The need for long-term treatment poses issues almost exclusively to the chronic psychotic illnesses, schizophrenia and schizoaffective disorder, although long-term antipsychotic treatment is sometimes used for manic patients, for ongoing psychosis in dementia patients, for *L*-dopa psychosis, and for adjunctive use in SSRI-unresponsive major depression. Safety concerns combined with limited long-term efficacy data have dampened enthusiasm for extended antipsychotic drug use in dementia patients (Jeste et al., 2008). The goal should be to optimize clinical and behavioral aspects of treatment in order to minimize the need for antipsychotic drugs in the dementia population. Justification for ongoing use, based on documentation of patient response to tapering of antipsychotic medication, is often mandated in long-term care settings. *L*-dopa psychosis represents a thorny clinical problem, as clinicians are caught between the Scylla of treatment-induced psychotic symptoms and the Charybdis of motoric worsening as a result of exposure to antipsychotic drugs. Parkinson disease patients who present with *L*-dopa psychosis usually have advanced disease and cannot tolerate reductions in dopamine agonist treatment without significant motoric worsening and on-off phenomena (Chapter 22). They are exquisitely sensitive to minute amounts of D₂ blockade (Zahodne and Fernandez, 2008). Clozapine, used in doses ranging from 6.25-50 mg/day, has the most extensive clinical evidence base. The necessity for routine hematological

monitoring for agranulocytosis has prompted the use of low doses of quetiapine, itself a very weak D_2 antagonist, although the evidence for quetiapine's efficacy in *L*-dopa psychosis is not compelling. Anecdotal evidence also exists for using low doses of the D_2 partial agonist aripiprazole (1-5 mg/day) in *L*-dopa psychosis (Zahodne and Fernandez, 2008).

The choice of antipsychotic agents for long-term schizophrenia treatment is based primarily on avoidance of adverse effects and, when available, prior history of patient response. Since schizophrenia spectrum disorders are lifelong diseases, treatment acceptability is paramount to effective illness management. Whether atypical antipsychotic agents are superior to typical antipsychotic agents has been the subject of significant and contentious debate. Large meta-analyses of predominantly industry-funded studies find only minute differences in relapse risk (Leucht et al., 2003). Atypical antipsychotic agents offer significant advantages related to reduced neurological risk, with long-term tardive dyskinesia rates < 1%, or approximately one-fifth to one-tenth of that seen with typical antipsychotic drugs (for haloperidol, the annual incidence of tardive dyskinesia is 4-5% in non-geriatric adult patients; lifetime risk ~20%). This advantage of the atypical agents is magnified in elderly patients, in whom tardive dyskinesia incidence is 5-fold greater than in younger patients, and for whom annual tardive dyskinesia rates with typical antipsychotic agents exceed 20% per year. The decreased affinity for D_2 receptors among atypical agents has also translated into reduced concerns over hyperprolactinemia with most atypical antipsychotic agents, although risperidone and paliperidone (9-OH risperidone) are exceptions; both agents cause dose-dependent increases in prolactin (see "Adverse Effects and Drug Interactions" later in the chapter).

While concerns over EPS and tardive dyskinesia have abated with the introduction of the atypical antipsychotic agents into clinical practice, there has been increased concern over metabolic effects of antipsychotic treatment: weight gain, dyslipidemia (particularly hypertriglyceridemia), and an adverse impact on glucose-insulin homeostasis, including new-onset type 2 DM, and diabetic ketoacidosis (DKA), with reported fatalities from the latter (American Diabetes Association et al., 2004). Clozapine and olanzapine have the highest metabolic risk and are only used as last resort. Olanzapine has been relegated in most treatment algorithms to third-tier status, and is considered only after failure of more

metabolically benign agents such as aripiprazole, ziprasidone, asenapine, iloperidone, risperidone, and paliperidone.

Acutely psychotic patients usually respond within hours after drug administration, but weeks may be required to achieve maximal drug response, especially for negative symptoms, which respond much less robustly to drug therapy. While 6 weeks of therapy has been considered an adequate antipsychotic trial, analyses of symptom response in clinical trials indicate that the majority of response to any antipsychotic treatment in acute schizophrenia is seen by week 4 (Agid et al., 2003; Emsley et al., 2006). Failure of response after 2 weeks should prompt a clinical reassessment, including determination of medication adherence, before a decision is made to increase the current dose or consideration of switching to another agent. First-episode schizophrenia patients often respond to modest doses, and more chronic patients may require doses that exceed recommended ranges. While the acute behavioral impact of treatment is seen within hours to days, long-term studies indicate improvement may not plateau for 6 months, underscoring the importance of ongoing antipsychotic treatment in functional recovery for schizophrenia patients.

Usual dosages for acute and maintenance treatment are noted in Table 16-1. Dosing should be adjusted based on clinically observable signs of antipsychotic benefit and adverse effects. For example, higher EPS risk is noted for risperidone doses that exceed 6 mg/day in non-elderly adult schizophrenia patients. However, in the absence of EPS, increasing the dose from 6-8 mg would be a reasonable approach in a patient with ongoing positive symptoms, albeit with appropriate monitoring for emerging EPS symptoms. Treatment-limiting adverse effects may include weight gain, sedation, orthostasis, and EPS, which to some degree can be predicted based on the potencies of the selected agent to inhibit neurotransmitter receptors (Table 16-2). The detection of dyslipidemia or hyperglycemia is based on laboratory monitoring (Table 16-1). Certain adverse effects such as hyperprolactinemia, EPS, orthostasis, and sedation may respond to dose reduction, but metabolic abnormalities improve only with discontinuation of the offending agent and a switch to a more metabolically benign medication. The decision to switch stable schizophrenia patients with antipsychotic-related metabolic dysfunction solely for metabolic benefit must be individualized, based on patient preferences, severity of the metabolic disturbance, likelihood of metabolic improvement with

^aFor further information on antipsychotic dosing in psychotic disorders, see Expert Consensus Panel for Optimizing Pharmacologic Treatment of Psychotic Disorders. The expert consensus guideline series. Optimizing pharmacologic treatment of psychotic disorders. *J Clin Psychiatry*, 2003, 64(Suppl 12):2–97.

Note that doses in first-episode, younger, or antipsychotic-naïve patients are lower than for chronic schizophrenia patients. Dose in elderly schizophrenia patients is approximately 50% of that used in younger adults with schizophrenia; dosing for dementia-related psychosis is approximately 25%.

^bDue to orthostasis risk, dose titration of iloperidone is 1 mg bid on day 1, increasing to 2, 4, 6, 8, 10, and 12 mg bid on days 2, 3, 4, 5, 6, and 7 (as needed). Safety data exist for daily doses up to 16 mg bid.

^cPaliperidone palmitate dosing: in acute schizophrenia, deltoid IM loading doses of 234 mg at day 1 and 156 mg at day 8 provide paliperidone levels equivalent to 6 mg oral paliperidone during the first week, and peaking on day 15 at a level comparable to 12 mg oral paliperidone. No oral antipsychotic needed in first week. Maintenance IM doses can be given in deltoid or gluteus every 4 weeks after day 8. Maintenance dose options: 39, 78, 117, 156, or 234 mg every 4 weeks. Failure to give initiation doses (except for those switching from depot) will result in subtherapeutic levels for months.

^dNot available in the U.S.

^eOral dose must be given with food (500 kcal) to facilitate absorption. Food increases the absorption of single doses of 20-, 40-, and 80-mg capsules by 48%, 87%, and 101%, respectively.

428 antipsychotic switching, and history of response to prior agents. Patients with refractory schizophrenia on clozapine are not good candidates for switching because they are resistant to other medications (see the definition of refractory schizophrenia later in this section).

There are many reasons for psychotic relapse or inadequate response to antipsychotic treatment in schizophrenia patients. Examples are ongoing substance use, psychosocial stressors, inherent refractory illness, and poor medication adherence. Outside of controlled settings, the problem of medication nonadherence remains a significant barrier to successful treatment, yet one that is not easily assessed. Serum drug levels can be obtained for most antipsychotic medications, but there is limited dose-response data for atypical antipsychotic agents (except for clozapine), leaving clinicians little guidance about the interpretation of antipsychotic drug levels. Even low or undetectable levels may not reflect nonadherence, but rather can be the result of genetic variation or induction of hepatic CYPs that decrease drug availability, such as the high prevalence of CYP2D6 ultrarapid metabolizers among individuals from North Africa and the Middle East. Nevertheless, the common problem of medication nonadherence among schizophrenia patients has led to the development of long-acting injectable (LAI) antipsychotic medications, often referred to as depot antipsychotics. They are more widely used in the E.U. Only < 5% of U.S. patients receive depot antipsychotic treatment. There are currently four available LAI forms in the U.S.: decanoate esters of fluphenazine and haloperidol, risperidone-impregnated microspheres, and paliperidone palmitate. Patients receiving LAI antipsychotic medications show consistently lower relapse rates compared to patients receiving comparable oral forms and may suffer fewer adverse effects. LAI risperidone and paliperidone palmitate are currently the only atypical antipsychotic agents in depot form. However, clinical trials of LAI aripiprazole and olanzapine are in progress and these agents should become available in the near future. LAI risperidone is administered as biweekly intramuscular (IM) injections of 25-50 mg. Based on extensive kinetic modeling of clinical data, paliperidone palmitate therapy in acute schizophrenia is initiated with IM deltoid loading doses of 234 mg at day 1 and 156 mg at day 8 to provide serum paliperidone levels equivalent to 6 mg oral paliperidone during the first week, obviating the need for oral antipsychotic supplementation. Serum paliperidone levels from these two injections peak on day 15 at a level comparable to 12 mg oral paliperidone. Maintenance IM doses are given in deltoid or gluteus muscle every 4 weeks after day 8. Unlike acute IM preparations or paliperidone palmitate, all other LAI antipsychotic medications require several weeks to attain therapeutic levels and months to reach steady state, necessitating the use of oral medications for the initial 4 weeks of treatment.

Lack of response to adequate antipsychotic drug doses for adequate periods of time may indicate treatment-refractory illness. Refractory schizophrenia is defined using the Kane criteria: failed 6-week trials of two separate agents and a third trial of a high-dose typical antipsychotic agent (e.g., haloperidol or fluphenazine 20 mg/day). In this patient population, response rates to typical antipsychotic agents, defined as 20% symptom

reduction using standard rating scales (e.g., Positive and Negative Syndrome Scale [PANSS]), are 0%, and for any atypical antipsychotic except clozapine, are < 10% (Leucht et al., 2009). Due to the long titration involved to minimize orthostasis, and to sedation and other tolerability issues, adequate clozapine trials often require 6 months, but response rates in 26-week-long studies are consistently 60% in refractory schizophrenia patients. The therapeutic clozapine dose for a specific patient is not predictable, but various studies have found correlations between trough serum clozapine levels > 327-504 ng/mL and likelihood of clinical response. When therapeutic serum concentrations are reached, response to clozapine occurs within 8 weeks.

In addition to agranulocytosis risk that mandates routine ongoing hematological monitoring, clozapine has numerous other adverse effects. Examples are high metabolic risk, dose-dependent lowering of the seizure threshold, orthostasis, sedation, anticholinergic effects (especially constipation), and sialorrhea related to muscarinic agonism at M_4 receptors. As a result, clozapine use is limited to refractory schizophrenia patients.

Electroconvulsive therapy is considered a treatment of last resort in refractory schizophrenia and is rarely employed. Despite widespread clinical use of combining several antipsychotic agents, there is virtually no data supporting this practice, and metabolic risk increases with use of multiple antipsychotic agents (Correll et al., 2007). In one of few instances where a sound pharmacological rationale exists for combination treatment, the addition of a potent D_2 antagonist (e.g., risperidone, haloperidol) to maximally tolerated doses of clozapine (a weak D_2 blocker), the results have been decidedly mixed. That multiple antipsychotic agents ("polypharmacy") are commonly used in clinical practice attests to the limitations of current treatment. Lastly, antipsychotic drug therapy is the foundation of schizophrenia treatment, yet adequate management of schizophrenia patients requires a multimodal approach that also includes psychosocial, cognitive, and vocational rehabilitation to promote functional recovery.

Pharmacology of Antipsychotic Agents

Chemistry. In the past, the chemical structure of selected agents was informative regarding their antipsychotic activity, since most were derived from phenothiazine or butyrophenone structures. Phenothiazines have a tricyclic structure in which two benzene rings are linked by a sulfur and a nitrogen atom (Table 16-1). The chemically related thioxanthenes have a carbon in place of the nitrogen at position 10 with the R_1 moiety linked through a double bond. Substitution of an electron-withdrawing group at position 2 increases the antipsychotic efficacy of phenothiazines (e.g., chlorpromazine). The nature of the substituent at position 10 also influences pharmacological activity, and the phenothiazines and thioxanthenes can be divided into three groups on the basis of substitution at this site. Those with an aliphatic side chain include chlorpromazine and are relatively low in potency. Those with a piperidine ring in the side chain include thioridazine, which has lower EPS risk, possibly due to increased central

antimuscarinic activity, but is rarely used due to concerns over QTc prolongation and risk of torsade de pointes. Several potent phenothiazine antipsychotic compounds have a piperazine group in the side chain (fluphenazine, perphenazine, and trifluoperazine) and have reduced affinity for H_1 , M , and α_1 receptors. Those with a free hydroxyl can also be esterified to long-chain fatty acids to produce LAI antipsychotic medications (e.g., fluphenazine decanoate). Thioxanthenes also have aliphatic or piperazine side-chain substituents. Piperazine-substituted thioxanthenes include the high potency agent thiothixene. Since thioxanthenes have an olefinic double bond between the central-ring C10 and the side chain, geometric isomers exist. The *cis* isomers are more active. The antipsychotic phenothiazines and thioxanthenes have three carbon atoms interposed between position 10 of the central ring and the first amino nitrogen atom of the side chain at this position; the amine is always tertiary. Antihistaminic phenothiazines (e.g., promethazine) or strongly anticholinergic phenothiazines have only two carbon atoms separating the amino group from position 10 of the central ring. Metabolic *N*-dealkylation of the side chain or increasing the size of amino *N*-alkyl substituents reduces antidopaminergic and antipsychotic activity. Additional tricyclic antipsychotic agents are the benzepines, containing a 7-member central ring, of which loxapine (a dibenzoxazepine) and clozapine (a dibenzodiazepine) are available in the U.S. Clozapine-like atypical antipsychotic agents may lack a substituent on the aromatic ring (e.g., quetiapine, a dibenzothiazepine), have an analogous methyl substituent (olanzapine), or have an electron-donating substituent at position 8 (e.g., clozapine). In addition to their moderate potencies at DA receptors, clozapine-like agents interact with varying affinities at several other classes of receptors (α_1 and α_2 adrenergic, 5-HT_{1A}, 5-HT_{2A}, 5-HT_{2C}, M , H_1). The prototypical butyrophenone (phenylbutylpiperidine) antipsychotic is haloperidol, originally developed as a substituted derivative of the phenylpiperidine analgesic meperidine. An analogous compound, droperidol, is a very short-acting and highly sedating agent that was used almost exclusively for emergency sedation and anesthesia until QTc and torsade de pointes concerns substantially curtailed its use and the use of the related diphenylbutylpiperidine pimozone. Several other classes of heterocyclic compounds have antipsychotic effects, of which only the indole molindone has generated any interest due to its unusual association with modest weight loss (Sikich et al., 2008a). The enantiomeric, substituted benzamides are another group of heterocyclic compounds that are relatively selective antagonists at central D₂ receptors and have antipsychotic activity. Examples (not available in the U.S.) include sulpiride and its congener, amisulpride.

The introduction of clozapine stimulated research into agents with antipsychotic activity and low EPS risk. This search led to a series of atypical antipsychotic agents with certain pharmacological similarities to clozapine: namely lower affinity for D₂ receptors than typical antipsychotic drugs and high 5-HT₂ antagonist effects. The currently available atypical antipsychotic medications include the structurally related olanzapine, quetiapine, and clozapine; the benzisoxazoles risperidone, its active metabolite paliperidone, and iloperidone; ziprasidone (a benzisothiazolipiperazinyllindolone derivative); asenapine (a dibenzo-oxepino pyrrole), and aripiprazole (a quinolinone derivative). Table 16–1.

Presently, antipsychotic agents include many different chemical structures with a range of activities at

different neurotransmitter receptors (e.g., 5-HT_{2A} antagonism, 5-HT_{1A} partial agonism). As a result, structure-function relationships that were relied upon in the past have become less important. Instead, receptor-function relationships and functional assays are more clinically relevant. Aripiprazole represents a good example of how an examination of the structure provides little insight into its mechanism, which is based on dopamine partial agonism (discussed later). Detailed knowledge of receptor affinities (Table 16–2) and the functional effect at specific receptors (e.g., full, partial or inverse agonism or antagonism) can provide important insight into the therapeutic and adverse effects of antipsychotic agents. Nevertheless, there are limits. For example, it is not known which properties are responsible for clozapine's unique effectiveness in refractory schizophrenia, although many hypotheses exist. Other notable antipsychotic properties not fully explained by receptor parameters include the reduced seizure threshold, the unexpected extent of prolactin elevation for risperidone and paliperidone, the effects of antipsychotic agents on metabolic function, and the increased risk for cerebrovascular events and mortality among dementia patients (see "Adverse Effects and Drug Interactions" later in the chapter).

Mechanism of Action. While emerging data indicate that stimulation of glutamate or muscarinic receptors may confer antipsychotic properties, no clinically available effective antipsychotic is devoid of D₂ antagonistic activity. This reduction in dopaminergic neurotransmission is presently achieved through one of two mechanisms: D₂ antagonism or partial D₂ agonism, of which aripiprazole is the only current example. Another partial agonist, bifeprunox, completed clinical trials but failed to gain FDA approval.

Aripiprazole has an affinity for D₂ receptors only slightly less than DA itself, but its intrinsic activity is ~25% that of dopamine. As depicted in Figure 16–3, when dopamine is given in increasing concentrations in an *in vitro* model, 100% stimulation of the available D₂ receptors occurs (as measured by forskolin-stimulated cyclic AMP accumulation). In the absence of DA, aripiprazole produces a maximal level of D₂ activity ~25% that of DA (Burriss et al., 2002). The potent D₂ antagonist haloperidol is capable of reducing dopamine's effect to zero, but when DA is incubated with increasing concentrations of aripiprazole, maximal inhibition of D₂ activity did not exceed 25% of the DA response, that is, the level of agonism provided by aripiprazole. Aripiprazole's capacity to stimulate D₂ receptors in brain areas where synaptic DA levels are limited (e.g., PFC neurons) or decrease dopaminergic activity when dopamine concentrations are high (e.g., mesolimbic cortex) is thought to be the basis for its clinical effects in schizophrenia. Evidence for its partial DA agonist properties is seen clinically as a reduction in

Figure 16-3. Aripiprazole activity at D_2 receptors in the presence or absence of dopamine. Aripiprazole is a partial D_2 agonist; thus it inhibits effects of DA and reduces stimulation at the D_2 receptor only to the extent of its own capacity as an agonist. Haloperidol, an antagonist without agonist activity, completely antagonizes D_2 receptor activation. Here, receptor activity was measured as inhibition of forskolin-induced cAMP accumulation in CHO cells transfected with human D_{2L} DNA. (Adapted from Burris et al., 2002.)

serum prolactin levels. Unlike other antipsychotic agents, in which striatal D_2 occupancy (i.e., reduction in postsynaptic D_2 signal) > 78% is associated with EPS, aripiprazole requires significantly higher D_2 occupancy levels. Even with 100% receptor occupancy, aripiprazole's intrinsic dopaminergic agonism can generate a 25% postsynaptic signal, implying a maximal 75% reduction in DA neurotransmission, below the 78% threshold that triggers EPS in most individuals, although rare reports of acute dystonia exist, primarily in antipsychotic-naïve, younger patients.

Animal models of antipsychotic activity have evolved over a half-century of antipsychotic drug development to incorporate emerging knowledge of psychosis pathophysiology. Prior to the elucidation of D_2 antagonism as a common mechanism for antipsychotic agents, early behavioral paradigms exploited known animal effects that predicted clinical efficacy. As expected, these models, including catalepsy induction and blockade of apomorphine-induced stereotypic behavior, were subsequently found to be dependent on potent D_2 receptor antagonism (Lieberman et al., 2008). Clozapine failed these early trials and was not suspected to possess antipsychotic activity until experimental human use in the mid-1960s revealed it to be an effective treatment for schizophrenia, particularly in patients who had failed other antipsychotic medications, and with virtually absent EPS risk. By 1989, the pharmacological basis for some of these atypical properties, namely clinical efficacy without EPS induction, was found to result from a significantly weaker D_2 antagonism than existing antipsychotic agents, combined with potent 5-HT_{2A} antagonism. Subsequent research demonstrated that

5-HT_{2A} receptor antagonism is responsible for facilitation of dopamine release in both mesocortical and nigrostriatal pathways. The behavioral pharmacology of 5-HT_{2A} antagonism and related 5-HT_{2C} and 5-HT_{1A} receptor agonism has since been characterized, and relevant animal behavioral assays developed. Clozapine possesses activity at numerous other receptors including antagonism and agonism at various muscarinic receptor subtypes and antagonism at dopamine D_4 receptors; however, subsequent D_4 antagonists that did not also have D_2 antagonism lacked antipsychotic activity. Clozapine's active metabolite, *N*-desmethylclozapine, is a potent muscarinic M_1 agonist (Li et al., 2005). Although *N*-desmethylclozapine failed clinical trials as schizophrenia monotherapy, it increased interest in cholinergic agonists as primary treatments or adjunctive cognitive enhancing medications for schizophrenia. Important targets of agents in preclinical and clinical drug development include M_1 agonism (Janowsky and Davis 2009), M_4 agonism (Chan et al., 2008), and $\alpha 7$ - and $\alpha 4\beta 2$ -nicotinic receptor agonism (Buchanan et al., 2007).

The glutamate hypofunction hypothesis of schizophrenia has led to novel animal models that examine the influence of proposed antipsychotic agents, including those in clinical development with agonist properties at metabotropic glutamate receptors mGlu₂ and mGlu₃ (Patil et al., 2007) and other subtypes. Atypical antipsychotic drugs are better than typical antipsychotic medications at reversing the negative symptoms, cognitive deficits and social withdrawal induced by glutamate antagonists. At the present time, however, it is unclear whether glutamate agonist that lack direct D_2 antagonist properties will prove as effective as serotonin-dopamine antagonists for schizophrenia treatment, or whether glutamate agonist mechanisms might be more useful when combined with D_2 modulation, much in the same manner as 5-HT_{2A} antagonism. Schizophrenia patients also exhibit specific neurophysiological abnormalities. For example, a disruption in the normal processing of sensory and cognitive information is exhibited in various preconscious inhibitory processes, including deficiencies in sensorimotor gating as assessed by prepulse inhibition (PPI) of the acoustic startle reflex. PPI is the automatic suppression of startle magnitude that occurs when the louder acoustic stimulus is preceded 30-500 ms by a weaker prepulse (Swerdlow et al., 2006). In schizophrenia patients, PPI is increased more robustly with atypical than typical antipsychotic agents, and in animal models, atypical antipsychotic agents are also more effective at opposing PPI disruption from NMDA antagonists. Increased understanding of the pharmacological basis for neurophysiological deficits provides another means for developing antipsychotic treatments that are specifically effective for schizophrenia and may not necessarily apply to other forms of psychosis.

Dopamine Receptor Occupancy and Behavioral Effects.

Dopaminergic projections from the midbrain terminate on septal nuclei, the olfactory tubercle and basal forebrain, the amygdala, and other structures within the temporal and prefrontal cerebral lobes and the hippocampus. The dopamine hypothesis has focused considerable attention on the mesolimbic and mesocortical systems as possible sites where antipsychotic effects are mediated. Recent research confirms that excessive dopaminergic functions in the limbic system are central to the positive

symptoms of psychosis. The behavioral effects and the time course of antipsychotic response parallel the rise in D_2 occupancy and include calming of psychomotor agitation, decreased hostility, decreased social isolation, and less interference from disorganized or delusional thought processes and hallucinations.

Levels of central D_2 occupancy estimated by positron emission tomography (PET) brain imaging in patients treated with antipsychotic drugs support conclusions arising from laboratory studies that receptor occupancy predicts clinical efficacy, EPS, and serum level-clinical response relationships. Occupation of $> 78\%$ of D_2 receptors in the basal ganglia is associated with a risk of EPS across all dopamine antagonist antipsychotic agents, while occupancies in the range of 60–75% are associated with antipsychotic efficacy (Figure 16–2) (Kapur et al., 2000b). With the exception of aripiprazole, all atypical antipsychotic drugs at low doses have much greater occupancy of 5-HT_{2A} receptors (e.g., 75–99%) than typical agents (Table 16–2). Among atypical agents, clozapine has the highest ratio of 5-HT_{2A}/ D_2 binding. Clozapine's D_2 occupancy 12-hours post-dose ranges from 51–63% (Kapur et al., 1999), providing evidence for its limited EPS risk. The trough D_2 occupancy for quetiapine is even lower ($< 30\%$), but PET studies obtained 2–3 hours after dosing reveal D_2 receptor occupancies in the expected therapeutic range (54–64%), albeit transiently. Ziprasidone absorption is sensitive to the presence of food, but PET studies demonstrate that clinical efficacy occurs when D_2 occupancy exceeds 60%, which corresponds to a minimum daily dose of 120 mg (with food) (Mamo et al., 2004).

Among the typical antipsychotic drugs, receptor occupancy is best studied for haloperidol. Haloperidol has complex metabolism and is susceptible to modulation by CYP inhibitors, inducers, and CYP polymorphisms (Table 16–3), complicating the establishment of dose-response relationships in patients. Nonetheless, the use of serum levels can predict D_2 occupancy (Fitzgerald et al., 2000):

$$\% D_2 \text{ receptor occupancy} = 100 \times (\text{Plasma haloperidol ng/mL}) / (0.40 \text{ ng/mL} + \text{Plasma haloperidol ng/mL})$$

Similar formulas also exist for several atypical antipsychotic drugs, although their plasma concentrations are rarely measured in the clinical setting.

