation of oral contraceptives for several weeks to a month to minimize the possibility of thromboembolism after surgery. These agents should be used with care in women with prior gestational diabetes or uterine fibroids, and low-dose pills should generally be used in such cases.

Progestin-only contraceptives are contraindicated in the presence of undiagnosed vaginal bleeding, benign or malignant liver disease, and known or suspected breast cancer. Depot MPA and levonorgestrel inserts are contraindicated in women with a history or predisposition to thrombophlebitis or thromboembolic disorders.

Choice of Contraceptive Preparations

Treatment should generally begin with preparations containing the minimum dose of steroids that provides effective contraceptive coverage. This is typically a pill with 30-35 μg of estrogen, but preparations with 20 μg may be adequate for lighter women or >40 years of age with perimenopausal symptoms; a preparation containing 50 μg of estrogen may be required for heavier women.

In women for whom estrogens are contraindicated or undesirable, progestin-only contraceptives may be an option. The progestin-only minipill may have enhanced effectiveness in several such types of women (e.g., nursing mothers and women >40 years of age, in whom fertility may be decreased).

The choice of a preparation also may be influenced by the specific 19-nor progestin component because this component may have varying degrees of androgenic and other activities. The androgenic activity of this component may contribute to untoward effects such as weight gain, acne due to increased sebaceous gland secretions, and unfavorable lipoprotein profiles. These side effects are greatly reduced in newer low-dose contraceptives that contain progestins with little to no androgenic activity.

In summary, for a given individual, both the efficacy and side effects of hormonal contraceptives may vary considerably among preparations. A number of choices are available to counter the development of side effects and improve patient tolerance, both in terms of specific components and routes of administration, without decreasing contraceptive efficacy. Risks for serious side effects as enumerated earlier should be considered before initiating contraceptives in any individual patient.

Noncontraceptive Health Benefits

It is generally accepted that combination oral contraceptives have substantial health benefits unrelated to their contraceptive use. Oral contraceptives significantly reduce the incidence of ovarian and endometrial cancer within 6 months of use, and the incidence is decreased 50% after 2 years of use. Depot MPA injections also reduce very substantially the incidence of uterine cancer. Furthermore, this protective effect persists for up to 15 years after oral contraceptive use.

is discontinued. These agents also decrease the incidence of ovarian cysts and benign fibrocystic breast disease.

Oral contraceptives have major benefits related to menstruation in many women. These include more regular menstruation, reduced menstrual blood loss and less iron-deficiency anemia, and decreased frequency of dysmenorrhea. There also is a decreased incidence of pelvic inflammatory disease and ectopic pregnancies, and endometriosis may be ameliorated. Some women also may obtain these benefits with progestin-only contraceptives. There are suggestions that MPA may improve hematological parameters in women with sickle-cell disease (Cullins, 1996).

From a purely statistical perspective, fertility regulation by oral contraceptives is substantially safer than pregnancy or childbirth for most women, even without considering the additional health benefits of these agents.

CLINICAL SUMMARY

Estrogens are most commonly used to treat vasomotor disturbances (“hot flashes”) in postmenopausal women. Other important benefits are amelioration of the effects of urogenital atrophy, a decreased incidence of colon cancer, and prevention of bone loss. A variety of preparations, including oral, transdermal, and vaginal, are available. *Regardless of the specific drug(s) selected, treatment should use the minimum dose and duration for the desired therapeutic end point.*

In postmenopausal women with an intact uterus, a progestin is included to prevent endometrial cancer. Medroxyprogesterone acetate is used in the U.S., but micronized progesterone is preferred; norethindrone and norgestrel/levonorgestrel are also commonly used. Women without a uterus are administered estrogen alone. Postmenopausal hormone therapy and contraception are the most frequent uses of progestins.

Tamoxifen, a selective estrogen receptor modulator or SERM, is widely used for the adjuvant treatment of breast cancer and for prophylaxis of the disease in high-risk women, but treatment should be limited to 5 years. The drug is most effective in the treatment of estrogen-receptor positive disease, and untoward effects include hot flashes as well as an increase in blood clots and uterine cancer. Another SERM, raloxifene, is used to prevent osteoporosis and decreases the incidence of vertebral fractures in postmenopausal women. Raloxifene is also licensed

for reduction of risk of breast cancer in high-risk patients. Raloxifene does not increase the risk of uterine cancer but does increase the incidence of thromboembolic events and hot flashes.