D₃ and D₄ Receptors in the Basal Ganglia and Limbic System. The discovery that D_3 and D_4 receptors are preferentially expressed in limbic areas has led to efforts to identify selective inhibitors for these receptors that might have antipsychotic efficacy and low EPS risk. As previously noted, clozapine has modest selectivity for D_4 receptors, which are preferentially localized in cortical and limbic brain regions in relatively low abundance, and are up-regulated after repeated administration of most typical and atypical antipsychotic drugs (Tarazi et al., 2001). These receptors may contribute to clinical antipsychotic actions, but agents that are D_4 selective (e.g., sonapiprazole) or mixed $D_4/5\text{-HT}_{2A}$ antagonists (e.g., fananserin) lack antipsychotic efficacy in clinical studies. In contrast to effects on D_2 and D_4 receptors, long-term administration of typical and atypical antipsychotic drugs does not alter D_3 receptor levels in rat forebrain regions (Tarazi et al., 2001). These findings suggest that D_3 receptors are unlikely to play a pivotal role in antipsychotic drug actions, perhaps because their avidity for endogenous DA prevents

their interaction with antipsychotic agents. The subtle and atypical functional activities of cerebral D_3 receptors suggest that D_3 agonists rather than antagonists may have useful psychotropic effects, particularly in antagonizing stimulant-reward and dependence behaviors. Aripiprazole possesses affinity and intrinsic activity at D_3 receptors equivalent to that at D_2 ; the clinical advantage of this property is not readily apparent, although preclinical data suggest some effects on substance use.

The Role of Non-Dopamine Receptors for Atypical Antipsychotic Agents. The concept of atypicality was initially based on clozapine's absence of EPS within the therapeutic range, combined with a prominent role of 5-HT₂ receptor antagonism. As subsequent agents were synthesized using clozapine's 5-HT₂/ D_2 ratio as a model, most of which possessed greater D_2 affinity and EPS risk than clozapine, there has been considerable debate on the definition of an atypical antipsychotic agent and its necessary properties. Aripiprazole in particular is problematic for the model based on ratios of 5-HT₂ to D_2 , since its action as partial agonist necessitates very high D_2 affinity. Loxapine is another problematic agent for the model since its receptor pharmacology suggests atypical properties based on 5-HT₂/ D_2 ratio; however, in clinical practice its use was associated with the expected higher level of EPS characteristic of typical antipsychotic drugs, perhaps related to the additive D_2 antagonist properties of the active metabolite amoxapine. These dilemmas have led some to suggest abandonment or modification of the atypical/typical antipsychotic terminology, perhaps in lieu of the designation by generation (e.g., first, second, etc.), as is used with antibiotics, or some other organizing scheme (Gründer et al., 2009). Nonetheless, the term "atypical" persists in common usage and designates lesser (but not absent) EPS risk and other decreased effects of excessive D_2 antagonism, or more accurately, reduction in D_2 -mediated neurotransmission.

The neuropharmacology and behavioral pharmacology of 5-HT₂ antagonism provide insights into the advantageous properties of medications with these effects (Marek et al., 2003). Antipsychotic agents with appreciable 5-HT₂ affinity have significant effects at both 5-HT_{2A} and 5-HT_{2C} receptors with individual medications varying in their relative potencies at each subtype (Tarazi et al., 2002). As discussed previously, atypical antipsychotic agents exhibit potent functional antagonism at both subtypes of 5-HT₂ receptors, but *in vitro* assays suggest that these effects result from inverse agonism at these G-coupled receptors.

5-HT_{2A} receptors are widely distributed, but antagonism exerts the greatest effect on prefrontal and basal ganglia DA release and midbrain noradrenergic outflow, with recent data implicating 5-HT_{2A} receptor polymorphisms in differential antidepressant response (McMahon et al., 2006). There are significant interrelationships between serotonin receptors, with evidence from animal studies that stimulation of either 5-HT_{1A} or 5-HT_{2C} receptors antagonizes the behavioral effects of 5-HT_{2A} agonists (Marek et al., 2003). This can be seen with agents that have direct effects on 5-HT_{2A} activity and also in studies of NMDA antagonists where there are opposing modulatory effects of 5-HT_{2A} and 5-HT_{2C} stimulation. By virtue of their impact on noradrenergic neurotransmission, 5-HT_{2A} antagonists

Table 16-3

Metabolism of Common Antipsychotic Drugs

AGENT	METABOLIC PATHWAYS	EFFECT OF CYP INHIBITION	EFFECT OF CYP INDUCTION
Atypical Antipsychotic Agents			
Aripiprazole	2D6 and 3A4 convert aripiprazole to active metabolite dehydro-aripiprazole. Metabolite has longer $t_{1/2}$ (75 vs. 94 hours) and represents 40% of AUC at steady state.	2D6 PMs experience 80% ↑ in aripiprazole AUC, and 30% ↓ in metabolite AUC (net effect is 60% ↑ in AUC for active moiety). Aripiprazole $t_{1/2} \approx 146$ hrs in PM. 2D6 inhibitors ↑ aripiprazole AUC by 112% and ↓ metabolite AUC by 35%. Ketoconazole (a potent 3A4 inhibitor) with a 15-mg single dose of aripiprazole ↑ the AUC of aripiprazole and its active metabolite by 63% and 77%, respectively.	3A4 induction ↓ maximum concentration and AUC of aripiprazole and metabolite by 70%.
Asenapine	Primarily glucuronidation (UGT 1A4), and limited oxidation via CYP 1A2, and to a lesser extent 2D6 and 3A4. No active metabolites.	Fluvoxamine, 25 mg twice daily for 8 days, ↑ C_{max} by 13% and AUC 29%. Paroxetine ↓ both C_{max} and AUC by 13%. Valproate, a UGT 1A4 inhibitor, ↑ C_{max} 2%, and ↓ AUC 1%.	Smoking had no effect on clearance or other kinetic parameters. Carbamazepine ↓ both C_{max} and AUC by 16%.
Clozapine	Multiple enzymes convert clozapine to active metabolite <i>N</i> -desmethylclozapine. The mean contributions of CYPs 1A2, 2C19, 3A4, 2C9, and 2D6 are 30%, 24%, 22%, 12%, and 6%, respectively. CYP1A2 is the most important form at low concentrations, which is in agreement with clinical findings.	Fluvoxamine ↑ C_p 5-10 fold. 2D6 inhibition may ↑ levels as much as 100%.	Loss of smoking-related 1A2 induction ↑ serum levels by 50%. Carbamazepine ↓ clozapine levels on average by 50%.

Iloperidone	2D6 and 3A4 convert iloperidone to active metabolites P88 and P95. In 2D6 EM, the $t_{1/2}$ of P88 and P95 are 26 and 23 hours, respectively; in PM, 37 and 31 hours, respectively. Only P88 has affinity for D_2 . P88 accounts for 19.5% and 34.0% of total exposure in EM and PM, respectively. P95 has K_i of 3.91 nM for $5HT_{2A}$ and 4.7 nM for α_{1A} , and accounts for 48% and 25% of total exposure in EM and PM, respectively.	Ketoconazole \uparrow AUC of a single 3-mg iloperidone dose and its metabolites P88 and P95 by 57%, 55%, and 35%, respectively. Fluoxetine \uparrow 3-mg single dose AUC of iloperidone and P88 metabolite 2-3 fold, and P95 AUC by 50%. Paroxetine \uparrow AUC of iloperidone and P88 metabolite 1.6-fold, and reduces P95 AUC by 50%. Paroxetine (8-12 mg twice daily) \uparrow steady state C_{max} of iloperidone and P88 by 1.6-fold, and \downarrow steady state C_{max} of P95 by 50%. Combined use \uparrow steady state C_{max} of iloperidone and P88 by 1.4-fold, and \downarrow steady state C_{max} of P95 1.4-fold.	Impact of 3A4 inducers not documented.
Olanzapine	Direct glucuronidation or 1A2 mediated oxidation to <i>N</i> -desmethylolanzapine (inactive).	Increase in olanzapine C_{max} following fluvoxamine is 54% in female nonsmokers and 77% in male smokers. The mean increase in olanzapine AUC is 52% and 108%, respectively.	Carbamazepine use \uparrow clearance by 50%. Olanzapine C_p lower in smokers (with equal dosing).
Paliperidone	59% excreted unchanged in urine, 32% excreted as metabolites. Phase 2 metabolism accounts for no more than 10%.	Unlikely to have much of an effect.	Carbamazepine use \downarrow steady state C_{max} and AUC by 37%.
Quetiapine	3A4 mediated sulfoxidation to active metabolite norquetiapine, $t_{1/2} \approx 12$ hours. Steady state mean C_{max} and AUC of norquetiapine are $\sim 25\%$ and $\sim 50\%$ of that for quetiapine.	Ketoconazole (200 mg once daily for 4 days), \downarrow oral clearance of quetiapine by 84%, resulting in a 335% \uparrow in maximum C_p .	Phenytoin increases clearance 5-fold.
Risperidone	2D6 converts risperidone to active metabolite 9-OH risperidone. In 2D6 PMs, half-lives are: risperidone, 20 hours; 9-OH risperidone, 30 hours	Fluoxetine and paroxetine \uparrow risperidone concentration ~ 2.5 fold and 3-9 fold, respectively. Fluoxetine did not affect 9-OH risperidone conc., but paroxetine lowered 9-OH risperidone (13%). Net effect: 2D6 inhibition \uparrow levels of active moiety up to 75%.	In a drug interaction study of risperidone 6 mg/day \times 3 weeks, followed by 3 weeks of carbamazepine, concentration of active moieties (risperidone + 9-OH risperidone) was decreased 50%.

(Continued)

Table 16-3

Metabolism of Common Antipsychotic Drugs (continued)

	METABOLIC PATHWAYS	EFFECT OF CYP INHIBITION	EFFECT OF CYP INDUCTION
Atypical Antipsychotic Agents			
Ziprasidone	3A4 (~1/3) Aldehyde Oxidase (~2/3)	Concomitant ketoconazole ↑ AUC by 35%	Carbamazepine ↓ AUC by 35%.
Typical Antipsychotic Agents			
Haloperidol	Multiple CYP pathways, particularly 2D6, 3A4, and minor pathway 1A2. Only active metabolite, reduced haloperidol (formed by ketone reductase). Reduced haloperidol inhibits CYP2D6 and may be re-oxidized to the parent drug. Therapeutic serum levels not well defined; 5-20 ng/mL used as a target for dosing.	Half-life prolonged in CYP 2D6 PMs Individuals with only one functional 2D6 allele experience 2-fold greater trough serum levels, those with no functioning alleles 3-4 fold higher.	Carbamazepine and phenytoin ↑ haloperidol clearance ~32%, with ↓ C _p (mean, 47%). Discontinuation of carbamazepine ↑ C _p 2-3 fold.
Chlorpromazine	CYP2D6. Over 10 identified human metabolites, most inactive. Chlorpromazine is a moderate 2D6 inhibitor, and also induces its own metabolism. Levels drop 25-33% during weeks 1-3 of treatment.	Case report of fluoxetine-chlorpromazine interaction, but no serum level data on extent of effect.	3A4/PGP inducers (e.g., phenobarbital, carbamazepine) decrease chlorpromazine levels by ~35%. Carbamazepine discontinuation ↑ C _p (30-80%).

AUC, area under the curve; PM, poor metabolizer; EM, extensive metabolizer; t_{1/2}, half life; C_p, plasma concentration; C_{max}, maximum plasma concentration.
^aMay have multiphasic elimination with much longer terminal t_{1/2}.

pass many preclinical *in vivo* assays of antidepressant activity; conversely, 5-HT_{2C} antagonists exhibit a similar spectrum of antidepressant properties, although pure 5-HT_{2A} or 5-HT_{2C} agents are, by themselves, not effective antidepressants in human trials (Marek et al., 2003). Data also indicate that 5-HT_{2C} agonism decreases mesolimbic DA neurotransmission, a mechanism that is being explored in clinical trials of vabicaserin, a pure 5-HT_{2C} agonist. At the cellular level, stimulation of 5-HT_{2A} and 5-HT_{1A} receptors causes depolarization and hyperpolarization, respectively, of cortical pyramidal cells (Marek et al., 2003). No atypical antipsychotic agent is a potent agonist of 5-HT_{1A} receptors, but several, including clozapine, ziprasidone and aripiprazole are partial agonists. The extent to which this contributes to any clinical effect is unknown, but more potent selective 5-HT_{1A} agonists have anxiolytic effects and appear to exert procognitive effects in schizophrenia patients when added to existing antipsychotic treatment.

Based upon trials of the selective α_2 adrenergic antagonist idazoxan, researchers have postulated effects of α_2 blockade on mood, but ongoing research into this mechanism has not been promising. Risperidone is the one antipsychotic with relatively high affinity for α_2 adrenergic receptors, at which it is an antagonist; however, the clinical correlate of this unique profile is unclear. Any benefit on major depressive symptoms from low-dose risperidone augmentation of SSRI antidepressants is more likely conveyed by effects at the 5-HT_{2A} receptor, at which risperidone has > 100-fold greater potency than at α_2 adrenergic receptors.

Tolerance and Physical Dependence. As defined in Chapter 24, antipsychotic drugs are not addicting; however, tolerance to the antihistaminic and anticholinergic effects of antipsychotic agents usually develops over days or weeks. Loss of efficacy with prolonged treatment is not known to occur with antipsychotic agents; however, tolerance to antipsychotic drugs and cross-tolerance among the agents are demonstrable in behavioral and biochemical experiments in animals, particularly those directed toward evaluation of the blockade of dopaminergic receptors in the basal ganglia (Tarazi et al., 2001). This form of tolerance may be less prominent in limbic and cortical areas of the forebrain. One correlate of tolerance in striatal dopaminergic systems is the development of receptor supersensitivity (mediated by upregulation of supersensitive DA receptors) referred to as D₂^{High} receptors (Lieberman et al., 2008). These changes may underlie the clinical phenomenon of withdrawal-emergent dyskinesias and may contribute to the pathophysiology of tardive dyskinesia. This may also partly explain the ability of certain chronic schizophrenia patients to tolerate high doses of potent DA antagonists with limited EPS.

Absorption, Distribution, and Elimination. The pharmacokinetic constants for these drugs may be found in Appendix II. Table 16–3 outlines the metabolic pathways of atypical antipsychotic agents available in the U.S. and selected typical agents in common use. Most antipsychotic drugs are highly lipophilic, highly membrane- or protein-bound, and accumulate in the brain, lung, and other tissues with a rich blood supply. They also enter the fetal circulation and breast milk. Despite half-lives that may be short, the biological

effects of single doses of most antipsychotic medications usually persist for at least 24 hours, permitting once-daily dosing for many agents once the patient has adjusted to initial side effects.

Elimination from the plasma may be more rapid than from sites of high lipid content and binding, notably the CNS, as evidenced by PET pharmacokinetic studies that demonstrate half-lives in the CNS that exceed those in plasma. For example, mean single-dose plasma half-lives of olanzapine and risperidone are 24.2 and 10.3 hours respectively, whereas a 50% reduction from peak striatal D₂ receptor occupancy requires 75.2 hours for olanzapine and 66.6 hours for risperidone (Tauscher et al., 2002). Similar discrepancies are seen between the time course of plasma levels and occupancy of extrastriatal D₂ and 5-HT_{2A} receptors (Tauscher et al., 2002). Metabolites of long acting injectable medications have been detected in the urine several months after drug administration was discontinued. Slow removal of drug may contribute to the typical delay of exacerbation of psychosis after stopping drug treatment. Depot decanoate esters of fluphenazine and haloperidol, paliperidone palmitate, as well as risperidone-impregnated microspheres, are absorbed and eliminated much more slowly than are oral preparations. For example, the $t_{1/2}$ of oral fluphenazine is ~20 hours while the IM decanoate ester has a $t_{1/2}$ of 14.3 days; oral haloperidol has a $t_{1/2}$ of 24–48 hours in CYP2D6-extensive metabolizers (de Leon et al., 2004), while haloperidol decanoate has a $t_{1/2}$ of 21 days (Altamura et al., 2003); paliperidone palmitate has a $t_{1/2}$ of 25–49 days compared to an oral paliperidone $t_{1/2}$ of 23 hours. Clearance of fluphenazine and haloperidol decanoate following repeated dosing can require 6–8 months. Effects of LAI *risperidone* (RISPERDAL CONSTA) are delayed for 4 weeks because of slow biodegradation of the microspheres and persist for at least 4–6 weeks after the injections are discontinued (Altamura et al., 2003). The dosing regimen recommended for starting patients on LAI paliperidone generates therapeutic levels in the first week, obviating the need for routine oral antipsychotic supplementation.

With the exception of asenapine, paliperidone and ziprasidone, all antipsychotic drugs undergo extensive phase 1 metabolism by CYPs and subsequent phase 2 glucuronidation, sulfation, and other conjugations (Table 16–3). Hydrophilic metabolites of these drugs are excreted in the urine and to some extent in the bile. Most oxidized metabolites of antipsychotic drugs are biologically inactive; a few (e.g., P88 metabolite of iloperidone, hydroxy metabolite of haloperidol 9-OH risperidone, *N*-desmethylclozapine, and dehydroaripiprazole) are active. These active metabolites may contribute to biological activity of the parent compound and complicate correlating serum drug levels with clinical effects. The active metabolite of risperidone, paliperidone (9-OH risperidone), is already the product of oxidative metabolism, and 59% is excreted unchanged in urine with a lesser amount (32%) excreted as metabolites or via phase 2 metabolism ($\leq 10\%$). Ziprasidone's primary metabolic pathway is through the aldehyde oxidase system that is neither saturable nor inhibitable by commonly encountered xenobiotics, with ~ one-third of ziprasidone's metabolism through CYP3A4 (Meyer, 2007). Asenapine is metabolized primarily through glucuronidation (UGT4), with a minor contribution from CYP1A2. The potential for drug-drug interactions is covered in "Adverse Effects and Drug Interactions" later in the chapter.

Absorption for most agents is quite high, and concurrent administration of anticholinergic anti-parkinsonian agents does not appreciably diminish intestinal absorption. Most orally-disintegrating tablets (ODT) and liquid preparations provide similar pharmacokinetics since there is little mucosal absorption and effects depend on swallowed drug. Asenapine remains the only exception. It is only available as an ODT preparation administered sublingually, and all absorption occurs via oral mucosa, with bioavailability of 35% by this route. If swallowed, the first pass effect is > 98%, indicating that drug swallowed with oral secretions is not bioavailable. Intramuscular administration avoids much of the first-pass enteric metabolism and provides measurable concentrations in plasma within 15-30 minutes. Most agents are highly protein bound, but this protein binding may include glycoprotein sites. Kinetic studies indicate that antipsychotic drugs do not significantly displace other pre-albumin- or albumin-bound medications. Antipsychotic medications are predominantly highly lipophilic with apparent volumes of distribution as high as 20 L/kg.

Therapeutic Uses

The use of antipsychotic medications for the treatment of schizophrenia spectrum disorders, for mania treatment, and as adjunctive use for treatment-resistant major depression has been discussed previously. Antipsychotic agents are also utilized in several nonpsychotic neurological disorders and as antiemetics.

Anxiety Disorders. There are two anxiety disorders in which double-blind, placebo-controlled trials have shown benefit of adjunctive treatment with antipsychotic drugs: obsessive compulsive disorder (OCD) and post-traumatic stress disorder (PTSD). While SSRI antidepressants remain the only psychotropic medication with FDA approval for PTSD treatment, adjunctive low-dose quetiapine, olanzapine, and particularly risperidone significantly reduce the overall level of symptoms in SSRI-resistant PTSD (Bartzokis et al., 2005). OCD patients with limited response to the standard 12-week regimen of high dose SSRI also benefit from adjunctive risperidone (mean dose 2.2 mg), even in the presence of comorbid tic disorders (McDougle et al., 2000). For generalized anxiety disorder, double-blind placebo controlled clinical trials demonstrate efficacy for quetiapine as monotherapy, and for adjunctive low-dose risperidone.

Tourette's Disorder. The ability of antipsychotic drugs to suppress tics in patients with Tourette's disorder has been known for decades, and relates to reduced D_2 neurotransmission in basal ganglia sites. In prior decades, the use of low-dose, high-potency typical antipsychotic agents (e.g., haloperidol, pimozide) was the treatment of choice, but these nonpsychotic patients were extremely sensitive to the impact of DA blockade on cognitive processing speed, and on reward centers. Safety concerns regarding pimozide's QTc prolongation and increased risk for ventricular arrhythmias have largely ended its clinical use. While lacking FDA approval for tic disorders, risperidone and aripiprazole have indications for child and adolescent schizophrenia and bipolar disorder (acute mania) treatment, and these agents (as well as ziprasidone) have published data supporting their use for tic suppression. Given the enormous sensitivity of preadolescent and teenage patients to antipsychotic-induced weight

gain, aripiprazole has an advantage in this patient population due to somewhat lower risk for weight gain, and low risk for hyperprolactinemia or concerns over QTc effects.

Huntington's Disease. Huntington's disease is another neuropsychiatric condition, which, like tic disorders, is associated with basal ganglia pathology. DA blockade can suppress the severity of choreoathetotic movements, but is not strongly endorsed due to the risks associated of excessive DA antagonism that outweigh the marginal benefit. Inhibition of the vesicular monoamine transporter type 2 (VMAT2) with tetrabenazine has replaced DA receptor blockade in the management of chorea (Chapter 22).

Autism. Autism is a disease whose neuropathology is incompletely understood, but in some patients is associated with explosive behavioral outbursts, and aggressive or self-injurious behaviors that may be stereotypical. Risperidone has FDA approval for irritability associated with autism in child and adolescent patients ages 5-16, with common use for disruptive behavior problems in autism and other forms of mental retardation. Initial risperidone daily doses are 0.25 mg for patients weighing < 20 kg, and 0.5 mg for others, with a target dose of 0.5 mg/day in those < 20 kg weight, and 1.0 mg/day for other patients, with a range 0.5-3.0 mg/day.

Anti-emetic Use. Most antipsychotic drugs protect against the nausea- and emesis-inducing effects of DA agonists such as apomorphine that act at central DA receptors in the chemoreceptor trigger zone of the medulla. Antipsychotic drugs are effective antiemetics already at low doses. Drugs or other stimuli that cause emesis by an action on the nodose ganglion, or locally on the GI tract, are not antagonized by antipsychotic drugs, but potent piperazines and butyrophenones are sometimes effective against nausea caused by vestibular stimulation. The commonly used antiemetic phenothiazines are weak DA antagonists (e.g., prochlorperazine) without antipsychotic activity, but can be associated with EPS or akathisia.

Adverse Effects and Drug Interactions

Adverse Effects Predicted by Monoamine Receptor Affinities

Dopamine D_2 Receptor. With the exception of the D_2 partial agonist aripiprazole (and the commercially unavailable agent bifeprunox), all other antipsychotic agents possess D_2 antagonist properties, the strength of which determines the likelihood for EPS, akathisia, long-term tardive dyskinesia risk, and hyperprolactinemia. The manifestations of EPS are described in Table 16-4, along with the usual treatment approach. Acute dystonic reactions occur in the early hours and days of treatment with highest risk among younger patients (peak incidence ages 10-19), especially antipsychotic-naïve individuals, in response to abrupt decreases in nigrostriatal D_2 neurotransmission. The dystonia typically involves head and neck muscles, the tongue, and in its severest form, the oculogyric crisis, extraocular muscles, and is very frightening to the patient.

Table 16-4

Neurological Side Effects of Antipsychotic Drugs

REACTION	FEATURES	TIME OF ONSET AND RISK INFO	PROPOSED MECHANISM	TREATMENT
Acute dystonia	Spasm of muscles of tongue, face, neck, back	Time: 1-5 days. Young, antipsychotic naïve patients at highest risk	Acute DA antagonism	Anti-parkinsonian agents are diagnostic and curative ^a
Akathisia	Subjective and objective restlessness; <i>not</i> anxiety or “agitation”	Time: 5-60 days	Unknown	Reduce dose or change drug; clonazepam, propranolol more effective than anti-parkinsonian agents ^b
Parkinsonism	Bradykinesia, rigidity, variable tremor, mask facies, shuffling gait	Time: 5-30 days. Elderly at greatest risk	DA antagonism	Dose reduction; change medication; anti-parkinsonian agents ^c
Neuroleptic malignant syndrome	Extreme rigidity, fever, unstable BP, myoglobinemia; can be fatal	Time: weeks–months. Can persist for days after stopping antipsychotic	DA antagonism	Stop antipsychotic immediately; supportive care; dantrolene and bromocriptine ^d
Perioral tremor (“rabbit syndrome”)	Perioral tremor (may be a late variant of parkinsonism)	Time: months or years of treatment	Unknown	Anti-parkinsonian agents often help ^c
Tardive dyskinesia	Orofacial dyskinesia; rarely widespread choreoathetosis or dystonia	Time: months, years of treatment. Elderly at 5-fold greater risk. Risk \propto potency of D ₂ blockade	Postsynaptic DA receptor supersensitivity, up-regulation	Prevention crucial; treatment unsatisfactory. May be reversible with early recognition and drug discontinuation

^aTreatment: diphenhydramine 25-50 mg IM, or benztropine 1-2 mg IM. Due to long antipsychotic $t_{1/2}$, may need to repeat, or follow with oral medication.

^bPropranolol often effective in relatively low doses (20–80 mg/day in divided doses). β_1 -Selective adrenergic receptor antagonists are less effective. Non-lipophilic β adrenergic antagonists have limited CNS penetration and are of no benefit (e.g., atenolol).

^cUse of amantadine avoids anticholinergic effects of benztropine or diphenhydramine.

^dDespite the response to dantrolene, there is no evidence of abnormal Ca²⁺ transport in skeletal muscle; with persistent antipsychotic effects (e.g., long-acting injectable agents), bromocriptine may be tolerated in large doses (10-40 mg/day). Anti-parkinsonian agents are not effective.

Parkinsonism resembling its idiopathic form occurs when striatal D₂ occupancy exceeds 78%, and often responds to dose reduction or switching to an antipsychotic with weaker D₂ antagonism. In situations where this is neither possible nor desirable, anti-parkinsonian medication may be employed. Clinically, there is a generalized slowing and impoverishment of volitional movement (bradykinesia) with masked facies

and reduced arm movements during walking. The syndrome characteristically evolves gradually over days to weeks as the risk of acute dystonia diminishes. The most noticeable signs are slowing of movements, and sometimes rigidity and variable tremor at rest, especially involving the upper extremities. “Pill-rolling” movements and other types of resting tremor (at a frequency of 3-5 Hz, as in Parkinson’s disease) may be

438 seen, although they are less prominent in antipsychotic-induced than in idiopathic parkinsonism. Bradykinesia and masked facies may be mistaken for clinical depression. Elderly patients are at greatest risk.