The pure estrogen antagonist fulvestrant is also used to treat breast cancer, especially in patients who become refractory to tamoxifen. Another estrogen antagonist, clomiphene, is used to treat infertility in anovulatory women. Both compounds may cause hot flashes.

Aromatase inhibitors, including letrozole, anastrozole, and exemestane, are highly effective for both adjuvant and metastatic treatment of breast cancer in postmenopausal subjects, and their prophylactic use is being explored. Untoward effects include hot flashes; potential long-term effects of these agents on osteoporosis and bone fractures remain to be established.

Mifepristone is used therapeutically as an anti-progestin for medical abortion, and it is administered with a prostaglandin for this purpose.

Estrogens and progestins are widely used as “combination” contraceptives and are 99% effective in preventing ovulation. These combinations are most often used orally, although transdermal preparations, once-monthly injections, and vaginal rings are available. Ethinyl estradiol (or mestranol) and 19-nor steroids such as norgestrel/levonorgestrel, norethindrone, or another synthetic progestin are commonly used. The greatest concern with these agents is the risk of stroke or other thromboembolic events; consequently, they should not be used in older women (>35 years of age) who smoke or have other risk factors (e.g., hypertension) for cardiovascular disease.

Several progestin-only contraceptives are available, including low-dose pills, long-lasting (e.g., 3-month) depot injections, and subdermal implants. These agents are also highly efficacious and exert a number of actions, including decreased frequency of ovulation and effects on cervical mucus, ovum transport, and implantation. They may be used in nursing mothers and in some women with contraindications for combined estrogen-progestin combinations. The most common untoward effect is unpredictable vaginal bleeding.

A levonorgestrel-only pill and high-dose estrogen-progestin oral contraceptives are available and effective for postcoital or emergency contraception within 72 hours of unprotected intercourse. These preparations are ineffective in cases of established pregnancy and should not be used to terminate pregnancy.

41 chapter

Androgens

Peter J. Snyder

TESTOSTERONE AND OTHER ANDROGENS

In men, testosterone is the principal secreted androgen. The Leydig cells synthesize the majority of testosterone by the pathways shown in Figure 41–1. In women, testosterone also is probably the principal androgen and is synthesized both in the corpus luteum and the adrenal cortex by similar pathways. The testosterone precursors androstenedione and dehydroepiandrosterone are weak androgens that can be converted peripherally to testosterone.

Secretion and Transport of Testosterone. The magnitude of testosterone secretion is greater in men than in women at almost all stages of life, a difference that explains many of the other differences between men and women. In the first trimester *in utero*, the fetal testes begin to secrete testosterone, which is the principal factor in male sexual differentiation, probably stimulated by human chorionic gonadotropin (hCG) from the placenta. By the beginning of the second trimester, the serum testosterone concentration is close to that of mid-puberty, ~250 ng/dL (Figure 41–2) (Dawood and Saxena, 1977; Forest, 1975). Testosterone production then falls by the end of the second trimester, but by birth the value is again ~250 ng/dL, possibly due to stimulation of the fetal Leydig cells by luteinizing hormone (LH) from the fetal pituitary gland. The testosterone value falls again in the first few days after birth, but it rises and peaks again at ~250 ng/dL at 2–3 months after birth and falls to <50 ng/dL by 6 months, where it remains until puberty (Forest, 1975).

During puberty, from ~12 to 17 years of age, the serum testosterone concentration in males increases to a much greater degree than in females, so that by early adulthood the serum testosterone concentration

is 500 ng/dL to 700 ng/dL in men, compared to 30 ng/dL to 50 ng/dL in women. The magnitude of the testosterone concentration in the male is responsible for the pubertal changes that further differentiate men from women. As men age, their serum testosterone concentrations gradually decrease, which may contribute to other effects of aging in men.

LH, secreted by the pituitary gonadotropes (Chapter 38), is the principal stimulus of testosterone secretion in men, perhaps potentiated by follicle-stimulating hormone (FSH), also secreted by gonadotropes. The secretion of LH by gonadotropes is positively regulated by hypothalamic gonadotropin-releasing hormone (GnRH), and testosterone directly inhibits LH secretion in a negative feedback loop. LH is secreted in pulses, which occur approximately every 2 hours and are greater in magnitude in the morning. The pulsatility appears to result from pulsatile secretion of GnRH from the hypothalamus. Pulsatile administration of GnRH to men who are hypogonadal due to hypothalamic disease results in normal LH pulses and testosterone secretion, but continuous administration does not (Crowley et al., 1985). Testosterone secretion is likewise pulsatile and diurnal, the highest plasma concentrations occurring at ~8 A.M. and the lowest at ~8 P.M. The morning peaks diminish as men age (Bremner et al., 1983).

In women, LH stimulates the corpus luteum (formed from the follicle after release of the ovum) to secrete testosterone. Under normal circumstances, however, estradiol and progesterone, not testosterone, are the principal inhibitors of LH secretion in women. Sex hormone-binding globulin (SHBG) binds ~40% of circulating testosterone with high affinity, rendering the bound hormone unavailable for biological effects. Albumin binds almost 60% of circulating testosterone with low affinity, leaving ~2% unbound or free. In some testosterone assays, the latter two components are considered as “bioavailable” testosterone.

Metabolism of Testosterone to Active and Inactive Compounds. Testosterone has many different effects in many tissues. One mechanism by which the varied effects are mediated is the metabolism of testosterone to two other active steroids, dihydrotestosterone and estradiol (Figure 41–3). Some effects of testosterone appear

Figure 41-1. Pathway of synthesis of testosterone in the Leydig cells of the testes. In Leydig cells, the 11 and 21 hydroxylases (present in adrenal cortex) are absent but CYP17 (17 α -hydroxylase) is present. Thus androgens and estrogens are synthesized; corticosterone and cortisol are not formed. Bold arrows indicate favored pathways.

to be mediated by testosterone itself, some by dihydrotestosterone, and some by estradiol.

The enzyme 5α -reductase catalyzes the conversion of testosterone to dihydrotestosterone. Although both testosterone and dihydrotestosterone act via the androgen receptor, dihydrotestosterone binds with higher affinity (Wilbert et al., 1983) and activates gene expression more efficiently (Deslypere et al., 1992). As

Figure 41-2. Schematic representation of the serum testosterone concentration from early gestation to old age.

a result, acting via dihydrotestosterone and in tissues expressing 5α -reductase, testosterone is able to affect tissues that would otherwise not be affected by circulating levels of testosterone. Two forms of 5α -reductase

Figure 41-3. Metabolism of testosterone to its major active and inactive metabolites.

have been identified: type I, which is found predominantly in nongenital skin, liver and bone, and type II, which is found predominantly in urogenital tissue in men and genital skin in men and women. The effects of dihydrotestosterone in these tissues are described later.

The enzyme complex aromatase, which is present in many tissues, especially the liver and adipose tissue, catalyzes the conversion of testosterone to estradiol. This conversion accounts for ~85% of circulating estradiol in men; the remainder is secreted directly by the testes, probably the Leydig cells (MacDonald et al., 1979). The effects of testosterone thought to be mediated via estradiol are described below.

Testosterone is metabolized in the liver to androsterone and etiocholanolone (Figure 41–3), which are biologically inactive. Dihydrotestosterone is metabolized to androsterone, androstenedione, and androstanediol.

Physiological and Pharmacological Effects of Androgens

The biological effects of testosterone are mediated by the receptor it activates and by the tissues in which the receptor and responses occur at various stages of life. Testosterone can act as an androgen either directly, by binding to the androgen receptor, or indirectly by conversion to dihydrotestosterone, which also binds to the androgen receptor. Testosterone also can act as an

estrogen by conversion to estradiol, which binds to the estrogen receptor (Figure 41–4).

Effects That Occur via the Androgen Receptor. Testosterone and dihydrotestosterone act as androgens via a single androgen receptor (Figure 41–5). The androgen receptor—officially designated NR3A—is a member of the nuclear receptor superfamily, which includes steroid hormone receptors, thyroid hormone receptors, and orphan receptors that lack a known ligand (Chapter 3).