The treatment of acute dystonia and antipsychotic-induced parkinsonism involves the use of anti-parkinsonian agents, although dose reduction should be considered as the initial strategy for parkinsonism. Muscarinic cholinergic receptors modulate nigrostriatal DA release, with blockade increasing synaptic DA availability. Important issues in the use of anticholinergics include the negative impact on cognition and memory, peripheral antimuscarinic adverse effects (e.g., urinary retention, dry mouth, cycloplegia, etc.), and the relative risk of exacerbating tardive dyskinesia. In patients receiving chronic anticholinergic therapy, there are also short-term risks of cholinergic rebound following abrupt anticholinergic withdrawal, which may include sleep disturbance (vivid dreams, nightmares) and also increased EPS if the patient continues to receive antipsychotic treatment. For parenteral administration, diphenhydramine (25-50 mg IM) and benztropine (1-2 mg IM) are the agents most commonly used. Diphenhydramine is an antihistamine that also possesses anticholinergic properties. Benztropine combines a benzhydryl group with a tropane group to create a compound which is more anticholinergic than trihexyphenidyl but less antihistaminic than diphenhydramine. The clinical effect of a single dose lasts 5 hours, thereby requiring 2 or 3 daily doses. Dosing usually starts at 0.5-1 mg bid, with a daily maximum of 6 mg, although slightly higher doses are used in rare circumstances. The piperidine compound trihexyphenidyl was one of the first synthetic anticholinergic agents available, and replaced the belladonna alkaloids for treatment of PD in the 1940s due to its more favorable side effect profile. Trihexyphenidyl inhibits the presynaptic DA reuptake transporter, and therefore has a concomitant higher risk of abuse than the antihistamines or benztropine. Trihexyphenidyl has good GI absorption, achieving peak plasma levels in 1-2 hours, with a serum $t_{1/2}$ ~10-12 hours, generally necessitating multiple daily dosing to achieve satisfactory clinical results. The total daily dosage range is 5-15 mg, given 2-3 times a day as divided doses. Biperiden (AKINETON) is another drug in this class.

Amantadine (SYMMETREL), originally marketed as an antiviral agent toward influenza A, represents the most commonly used non-anticholinergic medication for antipsychotic-induced parkinsonism. Its mechanism of action is unclear but appears to involve presynaptic DA reuptake blockade, facilitation of DA release, postsynaptic DA agonism, and receptor modulation. These properties are sufficient to reduce symptoms of drug-induced parkinsonism, and only rarely have been reported to exacerbate psychotic symptoms. Amantadine is well absorbed after oral administration, with peak levels achieved 1-4 hours after ingestion; clearance is renal, with > 90% recovered unmetabolized in the urine. The plasma $t_{1/2}$ is 12-18 hours in healthy young adults, but is sufficiently longer in those with renal impairment and the elderly that a 50% dose reduction is recommended. Starting dosage is 100 mg orally bid in healthy adults, which may be increased to 200 mg bid. A dose of 100 mg bid yields peak plasma levels of 0.5-0.8 $\mu\text{g/mL}$ and trough levels of 0.3 $\mu\text{g/mL}$. Toxicity is seen at serum levels of 1.0-5.0 $\mu\text{g/mL}$. Amantadine's primary advantage, especially in

older patients, is avoidance of adverse CNS and peripheral anticholinergic effects.

Tardive dyskinesia is a situation of increased nigrostriatal dopaminergic activity as the result of postsynaptic receptor supersensitivity and up-regulation from chronically high levels of postsynaptic D_2 blockade (and possible direct toxic effects of high-potency DA antagonists). Tardive dyskinesia occurs more frequently in older patients, and the risk may be somewhat greater in patients with mood disorders than in those with schizophrenia. Its prevalence averages 15-25% in young adults treated with typical antipsychotic agents for more than a year. The annual incidence was 3-5% with typical antipsychotic drugs, with a somewhat smaller annual rate of spontaneous remission, even with continued treatment. The risk is one-fifth to one-tenth that of an atypical antipsychotic drug.

Tardive dyskinesia is characterized by stereotyped, repetitive, painless, involuntary, quick choreiform (tic-like) movements of the face, eyelids (blinks or spasm), mouth (grimaces), tongue, extremities, or trunk. There are varying degrees of slower athetosis (twisting movements), while tardive dystonia and tardive akathisia are rarely encountered as use of high-dose, high-potency typical antipsychotic medications has abated. The movements all disappear in sleep (as do many other extrapyramidal syndromes), vary in intensity over time, and are dependent on the level of arousal or emotional distress, sometimes reappearing during acute psychiatric illnesses following prolonged disappearance. The dyskinetic movements can be suppressed partially by use of a potent DA antagonist, but such interventions over time may worsen the severity, as this was part of the initial pharmacological insult. Switching patients from potent D_2 antagonists to weaker agents, especially clozapine has at times proven effective. When possible, drug discontinuation may be beneficial, but usually cannot be offered to schizophrenia patients. Trials of the antioxidant vitamin E have proved ineffective and are not recommended, especially in light of adverse cardiovascular effects from chronic vitamin E exposure.

Unlike antipsychotic-induced parkinsonism and acute dystonia, the phenomenology and treatment of *akathisia* suggests involvement of structures outside the nigrostriatal pathway. Akathisia was seen quite commonly during treatment with high doses of high potency typical antipsychotic drugs, but also can be seen with atypical agents, including those with weak D_2 affinities (e.g., quetiapine), and aripiprazole. Among the predominantly antipsychotic drug-naïve population with major depression in clinical studies with adjunctive aripiprazole, akathisia incidence was 23% using a starting dose of 5 mg, suggesting that dopaminergic partial agonism, rather than antagonism, may be etiologic for this medication (Berman et al., 2007; Marcus et al., 2008). Despite the association with D_2 blockade, akathisia does not have a robust response to anti-parkinsonian drugs, so other treatment strategies must be employed, including the use of high-potency benzodiazepines (e.g., clonazepam), nonselective β blockers with good CNS penetration (e.g., propranolol), and also dose reduction, or switching to another

antipsychotic agent. That clonazepam and propranolol have significant cortical activity and are ineffective for other forms of EPS, points to an extrastriatal origin for akathisia symptoms.

The rare neuroleptic malignant syndrome (NMS) resembles a very severe form of parkinsonism, with signs of autonomic instability (hyperthermia and labile pulse, blood pressure, and respiration rate), stupor, elevation of creatine kinase in serum, and sometimes myoglobinemia with potential nephrotoxicity. At its most severe, this syndrome may persist for more than a week after the offending agent is discontinued, and is associated with mortality. This reaction has been associated with various types of antipsychotic agents, but its prevalence may be greater when relatively high doses of potent agents are used, especially when they are administered parenterally. Aside from cessation of antipsychotic treatment and provision of supportive care, including aggressive cooling measures, specific pharmacological treatment is unsatisfactory, although administration of dantrolene and the dopaminergic agonist bromocriptine may be helpful. While dantrolene also is used to manage the syndrome of malignant hyperthermia induced by general anesthetics, the neuroleptic-induced form of hyperthermia probably is not associated with a defect in Ca^{2+} metabolism in skeletal muscle. There are anecdotal reports of NMS with atypical antipsychotic agents, but this syndrome is now rarely seen in its full presentation.

Hyperprolactinemia results from blockade of the pituitary actions of the tuberoinfundibular dopaminergic neurons; these neurons project from the arcuate nucleus of the hypothalamus to the median eminence, where they deliver DA to the anterior pituitary via the hypophyseoportal blood vessels. D_2 receptors on lactotropes in the anterior pituitary mediate the tonic prolactin-inhibiting action of DA. Correlations between the D_2 potency of antipsychotic drugs and prolactin elevations are excellent. With the exception of risperidone and paliperidone, atypical antipsychotic agents show limited (asenapine, iloperidone, olanzapine, quetiapine, ziprasidone) to almost no effects (clozapine, aripiprazole) on prolactin secretion.

The hyperprolactinemia from antipsychotic drugs is rapidly reversible when the drugs are discontinued. Hyperprolactinemia can directly induce breast engorgement and galactorrhea. Approximately 33% of human breast cancers are prolactin-dependent *in vitro*, a factor of potential importance if the prescription of these drugs is contemplated in a patient with previously detected breast cancer. By suppressing the secretion of gonadotropins and sex steroids, hyperprolactinemia can cause amenorrhea in women and sexual dysfunction or infertility in men. The development of amenorrhea is of concern as it represents low serum estradiol levels and ongoing risk for bone density loss. The development of amenorrhea becomes a sensitive marker for sex hormone levels, and should prompt clinical action, while asymptomatic measurable increases in serum prolactin levels do not necessarily merit any intervention. Dose reduction can be tried to decrease serum prolactin levels, but caution must be exercised to keep treatment within the antipsychotic therapeutic range. When switching from offending antipsychotic agents is not feasible, bromocriptine can be employed. There is also anecdotal evidence that aripiprazole augmentation may be effective.

All DA antagonist antipsychotic drugs possess antiemetic properties by virtue of their actions at the medullary chemoreceptor trigger zone (Figure 46–4). The D_2 partial agonists aripiprazole (and bifeprunox), however, can be associated with nausea. For aripiprazole this effect was noted in clinical trials of oral medication for acute mania, bipolar maintenance, or schizophrenia (nausea incidence 15% for aripiprazole vs. 11% for placebo; vomiting incidence 11% for aripiprazole vs. 6% for placebo), and also in studies of pediatric bipolar mania in patients ages 10-17 (nausea incidence 11%) and in acute IM trials for agitation in schizophrenia or acute mania (nausea incidence 9%). Bifeprunox possessed a level of intrinsic DA agonism that was slightly greater than that for aripiprazole (25-28%), but was significant enough to cause clinical problems with nausea and vomiting, that a 10-day titration from an initial starting dose of 0.125 mg was necessary to reach the proposed effective dosage range of 10-30 mg (Glick and Peselow, 2008).

H_1 Receptors. Central antagonism of H_1 receptors is associated with two major adverse effects: sedation and weight gain via appetite stimulation. Examples of sedating antipsychotic drugs include low-potency typical agents such as chlorpromazine and thioridazine, and the atypical agents clozapine and quetiapine. The sedating effect is easily predicted by their high H_1 receptor affinities (Table 16–2). Some tolerance to the sedative properties will develop, a fact that must be kept in mind when switching patients to nonsedating agents.

There is an extended-release quetiapine preparation available, with markedly reduced C_{max} compared to the immediate-release form. Immediate-release quetiapine generates peak serum levels > 800 ng/mL within 2 hours of ingestion, while the extended release preparation has C_{max} ~50% lower, with peak serum levels seen 4-8 hours after ingestion. In clinical practice the onset of sedation for extended-release quetiapine is delayed for at least 3 hours after oral administration, and subjectively the sedation is much less profound than with the immediate-release form (Mamo et al., 2008).

Rapid discontinuation of sedating antipsychotic drugs is inevitably followed by significant complaints of rebound insomnia and sleep disturbance. If discontinuation of sedating antipsychotic treatment is deemed necessary, except for emergency cessation of clozapine for agranulocytosis, the medication should be tapered slowly over 4-8 weeks, and the clinician should be prepared to utilize a sedative when the end of the titration is reached. Generous dosing of another antihistamine (hydroxyzine), or the anticholinergic antihistamine diphenhydramine are reasonable replacement sedative medications, but others can be used, including benzodiazepines, non-benzodiazepine hypnotics that act at specific benzodiazepine sites (e.g., zolpidem, eszopiclone), and sedating antidepressants (e.g., trazodone). Sedation may be useful during acute psychosis, but excessive sedation can interfere with patient evaluation, may prolong emergency room and psychiatric hospital stays unnecessarily, and is poorly tolerated among elderly dementia and delirium patients, so appropriate caution must be exercised with the choice of agent and the dose.

Weight gain is a significant problem during long-term use of antipsychotic drugs and represents a major barrier to medication adherence, as well as a significant threat to the physical and emotional

health of the patient. Weight gain has effectively replaced concerns over EPS as the adverse effect causing the most consternation among patients and clinicians alike. Appetite stimulation is the primary mechanism involved, with little evidence to suggest that decreased activity (due to sedation) is a main contributor to antipsychotic-related weight gain (Gothelf et al., 2002). Recent animal studies indicate that medications with significant H_1 antagonism induce appetite stimulation through effects at hypothalamic sites (Kim et al., 2007). The low-potency phenothiazine chlorpromazine, and the atypical antipsychotic drugs olanzapine and clozapine, are the agents of highest risk, but weight gain of some extent is seen with nearly all antipsychotic drugs, partly related to the fact that acutely psychotic patients may lose weight; in placebo-controlled acute schizophrenia trials, the placebo cohort inevitably loses weight (Meyer, 2001). For clozapine and olanzapine, massive weight gains of 50 kg or more are not uncommon, and mean annual weight gains of 13 kg are reported in schizophrenia clinical trials, with 20% of subjects gaining $\geq 20\%$ of baseline weight. High-potency typical antipsychotic drugs (e.g., haloperidol, fluphenazine), and newer atypical antipsychotics asenapine, ziprasidone, and aripiprazole, are associated with mean annual weight gains < 2 kg in schizophrenia patients, with mean gains of 2.5-3 kg noted for iloperidone, risperidone, and quetiapine (Meyer, 2001). For unknown reasons, molindone is associated with modest weight loss. Younger and antipsychotic drug-naïve patients are much more sensitive to the weight gain from all antipsychotic agents, including those which appear roughly weight neutral in adult studies, leading some to conjecture that DA blockade may also play a small additive role in weight gain. 5-HT_{2C} antagonism is also thought to play an additive role in promoting weight gain for medications that possess high H_1 affinities (e.g., clozapine, olanzapine), but appears to have no effect in the absence of significant H_1 blockade, as seen with ziprasidone, a weight-neutral antipsychotic drug with extremely high 5-HT_{2C} affinity. Switching to more weight-neutral medications can achieve significant results; however, when not feasible or when unsuccessful, behavioral strategies must be employed, and should be considered for all chronically mentally ill patients given the high obesity prevalence in this patient population.

M_1 Receptors. Muscarinic antagonism is responsible for the central and peripheral anticholinergic effects of medications. Most of the atypical antipsychotic drugs, including risperidone, paliperidone, asenapine, iloperidone, ziprasidone, and aripiprazole, have no muscarinic affinity and no appreciable anticholinergic effects, while clozapine and low-potency phenothiazines have significant anticholinergic adverse effects (Table 16–2). Quetiapine has modest muscarinic affinity, but its active metabolite norquetiapine is likely responsible for anticholinergic complaints (Jensen et al., 2008). Clozapine is particularly associated with significant constipation, perhaps due to the severely ill population under treatment. Routine use of stool softeners, and repeated inquiry into bowel habits are necessary to prevent serious intestinal obstruction from undetected constipation. In general, avoidance of anticholinergic medications obviates the need to secondarily treat problems related

to central or peripheral antagonism. Medications with significant anticholinergic properties should be particularly avoided in elderly patients, especially those with dementia or delirium.

α_1 Receptors. α_1 Adrenergic antagonism is associated with risk of orthostatic hypotension and can be particularly problematic for elderly patients who have poor vasomotor tone. Compared to high-potency typical agents, low-potency typical agents have significantly greater affinities for α_1 receptors and greater risk for orthostasis. While risperidone has a K_i that indicates greater α_1 -adrenergic affinity than chlorpromazine, thioridazine, clozapine, and quetiapine, in clinical practice risperidone is used at 0.01-0.005 times the dosages of these medications, and thus causes a relatively lower incidence of orthostasis in non-elderly patients. Since clozapine-treated patients have few other antipsychotic options, the potent mineralocorticoid fludrocortisone is sometimes tried at the dose of 0.1 mg/day as a volume expander.

Adverse Effects Not Predicted by Monoamine Receptor Affinities

Adverse Metabolic Effects. Such effects have become the area of greatest concern during long-term antipsychotic treatment, paralleling the overall concern for high prevalence of pre-diabetic conditions and type 2 diabetes mellitus, and 2-fold greater CV mortality among patients with schizophrenia (Meyer and Nasrallah, 2009). Aside from weight gain, the two predominant metabolic adverse seen with antipsychotic drugs are dyslipidemia, primarily elevated serum triglycerides, and impairments in glycemic control.

Low-potency phenothiazines were known to elevate serum triglyceride values, but this effect was not seen with high-potency agents (Meyer and Koro, 2004). As atypical antipsychotic drugs became more widely used, significant increases in fasting triglyceride levels were noted during clozapine and olanzapine exposure, and to a lesser extent, with quetiapine (Meyer et al., 2008). Mean increases during chronic treatment of 50-100 mg/dL are common, with serum triglyceride levels exceeding 7000 mg/dL in some patients. Effects on total cholesterol and cholesterol fractions are significantly less, but show expected associations related to agents of highest risk: clozapine, olanzapine, and quetiapine. Risperidone and paliperidone have fewer effects on serum lipids, while asenapine, iloperidone, aripiprazole, and ziprasidone appear to have none (Meyer and Koro, 2004). Weight gain in general may induce deleterious lipid changes, but there is compelling evidence to indicate that antipsychotic-induced hypertriglyceridemia is a weight-independent adverse event that temporally occurs within weeks of starting an offending medication, and which similarly resolves within 6 weeks after medication discontinuation. The finding that

serum triglycerides may change 70-80 mg/dL during a period when weight has changed relatively little propelled the search for adiposity-independent physiological mechanisms to explain this phenomenon.

In individuals not exposed to antipsychotic drugs, elevated fasting triglycerides are a direct consequence of insulin resistance since insulin-dependent lipases in fat cells are normally inhibited by insulin. As insulin resistance worsens, inappropriately high levels of lipolysis lead to the release of excess amounts of free fatty acids that are hepatically transformed into triglyceride particles (Smith, 2007). Elevated fasting triglyceride levels thus become a sensitive marker of insulin resistance, leading to the hypothesis that the triglyceride increases seen during antipsychotic treatment are the result of derangements in glucose-insulin homeostasis. The ability of antipsychotic drugs to induce hyperglycemia was first noted during low-potency phenothiazine treatment, with chlorpromazine occasionally exploited for this specific property as adjunctive presurgical treatment for insulinoma. As atypical antipsychotic drugs found widespread use, numerous case series documented the association of new-onset diabetes and diabetic ketoacidosis associated with treatment with atypical antipsychotic drugs, with most of cases observed during clozapine and olanzapine therapy (Jin et al., 2002, 2004). Analysis of the FDA MedWatch database found that reversibility was high upon drug discontinuation (~78%) for olanzapine- and clozapine-associated diabetes and ketoacidosis, supporting the contention of a drug effect. Comparable rates for risperidone and quetiapine were significantly lower. The mechanism by which antipsychotic drugs disrupt glucose-insulin homeostasis is not known, but recent *in vivo* animal experiments document immediate dose-dependent effects of clozapine and olanzapine on whole-body and hepatic insulin sensitivity (Houseknecht et al., 2007).

Antipsychotic-induced weight gain, and other diabetes risk factors (e.g., age, family history, gestational diabetes, obesity, race, ethnicity, smoking) all contribute to metabolic dysfunction. There may also be inherent disease-related mechanisms that increase risk for metabolic disorders among patients with schizophrenia, but the medication itself is the primary modifiable risk factor. As a result, all atypical antipsychotic drugs have a hyperglycemia warning in the drug label in the U.S., although there is essentially no evidence that aripiprazole, iloperidone, aripiprazole, and ziprasidone cause hyperglycemia. Use of the metabolically more benign agents is recommended for the initial treatment of all patients where long-term treatment is expected. Clinicians should obtain baseline metabolic data, including fasting glucose, lipid panel, and also waist circumference, given the known association between central obesity and future type 2 diabetes risk. Ongoing follow-up of metabolic parameters is commonly built into psychiatric charts and community mental health clinic procedures to insure that all patients receive some level of metabolic monitoring. As with weight gain, the changes in fasting glucose and lipids should prompt reevaluation of ongoing treatment, institution of measures to improve metabolic health (diet, exercise, nutritional counseling), and consideration of switching antipsychotic agents.

Adverse Cardiac Effects. Ventricular arrhythmias and sudden cardiac death (SCD) are a concern with the use of antipsychotic agents. Most of the older antipsychotic agents (e.g., thioridazine) inhibit cardiac K⁺

channels, and all antipsychotic medications marketed in the U.S. carry a class label warning regarding QTc prolongation. A black box warning exists for thioridazine, mesoridazine, pimozide, IM droperidol, and IV (but not oral or IM) haloperidol due to reported cases of torsade de pointes and subsequent fatal ventricular arrhythmias (discussed next and in Chapter 29). Although the newer atypical agents are thought to have less effects on heart electrophysiology compared to the typical agents, a recent retrospective analysis found a dose-dependent increased risk for SCD among antipsychotic users of newer and older agents alike compared to antipsychotic nonusers, with a relative risk of 2 (Ray et al., 2009).

Cardiac arrhythmia is the most common etiology for SCD, but it is important to determine whether the arrhythmia is primary or secondary to structural changes related to cardiomyopathy, myocarditis, or acute myocardial infarction. Secondary ventricular arrhythmia is probably the most frequent form of fatal tachyarrhythmia, but the exact distribution of SCD deaths by etiology among antipsychotic-treated patients is unclear in the absence of large autopsy samples. The true incidence of drug-induced ventricular arrhythmia can only be estimated, due partly to underreporting, and the fact that drug-induced torsade de pointes is rarely captured with confirmatory EKG (Nielsen and Toft, 2009).

Multiple ion channels are involved in the depolarization and repolarization of cardiac ventricular cells, which are discussed in detail in Chapter 29. Myocyte depolarization is seen as the QRS complex on EKG, and is primarily mediated by ion channels that permit rapid Na⁺ influx. Antagonism of these voltage-gated Na⁺ channels causes QRS widening and an increase in the PR interval, with increased risk for ventricular arrhythmia. Thioridazine has been shown to inhibit Na⁺ channels at high dosages, but other antipsychotic medications have not (Nielsen and Toft, 2009). Repolarization is mediated in part by K⁺ efflux via two channels: the rapid I_{kr} and the slow I_{ks} channel. The I_{kr} channel is encoded by the human-ether-a-related-go-go gene (HERG), polymorphisms of which are involved in the congenital long QT syndrome associated with syncope and SCD. Many antipsychotic drugs block the I_{kr} channel to an extent comparable with that seen in congenital long QT syndrome. Antagonism of I_{kr} channels is the mechanism responsible for most cases of drug-induced QT prolongation, and is the suspected mechanism for the majority of antipsychotic-induced sudden cardiac deaths (Nielsen and Toft, 2009).

Aside from individual agents, where anecdotal and pharmacosurveillance data indicate risk for torsade de pointes (e.g., thioridazine, pimozide), most of the commonly used newer antipsychotic agents are associated with known risk for ventricular arrhythmias, including ziprasidone in overdose up to 12,000 mg. One exception is sertindole, an agent not available in the U.S. that was withdrawn in 1998 based on anecdotal reports of torsade de pointes, and then reintroduced in Europe in 2006 with strict EKG monitoring guidelines (Nielsen and Toft, 2009). Although *in vitro* data revealed sertindole's affinity for the K⁺ rectifier channel, several epidemiological studies published over the past decade were unable to confirm an

increased risk of sudden death due to sertindole exposure, thereby providing justification for its reintroduction. Aside from sertindole, the apparent safety of newer antipsychotic medications appears at odds with retrospective findings of SCD among antipsychotic users (Ray et al., 2009), thus confronting the clinician with contradictory information regarding antipsychotic drug-related SCD risk, and leading to conflicting clinical recommendations. Currently, there are no data that would suggest a benefit of routine EKG monitoring for prevention of SCD among antipsychotic drug users.

Other Adverse Effects. Seizure risk is an unusual adverse effect of antipsychotic drugs, with anecdotal reports of uncertain causality present for many agents. In the U.S., there is a class label warning for seizure risk on all antipsychotic agents, with reported incidences well below 1%. Among commonly used newer antipsychotic drugs, only clozapine has a dose-dependent seizure risk, with an incidence of 3-5% per year. The structurally related olanzapine had an incidence of 0.9% in premarketing studies. Seizure disorder patients who commence antipsychotic treatment must receive adequate prophylaxis, with consideration given to avoiding carbamazepine and phenytoin due to their capacity to induce CYPs and P-glycoprotein. Carbamazepine is also contraindicated during clozapine treatment due to its bone marrow effects, particularly leucopenia. Redistribution and increased spacing of doses to minimize high peak serum clozapine levels can help, but patients may eventually require antiseizure medication. Valproic acid derivatives (e.g., divalproex sodium) are often used, but will compound clozapine-associated weight gain.

Clozapine possesses a host of unusual adverse effects aside from seizure induction, the most concerning of which is agranulocytosis. Clozapine's introduction in the U.S. was based on its efficacy in refractory schizophrenia, but came with FDA-mandated CBC monitoring that is overseen by industry-created registries. Now that several generic forms of clozapine are available in addition to proprietary CLOZARIL, clinicians must verify with each manufacturer the history of prior exposure. The overall agranulocytosis incidence is slightly under 1%, with highest risk during the initial 6 months of treatment, peaking at months 2-3 and diminishing rapidly thereafter. The mechanism is immune mediated, and patients who have verifiable clozapine-related agranulocytosis should not be rechallenged. Increased risk is associated with certain HLA types and advanced age. An extensive algorithm guiding clinical response to agranulocytosis, and lesser forms of neutropenia, is available from manufacturer web sites, and must be followed, along with the current recommended CBC monitoring frequency.

While rarely used due to its risk of QTc prolongation, thioridazine is also associated with pigmentary retinopathy at daily doses ≥ 800 mg/day. Low-potency phenothiazines are associated with the development of photosensitivity, which necessitated warnings regarding sun exposure. Phenothiazines are also associated with development of a cholestatic picture on laboratory assessments (e.g., elevated alkaline phosphatase), and rarely elevations in hepatic transaminases.