The androgen receptor has an amino-terminal domain that contains a polyglutamine repeat of variable length, a DNA-binding domain consisting of two Zn finger motifs, and a carboxyterminal ligand-binding domain. The polyglutamine repeat of variable length is unique to the androgen receptor; a shorter length appears to increase its activity. In the absence of a ligand, the androgen receptor is located in the cytoplasm associated with a heat-shock protein complex. When testosterone or dihydrotestosterone binds to the ligand-binding domain, the androgen receptor dissociates from the heat-shock protein complex, dimerizes, and translocates to the nucleus. The dimer then binds via the DNA-binding domains to androgen response elements on certain responsive genes. The ligand-receptor complex recruits coactivators and acts as a transcription factor complex, stimulating or repressing expression of those genes (Agoulnik and Weigel, 2008; Brinkmann and Trapman, 2000).

The mechanisms by which androgens have different actions in diverse tissues have become clearer in recent years. One mechanism is the higher affinity with which dihydrotestosterone binds to and activates the

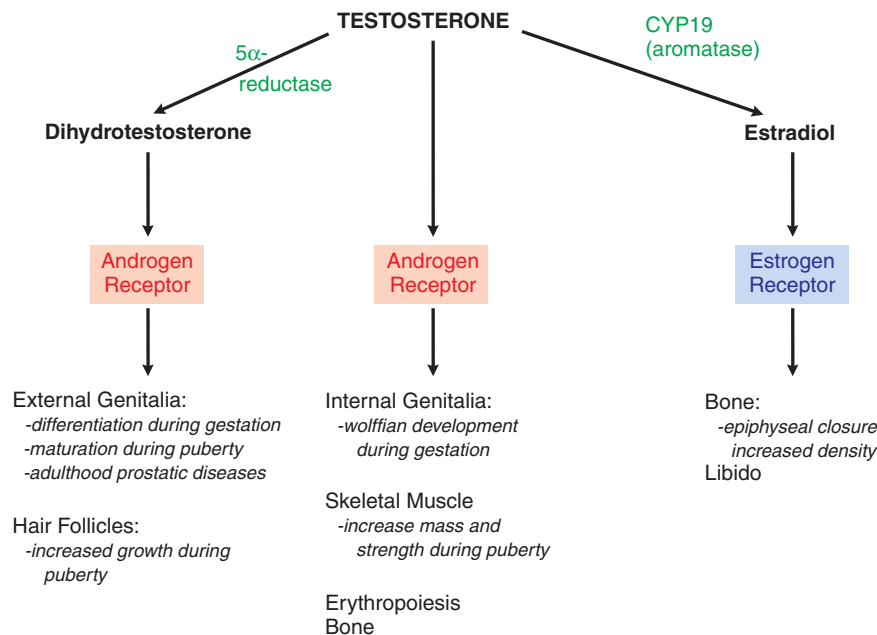

Figure 41–4. Direct effects of testosterone and effects mediated indirectly via dihydrotestosterone or estradiol.

Figure 41–5. Structure of the androgen receptor.

androgen receptor compared to testosterone (Deslypere et al., 1992). Another mechanism involves transcription cofactors, both coactivators and corepressors, which are tissue specific. At this time, the roles of cofactors are better described for other nuclear receptors than for the androgen receptor (Smith and O'Malley, 2004).

The importance of the androgen receptor is illustrated by the consequences of its mutations. Predictably, mutations that either alter the primary sequence of the protein or cause a single amino acid substitution in the hormone- or DNA-binding domains result in resistance to the action of testosterone, beginning *in utero* (McPhaul and Griffin, 1999). Male sexual differentiation therefore is incomplete, as is pubertal development.

Another kind of mutation occurs in patients who have spinal and bulbar muscular atrophy, known as Kennedy's disease. These patients have an expansion of the CAG repeat, which codes for glutamine, at the amino terminus of the molecule (Walcott and Merry, 2002). The result is very mild androgen resistance, manifest principally by gynecomastia (Dejager, 2002), and progressively severe motor neuron atrophy. The mechanism by which the neuronal atrophy occurs is unknown but pharmacological induction of autophagy in a model cell system degrades the mutant AR and rescues the cells from damage (Montie et al, 2009). Other trinucleotide repeats are also associated with neurological disorders (Molla et al., 2009).

Other kinds of androgen receptor mutations may explain why prostate cancer that is treated by androgen deprivation eventually becomes androgen-independent. At the time of its clinical presentation, prostate cancer is usually androgen-sensitive, and this sensitivity forms the basis for the initial treatment of metastatic prostate cancer by androgen deprivation. Metastatic prostate cancer often regresses initially in response to this treatment but then becomes unresponsive to continued deprivation. The androgen receptor not only continues to be expressed in androgen-independent prostate cancer, but its signaling remains active, as indicated by expression of the androgen receptor-dependent prostate-specific antigen (PSA). It has been postulated that these observations can be explained by mutations in the androgen receptor gene or changes in androgen receptor co-regulatory proteins. In some patients resistant to standard androgen deprivation therapy, the tumor responds to further depletion of androgens by inhibitors of adrenal androgen synthesis, such as abiraterone, a drug in late stages of clinical development (Chapter 63) (Heinlein and Chang, 2004).

Effects That Occur via the Estrogen Receptor. The effects of testosterone on at least one tissue are mediated by its conversion to estradiol, catalyzed by the

aromatase enzyme complex. In the rare cases in which a male does not express aromatase or the estrogen receptor (Smith, 1994), the epiphyses do not fuse and long-bone growth continues indefinitely; moreover, such patients are osteoporotic. Administration of estradiol corrects the bone abnormalities in patients with aromatase deficiency but not in those with an estrogen-receptor defect. Because men have larger bones than women, and bone expresses the androgen receptor (Colvard et al., 1989), testosterone also may have an effect on bone via the androgen receptor. The effect of testosterone on male libido also may be mediated by conversion to estradiol: administration of estradiol to a man with aromatase deficiency increased his libido (Rochira and Carani, 2009).

Effects of Androgens at Different Stages of Life.

In Utero. When the fetal testes, stimulated by hCG, begin to secrete testosterone at about the eighth week of gestation, the high local concentration of testosterone around the testes stimulates the nearby Wolffian ducts to differentiate into the male internal genitalia: the epididymis, vas deferens, and seminal vesicles. Further away, in the anlage of the external genitalia, testosterone is converted to dihydrotestosterone, which causes the development of the male external genitalia: the penis, scrotum, and prostate. The increase in testosterone at the end of gestation may result in further phallic growth.

Infancy. The consequences of the increase in testosterone secretion by the testes during the first few months of life are not yet known.

Puberty. Puberty in the male begins at a mean age of 12 years with an increase in the secretion of FSH and LH from the gonadotropes, stimulated by increased secretion of GnRH from the hypothalamus. The increased secretion of FSH and LH stimulates the testes; not surprisingly, the first sign of puberty is an increase in testicular size. The increase in testosterone production by Leydig cells and the effect of FSH on the Sertoli cells stimulate the development of the seminiferous tubules, which eventually produce mature sperm. Increased secretion of testosterone into the systemic circulation affects many tissues virtually simultaneously, and the changes in most of them occur gradually during the course of several years. The phallus enlarges in length and width, the scrotum becomes rugated, and the prostate begins secreting the fluid it contributes to the semen. The skin becomes coarser and oilier due to increased sebum production, which contributes to the development of acne. Sexual hair begins to grow, initially pubic and axillary hair, then hair on the lower legs, and finally other body hair and facial hair. Full development of the latter two may not occur until 10 years after the start of puberty and marks the completion of puberty. Muscle mass and strength, especially of the shoulder girdle, increase, and subcutaneous fat decreases. Epiphyseal bone growth accelerates, resulting in the pubertal growth spurt, but epiphyseal maturation leads eventually to a slowing and then cessation of growth. Bone also becomes thicker. The increase in muscle mass and bone result in a pronounced increase in weight. Erythropoiesis increases, resulting in higher hematocrit and hemoglobin concentrations in men than boys or women. The larynx thickens, resulting in a lower voice. Libido develops.

Other changes also may result from the increase in testosterone during puberty. Men tend to have a better sense of spatial relations than do women and to exhibit behavior that differs in some ways from that of women, including being more aggressive.

Adulthood. The serum testosterone concentration and the characteristics of the adult man are maintained largely during early adulthood and midlife. One change during this time is the gradual development of male pattern baldness, beginning with recession of hair at the temples and/or at the vertex.

Two changes that can occur in the prostate gland during adulthood are of much greater medical significance. One is the gradual development of benign prostatic hyperplasia, which occurs to a variable degree in almost all men, sometimes obstructing urine outflow by compressing the urethra as it passes through the prostate. This development is mediated by the conversion of testosterone to dihydrotestosterone by 5α -reductase II within prostatic cells (Wilson, 1980).