Increased Mortality in Dementia Patients. Perhaps the least understood adverse effect is the increased risk for cerebrovascular events and all-cause mortality among elderly dementia patients exposed to antipsychotic medications. All antipsychotic agents carry a mortality warning in the drug label regarding their use in dementia patients. The cerebrovascular adverse event rates in 10-week dementia trials range from 0.4-0.6% for placebo to 1.3-1.5% for risperidone,

olanzapine and aripiprazole (Jeste et al., 2008). The mortality warning indicates a 1.6-1.7 fold increased mortality risk for drug versus placebo. Mortality is due to heart failure, sudden death, or pneumonia. The underlying etiology for antipsychotic-related cerebrovascular and mortality risk is unknown, but the finding of virtually equivalent mortality risk for typical agents compared to atypical antipsychotic drugs (including aripiprazole) suggests an impact of reduced D_2 signaling regardless of individual antipsychotic mechanisms.

Overdose with typical antipsychotic agents is of particular concern with *low*-potency agents (e.g., chlorpromazine) due to the risk of torsades de pointes, sedation, anticholinergic effects, and orthostasis. Patients who overdose on *high*-potency typical antipsychotic drugs (e.g., haloperidol) and the substituted benzamides are at greater risk for EPS due to the high D_2 affinity, but also must be observed for EKG changes. Overdose experience with newer agents, including ziprasidone, indicates a much lower risk for torsade de pointes ventricular arrhythmias compared to older antipsychotic medications; however, combinations of antipsychotic agents with other medications can lead to fatality, primarily through respiratory depression (Ciranni et al., 2009).

Drug-Drug Interactions. Antipsychotic agents are not significant inhibitors of CYP enzymes with a few notable exceptions (chlorpromazine, perphenazine, and thioridazine inhibit CYP 2D6) (Otani and Aoshima, 2000). The plasma half-lives of a number of these agents are altered by induction or inhibition of hepatic CYPs and by genetic polymorphisms that alter specific CYP activities (Table 16-3). While antipsychotic drugs are highly protein bound, there is no evidence of significant displacement of other protein bound medications, so dosage adjustment is not required for anticonvulsants, warfarin, or other agents with narrow therapeutic indices. With respect to drug-drug interactions, it is important to consider the effects of environmental exposures (smoking, nutraceuticals, grapefruit juice), and changes in these behaviors.

Changes in smoking status can be especially problematic for clozapine-treated patients, and will alter serum levels by 50% or more. Within 2 weeks of smoking discontinuation (e.g., hospitalization in nonsmoking environment), the absence of aryl hydrocarbons will cause upregulated CYP1A2 activity to return to baseline levels, with a concomitant rise in serum clozapine concentrations (Rostami-Hodjegan et al., 2004). For smoking patients with high serum clozapine levels, this loss of enzyme induction may result in nonlinear increases in clozapine levels, with potentially catastrophic results. Conversely, patients discharged from nonsmoking wards to the community will be expected to resume smoking behavior, with an expected 50% decrease in clozapine levels. Monitoring of serum clozapine concentrations, anticipation of changes in smoking habits,

and dosage adjustment can minimize development of subtherapeutic or supratherapeutic levels.

Use in Pediatric Populations. Both risperidone and aripiprazole have indications for child and adolescent bipolar disorder (acute mania) for ages 10-17, and for adolescent schizophrenia (ages 13-17). Risperidone and aripiprazole are FDA-approved for irritability associated with autism in child and adolescent patients ages 5-16. As discussed in the sections on adverse effects, antipsychotic drug-naïve patients and younger patients are more susceptible to EPS and to weight gain. Use of the minimum effective dose can minimize EPS risk; aripiprazole and ziprasidone have the lowest risk, olanzapine the highest. Risperidone's effects on prolactin must be monitored by clinical inquiry, but long-term follow-up studies indicate some tolerance to hyperprolactinemia, with levels after 12 months of exposure significantly lower than peak levels, and close to baseline. Delayed sexual maturation was not seen in adolescents in clinical trials with risperidone, but should nevertheless be monitored.

Use in Geriatric Populations. The increased sensitivity to EPS, orthostasis, sedation, and anticholinergic effects are important issues for the geriatric population, and often dictate the choice of antipsychotic medication. Avoidance of drug-drug interactions is also important, as older patients on numerous concomitant medications have multiple opportunities for interactions. Dose adjustment can offset known drug-drug interactions, but clinicians must be attentive to changes in concurrent medications and the potential pharmacokinetic consequences. Vigilance must also be maintained for the additive pharmacodynamic effects of α_1 adrenergic, antihistaminic, and anticholinergic properties of other agents. Elderly patients have an increased risk for tardive dyskinesia and parkinsonism, with TD rates ~5-fold higher than those seen with younger patients. With typical antipsychotics, the reported annual TD incidence among elderly patients in 20-25% compared to 4-5% for younger patients. With atypical antipsychotic, the annual TD rate in elderly patients is much lower (2-3%). Increased risk for cerebrovascular events and all-cause mortality is also seen in elderly patients with dementia (see "Increased Mortality in Dementia Patients"). Compared to younger patients, antipsychotic-induced weight gain is lower in elderly patients.

Use During Pregnancy and Lactation. Antipsychotic agents carry pregnancy class B or C warnings. Human data from anecdotal case reports and manufacturer registries indicate limited or no patterns of toxicity and no consistent increased rates of malformations. Nonetheless, the use of any medication during pregnancy must be balanced by concerns over fetal impact, especially first-trimester exposure, and the mental health of the mother. Haloperidol is often cited as the agent with the best safety record based on decades of accumulated human exposure reports, but newer antipsychotic drugs, such as risperidone, have not generated any signals of concern (Viguera et al., 2009). As antipsychotic drugs are designed to cross the blood-brain barrier, all have high rates of placental passage. Placental passage ratios are estimated to be highest for olanzapine (72%), followed by haloperidol (42%), risperidone (49%), and quetiapine (24%). Neonates exposed to olanzapine, the atypical agent with highest placental passage ratio, exhibit a trend towards greater neonatal intensive care unit admission (Viguera et al., 2009). Use in lactation presents a separate set of concerns due to the low level of infant hepatic catabolic activity in the first 2 postpartum months. While breast milk presents an important source of protective antibodies

for the baby, the inability of the newborn to adequately metabolize xenobiotics presents a significant risk for antipsychotic drug toxicity. The available data do not provide adequate guidance on choice of agent.

Major Drugs Available in the Class

In the U.S., atypical antipsychotic drugs have largely replaced older agents, primarily due to their more favorable EPS profile, although typical agents are widely used throughout the world. Table 16-1 describes the acute and maintenance doses for adult schizophrenia treatment based on consensus recommendations.

Acute IM forms exist for many typical antipsychotic drugs, and also for aripiprazole, ziprasidone, and olanzapine, with the latter being the most sedating due to its antihistaminic and anticholinergic properties. The standard IM doses are 9.75 mg for aripiprazole, 10 mg for olanzapine, and 20 mg for ziprasidone (Altamura et al., 2003). The 20-mg IM ziprasidone dose generates serum levels that exceed those from 160 mg/day orally, but has not been associated with reports of torsade de pointes or cardiac dysrhythmia. There are numerous LAI (long-acting injectable) formulations of typical antipsychotics, but in the U.S., the only available LAI typical agents are fluphenazine and haloperidol (as decanoate esters), with usual dosages 12.5-25 mg IM every 2 weeks and 50-200 mg (not to exceed 100 mg as the initial dose) IM monthly, respectively. Haloperidol decanoate has more predictable kinetics, while fluphenazine decanoate's serum level can increase within days after administration and induce adverse effects (Altamura et al., 2003). EPS remains a significant barrier for using these agents. LAI risperidone was studied at doses of 25, 50, and 75 mg IM biweekly, but the higher dose was found to be without increased efficacy and with greater EPS rates. Current available doses, all distributed as complete, single-dose kits, are 12.5, 25, 37.5, and 50 mg, given as a 2-mL water-based injection. LAI risperidone is impregnated into organic microspheres that require several weeks to liberate free drug. The impact of any dosage change (or missed dose) of LAI risperidone is seen 4 weeks later. LAI paliperidone has recently become available, and dosing is initiated with two loading IM deltoid injections given at days 1 (234 mg) and 8 (156 mg), followed by injections every 4 weeks starting at day 36. This loading strategy can be omitted if transitioning patients from another LAI antipsychotic, with LAI paliperidone given in lieu of the next injection, and the every 4 weeks thereafter. The package insert provides detailed information on dose equivalency with oral paliperidone, and on handling missed injections. ODT forms are available for aripiprazole, clozapine, olanzapine, and risperidone, and are the only form for asenapine. These ODT preparations are commonly used in emergency and inpatient settings where patients may be prone to cheeking or spitting out oral tablets.

Clinical Summary: Treatment of Psychosis

The pharmacological profile of newer, atypical antipsychotic drugs has expanded the uses of antipsychotic medications during the last decade to include adjunctive use for major depression and bipolar depression, with

supporting data for certain anxiety disorders. Considerable debate exists over the clinical superiority touted for the newer antipsychotic drugs for the treatment of schizophrenia compared to older, typical agents. What is clear is that the more favorable therapeutic indices of newer agents (e.g., fewer neurological adverse effects) permit clinicians to avoid the effects of excessive antagonism of D₂ dopamine receptors. Aside from refractory schizophrenia, where clozapine exhibits superior effectiveness, drug choice primarily revolves around the avoidance of adverse effects, concerns regarding drug-drug interactions, and the availability of acute injectable, long-acting injectable, or orally dissolving tablet forms. Atypical antipsychotic drugs have generated considerable interest in non-dopaminergic mechanisms of action, including the useful property of 5-HT_{2A} antagonism. The greater understanding of schizophrenia pathophysiology has furthered investigation into glutamatergic and cholinergic agents, some of which have advanced to later-stage clinical trials. Knowledge of receptor binding affinities combined with neuroimaging data on CNS receptor occupancy provide a guide to gauging the risk of most adverse effects of a particular drug. However, the pathophysiology for adiposity-independent effects on glucose-insulin homeostasis seen with certain antipsychotic medications has yet to be elucidated. Given the inherent cardiometabolic risk factors common among the severely mentally ill, close medical monitoring during long-term antipsychotic therapy is considered the standard of care, regardless of the metabolic risk of the specific antipsychotic agent. Judicious use of antipsychotic drugs with more favorable risk profiles is the primary guide to medication choice.

TREATMENT OF MANIA

Mania is a period of elevated, expansive or irritable mood with co-existing symptoms of increased energy and goal-directed activity, and decreased need for sleep (discussed later). Mania represents one pole of what had been termed manic-depressive illness, but is now referred to as bipolar disorder (American Psychiatric Association, 2000). As with psychosis, mania may be induced by medications (e.g., DA agonists, antidepressants, stimulants) or substances of abuse, primarily cocaine and amphetamines, although periods of substance-induced mania should not be relied upon solely to make a diagnosis of bipolar disorder. Nonetheless, there is recognition that patients who develop antidepressant-induced mania do have a bipolar

diathesis even with no prior independent history of mania, and should be followed carefully, especially if antidepressant treatment is again considered during periods of major depression.

Mania is distinguished from its less severe form, hypomania, by the fact that hypomania, by definition, does not result in functional impairment or hospitalization, and is not associated with psychotic symptoms. Patients who experience periods of hypomania and major depression have bipolar II disorder, those with mania at any time, bipolar I, and those with hypomania, but less severe forms of depression, cyclothymia (American Psychiatric Association, 2000). The prevalence of bipolar I disorder is roughly 1% of the population, and the prevalence of all forms of bipolar disorder 3-5%.

Genetics studies of bipolar disorder have yielded several loci of interest associated with disease risk and predictors of treatment response, but the data are not yet at the phase of clinical application. Unlike schizophrenia, where the biological understanding of monoamine neurotransmission has permitted synthesis of numerous effective compounds, no medication has yet been designed to treat the full spectrum of bipolar disorder based on preformed biological hypotheses of the illness, although candidate medications have passed certain *in vitro* and *in vivo* assays. Lithium carbonate was introduced fortuitously in 1949 for the treatment of mania (Cade, 1949) and approved for this purpose in the U.S. in 1970. While many classes of agents demonstrate efficacy in acute mania, including lithium, antipsychotic drugs, and certain anticonvulsants, no medication has surpassed lithium's efficacy for prophylaxis of future manic and depressive phases of bipolar disorder, and no other medication has demonstrated lithium's reduction in suicidality among bipolar patients.

Pharmacological Properties of Agents for Mania

Antipsychotic Agents. The chemistry and pharmacology of antipsychotic medications are addressed earlier in this chapter.

Anticonvulsants. The pharmacology and chemistry of the anticonvulsants with significant data for acute mania (valproic acid compounds, carbamazepine) and for bipolar maintenance (lamotrigine) are covered extensively in Chapter 21. These compounds are of diverse chemical classes, but share the common property of functional blockade of voltage-gated Na⁺ channels, albeit with differing binding sites. Valproate exhibits non-specific binding to voltage-gated Na⁺ channels, while carbamazepine (and its congeners) and lamotrigine have specific high affinity for the open-channel configuration of the alpha subunit (Söderpalm, 2002). These anticonvulsants have varying affinities for voltage-dependent Ca²⁺ channels, and differ in their ability to facilitate GABA-ergic (valproate) or

inhibit glutamatergic neurotransmission (lamotrigine). The extent to which any of these actions is necessary for antimanic or other mood stabilizing activity is unknown, but the failure of phenytoin, gabapentin, and topiramate to be effective antimanic and mood-stabilizing medications suggests that potent blockade of voltage-gated Na^+ channels (which gabapentin and topiramate lack) is necessary but not sufficient, since phenytoin is very active at these channels.

Lithium. Lithium (Li^+) is the lightest of the alkali metals (group Ia); the salts of this monovalent cation share some characteristics with those of Na^+ and K^+ . Li^+ is readily assayed in biological fluids and can be detected in brain tissue by magnetic resonance spectroscopy (Soares et al., 2000). Traces of the ion occur normally in animal tissues, but it has no known physiological role. Lithium carbonate and lithium citrate currently are used therapeutically in the U.S.

Mechanism of Action. Therapeutic concentrations of Li^+ have almost no discernible psychotropic effects in individuals without psychiatric symptoms. There are numerous molecular and cellular actions of Li^+ , some of which overlap with identified properties of other mood-stabilizing agents (particularly valproate), and are discussed below. An important characteristic of Li^+ is that, unlike Na^+ and K^+ , Li^+ develops a relatively small gradient across biological membranes. Although it can replace Na^+ in supporting a single action potential in a nerve cell, it is not a substrate for the Na^+ pump and therefore cannot maintain membrane potentials. It is uncertain whether therapeutic concentrations of Li^+ (0.5–1.0 mEq/L) affect the transport of other monovalent or divalent cations by nerve cells.

Hypotheses for the Mechanism of Action of Lithium, and Relationship to Anticonvulsants. Plausible hypotheses focus on lithium's impact on monoamines implicated in the pathophysiology of mood disorders, and on second-messenger and other intracellular molecular mechanisms involved in signal transduction, gene regulation, and cell survival (Quiroz et al., 2004). In animal brain tissue, lithium at concentrations of 1–10 mEq/L inhibits the depolarization-provoked and Ca^{++} -dependent release of NE and DA, but not 5-HT, from nerve terminals. Li^+ may even transiently enhance release of 5-HT, especially in the limbic system, but has limited effects on catecholamine-sensitive adenylyl cyclase activity or on the binding of ligands to monoamine receptors in brain tissue, although it does influence response of 5-HT autoreceptors to agonists (Lenox and Wang, 2003). Li^+ modifies some hormonal responses mediated by adenylyl cyclase or PLC in other tissues, including the actions of vasopressin and thyroid-stimulating hormone on their peripheral target tissues (Quiroz et al., 2004). Li^+ can inhibit the effects of receptor-blocking agents that cause supersensitivity in such systems. In part, the actions of Li^+ may reflect its ability to interfere with the activity of both stimulatory and inhibitory G proteins (G_s and G_i) by keeping them in their inactive $\alpha\beta$ trimeric state (Jope, 1999).

Considered by many as relevant for lithium's therapeutic efficacy is its inhibition of inositol monophosphatase and interference with the phosphatidylinositol pathway (Figure 16–1), leading to decreased cerebral inositol concentrations (Williams et al., 2002). Phosphatidylinositol (PI) is a membrane lipid that is phosphorylated to form phosphatidylinositol bisphosphate (PIP_2). Activated phospholipase C cleaves PIP_2 into diacylglycerol and inositol

1,4,5- trisphosphate (IP_3), with the latter stimulating Ca^{2+} release from cellular stores. IP_3 is dephosphorylated to inositol monophosphate (IP) and thence to inositol by inositol monophosphatase. Within its range of therapeutic concentrations, Li^+ uncompetitively inhibits this last step (Chapter 3), with resultant decrease in available inositol for resynthesis into PIP_2 (Shaldubina et al., 2001). The inositol depletion effect can be detected *in vivo* with magnetic resonance spectroscopy (Manji and Lenox, 2000). A recent genome-wide association study has implicated diacylglycerol kinase in the etiology of bipolar disorder, strengthening the association between Li^+ actions and PI metabolism (Baum et al., 2008). Further support for the role of inositol signaling in mania rests on the finding that valproate, and valproate derivatives, decrease intracellular inositol concentrations (Shaltiel et al., 2007). Unlike Li^+ , valproate decreases inositol through inhibition of myo-inositol-1-phosphate synthase. Carbamazepine exposure in cultured sensory neurons alters the dynamic behavior of neuron growth cones, effects that are remediated through inositol supplementation, implicating inositol depletion as a mechanism underlying carbamazepine's mood stabilizing properties (Williams et al., 2002).

Stimulation of NMDA receptors results in IP_3 accumulation in primate brain, leading some to postulate that lithium's activity in the inositol pathway might also relate to glutamatergic effects (Dixon and Hokin, 1998). Subsequent experiments demonstrated the ability of acute high lithium levels to increase synaptic glutamate in mice and non-human primates, primarily through inhibition of glutamate reuptake at presynaptic nerve terminals by lowering the V_{max} of glutamate transport, but not glutamate binding to the transporter (Dixon and Hokin, 1998). The impact of suprathreshold Li^+ on synaptic glutamate may be implicated in lithium-induced neurotoxicity during overdose; conversely, chronic Li^+ administration at therapeutic CNS concentrations results in increased glutamate uptake and increased levels of glutamate in presynaptic synaptosomes (Dixon and Hokin, 1998). This effect occurs at therapeutic Li^+ serum concentrations, leading to speculation that the neuroprotective effects of Li^+ seen in models of excitotoxic cell death may be mediated through modulation of synaptic glutamate availability (Bauer et al., 2003).

Li^+ treatment also leads to consistent decreases in the functioning of protein kinases in brain tissue, including PKC, particularly isoforms α and β (Jope, 1999; Manji and Lenox, 2000; Quiroz et al., 2004). Among other proposed antimanic or mood-stabilizing agents, this effect is also shared with valproic acid (particularly for PKC) but not with carbamazepine (Manji and Lenox, 2000). Long-term treatment of rats with lithium carbonate or valproate decreases cytoplasm-to-membrane translocation of PKC and reduces PKC stimulation-induced release of 5-HT from cerebral cortical and hippocampal tissue. Excessive PKC activation can disrupt prefrontal cortical regulation of behavior, but pretreatment of monkeys and rats with lithium carbonate or valproate blocks the impairment in working memory induced by activation of PKC in a manner also seen with the PKC inhibitor chelerythrine (Yildiz et al., 2008). The impact of Li^+ or valproate on PKC activity may secondarily alter the release of amine neurotransmitters and hormones as well as the activity of tyrosine hydroxylase (Manji and Lenox, 2000). A major substrate for cerebral PKC is the myristolated alanine-rich C-kinase substrate (MARCKS) protein, which has been implicated in synaptic and neuronal plasticity. The expression of MARCKS protein is reduced by

treatment with both Li^+ and valproate, but not by carbamazepine, antipsychotic medications, or antidepressants (Watson and Lenox, 1996). This proposed mechanism of PKC inhibition has been the basis for therapeutic trials of tamoxifen, a selective estrogen receptor modulator that is also a potent centrally active PKC inhibitor (Einat et al., 2007). In acutely manic bipolar I patients, tamoxifen has shown evidence of efficacy as adjunctive treatment, and in two double-blind, placebo-controlled monotherapy trials (Yildiz et al., 2008; Zarate et al., 2007).

Both Li^+ and valproate treatment also inhibit the activity of glycogen synthase kinase-3 β (GSK-3 β) (Williams et al., 2002). Of relevance to mood disorders, GSK-3 inhibition increases hippocampal levels of β -catenin, a function implicated in mood stabilization (Kozikowski et al., 2007). GSK-3 β has been found to regulate mood stabilizer-induced axonal growth and synaptic remodeling and to modulate brain-derived neurotrophic factor response. Mice with mutant forms of the GSK-3 β gene demonstrate abnormalities of biological rhythms that are proposed endophenotypes for the circadian disruption seen in manic patients. In animal models, Li^+ induces molecular and behavioral effects comparable to that seen when one GSK-3 β gene locus is inactivated. Potent and selective GSK-3 β inhibitors show expected activity in mouse models of mania, thus providing further stimulus for exploring this mechanism (Kozikowski et al., 2007).

Another proposed common mechanism for the actions of Li^+ and valproate relates to reduction in arachidonic acid turnover in brain membrane phospholipids (Rao et al., 2008). Rats fed Li^+ in amounts that achieve therapeutic CNS drug levels have reduced turnover of PI (\downarrow 83%) and phosphatidylcholine (\downarrow 73%); chronic intraperitoneal valproate achieves reductions of 34% and 36%, respectively. Li^+ also decreased gene expression of PLA₂ and decreased levels of COX-2 and its products (Rapoport and Bosetti 2002).

5-HT release from presynaptic terminals is regulated by 5-HT_{1A} autoreceptors located on the cell body and 5-HT_{1B} receptors on the nerve terminal. *In vitro* electrophysiological studies suggest that Li^+ facilitates 5-HT release. Li^+ augments effects of antidepressants, and in animal models of depression, lithium's activity appears to be mediated through desensitizing actions at 5-HT_{1B} sites; Li^+ also antagonizes mouse behaviors induced by administration of selective 5-HT_{1B} agonists (Shaldubina et al., 2001).

Li^+ and valproic acid both interact with nuclear regulatory factors that affect gene expression (e.g., AP-1, AMI-1 β , PEBP-2 β); both agents increase expression of Bcl-2, which is associated with protection against neuronal degeneration/apoptosis (Manji and Chen, 2002).

Absorption, Distribution, and Elimination. Li^+ is absorbed readily and almost completely from the GI tract. Complete absorption occurs in ~ 8 hours, with peak plasma concentrations occurring 2-4 hours after an oral dose (Sproule, 2002). Slow-release preparations of lithium carbonate minimize early peaks in plasma concentrations, and to some extent may decrease local GI adverse effects, but the increased trough levels may increase the risk for, and the extent of, nephrogenic diabetes insipidus (Schou et al., 1982). Li^+ initially is distributed in the extracellular fluid, and gradually accumulates in various tissues; it does not bind appreciably to plasma proteins. The concentration gradient across plasma membranes is much smaller than those for Na^+ and K^+ . The final volume of distribution (0.7-0.9 L/kg) approaches

that of total body water and is lower than agents that are lipophilic and protein bound. Passage through the blood-brain barrier is slow, and when a steady state is achieved, the concentration of Li^+ in the cerebrospinal fluid and in brain tissue is ~ 40-50% of the concentration in plasma. The kinetics of Li^+ can be monitored in human brain with magnetic resonance spectroscopy (Soares et al., 2000).

Approximately 95% of a single dose of Li^+ is eliminated in the urine. From one- to two-thirds of an acute dose is excreted during a 6-12 hour initial phase of excretion, followed by slow excretion over the next 10-14 days (Goodnick and Schorr-Cain, 1991). The elimination $t_{1/2}$ averages 20-24 hours, obviating the need for multiple daily dosing. Once-daily dosing not only improves adherence, but is also associated with decreased polyuria (Schou et al., 1982). With repeated administration, Li^+ excretion increases during the first 5-6 days until a steady state is achieved after ~5 half-lives. When Li^+ is stopped, there is a rapid phase of renal excretion followed by a slow 10- to 14-day phase. Since 80% of the filtered Li^+ is reabsorbed by the proximal renal tubules, clearance of Li^+ by the kidney is ~ 20% of that for creatinine, 15-30 mL/min (Goodnick and Schorr-Cain 1991; Hopkins and Gelenberg 2000); this rate is somewhat lower in elderly patients (10-15 mL/min) (Juurlink et al., 2004; Tueth et al., 1998). Loading with Na^+ produces a small enhancement of Li^+ excretion, but Na^+ depletion promotes a clinically important degree of Li^+ retention. Although the pharmacokinetics of Li^+ varies considerably among subjects, the volume of distribution and clearance are relatively stable in an individual patient.

Li^+ is completely filtered, and 80% is reabsorbed in the proximal tubules (Goodnick and Schorr-Cain, 1991). Li^+ competes with Na^+ for reabsorption, and Li^+ retention can be increased by Na^+ loss related to diuretic use, or febrile, diarrheal, or other GI illness. Heavy sweating leads to a preferential secretion of Li^+ over Na^+ (Jefferson et al., 1982); however, the repletion of excessive sweating using free water without electrolytes can cause hyponatremia, and promote Li^+ retention. Thiazide diuretics deplete Na^+ and can cause significant reductions in Li^+ clearance that result in toxic levels. The K^+ -sparing diuretics triamterene, spironolactone, and amiloride have modest effects on the excretion of Li^+ , with concomitantly smaller increases in serum levels. Loop diuretics such as furosemide seem to have limited impact on Li^+ levels (Juurlink et al., 2004). Renal excretion can be increased by administration of osmotic diuretics or acetazolamide, but not sufficiently for the management of acute Li^+ intoxication. Through alteration of renal perfusion, some nonsteroidal anti-inflammatory agents can facilitate renal proximal tubular resorption of Li^+ and thereby increase serum concentrations (Phelan et al., 2003). This interaction appears to be particularly prominent with indomethacin, but also may occur with ibuprofen, naproxen, and COX-2 inhibitors, and possibly less so with sulindac and aspirin (Phelan et al., 2003). Angiotensin-converting enzyme inhibitors, particularly the renally cleared lisinopril, also cause Li^+ retention, with isolated reports of toxicity among stable lithium-treated patients switched from fosinopril to lisinopril (Meyer et al., 2005).

Less than 1% of ingested Li^+ leaves the human body in the feces; 4-5% is secreted in sweat (Sproule, 2002). Li^+ is secreted in saliva in concentrations about twice those in plasma, while its concentration in tears is about equal to that in plasma. As noted under "Pregnancy and Lactation" later in the chapter, Li^+ is secreted in human milk, but serum levels in breast-fed infants are ~20% that of

maternal levels, and are not associated with notable behavioral effects (Viguera et al., 2007).

Serum Level Monitoring and Dose. Because of the low therapeutic index for Li^+ , periodic determination of serum concentrations is crucial. Li^+ cannot be used with adequate safety in patients who cannot be tested regularly. Concentrations considered to be effective and acceptably safe are between 0.6 and 1.5 mEq/L. The range of 1.0-1.5 mEq/L is favored for treatment of acutely manic or hypomanic patients (Sproule, 2002). Somewhat lower values (0.6-1.0 mEq/L) are considered adequate and are safer for long-term prophylaxis. Serum concentrations of Li^+ have been found to follow a clear dose-effect relationship between 0.4 and 1.0 mEq/L, but with a corresponding dose-dependent rise in polyuria and tremor as indices of adverse effects. Nonetheless, patients who maintain trough levels of 0.8-1.0 mEq/L experience decreased relapse risk compared to those maintained at lower serum concentrations. There are patients who may do well with serum levels of 0.5-0.8 mEq/L, but there are no current clinical or biological predictors to permit *a priori* identification of these individuals. Individualization of serum levels is often necessary to obtain a favorable risk-benefit relationship.

The concentration of Li^+ in blood usually is measured at a trough of the daily oscillations that result from repetitive administration (i.e., from samples obtained 10-12 hours after the last oral dose of the day). Peaks can be two or three times higher at a steady state. When the peaks are reached, intoxication may result, even when concentrations in morning samples of plasma at the daily nadir are in the acceptable range of 0.6-1 mEq/L. Single daily doses generate relatively large oscillations of plasma Li^+ concentration but lower mean trough levels than with multiple daily dosing, and are associated with a reduction in the extent and risk for polyuria (Schou et al., 1982); moreover, single nightly dosing means that peak serum levels occur during sleep, so complaints regarding CNS adverse effects are minimized. While relatively uncommon, GI complaints are one compelling reason for multiple daily dosing or using delayed release Li^+ preparations, bearing in mind the increased polyuria risk from these strategies.

Therapeutic Uses

Drug Treatment of Bipolar Disorder. Treatment with Li^+ ideally is conducted in patients with normal cardiac and renal function. Occasionally, patients with severe systemic illnesses are treated with Li^+ , provided that the indications are compelling, but the need for diuretics, nonsteroidal anti-inflammatory agents, or other medications that pose potential kinetic problems often precludes lithium use in those with multiple medical problems. Treatment of acute mania and the prevention of recurrences of bipolar illness in adults or adolescents are uses approved by the FDA. Li^+ is the only mood stabilizer with data on suicide reduction in bipolar patients (Cipriani et al., 2005; Goodwin et al., 2003; Tondo et al., 2001), and Li^+ also has abundant efficacy data for augmentation in unipolar depressive patients who are

inadequate responders to antidepressant therapy (Bschor et al., 2002).

Drug Treatment of Mania. The modern treatment of the manic, depressive, and mixed-mood phases of bipolar disorder was revolutionized by the introduction of Li^+ in 1949, its gradual acceptance worldwide by the 1960s, and late official acceptance in the U.S. in 1970, initially for acute mania only, and later primarily for prevention of recurrences of mania. While Li^+ , valproate, and carbamazepine have efficacy in acute mania, in clinical practice these are usually combined with atypical antipsychotic drugs, even in manic patients without psychotic features, due to their delayed onset of action. Li^+ , carbamazepine, and valproic acid preparations are only effective with daily dosing that maintains adequate serum levels, and require serum level monitoring. Mania patients are often irritable and poorly cooperative with medication administration and phlebotomy, thus, atypical antipsychotic drugs may be the sole initial therapy, and have proven efficacy as monotherapy (Scherk et al., 2007); moreover, acute IM forms of olanzapine, ziprasidone, and aripiprazole can be used to achieve rapid control of psychosis and agitation. Benzodiazepines are often used adjunctively for agitation and sleep induction.

Li^+ is effective in acute mania, but is rarely employed as a sole treatment for reasons noted above, and because 5-7 days are required for clinical effect. A 600-mg loading dose of Li^+ can be given to hasten the time to steady state, and can also be used to predict dosage requirements based on the 24-hour serum Li^+ result, with a very high correlation coefficient ($r = 0.972$) (Cooper et al., 1973). Acutely manic patients may require higher dosages to achieve therapeutic serum levels, and downward adjustment may be necessary once the patient is euthymic. When adherence with oral capsules or tablets is an issue, the liquid Li^+ citrate can be used. Each 5 mL of lithium citrate syrup provides 8.12 mEq of Li^+ , equivalent to 300 mg of lithium carbonate.

The anticonvulsant sodium valproate provides more rapid antimanic effects than Li^+ , with therapeutic benefit seen within 3-5 days. The most common form of valproate in use is divalproex sodium, preferred over valproic acid due to lower incidence of GI and other adverse effects. Divalproex is initiated at 25 mg/kg once daily and titrated to effect or the desired serum concentration. Serum concentrations of 90-120 $\mu\text{g/mL}$ show the best response in clinical studies (Bowden et al., 2006). With immediate release forms of valproic acid and divalproex sodium, 12-hour troughs are used to guide treatment. With the extended-release divalproex preparation, patients respond best when the 24-hour trough levels are in the high therapeutic range (Bowden et al., 2006).

Carbamazepine is effective for acute mania. Immediate release forms of carbamazepine cannot be loaded or rapidly titrated over 24 hours as with valproate due to the development of neurological adverse effects such as dizziness or ataxia, even within the

therapeutic range (6-12 µg/mL) (Post et al., 2007); the extended-release form of carbamazepin was FDA-approved for acute mania in 2005. The extended-release form is better tolerated compared to older preparations, and effective as monotherapy with once-daily dosing (Weisler et al., 2006). Carbamazepine response rates are lower than those for valproate compounds or Li⁺, with mean rates of 45-60% cited in the literature (Post et al., 2007). Nevertheless, certain individuals respond to carbamazepine after failing Li⁺ and valproate. Initial doses are 400 mg/day, with the larger dose given at bedtime due to the sedating properties of carbamazepine. Titration proceeds by 200-mg increments every 24-48 hours based on clinical response and serum trough levels. Due to increased risk of Stevens-Johnson syndrome in Asian individuals (especially those from China, Hong Kong, Malaysia, and the Philippines where HLA-B*1502 prevalence is > 15%), HLA testing must be performed prior to treatment in populations at risk.

Lamotrigine has no role in acute mania due to the slow, extended titration necessary to minimize risk of Stevens-Johnson syndrome (Hahn et al., 2004).

Prophylactic Treatment of Bipolar Disorder. The choice of ongoing prophylaxis is determined by the need for continued antipsychotic drug use and for use of a mood-stabilizing agent. Both aripiprazole and olanzapine are effective as monotherapy for mania prophylaxis, but olanzapine use is eschewed out of concern for metabolic effects, and aripiprazole shows no benefit for prevention of depressive relapse.

In the pivotal maintenance trials, the mean endpoint aripiprazole dose was 27.9 mg (Keck et al., 2007), and mean olanzapine dose 16.2 mg (Tohen et al., 2003). In 2009, LAI risperidone was also approved for bipolar maintenance treatment to be used adjunctively with Li⁺ or valproate, or as monotherapy. If used as monotherapy, coverage with an oral antipsychotic is necessary for the first 4 weeks after the initial injection. When antipsychotic drugs have been employed as adjunctive agents, the optimal duration treatment is unclear, but most clinicians will continue with combination treatment for 2-4 months after the acute manic phase has been controlled. Clozapine can be beneficial in refractory mania patients as adjunctive therapy and as monotherapy (Hummel et al., 2002).

The overriding concern guiding bipolar treatment is the high recurrence rate. Individuals who experience mania have an 80-90% lifetime risk of subsequent manic episodes. As with schizophrenia, lack of insight, poor psychosocial support, and substance abuse all interfere with treatment adherence. While the anticonvulsants lamotrigine, carbamazepine, and divalproex have data supporting their use in bipolar prophylaxis, only concern has consistently been shown to reduce the risk of suicide compared to non-lithium users (Cipriani et al., 2005; Tondo et al., 2001), and compared to bipolar patients on valproate acid derivatives (Goodwin et al., 2003). Early case series and retrospective clinical literature indicated preferential

benefit of valproate over concern in rapid-cycling patients, but a recent large trial failed to substantiate this effect, and found no significant differences in time to relapse between the two agents (Calabrese et al., 2005b). Based largely on subanalyses of acute mania trials, there are also claims that valproate may be superior to concern for patients experiencing mixed episodes, but the lack of prospective data from randomized trials also raises questions about the validity of these findings. Lamotrigine was effective in two large, 18-month long maintenance trials for bipolar patients whose most recent mood episode was manic or depressed, with greater effect on depressive relapse (Bowden et al., 2003; Calabrese et al., 2003). The ability to provide prophylaxis for future depressive episodes combined with data in acute bipolar depression (Hahn et al., 2004) has made lamotrigine a useful choice for bipolar treatment, given that bipolar I and II patients spend large amounts of time in depressive phases (32% and 50%, respectively) (Judd et al., 2003).

Bipolar disorder is a lifetime illness with high recurrence rates. Individuals who experience an episode of mania should be educated about the probable need for ongoing treatment. Stopping mood stabilizer therapy can be considered in patients who have experienced only one lifetime manic episode, particularly when there may have been a pharmacological precipitant (e.g., substance or antidepressant use), and who have been euthymic for extended periods. For bipolar II patients, the impact of hypomania is relatively limited, so the decision to recommend prolonged maintenance treatment with a mood stabilizer is based on clinical response and risk:benefit ratio. Discontinuation of maintenance Li⁺ treatment in bipolar I patients carries a high risk of early recurrence and of suicidal behavior over a period of several months, even if the treatment had been successful for several years. Recurrence is much more rapid than is predicted by the natural history of untreated bipolar disorder, in which cycle lengths average ~1 year. This risk may be moderated by slow, gradual removal of Li⁺, while rapid discontinuation should be avoided unless dictated by medical emergencies.

Other Uses of Lithium. Li⁺ has been shown to be effective as adjunct therapy in treatment-resistant major depression (Bschor et al., 2002). Clinical data also support Li⁺ use as monotherapy for unipolar depression. Meta-analyses indicate that lithium's benefit on suicide reduction extends to unipolar mood disorder patients (Cipriani et al., 2005; Tondo et al., 2001). While maintenance Li⁺ levels of 0.6-1.0 mEq/L are used for bipolar prophylaxis, a lower range (0.4-0.8 mEq/L) is recommended for antidepressant augmentation.

Based on its neuroprotective properties, there has been consideration of Li⁺ treatment for conditions associated with excitotoxic and apoptotic cell death, such as stroke and spinal cord injury, as well as in neurodegenerative disorders, including dementia of the Alzheimer type, stroke, Parkinson's disease, Huntington's disease, amyotrophic lateral sclerosis, progressive supranuclear palsy, and spinocerebellar ataxia type I (Aghdam and Barger 2007; Bauer et al., 2003; Chuang, 2004).

Interactions with Other Drugs. Interactions between Li⁺ and diuretics (especially thiazides spironolactone and amiloride), angiotensin-converting enzyme inhibitors, and nonsteroidal anti-inflammatory agents have been discussed earlier. Amiloride has been used

safely to reverse the syndrome of nephrogenic diabetes insipidus associated with Li^+ therapy, but requires careful monitoring and Li^+ dosage reduction to prevent lithium toxicity (Kosten and Forrest, 1986).

Adverse Effects

CNS Effects. The most common CNS effect of Li^+ in the therapeutic dose range is fine postural hand tremor, indistinguishable from essential tremor. Severity and risk for tremor are dose-dependent, with incidence ranging from 15-70%. Some tolerance may develop over time, but tremor may be sufficiently bothersome to require intervention. In addition to the avoidance of caffeine and other agents that increase tremor amplitude, therapeutic options include dose reduction (bearing in mind the increased relapse risk with lower serum Li^+ levels), or in those without contraindications for β adrenergic blockade, use of propranolol, starting at 20 mg/day in divided doses, and gradually increased until the desired clinical effect is achieved (typically at doses \leq 160 mg/day). Valproate treatment has a similar problem, and the approach to valproate-induced tremor is identical. At peak serum (and CNS) levels, some individuals may complain of incoordination, ataxia, or slurred speech, all of which can be avoided by dosing Li^+ at bedtime. Patients may also complain of mental fatigue or cognitive dulling at higher serum Li^+ levels, but this should be carefully assessed to determine whether this reflects a true side effect or a desire to regain the mental high from hypomania.

Li^+ routinely causes EEG changes characterized by diffuse slowing, widened frequency spectrum, and potentiation with disorganization of background rhythm. Seizures have been reported in non-epileptic patients with therapeutic plasma concentrations of Li^+ . Li^+ treatment has also been associated with increased risk of post-ECT confusion, and is generally tapered off prior to a course of ECT.

Li^+ (and valproate) treatment results in significant weight gain, a problem that is magnified by concurrent use of antipsychotic drugs. Mean weight gain at one year in prospective Li^+ trials ranges from -1 kg to $+4$ kg, but the proportion of individuals who gain $> 5\%$ of baseline weight is 13-62% (Keck and McElroy, 2003). Although the mechanism is unclear, central appetite stimulation at hypothalamic sites is the most plausible explanation (Keck and McElroy, 2003).

Renal Effects. Long-term renal effects of Li^+ treatment are an important concern. The kidneys' ability to concentrate urine decreases during Li^+ therapy, and $\sim 60\%$ of individuals exposed to Li^+ experience some form of polyuria and compensatory polydipsia. The mechanism of polyuria is unclear, but the result is decreased vasopressin stimulation of renal reabsorption of water, and the clinical picture of nephrogenic diabetes insipidus. Mean 24-hour urinary volumes of 3 L/day are common among long-term Li^+ users, but Li^+ discontinuation or a switch to single daily dosing may reverse the impact on renal concentrating ability in patients with < 5 years of Li^+ exposure (Kusalic and Engelsmann, 1996). Patients exposed to multiple daily dosing or sustained-release Li^+ preparations are at greatest risk for renal effects. Renal function should be monitored with biyearly serum blood urea nitrogen and creatinine levels, calculation of estimated GFR using standard formulas (Morris and Benjamin, 2008), and annual measurement of 24-hour urinary volume. Reassessment of Li^+ treatment, more frequent renal function tests,

and possible nephrology consultation should be considered when estimated GFR is < 60 mL/min on several periodic measurements, daily urinary volume exceeds 4 L, or serum creatinine continues to rise on three separate occasions (Morris and Benjamin, 2008).

Thyroid and Endocrine Effects. A small number of patients on Li^+ develop a benign, diffuse, nontender thyroid enlargement suggestive of compromised thyroid function, although many of these patients will have normal thyroid function. Measurable effects of Li^+ on thyroid indices are seen in a fraction of patients: 7-10% develop overt hypothyroidism (Jefferson, 2000), and 23% have subclinical disease, with women at 3-9 times greater risk (Kleiner et al., 1999). There appears to be no plateau in the incidence of hypothyroidism in studies covering up to 10 years' exposure; thus, ongoing monitoring of TSH and free T_4 is recommended throughout the course of Li^+ treatment. The development of hypothyroidism is easily treated through exogenous replacement, and is not a reason to discontinue Li^+ therapy. Rare reports of hyperthyroidism during Li^+ treatment also exist (Jefferson, 2000).

EKG Effects. The prolonged use of Li^+ causes a benign and reversible T-wave flattening in $\sim 20\%$ of patients and the appearance of U waves, effects unrelated to depletion of Na^+ or K^+ . At therapeutic concentrations there are rare reports of Li^+ -induced effects on cardiac conduction and pacemaker automaticity, effects that become pronounced during overdose and lead to sinus bradycardia, atrioventricular blocks, and possible cardiovascular compromise. Routine EKG monitoring is not recommended in younger patients, but may be considered in older patients, particularly those with a history of arrhythmia or coronary heart disease.

Skin Effects. Allergic reactions such as dermatitis, folliculitis, and vasculitis can occur with Li^+ administration. Worsening of acne vulgaris, psoriasis, and other dermatological conditions is a common problem that is usually treatable by topical measures, but in a small number may improve only upon discontinuation of Li^+ . Some patients on Li^+ (and valproate) may experience alopecia; daily supplementation with a multivitamin containing at least 100 μg of selenium and 15 mg of zinc may be beneficial.

Pregnancy and Lactation. Li^+ is classified as risk category D (see Appendix I). The use of Li^+ in early pregnancy may be associated with an increase in the incidence of cardiovascular anomalies of the newborn, especially Ebstein's malformation (Freeman and Freeman, 2006). The basal risk of Ebstein's anomaly of ~ 1 per 20,000 live births may rise several-fold with first-trimester Li^+ exposure, but probably not above 1 per 2500. Moreover, the defect typically is detectable *in utero* by ultrasonography and often is surgically correctable after birth. Although the anticonvulsants valproic acid and carbamazepine are also pregnancy risk category D, these agents are associated with irreversible neural tube defects. In balancing the risk vs. benefit of using Li^+ in pregnancy, it is important to evaluate the risk of inadequate prophylaxis for the bipolar disorder patient, and subsequent risk that mania poses for the patient and fetus. In patients who choose to forego medication exposure during the first trimester, potentially safer treatments for acute mania include antipsychotic drugs or ECT (Dodd and Berk, 2006; Yonkers et al., 2004).

In pregnancy, maternal polyuria may be exacerbated by Li^+ . Concomitant use of Li^+ with medications that waste Na^+ or a low- Na^+ diet during pregnancy can contribute to maternal and neonatal

Li⁺ intoxication. Li⁺ freely crosses the placenta, and fetal or neonatal Li⁺ toxicity may develop when maternal blood levels are within the therapeutic range. Fetal Li⁺ exposure is associated with neonatal goiter, CNS depression, hypotonia (“floppy baby” syndrome), and cardiac murmur. Most recommend withholding lithium therapy for 24–48 hours before delivery, and this is considered standard practice to avoid the potentially toxic increases in maternal and fetal serum Li⁺ levels associated with postpartum diuresis. This brief period of discontinuation results in a mean decrease of 0.28 mEq/L in maternal Li⁺ concentrations (Newport et al., 2005). The physical and CNS sequelae of late-term neonatal Li⁺ exposure are reversible once Li⁺ exposure has ceased, and no long-term neurobehavioral consequences are observed (Viguera et al., 2007).

Other Effects. A benign, sustained increase in circulating polymorphonuclear leukocytes (12,000–15,000 cells/mm³) occurs during the chronic use of Li⁺ and is reversed within a week after termination of treatment. Some patients complain of a metallic taste, making food less palatable. Myasthenia gravis may worsen during treatment with Li⁺.

Acute Toxicity and Overdose. The occurrence of toxicity is related to the serum concentration of Li⁺ and its rate of rise following administration. Acute intoxication is characterized by vomiting, profuse diarrhea, coarse tremor, ataxia, coma, and convulsions. Symptoms of milder toxicity are most likely to occur at the absorptive peak of Li⁺ and include nausea, vomiting, abdominal pain, diarrhea, sedation, and fine tremor. The more serious effects involve the nervous system and include mental confusion, hyperreflexia, gross tremor, dysarthria, seizures, and cranial nerve and focal neurological signs, progressing to coma and death. Sometimes both cognitive and motor neurological damage may be irreversible, with persistent cerebellar tremor being the most common (El-Mallakh, 1986). Other toxic effects are cardiac arrhythmias, hypotension, and albuminuria.

Treatment of Lithium Intoxication. There is no specific antidote for Li⁺ intoxication, and treatment is supportive, including intubation if indicated, and continuous cardiac monitoring. Levels > 1.5 mEq/L are considered toxic, but inpatient medical admission is usually not indicated (in the absence of symptoms) until levels exceed 2 mEq/L. Care must be taken to assure that the patient is not Na⁺ and water depleted. Dialysis is the most effective means of removing Li⁺ and is necessary in severe poisonings, that is, in patients exhibiting symptoms of toxicity or patients with serum Li⁺ concentrations ≥ 3 mEq/L in acute overdoses. A review of 213 case reports of acute Li⁺ toxicity between 1948 and 1984, found that complete recovery occurred with an average maximal level of 2.5 mEq/L, permanent neurological symptoms with mean levels of 3.2 mEq/L, and death with mean maximal levels of 4.2 mEq/L (El-Mallakh, 1986). The most common neurological sequelae are due to cerebellar damage, and manifest clinically as ataxia, tremor, dysarthria, and dysmetria (Mangano et al., 1997).

Use in Pediatric and Geriatric Populations

Pediatric Use. The anticonvulsants all have pediatric indications for epilepsy, but only Li⁺ has FDA approval for child/adolescent bipolar disorder for ages ≥ 12 years (Tueth et al., 1998). Recently, aripiprazole and risperidone were FDA-approved for acute mania in children and adolescents ages 10–17. Children and adolescents have higher volumes of body water and higher GFR than adults. The

resulting shorter $t_{1/2}$ of Li⁺ demands dosing increases on a mg/kg basis, and multiple daily dosing is often required. In children ages 6–12 years, a dose of 30 mg/kg/day given in three divided doses will produce a Li⁺ concentration of 0.6–1.2 mEq/L in 5 days (Danielyan and Kowatch, 2005), although ongoing dosing is always guided by serum levels and clinical response. Use in children under 12 represents an off-label use for Li⁺ and care givers should be alert to evidence of the development of toxicity. As with adults, ongoing monitoring of renal and thyroid function is important, along with clinical inquiry into extent of polyuria.

A limited number of controlled studies suggest that valproate has efficacy comparable to that of Li⁺ for mania in children or adolescents (Danielyan and Kowatch, 2005). As with Li⁺, weight gain and tremor can be problematic; moreover, there are reports of hyperammonemia in children with urea-cycle disorders. Ongoing monitoring of platelets and liver function tests, in addition to serum drug levels, is recommended. There have been no controlled studies of carbamazepine for the treatment of children and adolescents with mania, although there is substantial safety data for epilepsy indications in this age group.

Geriatric Use. The majority of older patients on Li⁺ therapy are those maintained for years on the medication. Less than 10% of individuals with bipolar disorder experience their first manic episode at age 50 or above. Elderly patients frequently take numerous medications for other illnesses and the potential for contraindications or drug-drug interactions is substantial. For patients naïve to Li⁺, these issues can be addressed relatively easily prior to commencement of Li⁺ treatment. The more difficult clinical decision revolves around switching treatment in stable patients who have taken Li⁺ for years or decades with excellent clinical response. In addition, age-related reductions in total body water and creatinine clearance reduce the safety margin for Li⁺ treatment in older patients. Targeting lower maintenance serum levels (0.6–0.8 mEq/L) may reduce the risk of toxicity. As GFR drops below 60 mL/min, strong consideration must be given to a search for alternative agents, despite lithium’s therapeutic advantages (Morris and Benjamin, 2008). Li⁺ toxicity occurs more frequently in elderly patients, in part as the result of concurrent use of loop diuretics and angiotensin-converting enzyme inhibitors (Juurink et al., 2004). Anticonvulsants, especially extended-release divalproex, are a reasonable alternative to Li⁺. Elderly patients who are drug-naïve may be more sensitive to CNS adverse effects of all types of medications used for acute mania, especially parkinsonism and tardive dyskinesia from D₂ antagonism, confusion from antipsychotic medications with antimuscarinic properties, and ataxia or sedation from Li⁺ or anticonvulsants.

Major Drugs Available in the Class

Formulations. Most Li⁺ preparations currently used in the U.S. are tablets or capsules of lithium carbonate in strengths of 150, 300, and 600 mg. Slow-release preparations of lithium carbonate also are available in strengths of 300 and 450 mg, as is lithium citrate syrup (with 8 mEq of Li⁺/5 mL citrate liquid, equivalent to 300 mg of lithium carbonate). Salts other than the carbonate have been used, but the carbonate salt is favored for tablets and capsules because it is relatively less

hygroscopic and less irritating to the gut than other salts, especially the chloride. Since slow-release forms carry an increased risk for polyuria, their use should be limited to patients who experience GI side effects related to rapid absorption.

Novel Treatments for Psychosis and Mania

There are several molecular targets for antipsychotic drug development, including glutamate, serotonergic, and cholinergic receptor systems. The glutamate hypofunction hypothesis for schizophrenia has opened the door to exploration of metabotropic glutamate receptor agonists, and agonists at co-transmitter sites. The glutamate receptor family is divided into the excitatory ionotropic receptors, broadly distributed in the CNS, and metabotropic glutamate receptors that exert modulatory functions (Chapter 14). The former are not viable targets for drug activity due to the global impact on CNS function that may result. Metabotropic glutamate receptors show significant promise, with agents synthesized based on the distribution of the three receptor groups (Krivoy et al., 2008).

The mGlu 2/3 receptor agonist LY2140023 showed efficacy in a 4-week phase 2 schizophrenia monotherapy trial (Patil et al., 2007), and while subsequent data were problematic, similar compounds are still in development.

Glycine is a co-transmitter at glutamate receptors whose synaptic action is terminated by presynaptic reuptake transporters. There are two human forms of the glycine reuptake pump: GlyT1, which is localized to cortical areas; and GlyT2, which is concentrated in spinal cord. The GlyT1 inhibitor SSR504734 was as effective as haloperidol in blocking PCP-induced CNS metabolic changes in rats. Lurasidone is a novel 5-HT/DA antagonist that filed for FDA approval in late 2009. Lurasidone possesses potent activity at 5-HT₇ receptor sites, actions that, based on preclinical and early clinical studies, may be associated with cognitive benefits (Meyer et al., 2009). Muscarinic receptor modulators at M₁ and M₄ sites have passed several preclinical antipsychotic tests (Chan et al., 2008; Janowsky and Davis, 2009), and xanomeline, an M₁/M₄ agonist, has shown antipsychotic and procognitive affects in a 4-week, double-blind placebo-controlled schizophrenia trial (Shekhar et al., 2008). Certain targets (e.g., $\alpha 7$ and $\alpha 4\beta 2$ nicotinic receptors) are being exploited solely for the purposes of cognitive enhancement in schizophrenia, and may not confer antipsychotic activity (Buchanan et al., 2007).