The other change that can occur in the prostate during adulthood is the development of cancer. Although no direct evidence suggests that testosterone causes the disease, prostate cancer depends on androgen stimulation. This dependency is the basis of treating metastatic prostate cancer by lowering the serum testosterone concentration or by blocking its action at the receptor.

Senescence. As men age, the serum testosterone concentration gradually declines (Figure 41–2), and the SHBG concentration gradually increases, so that by age 80, the total testosterone concentration is ~80% and the free testosterone is ~40% of those at age 20 (Harman et al., 2001). This fall in serum testosterone could contribute to several other changes that occur with increasing age in men, including decreases in energy, libido, muscle mass (Forbes, 1976) and strength (Murray et al., 1980), and bone mineral density. Androgen deprivation also leads to insulin resistance, truncal obesity, and abnormal serum lipids, as observed in patients with metastatic prostate cancer receiving this treatment (see also Chapter 63). A causal role is suggested by the occurrence of similar changes when men develop hypogonadism at a younger age caused by known diseases, as discussed later in this chapter.

Consequences of Androgen Deficiency

The consequences of androgen deficiency depend on the stage of life during which the deficiency first occurs and on the degree of the deficiency.

During Fetal Development. Testosterone deficiency in a male fetus during the first trimester *in utero* causes incomplete sexual differentiation. Testosterone deficiency in the first trimester results only from testicular disease, such as deficiency of 17α -hydroxylase (CYP17); deficiency of LH secretion because of pituitary or hypothalamic disease does not result in testosterone deficiency during the first trimester, presumably because Leydig cell secretion of testosterone at that time is regulated by placental hCG. Complete deficiency of testosterone secretion results in entirely female external genitalia; less severe testosterone

deficiency results in incomplete virilization of the external genitalia proportionate to the degree of deficiency. Testosterone deficiency at this stage of development also leads to failure of the wolffian ducts to differentiate into the male internal genitalia, such as the vas deferens and seminal vesicles, but the müllerian ducts do not differentiate into the female internal genitalia as long as testes are present and secrete müllerian inhibitory substance. Similar changes occur if testosterone is secreted normally, but its action is diminished because of an abnormality of the androgen receptor or of the 5α -reductase enzyme. Abnormalities of the androgen receptor can have quite varied effects. The most severe form results in complete absence of androgen action and a female phenotype; moderately severe forms result in partial virilization of the external genitalia; and the mildest forms permit normal virilization *in utero* and result only in impaired spermatogenesis in adulthood (McPhaul and Griffin, 1999). Abnormal 5α -reductase results in incomplete virilization of the external genitalia *in utero* but normal development of the male internal genitalia, which requires only testosterone (Wilson et al., 1993).

Testosterone deficiency during the third trimester, caused either by a testicular disease or a deficiency of fetal LH secretion, has two known consequences. First, the phallus fails to grow as much as it would normally. The result, called micropallus, is a common occurrence in boys later discovered to be unable to secrete LH due to abnormalities of GnRH synthesis. Second, the testes fail to descend into the scrotum; this condition, called cryptorchidism, occurs commonly in boys whose LH secretion is subnormal (Chapter 38).

Before Completion of Puberty. When a boy can secrete testosterone normally *in utero* but loses the ability to do so before the anticipated age of puberty, the result is failure to complete puberty. All of the pubertal changes previously described, including those of the external genitalia, sexual hair, muscle mass, voice, and behavior, are impaired to a degree proportionate to the abnormality of testosterone secretion. In addition, if growth hormone secretion is normal when testosterone secretion is subnormal during the years of expected puberty, the long bones continue to lengthen because the epiphyses do not close. The result is longer arms and legs relative to the trunk; these proportions are referred to as eunuchoid. Another consequence of subnormal testosterone secretion during the age of expected puberty is enlargement of glandular breast tissue, called gynecomastia.

After Completion of Puberty. When testosterone secretion becomes impaired after puberty (e.g., castration or anti-androgen treatment), regression of the pubertal effects of testosterone depends on both the degree and the duration of testosterone deficiency. When the degree of testosterone deficiency is substantial, libido and energy decrease within a week or two, but other testosterone-dependent characteristics decline more slowly. Decreases in muscle mass and strength probably can be detected by testing groups of men within a few months, but a clinically detectable decrease in muscle mass in an individual does not occur for several years. A pronounced decrease in hematocrit and hemoglobin will occur within several months. A decrease in bone mineral density probably can be detected by dual energy absorptiometry within 2 years, but an increase in fracture incidence would not be likely to occur for many years. A loss of sexual hair takes many years.