The expanded role for atypical antipsychotics in bipolar treatment is primarily in acute mania, although quetiapine possesses unique effectiveness for bipolar depression based on antidepressant properties conferred by the metabolite norquetiapine. Improved understanding of the biological basis for Li⁺ and anticonvulsant actions in mania has generated several possible targets. No agents acting on IP₃ have been developed, but several inhibitors of GSK-3 β that are 3-benzofuranyl-4-indolylmaleimide compounds have been identified, with one showing activity in a murine mania model (Kozikowski et al., 2007). PKC inhibition has emerged as the most viable novel candidate for antimanic activity, based on several positive tamoxifen trials in acute mania (Einat et al., 2007; Yildiz et al., 2008; Zarate et al., 2007). There is still no medication that possesses lithium's unique broad spectrum of pharmacological activities for bipolar disorder, and particular aspects of lithium's actions that are

addressed in a limited fashion by current medications (e.g., lamotrigine and quetiapine for bipolar depression), or not at all (e.g., neuroprotection), remain important targets for novel treatments (Quiroz et al., 2004).

Clinical Summary: Treatment of Mania

Despite decades of data substantiating the superior efficacy of Li⁺ in bipolar patients, including suicide reduction, Li⁺ remains underutilized. Long-term studies spanning 10 or more years demonstrate that while polyuria may be relatively common, significant declines in renal function and renal failure are rare during Li⁺ treatment. Many agents are effective for acute mania, but long-term treatment requires careful consideration of extent and severity of prior depressive episodes, past history of treatment response, concurrent medical illness and medication use, patient preference, and concerns over particular adverse effects (e.g., weight gain). Combining mood stabilizers and antipsychotic agents shows greater benefit for acute mania than monotherapy of either agent class, but may be associated with increased long-term weight gain. A realistic discussion with patients regarding long-term side effects for various treatments and clinical outcomes is paramount to improve adherence. Serum level monitoring is necessary for Li⁺, valproate acid compounds, and carbamazepine. Lamotrigine may be particularly useful in type II bipolar patients, where mania prophylaxis is not a concern. The clinical data make a compelling argument for Li⁺ as the treatment of choice in bipolar I disorder. Ongoing research into lithium's mechanism of action may yield new agents without lithium's adverse effect profile, and genetic predictors of Li⁺ response.

chapter

Hypnotics and Sedatives

S. John Mihic
and R. Adron Harris

Many agents can depress the function of the central nervous system and produce calming or drowsiness (sedation). The CNS depressants discussed in this chapter include benzodiazepines, other benzodiazepine receptor agonists (the “Z compounds”), barbiturates, and sedative-hypnotic agents of diverse chemical structure. Older sedative-hypnotic drugs depress the CNS in a dose-dependent fashion, progressively producing a spectrum of responses from mild sedation to coma and death.

A *sedative* drug decreases activity, moderates excitement, and calms the recipient, whereas a *hypnotic* drug produces drowsiness and facilitates the onset and maintenance of a state of sleep that resembles natural sleep in its electroencephalographic characteristics and from which the recipient can be aroused easily.

Sedation is a side effect of many drugs that are not general CNS depressants (e.g., antihistamines and antipsychotic agents). Although such agents can intensify the effects of CNS depressants, they usually produce more specific therapeutic effects at concentrations far lower than those causing substantial CNS depression. For example, they cannot induce surgical anesthesia in the absence of other agents. The benzodiazepine sedative-hypnotics resemble such agents; although coma may occur at very high doses, neither surgical anesthesia nor fatal intoxication is produced by benzodiazepines in the absence of other drugs with CNS-depressant actions; an important exception is midazolam, which has been associated with decreased tidal volume and respiratory rate. Moreover, specific antagonists of benzodiazepines exist. This constellation of properties sets the benzodiazepine receptor agonists apart from other sedative-hypnotic drugs and imparts a measure of safety such that benzodiazepines and the newer Z compounds

have largely displaced older agents for the treatment of insomnia and anxiety.

The sedative-hypnotic drugs that do not specifically target the benzodiazepine receptor belong to a group of agents that depress the CNS in a dose-dependent fashion, progressively producing calming or drowsiness (sedation), sleep (pharmacological hypnosis), unconsciousness, coma, surgical anesthesia, and fatal depression of respiration and cardiovascular regulation. They share these properties with a large number of chemicals, including general anesthetics (Chapter 19) and aliphatic alcohols, most notably ethanol (Chapter 23). Only two landmarks on the continuum of CNS depression produced by increasing concentrations of these agents can be defined with a reasonable degree of precision: surgical anesthesia, a state in which painful stimuli elicit no behavioral or autonomic response (Chapter 19), and death, resulting from sufficient depression of medullary neurons to disrupt coordination of cardiovascular function and respiration. The “end points” at lower concentrations of CNS depressants are defined with less precision—in terms of deficits in cognitive function (including attention to environmental stimuli) or motor skills (e.g., ataxia) or of the intensity of sensory stimuli needed to elicit some reflex or behavioral response. Other important indices of decreased CNS activity, such as analgesia and seizure suppression, do not necessarily fall along this continuum; they may not be present at sub-anesthetic concentrations of a CNS depressant drug (e.g., a barbiturate), or they may be achieved with minimal sedation or other evidence of CNS depression (e.g., with low doses of opioids, phenytoin, or ethosuximide).

History. Since antiquity, alcoholic beverages and potions containing laudanum and various herbals have been used to induce sleep. In the middle of the nineteenth century, bromide was the first agent to be introduced specifically as a sedative-hypnotic. Chloral hydrate, paraldehyde, urethane, and sulfonal came into use before the introduction of barbital in 1903 and phenobarbital in 1912. Their success spawned the synthesis and testing of >2500 barbiturates, of which ~50 were distributed commercially. The barbiturates were so dominant that less than a dozen other sedative-hypnotics were marketed successfully before 1960.

The partial separation of sedative-hypnotic-anesthetic from anticonvulsant properties embodied in phenobarbital led to

searches for agents with more selective effects on CNS functions. As a result, relatively non-sedating anticonvulsants, notably phenytoin and trimethadione, were developed in the late 1930s and early 1940s (Chapter 21). The advent of chlorpromazine and meprobamate in the early 1950s, with their taming effects in animals, and the development of increasingly sophisticated methods for evaluating the behavioral effects of drugs set the stage in the 1950s for the synthesis of chlordiazepoxide by Sternbach and the discovery of its unique pattern of actions by Randall. The introduction of chlordiazepoxide into clinical medicine in 1961 ushered in the era of benzodiazepines. Most of the benzodiazepines that have reached the marketplace were selected for high anxiolytic potency in relation to their depression of CNS function. However, all benzodiazepines possess sedative-hypnotic properties to varying degrees; these properties are exploited extensively clinically, especially to facilitate sleep. Mainly because of their remarkably low capacity to produce fatal CNS depression, the benzodiazepines have displaced the barbiturates as sedative-hypnotic agents.

BENZODIAZEPINES

All benzodiazepines in clinical use have the capacity to promote the binding of the major inhibitory neurotransmitter γ -aminobutyric acid (GABA) to the GABA_A subtype of GABA receptors, which exist as multi-subunit, ligand-gated chloride channels, thereby enhancing the GABA-induced ionic currents through these channels (see Figure 14–11). Pharmacological data suggest heterogeneity among sites of binding and action of benzodiazepines; biochemical and molecular biological investigations reveal the numerous varieties of subunits that make up the GABA-gated chloride channels expressed in different neurons. Since receptor subunit composition appears to govern the interaction of various allosteric modulators with these channels, there has been a surge in efforts to find agents displaying different combinations of benzodiazepine-like properties that may reflect selective actions on one or more subtypes of GABA receptors. These efforts led to the development of zolpidem (AMBIEN), an imidazopyridine, the pyrazolopyrimidines zaleplon (SONATA) and the cyclopyrrolones zopiclone and eszopiclone (LUNESTA); these so-called “Z compounds” all apparently exert sedative-hypnotic effects by interacting with a subset of benzodiazepine binding sites.

Although the benzodiazepines exert qualitatively similar clinical effects, important quantitative differences in their pharmacodynamic spectra and pharmacokinetic properties have led to varying patterns of therapeutic application. A number of distinct mechanisms of action are thought to contribute to the sedative-hypnotic, muscle-relaxant, anxiolytic, and

anticonvulsant effects of the benzodiazepines, and specific subunits of the GABA_A receptor are responsible for specific pharmacological properties of benzodiazepines. While only the benzodiazepines used primarily for hypnosis are discussed in detail, this chapter describes the general properties of the group and important differences among individual agents (see also Chapters 15 and 21).

Chemistry. The structures of the benzodiazepines in use in the U.S. are shown in Table 17–1, as are those of a few related compounds discussed later.

The term *benzodiazepine* refers to the portion of the structure composed of a benzene ring (A) fused to a seven-membered diazepine ring (B). Since all the important benzodiazepines contain a 5-aryl substituent (ring C) and a 1,4-diazepine ring, the term has come to mean the 5-aryl-1,4-benzodiazepines. Various modifications in the structure of the ring systems have yielded compounds with similar activities, including 1,5-benzodiazepines (e.g., clobazam) and compounds in which the fused benzene ring is replaced with heteroaromatic systems such as thieno (e.g., brotizolam). The chemical nature of substituents at positions 1 to 3 can vary widely and can include triazolo or imidazolo rings fused at positions 1 and 2. Replacement of ring C with a keto function at position 5 and a methyl substituent at position 4 is an important structural feature of the benzodiazepine receptor antagonist flumazenil (ROMAZICON).

In addition to various benzodiazepine or imidazobenzodiazepine derivatives, a large number of non-benzodiazepine compounds compete with classic benzodiazepines or flumazenil for binding at specific sites in the CNS. These include representatives from the β -carbolines (containing an indole nucleus fused to a pyridine ring), imidazopyridines (e.g., zolpidem, discussed later), imidazopyrimidines, imidazoquinolones, and cyclopyrrolones (e.g., eszopiclone).

Pharmacological Properties

Virtually all effects of the benzodiazepines result from their actions on the CNS. The most prominent of these effects are sedation, hypnosis, decreased anxiety, muscle relaxation, anterograde amnesia, and anticonvulsant activity. Only two effects of these drugs result from peripheral actions: coronary vasodilation, seen after intravenous administration of therapeutic doses of certain benzodiazepines, and neuromuscular blockade, seen only with very high doses.

A number of benzodiazepine-like effects have been observed *in vivo* and *in vitro* and have been classified as full agonistic effects (i.e., faithfully mimicking agents such as diazepam with relatively low fractional occupancy of binding sites) or partial agonistic effects (i.e., producing less intense maximal effects or requiring relatively high fractional occupancy compared with agents such as diazepam). Some compounds produce

Table 17-1

Benzodiazepines: Names and Structures*

effects opposite to those of diazepam in the absence of benzodiazepine-like agonists and have been termed inverse agonists; partial inverse agonists also have been recognized (Chapters 2 and 3). The vast majority of effects of agonists and inverse agonists can be reversed or prevented by the benzodiazepine antagonist flumazenil,

which competes with agonists and inverse agonists for binding to the GABA_A receptor.

Central Nervous System. While benzodiazepines affect activity at all levels of the neuraxis, some structures are affected preferentially. The benzodiazepines do not produce the same degrees of neuronal depression produced

by barbiturates and volatile anesthetics. All the benzodiazepines have similar pharmacological profiles. Nevertheless, the drugs differ in selectivity, and the clinical usefulness of individual benzodiazepines thus varies considerably.

As the dose of a benzodiazepine is increased, sedation progresses to hypnosis and then to stupor. The clinical literature often refers to the “anesthetic” effects and uses of certain benzodiazepines, but the drugs do not cause a true general anesthesia because awareness usually persists, and immobility sufficient to allow surgery cannot be achieved. However, at “preanesthetic” doses, there is amnesia for events subsequent to administration of the drug.

Although considerable attempts have been made to separate the anxiolytic actions of benzodiazepines from their sedative-hypnotic effects, distinguishing between these behaviors still is problematic. Measurements of anxiety and sedation are difficult in humans, and the validity of animal models for anxiety and sedation is uncertain. The existence of multiple benzodiazepine receptors may explain in part the diversity of pharmacological responses in different species.

Animal Models of Anxiety. In animal models of anxiety, most attention has focused on the ability of benzodiazepines to increase locomotor, feeding, or drinking behavior that has been suppressed by novel or aversive stimuli. In one paradigm, animal behaviors that previously had been rewarded by food or water are punished periodically by an electric shock. The time during which shocks are delivered is signaled by some auditory or visual cue, and untreated animals stop performing almost completely when the cue is perceived. The difference in behavioral responses during the punished and unpunished periods is eliminated by benzodiazepine receptor agonists, usually at doses that do not reduce the rate of unpunished responses or produce other signs of impaired motor function. Similarly, rats placed in an unfamiliar environment exhibit markedly reduced exploratory behavior (neophobia), whereas animals treated with benzodiazepines do not. Opioid analgesics and antipsychotic drugs do not increase suppressed behaviors, and phenobarbital and meprobamate usually do so only at doses that also reduce spontaneous or unpunished behaviors or produce ataxia.

The difference between the dose required to impair motor function and that necessary to increase punished behavior varies widely among the benzodiazepines and depends on the species and experimental protocol. Although such differences may have encouraged the marketing of some benzodiazepines as selective sedative-hypnotic agents, they have not predicted with any accuracy the magnitude of sedative effects among those benzodiazepines marketed as anxiolytic agents.

Tolerance to Benzodiazepines. Studies on tolerance in laboratory animals often are cited to support the belief that disinhibitory effects of benzodiazepines are distinct from their sedative-ataxic effects. For example, tolerance to the depressant effects on rewarded or neutral behavior occurs after several days of treatment with benzodiazepines;

the disinhibitory effects of the drugs on punished behavior are augmented initially and decline after 3–4 weeks (File, 1985). Although most patients who ingest benzodiazepines chronically report that drowsiness wanes over a few days, tolerance to the impairment of some measures of psychomotor performance (e.g., visual tracking) usually is not observed. Whether tolerance develops to the anxiolytic effects of benzodiazepines remains a subject of debate. Many patients can maintain themselves on a fairly constant dose; increases or decreases in dosage appear to correspond with changes in problems or stresses. On the other hand, some patients either do not reduce their dosage when stress is relieved or steadily escalate dosage. Such behavior may be associated with the development of drug dependence (Chapter 24).

Some benzodiazepines induce muscle hypotonia without interfering with normal locomotion and can decrease rigidity in patients with cerebral palsy. In contrast to effects in animals, there is only a limited degree of selectivity in humans. Clonazepam in non-sedative doses does cause muscle relaxation, but diazepam and most other benzodiazepines do not. Tolerance occurs to the muscle relaxant and ataxic effects of these drugs.

Experimentally, benzodiazepines inhibit seizure activity induced by either pentylenetetrazol or picrotoxin, but strychnine- and maximal electroshock-induced seizures are suppressed only at doses that also severely impair locomotor activity. Clonazepam, nitrazepam, and nordazepam have more selective anticonvulsant activity than most other benzodiazepines. Benzodiazepines also suppress photic seizures in baboons and ethanol-withdrawal seizures in humans. However, the development of tolerance to the anticonvulsant effects has limited the usefulness of benzodiazepines in the treatment of recurrent seizure disorders in humans (Chapter 21).

Although analgesic effects of benzodiazepines have been observed in experimental animals, only transient analgesia is apparent in humans after intravenous administration. Such effects actually may involve the production of amnesia. Unlike barbiturates, benzodiazepines do not cause hyperalgesia.

Effects on the Electroencephalogram (EEG) and Sleep Stages. The effects of benzodiazepines on the waking EEG resemble those of other sedative-hypnotic drugs. Alpha activity is decreased, but there is an increase in low-voltage fast activity. Tolerance occurs to these effects.

Benzodiazepines decrease sleep latency, especially when first used, and diminish the number of awakenings and the time spent in stage 0 (a stage of wakefulness). Time in stage 1 (descending drowsiness) usually is decreased, and there is a prominent decrease in the time spent in slow-wave sleep (stages 3 and 4). Most benzodiazepines increase the time from onset of spindle sleep to the first burst of rapid-eye-movement (REM) sleep, and the time spent in REM sleep usually is shortened. However, the number of cycles of REM sleep usually is increased, mostly late in the sleep time. Zolpidem and zaleplon suppress REM sleep to a lesser extent than do benzodiazepines and thus may be superior to benzodiazepines for use as hypnotics (Dujardin et al., 1998).

Despite the shortening of stage 4 and REM sleep, benzodiazepine administration typically increases total sleep time, largely by increasing the time spent in stage 2 (which is the major fraction of non-REM sleep). The effect is greatest in subjects with the shortest baseline total sleep time. In addition, despite the increased number of

REM cycles, the number of shifts to lighter sleep stages (1 and 0) and the amount of body movement are diminished. Nocturnal peaks in the secretion of growth hormone, prolactin, and luteinizing hormone are not affected. During chronic nocturnal use of benzodiazepines, the effects on the various stages of sleep usually decline within a few nights. When such use is discontinued, the pattern of drug-induced changes in sleep parameters may “rebound,” and an increase in the amount and density of REM sleep may be especially prominent. If the dosage has not been excessive, patients usually will note only a shortening of sleep time rather than an exacerbation of insomnia.

Although some differences in the patterns of effects exerted by the various benzodiazepines have been noted, their use usually imparts a sense of deep or refreshing sleep. It is uncertain to which effect on sleep parameters this feeling can be attributed. As a result, variations in the pharmacokinetic properties of individual benzodiazepines appear to be much more important determinants of their effects on sleep than are any potential differences in their pharmacodynamic properties.

Molecular Targets for Benzodiazepine Actions in the CNS.

Benzodiazepines appear to exert most of their effects by interacting with inhibitory neurotransmitter receptors directly activated by GABA (Chapter 14). The ionotropic GABA_A receptors consist of five subunits that co-assemble to form an integral chloride channel (Figure 14–11). GABA_A receptors are responsible for most inhibitory neurotransmission in the CNS. Benzodiazepines act at GABA_A receptors by binding directly to a specific site that is distinct from that of GABA binding. Unlike barbiturates, benzodiazepines do not activate GABA_A receptors directly; rather, benzodiazepines act allosterically by modulating the effects of GABA. Benzodiazepines and GABA analogs bind to their respective sites on brain membranes with nanomolar affinity. Benzodiazepines modulate GABA binding, and GABA alters benzodiazepine binding in an allosteric fashion.

Benzodiazepines and related compounds can act as agonists, antagonists, or inverse agonists at the benzodiazepine-binding site on GABA_A receptors. Agonists at the binding site increase, and inverse agonists decrease, the amount of chloride current generated by GABA_A-receptor activation. Agonists at the benzodiazepine binding site shift the GABA concentration-response curve to the left, whereas inverse agonists shift the curve to the right. Both these effects are blocked by antagonists at the benzodiazepine binding site. In the absence of an agonist or inverse agonist for the benzodiazepine binding site, an antagonist for this binding site does not affect GABA_A receptor function. One such antagonist, flumazenil, is used clinically to reverse the effects of high doses of benzodiazepines. The behavioral and electrophysiological effects of benzodiazepines also can be reduced or prevented by prior treatment with antagonists at the GABA binding site (e.g., bicuculline).

The strongest evidence that benzodiazepines act directly on GABA_A receptors comes from recombinant expression of cDNAs encoding subunits of the receptor complex, which resulted in high-affinity benzodiazepine binding sites and GABA-activated chloride conductances that were enhanced by benzodiazepine receptor agonists (Burt, 2003). The properties of the expressed receptors generally resemble those of GABA_A receptors found in most CNS neurons. Each GABA_A receptor is believed to consist of a pentamer of homologous subunits. Thus far 16 different subunits have been identified and classified into seven subunit families: six α , three β , three γ , and single δ , ϵ , π , and θ subunits. Additional complexity

arises from RNA splice variants of some of these subunits (e.g., $\gamma 2$ and $\alpha 6$). The exact subunit structures of native GABA receptors still are unknown, but it is thought that most GABA receptors are composed of α , β , and γ subunits that co-assemble with some uncertain stoichiometry. The multiplicity of subunits generates heterogeneity in GABA_A receptors and is responsible, at least in part, for the pharmacological diversity in benzodiazepine effects in behavioral, biochemical, and functional studies. Studies of cloned GABA_A receptors have shown that the co-assembly of a γ subunit with α and β subunits confers benzodiazepine sensitivity to GABA_A receptors (Burt, 2003). Receptors composed solely of α and β subunits produce functional GABA_A receptors that also respond to barbiturates, but they neither bind nor are affected by benzodiazepines. Benzodiazepines are believed to bind at the interface between α and γ subunits, and both subunits determine the pharmacology of the benzodiazepine binding site (Burt, 2003). For example, receptors containing the $\alpha 1$ subunit are pharmacologically distinct from receptors containing $\alpha 2$, $\alpha 3$, or $\alpha 5$ subunits (Pritchett and Seeburg, 1990), reminiscent of the pharmacological heterogeneity detected with radioligand-binding studies using brain membranes. Receptors containing the $\alpha 6$ subunit do not display high-affinity binding of diazepam and appear to be selective for the benzodiazepine receptor inverse agonist RO 15-4513, which has been tested as an alcohol antagonist (Lüddens et al., 1990). The subtype of γ subunit also modulates benzodiazepine pharmacology, with lower-affinity binding observed in receptors containing the $\gamma 1$ subunit. Although theoretically ~1 million different GABA_A receptors could be assembled from all these different subunits, constraints for the assembly of these receptors apparently limit their numbers (Sieghart et al., 1999).

An understanding of which GABA_A receptor subunits are responsible for particular effects of benzodiazepines *in vivo* has emerged. The mutation to arginine of a histidine residue at position 101 of the GABA_A receptor $\alpha 1$ subunit renders receptors containing that subunit insensitive to the GABA-enhancing effects of diazepam (Kleingoor et al., 1993). Mice bearing these mutated subunits fail to exhibit the sedative, the amnestic, and in part the anticonvulsant effects of diazepam while retaining sensitivity to the anxiolytic, muscle-relaxant, and ethanol-enhancing effects. Conversely, mice bearing the equivalent mutation in the $\alpha 2$ subunit of the GABA_A receptor are insensitive to the anxiolytic effects of diazepam (Burt, 2003). The attribution of specific behavioral effects of benzodiazepines to individual receptor subunits will aid in the development of new compounds exhibiting fewer undesired side effects.

Electrophysiological studies *in vitro* have shown that the enhancement of GABA-induced chloride currents by benzodiazepines results primarily from an increase in the frequency of bursts of chloride channel opening produced by submaximal amounts of GABA (Twyman et al., 1989). Inhibitory synaptic transmission measured after stimulation of afferent fibers is potentiated by benzodiazepines at therapeutically relevant concentrations. Prolongation of spontaneous miniature inhibitory postsynaptic currents (IPSCs) by benzodiazepines also has been observed. Although sedative barbiturates also enhance such chloride currents, they do so by prolonging the duration of individual channel-opening events. Macroscopic measurements of GABA_A receptor-mediated currents indicate that benzodiazepines shift the GABA concentration-response curve to the left without increasing the maximum current evoked with GABA. These findings collectively are consistent with

a model in which benzodiazepines exert their major actions by increasing the gain of inhibitory neurotransmission mediated by GABA_A receptors.

GABA_A receptor subunits also may play roles in the targeting of assembled receptors to their proper locations in synapses. In knockout mice lacking the $\gamma 2$ subunit, GABA_A receptors did not localize to synapses, although they were formed and translocated to the cell surface (Essrich et al., 1998). The synaptic clustering molecule gephyrin also plays a role in receptor localization.

GABA_A Receptor-Mediated Electrical Events: *in vivo* Properties. The remarkable safety of the benzodiazepines is likely related to the fact that their effects *in vivo* depend on the presynaptic release of GABA; in the absence of GABA, benzodiazepines have no effects on GABA_A receptor function. Although barbiturates also enhance the effects of GABA at low concentrations, they directly activate GABA receptors at higher concentrations, which can lead to profound CNS depression (discussed later). Further, the behavioral and sedative effects of benzodiazepines can be ascribed in part to potentiation of GABA-ergic pathways that serve to regulate the firing of neurons containing various monoamines (Chapter 14). These neurons are known to promote behavioral arousal and are important mediators of the inhibitory effects of fear and punishment on behavior. Finally, inhibitory effects on muscular hypertonia or the spread of seizure activity can be rationalized by potentiation of inhibitory GABA-ergic circuits at various levels of the neuraxis. In most studies conducted *in vivo* or *in situ*, the local or systemic administration of benzodiazepines reduces the spontaneous or evoked electrical activity of major (large) neurons in all regions of the brain and spinal cord. The activity of these neurons is regulated in part by small inhibitory interneurons (predominantly GABA-ergic) arranged in feedback and feedforward types of circuits. The magnitude of the effects produced by benzodiazepines varies widely depending on such factors as the types of inhibitory circuits that are operating, the sources and intensity of excitatory input, and the manner in which experimental manipulations are performed and assessed. For example, feedback circuits often involve powerful inhibitory synapses on the neuronal soma near the axon hillock, which are supplied predominantly by recurrent pathways. The synaptic or exogenous application of GABA to this region increases chloride conductance and can prevent neuronal discharge by shunting currents that otherwise would depolarize the membrane of the initial segment. Accordingly, benzodiazepines markedly prolong the period after brief activation of recurrent GABA-ergic pathways during which neither spontaneous nor applied excitatory stimuli can evoke neuronal discharge; this effect is reversed by the GABA_A receptor antagonist bicuculline (see Figure 14–10).

The macromolecular complex containing GABA-regulated chloride channels also may be a site of action of general anesthetics, ethanol, inhaled drugs of abuse, and certain metabolites of endogenous steroids (Whiting, 2003). Among the latter, allopregnanolone (3 α -hydroxy, 5 α -dihydroprogesterone) is of particular interest. This compound, a metabolite of progesterone that can be formed in the brain from precursors in the circulation and also synthesized by glial cells, produces barbiturate-like effects, including promotion of GABA-induced chloride currents and enhanced binding of benzodiazepines and GABA-receptor agonists. As with the barbiturates, higher concentrations of the steroid activate chloride currents in the absence of GABA, and its effects do not require the presence of a

γ subunit in GABA_A receptors expressed in transfected cells. Unlike the barbiturates, however, the steroid cannot reduce excitatory responses to glutamate (discussed later). These effects are produced very rapidly and apparently are mediated by interactions at sites on the cell surface. A congener of allopregnanolone (alfaxalone) was used previously outside the U.S. for the induction of anesthesia.

Respiration. Hypnotic doses of benzodiazepines are without effect on respiration in normal subjects, but special care must be taken in the treatment of children (Kriel et al., 2000) and individuals with impaired hepatic function, such as alcoholics (Guglielminotti et al., 1999). At higher doses, such as those used for preanesthetic medication or for endoscopy, benzodiazepines slightly depress alveolar ventilation and cause respiratory acidosis as the result of a decrease in hypoxic rather than hypercapnic drive; these effects are exaggerated in patients with chronic obstructive pulmonary disease (COPD), and alveolar hypoxia and CO₂ narcosis may result. These drugs can cause apnea during anesthesia or when given with opioids. Patients severely intoxicated with benzodiazepines only require respiratory assistance when they also have ingested another CNS-depressant drug, most commonly ethanol.

In contrast, hypnotic doses of benzodiazepines may worsen sleep-related breathing disorders by adversely affecting control of the upper airway muscles or by decreasing the ventilatory response to CO₂. The latter effect may cause hypoventilation and hypoxemia in some patients with severe COPD, although benzodiazepines may improve sleep and sleep structure in some instances. In patients with obstructive sleep apnea (OSA), hypnotic doses of benzodiazepines may decrease muscle tone in the upper airway and exaggerate the impact of apneic episodes on alveolar hypoxia, pulmonary hypertension, and cardiac ventricular load. Many clinicians consider the presence of OSA to be a contraindication to the use of alcohol or any sedative-hypnotic agent, including a benzodiazepine; caution also should be exercised with patients who snore regularly, because partial airway obstruction may be converted to OSA under the influence of these drugs. In addition, benzodiazepines may promote the appearance of episodes of apnea during REM sleep (associated with decreases in oxygen saturation) in patients recovering from a myocardial infarction; however, no impact of these drugs on survival of patients with cardiac disease has been reported.

Cardiovascular System. The cardiovascular effects of benzodiazepines are minor in normal subjects except in severe intoxication; the adverse effects in patients with obstructive sleep disorders or cardiac disease were noted above. In preanesthetic doses, all benzodiazepines decrease blood pressure and increase heart rate. With midazolam, the effects appear to be secondary to a decrease in peripheral resistance, but with diazepam, they are secondary to a decrease in left ventricular work and cardiac output. Diazepam increases coronary flow, possibly by an action to increase interstitial concentrations of adenosine, and the accumulation of this cardiodepressant metabolite also may explain the negative inotropic effects of the drug. In large doses, midazolam decreases cerebral blood flow and oxygen assimilation considerably (Nugent et al., 1982).

GI Tract. Benzodiazepines are thought by some gastroenterologists to improve a variety of “anxiety related” gastrointestinal disorders. There is a paucity of evidence for direct actions. Benzodiazepines partially protect against stress ulcers in rats, and diazepam markedly decreases nocturnal gastric secretion in humans. Other

agents are considerably more effective in acid-peptic disorders (Chapter 45).

Absorption, Fate, and Excretion. The physicochemical and pharmacokinetic properties of the benzodiazepines greatly affect their clinical utility. They all have high lipid–water distribution coefficients in the non-ionized form; nevertheless, lipophilicity varies >50-fold according to the polarity and electronegativity of various substituents.

All the benzodiazepines are absorbed completely, with the exception of clorazepate; this drug is decarboxylated rapidly in gastric juice to *N*-desmethyldiazepam (nordazepam), which subsequently is absorbed completely. Drugs active at the benzodiazepine receptor may be divided into four categories based on their elimination $t_{1/2}$:

- Ultra-short-acting benzodiazepines
- Short-acting agents ($t_{1/2}$ <6 hours), including triazolam, the non-benzodiazepine zolpidem ($t_{1/2}$ ~2 hours), and eszopiclone ($t_{1/2}$ 5-6 hours)
- Intermediate-acting agents ($t_{1/2}$ 6-24 hours), including estazolam and temazepam
- Long-acting agents ($t_{1/2}$ >24 hours), including flurazepam, diazepam, and quazepam

Flurazepam itself has a short $t_{1/2}$ (~2.3 hours), but a major active metabolite, *N*-des-alkyl-flurazepam, is long-lived ($t_{1/2}$ 47-100 hours), which complicates the classification of individual benzodiazepines.

The benzodiazepines and their active metabolites bind to plasma proteins. The extent of binding correlates strongly with lipid solubility and ranges from ~70% for alprazolam to nearly 99% for diazepam. The concentration in the cerebrospinal fluid is approximately equal to the concentration of free drug in plasma. While competition with other protein-bound drugs may occur, no clinically significant examples have been reported.

The plasma concentrations of most benzodiazepines exhibit patterns that are consistent with two-compartment models (Chapter 2), but three-compartment models appear to be more appropriate for the compounds with the highest lipid solubility. Accordingly, there is rapid uptake of benzodiazepines into the brain and other highly perfused organs after intravenous administration (or oral administration of a rapidly absorbed compound); rapid uptake is followed by a phase of redistribution into tissues that are less well perfused, especially muscle and fat. Redistribution is most rapid for drugs with the highest lipid solubility. In the regimens used for nighttime sedation, the rate of redistribution sometimes can have a greater influence than the rate of biotransformation on the duration of CNS effects (Dettli, in Symposium, 1986a). The kinetics of redistribution of diazepam and other lipophilic benzodiazepines are complicated by enterohepatic circulation. The volumes of distribution of the benzodiazepines are large and in many cases are increased in elderly patients. These drugs cross the placental barrier and are secreted into breast milk.

The benzodiazepines are metabolized extensively by hepatic CYPs, particularly CYPs 3A4 and 2C19. Some benzodiazepines, such as oxazepam, are conjugated directly and are not metabolized by these enzymes (Tanaka, 1999). Erythromycin, clarithromycin, ritonavir, itraconazole, ketoconazole, nefazodone, and grapefruit juice are inhibitors of CYP3A4 (Chapter 6) and can affect the metabolism of benzodiazepines (Dresser et al., 2000). Because active metabolites of some benzodiazepines are biotransformed more slowly than are the parent compounds, the duration of action of many benzodiazepines bears little relationship to the $t_{1/2}$ of elimination of the parent drug that was administered, as noted above for flurazepam. Conversely, the rate of biotransformation of agents that are inactivated by the initial reaction is an important determinant of their duration of action; these agents include oxazepam, lorazepam, temazepam, triazolam, and midazolam.

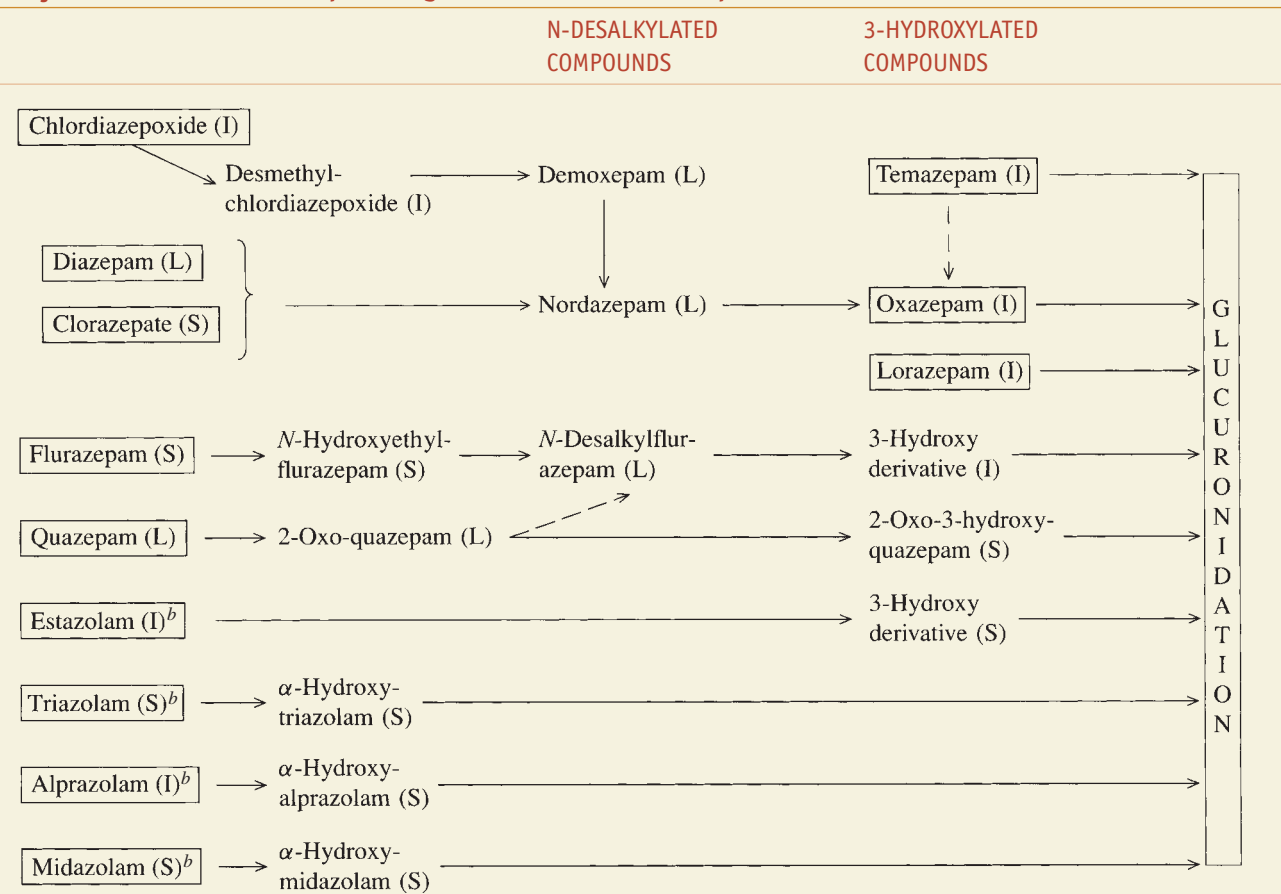

Metabolism of the benzodiazepines occurs in three major stages. These and the relationships between the drugs and their metabolites are shown in Table 17–2.

For benzodiazepines that bear a substituent at position 1 (or 2) of the diazepine ring, the initial and most rapid phase of metabolism involves modification and/or removal of the substituent. With the exception of triazolam, alprazolam, estazolam, and midazolam, which contain either a fused triazolo or a imidazolo ring, the eventual products are *N*-desalkylated compounds that are biologically active. One such compound, nordazepam, is a major metabolite common to the biotransformation of diazepam, clorazepate, and prazepam; it also is formed from demoxepam, an important metabolite of chlordiazepoxide.

The second phase of metabolism involves hydroxylation at position 3 and also usually yields an active derivative (e.g., oxazepam from nordazepam). The rates of these reactions are usually very much slower than the first stage ($t_{1/2}$ >40-50 hours) such that appreciable accumulation of hydroxylated products with intact substituents at position 1 does not occur. There are two significant exceptions to this rule: (1) small amounts of temazepam accumulate during the chronic administration of diazepam and (2) following the replacement of S with O in quazepam, most of the resulting 2-oxoquazepam is hydroxylated slowly at position 3 without removal of the *N*-alkyl group. However, only small amounts of the 3-hydroxyl derivative accumulate during chronic administration of quazepam because this compound is conjugated at an unusually rapid rate. In contrast, the *N*-desalkylflurazepam that is formed by the “minor” metabolic pathway does accumulate during quazepam administration, and it contributes significantly to the overall clinical effect.

The third major phase of metabolism is the conjugation of the 3-hydroxyl compounds, principally with glucuronic acid; the $t_{1/2}$ of these reactions usually are ~6-12 hours, and the products invariably are inactive. Conjugation is the only major route of metabolism for oxazepam and lorazepam and is the preferred pathway for temazepam because of the slower conversion of this compound to oxazepam. Triazolam and alprazolam are metabolized principally by initial hydroxylation of the methyl group on the fused triazolo ring; the absence of a chlorine residue in ring C of alprazolam slows this reaction significantly. The products, sometimes referred to as α -hydroxylated compounds, are quite active but are metabolized very

Table 17-2

Major Metabolic Relationships among Some of the Benzodiazepines^a

^aCompounds enclosed in boxes are marketed in the U.S. The approximate half-lives of the various compounds are denoted in parentheses; S (short-acting), $t_{1/2} < 6$ hours; I (intermediate-acting), $t_{1/2} = 6-24$ hours; L (long-acting), $t_{1/2} = >24$ hours. All compounds except clorazepate are biologically active; the activity of 3-hydroxydesalkylflurazepam has not been determined. Clonazepam (not shown) is an *N*-desalkyl compound, and it is metabolized primarily by reduction of the 7-NO₂ group to the corresponding amine (inactive), followed by acetylation; its $t_{1/2}$ is 20-40 hours. ^bSee text for discussion of other pathways of metabolism.

rapidly, primarily by conjugation with glucuronic acid, such that there is no appreciable accumulation of active metabolites. The fused triazolo ring in estazolam lacks a methyl group and is hydroxylated to only a limited extent; the major route of metabolism involves the formation of the 3-hydroxyl derivative. The corresponding hydroxyl derivatives of triazolam and alprazolam also are formed to a significant extent. Compared with compounds without the triazolo ring, the rate of this reaction for all three drugs is unusually swift, and the 3-hydroxyl compounds are rapidly conjugated or oxidized further to benzophenone derivatives before excretion.

Midazolam is metabolized rapidly, primarily by hydroxylation of the methyl group on the fused imidazo ring; only small amounts of 3-hydroxyl compounds are formed. The α -hydroxylated compound, which has appreciable biological activity, is eliminated with a $t_{1/2}$ of 1 hour after conjugation with glucuronic acid. Variable

and sometimes substantial accumulation of this metabolite has been noted during intravenous infusion (Oldenhof et al., 1988).

The aromatic rings (A and C) of the benzodiazepines are hydroxylated only to a small extent. The only important metabolism at these sites is reduction of the 7-nitro substituents of clonazepam, nitrazepam, and flunitrazepam; the $t_{1/2}$ of these reactions are usually 20-40 hours. The resulting amines are inactive and are acetylated to varying degrees before excretion.

Because the benzodiazepines apparently do not significantly induce the synthesis of hepatic CYPs, their chronic administration usually does not result in the accelerated metabolism of other substances or of the benzodiazepines. Cimetidine and oral contraceptives inhibit *N*-dealkylation and 3-hydroxylation of benzodiazepines. Ethanol, isoniazid, and phenytoin are less effective in this regard. These reactions usually are reduced to a greater extent in elderly

patients and in patients with chronic liver disease than are those involving conjugation.

Pharmacokinetics and the Ideal Hypnotic. An ideal hypnotic agent would have a rapid onset of action when taken at bedtime, a sufficiently sustained action to facilitate sleep throughout the night, and no residual action by the following morning. Among the benzodiazepines that are used commonly as hypnotic agents, triazolam theoretically fits this description most closely. Because of the slow rate of elimination of desalkylflurazepam, flurazepam (or quazepam) might seem to be unsuitable for this purpose. In practice, there appear to be some disadvantages to the use of agents that have a relatively rapid rate of disappearance, including the early-morning insomnia that is experienced by some patients and a greater likelihood of rebound insomnia on drug discontinuation (Gillin et al., 1989; Roth and Roehrs, 1992). With careful selection of dosage, flurazepam and other benzodiazepines with slower rates of elimination than triazolam can be used effectively. The biotransformation and pharmacokinetic properties of the benzodiazepines have been reviewed (Laurijssens and Greenblatt, 1996).

Therapeutic Uses

The therapeutic uses and routes of administration of individual benzodiazepines that are marketed in the U.S. are summarized in Table 17–3. Most benzodiazepines can be used interchangeably. For example, diazepam can be used for alcohol withdrawal, and most benzodiazepines work as hypnotics. In general, the therapeutic uses of a given benzodiazepine depend on its $t_{1/2}$ and may not match the FDA-approved indications. Benzodiazepines that are useful as anticonvulsants have a long $t_{1/2}$, and rapid entry into the brain is required for efficacy in treatment of status epilepticus. A short elimination $t_{1/2}$ is desirable for hypnotics, although this carries the drawback of increased abuse liability and severity of withdrawal after drug discontinuation. Anti-anxiety agents, in contrast, should have a long $t_{1/2}$ despite the drawback of the risk of neuropsychological deficits caused by drug accumulation.

Untoward Effects. At the time of peak concentration in plasma, hypnotic doses of benzodiazepines can be expected to cause varying degrees of light-headedness, lassitude, increased reaction time, motor incoordination, impairment of mental and motor functions, confusion, and anterograde amnesia. Cognition appears to be affected less than motor performance. *All of these effects can greatly impair driving and other psychomotor skills, especially if combined with ethanol.* When the drug is given at the intended time of sleep, the persistence of these effects during the waking hours is adverse. These dose-related residual effects can be insidious because most subjects underestimate the degree of their impairment. Residual daytime sleepiness also may occur, even though successful drug therapy can reduce the daytime sleepiness resulting from chronic insomnia (Dement, 1991). The intensity and incidence of CNS toxicity generally increase with age; both pharmacokinetic and pharmacodynamic factors are involved (Monane, 1992).

Other relatively common side effects of benzodiazepines are weakness, headache, blurred vision, vertigo, nausea and vomiting, epigastric distress, and diarrhea; joint pains, chest pains, and incontinence are much rarer. Anticonvulsant benzodiazepines sometimes actually increase the frequency of seizures in patients with epilepsy. The possible adverse effects of alterations in the sleep pattern are discussed later.

Adverse Psychological Effects. Benzodiazepines may cause paradoxical effects. Flurazepam occasionally increases the incidence of nightmares—especially during the first week of use—and sometimes causes garrulousness, anxiety, irritability, tachycardia, and sweating. Amnesia, euphoria, restlessness, hallucinations, sleep-walking, sleep-talking, other complex behaviors, and hypomanic behavior have been reported to occur during use of various benzodiazepines. The release of bizarre uninhibited behavior has been noted in some users, whereas hostility and rage may occur in others; collectively, these are sometimes referred to as *disinhibition* or *dyscontrol reactions*. Paranoia, depression, and suicidal ideation also occasionally may accompany the use of these agents. Such paradoxical or disinhibition reactions are rare and appear to be dose related. Because of reports of an increased incidence of confusion and abnormal behaviors, triazolam has been banned in the U.K., although the FDA declared triazolam to be safe and effective in low doses of 0.125–0.25 mg. Surveys in the U.K. after the ban found that patients did not have fewer side effects with replacement treatments (Hindmarch et al., 1993), which is consonant with controlled studies that do not support the conclusion that such reactions occur more frequently with any one benzodiazepine than with others (Jonas et al., 1992; Rothschild, 1992).

Chronic benzodiazepine use poses a risk for development of dependence and abuse (Woods et al., 1992), but not to the same extent as seen with older sedatives and other recognized drugs of abuse (Uhlenhuth et al., 1999). Abuse of benzodiazepines includes the use of flunitrazepam (rohypnol; not licensed for use in the U.S.) as a “date-rape drug” (Woods and Winger, 1997). Mild dependence may develop in many patients who have taken therapeutic doses of benzodiazepines on a regular basis for prolonged periods. Withdrawal symptoms may include temporary intensification of the problems that originally prompted their use (e.g., insomnia or anxiety). Dysphoria, irritability, sweating, unpleasant dreams, tremors, anorexia, and faintness or dizziness also may occur, especially when withdrawal of the benzodiazepine occurs abruptly (Petursson, 1994). Hence, it is prudent to taper the dosage gradually when therapy is to be discontinued. Despite their adverse effects, benzodiazepines are relatively safe drugs. Even huge doses are rarely fatal unless other drugs are taken concomitantly. Ethanol is a common contributor to deaths involving benzodiazepines, and true coma is uncommon in the absence of another CNS depressant. Although overdosage with a benzodiazepine rarely causes severe cardiovascular or respiratory depression, therapeutic doses can further compromise respiration in patients with COPD or obstructive sleep apnea (see “Respiration” earlier in the chapter).

A wide variety of serious allergic, hepatotoxic, and hematologic reactions to the benzodiazepines may occur, but the incidence is quite low; these reactions have been associated with the use of flurazepam, triazolam, and temazepam. Large doses taken just before or during labor may cause hypothermia, hypotonia, and mild respiratory

Table 17-3

Trade Names, Routes of Administration, and Therapeutic Uses of Benzodiazepines

COMPOUND (TRADE NAME)	ROUTES OF ADMINISTRATION ^a	EXAMPLES OF THERAPEUTIC USES ^b	COMMENTS	$t_{1/2}$, hours ^c	USUAL SEDATIVE- HYPNOTIC DOSAGE, mg ^d
Alprazolam (XANAX)	Oral	Anxiety disorders, agoraphobia	Withdrawal symptoms may be especially severe	12±2	—
Chlordiazepoxide (LIBRIUM, others)	Oral, IM, IV	Anxiety disorders, management of alcohol withdrawal, anesthetic premedication	Long-acting and self-tapering because of active metabolites	10±3.4	50-100, qd–qid ^e
Clonazepam (KLONOPIN)	Oral	Seizure disorders, adjunctive treatment in acute mania and certain movement disorders	Tolerance develops to anticonvulsant effects	23±5	—
Clorazepate (TRANXENE, others)	Oral	Anxiety disorders, seizure disorders	Prodrug; activity due to formation of nordazepam during absorption	2.0±0.9	3.75-20, bid–qid ^e
Diazepam (VALIUM, others)	Oral, IM, IV, rectal	Anxiety disorders, status epilepticus, skeletal muscle relaxation, anesthetic premedication	Prototypical benzodiazepine	43±13	5-10, tid–qid ^e
Estazolam (PROSOM)	Oral	Insomnia	Contains triazolo ring; adverse effects may be similar to those of triazolam	10–24	1-2
Flurazepam (DALMANE)	Oral	Insomnia	Active metabolites accumulate with chronic use	74±24	15-30
Lorazepam (ATIVAN)	Oral, IM, IV	Anxiety disorders, preanesthetic medication	Metabolized solely by conjugation	14±5	2-4
Midazolam (VERSED)	IV, IM	Preanesthetic and intraoperative medication	Rapidly inactivated	1.9±0.6	— ^f
Oxazepam (SERAX)	Oral	Anxiety disorders	Metabolized solely by conjugation	8.0±2.4	15-30, tid–qid ^e
Quazepam (DORAL)	Oral	Insomnia	Active metabolites accumulate with chronic use	39	7.5-15
Temazepam (RESTORIL)	Oral	Insomnia	Metabolized mainly by conjugation	11±6	7.5-30
Triazolam (HALCION)	Oral	Insomnia	Rapidly inactivated; may cause disturbing daytime side effects	2.9±1.0	0.125-0.25

^aIM, intramuscular injection; IV, intravenous administration; qd, once a day; bid, twice a day; tid, three times a day; qid, four times a day. ^bThe therapeutic uses are identified as examples to emphasize that most benzodiazepines can be used interchangeably. In general, the therapeutic uses of a given benzodiazepine are related to its $t_{1/2}$ and may not match the marketed indications. The issue is addressed more extensively in the text. ^cHalf-life of active metabolite may differ. See Appendix II for additional information. ^dFor additional dosage information, see Chapter 13 (anesthesia), Chapter 17 (anxiety), and Chapter 19 (seizure disorders). ^eApproved as a sedative-hypnotic only for management of alcohol withdrawal; doses in a nontolerant individual would be smaller. ^fRecommended doses vary considerably depending on specific use, condition of patient, and concomitant administration of other drugs.

depression in the neonate. Abuse by the pregnant mother can result in a withdrawal syndrome in the newborn.

Except for additive effects with other sedative or hypnotic drugs, reports of clinically important pharmacodynamic interactions between benzodiazepines and other drugs have been infrequent. Ethanol increases both the rate of absorption of benzodiazepines and the associated CNS depression. Valproate and benzodiazepines in combination may cause psychotic episodes. Pharmacokinetic interactions were discussed earlier.

Novel Benzodiazepine Receptor Agonists

Hypnotics in this class are commonly referred to as “Z compounds”. They include zolpidem (AMBIEN), zaleplon (SONATA), zopiclone (not marketed in the U.S.), and eszopiclone (LUNESTA), which is the S(+) enantiomer of zopiclone. Although the Z compounds are structurally unrelated to each other and to benzodiazepines, their therapeutic efficacy as hypnotics is due to agonist effects on the benzodiazepine site of the GABA_A receptor. Compared to benzodiazepines, Z compounds are less effective as anticonvulsants or muscle relaxants, which may be related to their relative selectivity for GABA_A receptors containing the $\alpha 1$ subunit. Over the last decade, Z compounds have largely replaced benzodiazepines in the treatment of insomnia. Z compounds were initially promoted as having less potential for dependence and abuse than traditional benzodiazepines. However, based on post-marketing clinical experience with zopiclone and zolpidem, tolerance and physical dependence can be expected during long-term use of Z compounds, especially with higher doses (Zammit, 2009). Reports of abuse of Z compounds are on the rise world-wide (Victorri-Vigneau, 2007). Zopiclone and its isomers are classified as schedule IV drugs in the U.S. The clinical presentation of overdose with Z compounds is similar to that of benzodiazepine overdose and can be treated with the benzodiazepine antagonist flumazenil.

Zaleplon and zolpidem are effective in relieving sleep-onset insomnia. Both drugs have been approved by the FDA for use for up to 7-10 days at a time. Zaleplon and zolpidem have sustained hypnotic efficacy without occurrence of rebound insomnia on abrupt discontinuation (Mitler, 2000; Walsh et al., 2000). Zaleplon and zolpidem have similar degrees of efficacy. Zolpidem has a $t_{1/2}$ of ~2 hours, which is sufficient to cover most of a typical 8-hour sleep period, and is presently approved for bedtime use only. Zaleplon has a shorter $t_{1/2}$ ~1 hour, which offers the possibility for safe dosing later in the night, within 4 hours of the anticipated rising time. As a result, zaleplon is approved for use immediately at bedtime or when the patient has difficulty falling asleep after bedtime. Because of its short $t_{1/2}$, zaleplon has not been shown to be different from placebo in measures of duration of sleep and number of awakenings. Zaleplon and zolpidem differ in residual side effects; late-night administration of zolpidem has been associated with morning sedation, delayed reaction time, and anterograde amnesia, whereas zaleplon does not differ from placebo.