In Women. Loss of androgen secretion in women results in a decrease in sexual hair, but not for many years. Androgens may have other important effects in women, and the loss of androgens (especially with the severe loss of ovarian and adrenal androgens that occurs in panhypopituitarism) may result in the loss of these effects. Testosterone preparations that can yield serum testosterone concentrations in the physiological range in women currently are being developed. The availability of such preparations will allow clinical trials to determine if testosterone replacement in androgen-deficient women improves their libido, energy, muscle mass and strength, and bone mineral density.

Therapeutic Androgen Preparations

The need for a creative approach to pharmacotherapy with androgens arises from the fact that ingestion of testosterone is not an effective means of replacing testosterone deficiency. Even though ingested testosterone is readily absorbed into the hepatic circulation, the rapid hepatic catabolism ensures that hypogonadal men generally cannot ingest it in sufficient amounts and with sufficient frequency to maintain a normal serum testosterone concentration. Most pharmaceutical preparations of androgens, therefore, are designed to bypass hepatic catabolism of testosterone.

Testosterone Esters. Esterifying a fatty acid to the 17α hydroxyl group of testosterone creates a compound that is even more lipophilic than testosterone itself. When an ester, such as testosterone enanthate (heptanoate) or cypionate (cyclopentylpropionate) (Figure 41–6) is

dissolved in oil and administered intramuscularly every 2–4 weeks to hypogonadal men, the ester hydrolyzes *in vivo* and results in serum testosterone concentrations that range from higher than normal in the first few days after the injection to low normal just before the next injection (Figure 41–7). Attempts to decrease the frequency of injections by increasing the amount of each injection result in wider fluctuations and poorer therapeutic outcomes. The undecanoate ester of testosterone (Figure 41–6), when dissolved in oil and ingested orally, is absorbed into the lymphatic circulation, thus bypassing initial hepatic catabolism. Testosterone undecanoate in oil also can be injected and produces stable serum testosterone concentrations for 2 months (Schubert et al., 2004). The undecanoate ester of testosterone is not currently marketed in the U.S.

Alkylated Androgens. Several decades ago, chemists found that adding an alkyl group to the 17α position of testosterone (Figure 41–6) retarded its hepatic catabolism. Consequently, 17α -alkylated androgens are androgenic when administered orally; however, they are less androgenic than testosterone itself, and they cause hepatotoxicity (Cabasso, 1994), whereas native testosterone does not.

Transdermal Delivery Systems. Recent attempts to avoid the “first pass” inactivation of testosterone by the liver have employed novel delivery systems; chemicals called excipients are used to facilitate the absorption of native testosterone across the skin in a controlled fashion. These transdermal preparations provide more stable serum testosterone concentrations than do injections of testosterone esters. The first such preparations were patches, one of which (ANDRODERM) is still available. Newer preparations include gels (ANDROGEL, TESTIM) and a buccal tablet (STRIANT). These preparations produce mean serum testosterone concentrations within normal range in hypogonadal men (Figure 41–7).

Attempts to Design Selective Androgens

Alkylated Androgens. Decades ago, investigators attempted to synthesize analogs of testosterone that possessed greater anabolic effects than androgenic effects compared to native testosterone. Several compounds appeared to have such differential effects, based on a greater effect on the levator ani muscle compared to the ventral prostate of the rat. These compounds were called anabolic steroids, and most are 17α -alkylated androgens. None of these compounds, however, has been convincingly demonstrated to have such a differential effect in human beings. Nonetheless, they have

Testosterone (HISTERONE, others)

Testosterone Esters

Testosterone enanthate
(DELATESTRYL, others)

Testosterone cypionate
(DEPO-TESTOSTERONE, others)

Testosterone undecanoate
(ANDRIOL)

17 α -Alkylated Androgens

Methyltestosterone
(ORETIN METHYL, others)

Oxandrolone
(OXANDRIN)

Stanozolol
(WINSTROL)

Fluoxymesterone
(HALOTESTIN)

Danazol
(DANOCRINE)

Other

7 α -Methyl-19-nortestosterone

Tetrahydrogestrinone