Zaleplon. Zaleplon (SONATA, generic) is a non-benzodiazepine and is a member of the pyrazolopyrimidine class of compounds.

Zaleplon preferentially binds to the benzodiazepine-binding site on GABA_A receptors containing the $\alpha 1$ receptor subunit. Zaleplon is absorbed rapidly and reaches peak plasma concentrations in ~1 hour. Its bioavailability is ~30% because of presystemic metabolism. Zaleplon has a volume of distribution of ~1.4 L/kg and plasma-protein binding of ~60%. Zaleplon is metabolized largely by aldehyde oxidase and to a lesser extent by CYP3A4. Its oxidative metabolites are converted to glucuronides and eliminated in urine. Less than 1% of zaleplon is excreted unchanged in urine. None of zaleplon's metabolites are pharmacologically active.

Zaleplon (usually administered in 5-, 10-, or 20-mg doses) has been studied in clinical trials of patients with chronic or transient insomnia (Dooley and Plosker, 2000), focusing on the drug's effects in decreasing sleep latency. Zaleplon-treated subjects with either chronic or transient insomnia have experienced shorter periods of sleep latency than have placebo-treated subjects.

Zolpidem. Zolpidem (AMBIEN, others) is a non-benzodiazepine sedative-hypnotic drug. It is classified as an imidazopyridine:

Although the actions of zolpidem are due to agonist effects on GABA_A receptors and generally resemble those of benzodiazepines, it produces only weak anticonvulsant effects in experimental animals, and its relatively strong sedative actions appear to mask anxiolytic effects in various animal models of anxiety (Langtry and Benfield, 1990). Although chronic administration of zolpidem to rodents produces neither tolerance to its sedative effects nor signs of withdrawal when the drug is discontinued and flumazenil is injected (Perrault et al., 1992), tolerance and physical dependence have been observed with chronic administration of zolpidem to baboons (Griffiths et al., 1992). During U.S. clinical trials, withdrawal effects within 48 hours of drug discontinuation occurred at an

468 incidence of 1% or less. Post-marketing reports of abuse, dependence, and withdrawal have been recorded.

Unlike the benzodiazepines, zolpidem has little effect on the stages of sleep in normal human subjects. The drug is as effective as benzodiazepines in shortening sleep latency and prolonging total sleep time in patients with insomnia. After discontinuation of zolpidem, the beneficial effects on sleep reportedly persist for up to 1 week (Herrmann et al., 1993), but mild rebound insomnia on the first night also has occurred. Tolerance and physical dependence develop only rarely and under unusual circumstances (Cavallaro et al., 1993; Morselli, 1993). Indeed, zolpidem-induced improvement in sleep time of chronic insomniacs was sustained during as much as 6 months of treatment without signs of withdrawal or rebound after stopping the drug (Kummer et al., 1993). Nevertheless, zolpidem is approved only for the short-term treatment of insomnia. At therapeutic doses (5 to 10 mg), zolpidem infrequently produces residual daytime sedation or amnesia, and the incidence of other adverse effects (e.g., GI complaints or dizziness) also is low. As with the benzodiazepines, large overdoses of zolpidem do not produce severe respiratory depression unless other agents (e.g., ethanol) also are ingested (Garnier et al., 1994). Hypnotic doses increase the hypoxia and hypercarbia of patients with obstructive sleep apnea.

Zolpidem is absorbed readily from the GI tract; first-pass hepatic metabolism results in an oral bioavailability of ~70%, but this value is lower when the drug is ingested with food because of slowed absorption and increased hepatic blood flow. Zolpidem is eliminated almost entirely by conversion to inactive products in the liver, largely through oxidation of the methyl groups on the phenyl and imidazopyridine rings to the corresponding carboxylic acids. Its plasma $t_{1/2}$ is ~2 hours in individuals with normal hepatic blood flow or function. This value may be increased 2-fold or more in those with cirrhosis and also tends to be greater in older patients; adjustment of dosage often is necessary in both categories of patients. Although little or no unchanged zolpidem is found in the urine, elimination of the drug is slower in patients with chronic renal insufficiency largely owing to an increase in its apparent volume of distribution.

Eszopiclone. Eszopiclone (LUNESTA) is the active S(+) enantiomer of zopiclone. Eszopiclone has no structural similarity to benzodiazepines, zolpidem, or zaleplon.

Eszopiclone is used for the long-term treatment of insomnia and for sleep maintenance. It is prescribed to patients who have difficulty falling asleep as well as those who experience difficulty staying asleep, and is available in 1-, 2-, or 3-mg tablets.

Eszopiclone received FDA approval based on six randomized placebo-controlled clinical trials that showed it has efficacy in treating transient (Rosenberg et al., 2005) and chronic insomnia. In the transient insomnia study subjects receiving the drug showed a decreased latency to attain sleep, increased sleep efficiency, and fewer awakenings, as measured by both polysomnography and a morning questionnaire. There were no observed psychomotor after-effects observed the next day. Eszopiclone also possesses efficacy as a sleep aid when taken chronically, for as long as 12 months (Melton et al., 2005). All chronic studies conducted to date found that eszopiclone decreased the latency to onset of sleep. No tolerance was observed, nor were signs of serious withdrawal, such as seizures or rebound insomnia, seen upon discontinuation of the drug. However, there are such reports for zopiclone, the racemate used outside the U.S. Mild withdrawal consisting of abnormal dreams, anxiety, nausea, and upset stomach can occur (rate $\leq 2\%$). A minor reported adverse effect of eszopiclone was a bitter taste. Eszopiclone is a schedule IV controlled substance in the U.S.

Eszopiclone is absorbed rapidly after oral administration, with a bioavailability of ~80%, and shows wide distribution throughout the body. It is 50-60% bound to plasma proteins and has a $t_{1/2}$ of ~6 hours. It is metabolized by CYPs 3A4 and 2E1. Eszopiclone is believed to exert its sleep-promoting effects through its enhancement of GABA_A receptor function at the benzodiazepine binding site (Hanson et al., 2008; Jia et al., 2009).

FLUMAZENIL: A BENZODIAZEPINE RECEPTOR ANTAGONIST

Flumazenil (ROMAZICON, generic), the only member of this class, is an imidazobenzodiazepine (Table 17-1) that behaves as a specific benzodiazepine receptor antagonist (Hoffman and Warren, 1993). Flumazenil binds with high affinity to specific sites on the GABA_A receptor, where it competitively antagonizes the binding and allosteric effects of benzodiazepines and other ligands. Flumazenil antagonizes both the electrophysiological and behavioral effects of agonist and inverse-agonist benzodiazepines and β -carbolines. The drug is given intravenously.

In animal models, the intrinsic pharmacological actions of flumazenil have been subtle; effects resembling those of inverse agonists sometimes have been detected at low doses, whereas slight benzodiazepine-like effects often have been evident at high doses. The evidence for intrinsic activity in human subjects is even more vague, except for modest anticonvulsant effects at high doses. However, anticonvulsant effects cannot be relied on for therapeutic utility because the administration of flumazenil may precipitate seizures under certain circumstances (discussed later).

Flumazenil is available only for intravenous administration. On intravenous administration, flumazenil is eliminated almost entirely by hepatic metabolism to inactive products with a $t_{1/2}$ of ~1 hour; the duration of clinical effects usually is only 30-60 minutes. Although absorbed rapidly after oral administration, <25% of the drug reaches the systemic circulation owing to extensive first-pass hepatic metabolism; effective oral doses are apt to cause headache and dizziness.

The primary indications for the use of flumazenil are the management of suspected benzodiazepine overdose and the reversal of sedative effects produced by benzodiazepines administered during either general anesthesia or diagnostic and/or therapeutic procedures.

The administration of a series of small injections is preferred to a single bolus injection. A total of 1 mg flumazenil given over 1-3 minutes usually is sufficient to abolish the effects of therapeutic doses of benzodiazepines; patients with suspected benzodiazepine overdose should respond adequately to a cumulative dose of 1-5 mg given over 2-10 minutes; a lack of response to 5 mg flumazenil strongly suggests that a benzodiazepine is not the major cause of sedation. Additional courses of treatment with flumazenil may be needed within 20-30 minutes should sedation reappear.

Flumazenil is not effective in single-drug overdoses with either barbiturates or tricyclic antidepressants. To the contrary, the administration of flumazenil in these settings may be associated with the onset of seizures, especially in patients poisoned with tricyclic antidepressants (Spivey, 1992). Seizures or other withdrawal symptoms also may be precipitated in patients who had been taking benzodiazepines for protracted periods and in whom tolerance and/or dependence may have developed.

MELATONIN CONGENERS

Ramelteon. Ramelteon (ROZEREM) is a synthetic tricyclic analog of melatonin with the chemical name (S)-N-[2-(1,6,7,8-tetrahydro-2H-indeno[5,4-b]furan-8-yl)ethyl]propionamide. It was approved in the U.S. in 2005 for the treatment of insomnia, specifically sleep onset difficulties. Unlike other drugs licensed by the FDA for insomnia, ramelteon is not a controlled substance.

Mechanism of Action. Melatonin levels in the suprachiasmatic nucleus rise and fall in a circadian fashion, with concentrations increasing in the evening as an individual prepares for sleep, and then reaching a plateau and ultimately decreasing as the night progresses. Two GPCRs for melatonin, MT₁ and MT₂, are found in the suprachiasmatic nucleus, each playing a different role in sleep. Binding of agonists, such as melatonin, to MT₁ receptors promotes

the onset of sleep while melatonin binding to MT₂ receptors shifts the timing of the circadian system (Liu et al., 1997). Ramelteon binds to both MT₁ and MT₂ receptors with high affinity but, unlike melatonin, it does not bind appreciably to quinone reductase 2, the structurally unrelated MT₃ receptor (Nosjean et al., 2000). Ramelteon is not known to bind to any other classes of receptors, such as nicotinic acetylcholine, neuropeptide, dopamine, or opiate receptors, or the benzodiazepine-binding site on GABA_A receptors.

Clinical Pharmacology. Prescribing guidelines suggest that an 8-mg tablet be taken ~30 minutes before bedtime. Ramelteon is rapidly absorbed from the GI tract and a peak serum concentration is obtained within an hour (Hibberd and Stevenson 2004). Because of the significant first-pass metabolism that occurs after oral administration, ramelteon bioavailability is <2% (Amakye et al., 2004). In the bloodstream, ~80% of ramelteon is protein bound (Takeda Pharmaceuticals North America, 2006). The drug is largely metabolized by the hepatic CYPs 1A2, 2C, and 3A4, with $t_{1/2}$ of ~2 hours in humans. Of the four metabolites, one, M-II, acts as an agonist at MT₁ and MT₂ receptors and may contribute to the sleep-promoting effects of ramelteon.

Ramelteon is efficacious in combating both transient and chronic insomnia. Subjects given 16 or 64 mg of ramelteon in a clinical trial showed a significantly shorter latency to sleep onset, as well as increased total sleep time, compared to placebo controls (Roth et al., 2005); the drug was generally well tolerated by patients and did not impair next-day cognitive function. Ramelteon is also useful in the treatment of chronic insomnia, with no tolerance occurring in its reduction of sleep onset latency even after 6 months of drug administration (Mayer et al., 2009). Sleep latency, evaluated by polysomnography as well as by subject questionnaires, was consistently found to be shorter in patients given ramelteon compared to placebo controls (Erman et al., 2006; Zammit et al., 2007). No evidence of rebound insomnia or withdrawal effects were noted upon ramelteon withdrawal. Ramelteon appears to act by producing a phase advance of the endogenous circadian rhythm (Richardson et al., 2008).

In animals, ramelteon does not produce discriminative stimulus effects similar to those of benzodiazepine receptor agonists, and long-term administration has no effects on spontaneous or operant behaviors, motor activity or posture (France et al., 2006). In addition, ramelteon has no demonstrated positive reinforcing effects in intravenous self-administration experiments performed in rhesus monkeys and there is no indication of abuse liability in humans (Griffiths and Johnson, 2005).

BARBITURATES

The barbiturates were once used extensively as sedative-hypnotic drugs. Except for a few specialized uses, they have been largely replaced by the much safer benzodiazepines.

Chemistry. Barbituric acid is 2,4,6-trioxohexahydropyrimidine. This compound lacks central depressant activity, but the presence of alkyl or aryl groups at position 5 confers sedative-hypnotic and sometimes other activities. The general structural formula for the barbiturates and the structures of selected compounds are included in Table 17-4.

Table 17-4

Structures, Trade Names, and Major Pharmacological Properties of Selected Barbiturates

COMPOUND (TRADE NAMES)	R ₃	R _{5a}	R _{5b}	DOSAGE FORMS ^b	t _{1/2} (hours)	THERAPEUTIC USES	COMMENTS
Amobarbital (AMYTAL)	—H	—C ₂ H ₅	—CH ₂ CH ₂ CH(CH ₃) ₂	IM, IV	10-40	Insomnia, pre-op sedation, emergency management of seizures	Only Na ⁺ salt administered parenterally
Butobarbital (BUTISOL, others)	—H	—C ₂ H ₅	—CH(CH ₃)CH ₂ CH ₃	Oral	35-50	Insomnia, pre-op sedation	Redistribution shortens duration of action of single dose to 8 hours
Mephobarbital (MEBARAL)	—CH ₃	—C ₂ H ₅		Oral	10-70	Seizure disorders, daytime sedation	Second-line anticonvulsant
Methohexital (BREVITAL)	—CH ₃	—CH ₂ CH=CH ₂	—CH(CH ₃)C≡CCH ₂ CH ₃	IV	3-5 ^c	Induction and maintenance of anesthesia	Only Na ⁺ salt available; single dose provides 5-7 min of anesthesia ^c
Pentobarbital (NEMBUTAL)	—H	—C ₂ H ₅	—CH(CH ₃)CH ₂ CH ₂ CH ₃	Oral, IM, IV, rectal	15-50	Insomnia, pre-op sedation, emergency management of seizures	Only Na ⁺ salt administered parenterally
Phenobarbital (LUMINAL, others)	—H	—C ₂ H ₅		Oral, IM, IV	80-120	Seizure disorders, status epilepticus, daytime sedation	First-line anticonvulsant; only Na ⁺ salt administered parenterally
Secobarbital (SECONAL)	—H	—CH ₂ CH=CH ₂	—CH(CH ₃)CH ₂ CH ₂ CH ₃	Oral	15-40	Insomnia, preoperative sedation	Only Na ⁺ salt available
Thiopental (PENTOTHAL)	—H	—C ₂ H ₅	—CH(CH ₃)CH ₂ CH ₂ CH ₃	IV	8-10 ^c	Induction/maintenance of anesthesia, pre-op sedation, emergency management of seizures	Only Na ⁺ salt available; single dose provides brief of anesthesia ^c

^aO except in thiopental, where it is replaced by S. ^bIM, intramuscular injection; IV, intravenous administration. ^cValue represents terminal t_{1/2} due to metabolism by the liver; redistribution following parenteral administration produces effects lasting only a few minutes

The carbonyl group at position 2 takes on acidic character because of lactam–lactim (“keto”–“enol”) tautomerization, which is favored by its location between the two electronegative amido nitrogens. The lactim form is favored in alkaline solution, and salts result. Barbiturates in which the oxygen at C2 is replaced by sulfur sometimes are called *thiobarbiturates*. These compounds are more lipid-soluble than the corresponding *oxybarbiturates*. In general, structural changes that increase lipid solubility decrease duration of action, decrease latency to onset of activity, accelerate metabolic degradation, and increase hypnotic potency.

Pharmacological Properties

The barbiturates reversibly depress the activity of all excitable tissues. The CNS is exquisitely sensitive, and even when barbiturates are given in anesthetic concentrations, direct effects on peripheral excitable tissues are weak. However, serious deficits in cardiovascular and other peripheral functions occur in acute barbiturate intoxication.

Central Nervous System

Sites and Mechanisms of Action on the CNS. Barbiturates act throughout the CNS; non-anesthetic doses preferentially suppress polysynaptic responses. Facilitation is diminished, and inhibition usually is enhanced. The site of inhibition is either postsynaptic, as at cortical and cerebellar pyramidal cells and in the cuneate nucleus, substantia nigra, and thalamic relay neurons, or pre-synaptic, as in the spinal cord. Enhancement of inhibition occurs primarily at synapses where neurotransmission is mediated by GABA acting at GABA_A receptors.

The barbiturates exert several distinct effects on excitatory and inhibitory synaptic transmission. For example, (–)-pentobarbital potentiates GABA-induced increases in chloride conductance and depresses voltage-activated Ca²⁺ currents at similar concentrations (below 10 μM) in isolated hippocampal neurons; above 100 μM, chloride conductance is increased in the absence of GABA (French-Mullen et al., 1993). Phenobarbital is less efficacious and much less potent in producing these effects, whereas (+)-pentobarbital has only weak activity. Thus, the more selective anticonvulsant properties of phenobarbital and its higher therapeutic index may be explained by its lower capacity to depress neuronal function as compared with the anesthetic barbiturates.

The mechanisms underlying the actions of barbiturates on GABA_A receptors appear to be distinct from those of either GABA or the benzodiazepines for reasons that include the following:

- Like benzodiazepines, barbiturates enhance the binding of GABA to GABA_A receptors in a Cl[–]-dependent and picrotoxin-sensitive fashion; however, barbiturates promote (rather than reduce) the binding of benzodiazepines.
- Barbiturates potentiate GABA-induced Cl[–] currents by prolonging periods during which bursts of channel opening occur rather

than by increasing the frequency of these bursts, as benzodiazepines do.

- Only α and β (not γ) subunits are required for barbiturate action.
- Barbiturate-induced increases in Cl[–] conductance are not affected by the deletion of the tyrosine and threonine residues in the β subunit that govern the sensitivity of GABA_A receptors to activation by agonists (Amin and Weiss, 1993).

Sub-anesthetic concentrations of barbiturates also can reduce glutamate-induced depolarizations (Macdonald and McLean, 1982) (Chapter 12); only the AMPA subtypes of glutamate receptors sensitive to kainic acid (Figure 14–10) or quisqualic acid appear to be affected (Marszalec and Narahashi, 1993). At higher concentrations that produce anesthesia, pentobarbital suppresses high-frequency repetitive firing of neurons, apparently as a result of inhibiting the function of voltage-dependent, tetrodotoxin-sensitive Na⁺ channels (Figure 11–4); in this case, however, both stereoisomers are about equally effective (Frenkel et al., 1990). At still higher concentrations, voltage-dependent K⁺ conductances are reduced. Taken together, the findings that barbiturates activate inhibitory GABA_A receptors and inhibit excitatory AMPA receptors can explain their CNS-depressant effects (Saunders and Ho, 1990).

Barbiturates can produce all degrees of depression of the CNS, ranging from mild sedation to general anesthesia. The use of barbiturates for general anesthesia is discussed in Chapter 19. Certain barbiturates, particularly those containing a 5-phenyl substituent (e.g., phenobarbital and mephobarbital), have selective anticonvulsant activity (Chapter 21). The anti-anxiety properties of the barbiturates are inferior to those exerted by the benzodiazepines.

Except for the anticonvulsant activities of phenobarbital and its congeners, the barbiturates possess a low degree of selectivity and a narrow therapeutic index. Thus, it is not possible to achieve a desired effect without evidence of general depression of the CNS. Pain perception and reaction are relatively unimpaired until the moment of unconsciousness, and in small doses, barbiturates increase reactions to painful stimuli. Hence, they cannot be relied on to produce sedation or sleep in the presence of even moderate pain.

Effects on Stages of Sleep. Hypnotic doses of barbiturates increase the total sleep time and alter the stages of sleep in a dose-dependent manner. Like the benzodiazepines, these drugs decrease sleep latency, the number of awakenings, and the durations of REM and slow-wave sleep. During repetitive nightly administration, some tolerance to the effects on sleep occurs within a few days, and the effect on total sleep time may be reduced by as much as 50% after 2 weeks of use. Discontinuation leads to rebound increases in all the parameters reported to be decreased by barbiturates.

Tolerance. Pharmacodynamic (functional) and pharmacokinetic tolerance to barbiturates can occur. The former contributes more to the decreased effect than does the latter. With chronic administration of gradually increasing doses, pharmacodynamic tolerance continues to develop over a period of weeks to months, depending on the dosage schedule, whereas pharmacokinetic tolerance reaches its peak in a few days to a week. Tolerance to the effects on mood, sedation, and hypnosis occurs more readily and is greater than that to the anticonvulsant and lethal effects; thus, as tolerance increases, the therapeutic index decreases. Pharmacodynamic tolerance to barbiturates confers cross-tolerance to all general CNS-depressant drugs, including ethanol.

472 Abuse and Dependence. Like other CNS depressant drugs, barbiturates are abused, and some individuals develop a dependence on them (Chapter 24). Moreover, the barbiturates may have euphoriant effects.

Peripheral Nervous Structures. Barbiturates selectively depress transmission in autonomic ganglia and reduce nicotinic excitation by choline esters. This effect may account, at least in part, for the fall in blood pressure produced by intravenous oxybarbiturates and by severe barbiturate intoxication. At skeletal neuromuscular junctions, the blocking effects of both tubocurarine and decamethonium are enhanced during barbiturate anesthesia. These actions probably result from the capacity of barbiturates at hypnotic or anesthetic concentrations to inhibit the passage of current through nicotinic cholinergic receptors. Several distinct mechanisms appear to be involved, and little stereoselectivity is evident.

Respiration. Barbiturates depress both the respiratory drive and the mechanisms responsible for the rhythmic character of respiration. The neurogenic drive is diminished by hypnotic doses but usually no more so than during natural sleep. However, neurogenic drive is essentially eliminated by a dose three times greater than that used normally to induce sleep. Such doses also suppress the hypoxic drive and, to a lesser extent, the chemoreceptor drive. At still higher doses, the powerful hypoxic drive fails. However, the margin between the lighter planes of surgical anesthesia and dangerous respiratory depression is sufficient to permit the ultra-short-acting barbiturates to be used, with suitable precautions, as anesthetic agents.

The barbiturates only slightly depress protective reflexes until the degree of intoxication is sufficient to produce severe respiratory depression. Coughing, sneezing, hiccoughing, and laryngospasm may occur when barbiturates are employed as intravenous anesthetic agents. Indeed, laryngospasm is one of the chief complications of barbiturate anesthesia.

Cardiovascular System. When given orally in sedative or hypnotic doses, barbiturates do not produce significant overt cardiovascular effects except for a slight decrease in blood pressure and heart rate such as occurs in normal sleep. In general, the effects of thiopental anesthesia on the cardiovascular system are benign in comparison with those of the volatile anesthetic agents; there usually is either no change or a fall in mean arterial pressure (Chapter 19).

Apparently, a decrease in cardiac output usually is sufficient to offset an increase in peripheral resistance, which sometimes is accompanied by an increase in heart rate. Cardiovascular reflexes are obtunded by partial inhibition of ganglionic transmission. This is most evident in patients with congestive heart failure or hypovolemic shock, whose reflexes already are operating maximally and in whom barbiturates can cause an exaggerated fall in blood pressure. Because barbiturates also impair reflex cardiovascular adjustments to inflation of

the lung, positive-pressure respiration should be used cautiously and only when necessary to maintain adequate pulmonary ventilation in patients who are anesthetized or intoxicated with a barbiturate.

Other cardiovascular changes often noted when thiopental and other intravenous thiobarbiturates are administered after conventional preanesthetic medication include decreased renal and cerebral blood flow with a marked fall in CSF pressure. Although cardiac arrhythmias are observed only infrequently, intravenous anesthesia with barbiturates can increase the incidence of ventricular arrhythmias, especially when epinephrine and halothane also are present. Anesthetic concentrations of barbiturates have direct electrophysiological effects on the heart; in addition to depressing Na⁺ channels, they reduce the function of at least two types of K⁺ channels (Nattel et al., 1990; Pancrazio et al., 1993). However, direct depression of cardiac contractility occurs only when doses several times those required to cause anesthesia are administered, which probably contributes to the cardiovascular depression that accompanies acute barbiturate poisoning.

GI Tract. The oxybarbiturates tend to decrease the tone of the GI musculature and the amplitude of rhythmic contractions. The locus of action is partly peripheral and partly central, depending on the dose. A hypnotic dose does not significantly delay gastric emptying in humans. The relief of various GI symptoms by sedative doses is probably largely due to the central-depressant action.

Liver. The best-known effects of barbiturates on the liver are those on the microsomal drug-metabolizing system (Chapter 6), a site at which significant drug-drug interactions can occur. These effects vary with the duration of exposure to the barbiturate.

Acutely, the barbiturates combine with several CYPs and inhibit the biotransformation of a number of other drugs and endogenous substrates, such as steroids; other substrates may reciprocally inhibit barbiturate biotransformations. Drug interactions may result even when the other substances and barbiturates are oxidized by different microsomal enzyme systems.

Chronic administration of barbiturates markedly increases the protein and lipid content of the hepatic smooth endoplasmic reticulum, as well as the activities of glucuronyl transferase and CYPs 1A2, 2C9, 2C19, and 3A4. The induction of these enzymes increases the metabolism of a number of drugs and endogenous substances, including steroid hormones, cholesterol, bile salts, and vitamins K and D. This also results in an increased rate of barbiturate metabolism, which partly accounts for tolerance to barbiturates. Many sedative-hypnotics, various anesthetics, and ethanol also are metabolized by and/or induce the microsomal enzymes, and some degree of cross-tolerance therefore can occur. *Not all microsomal biotransformations of drugs and endogenous substrates are affected equally, but a convenient rule of thumb is that at maximal induction in humans, the rates are approximately doubled.* The inducing effect is not limited to the microsomal enzymes; for example, there are increases in δ -aminolevulinic acid (ALA) synthetase, a mitochondrial enzyme, and aldehyde dehydrogenase, a cytosolic enzyme. The effect of barbiturates on ALA synthetase can cause dangerous disease exacerbations in persons with intermittent porphyria.

Kidney. Severe oliguria or anuria may occur in acute barbiturate poisoning largely as a result of the marked hypotension.

Absorption, Fate, and Excretion. For sedative-hypnotic use, the barbiturates usually are administered orally (Table 17–4). Such doses are absorbed rapidly and probably completely; Na⁺ salts are absorbed more rapidly than the corresponding free acids, especially from liquid formulations. The onset of action varies from 10–60 minutes, depending on the agent and the formulation, and is delayed by the presence of food in the stomach. When necessary, intramuscular injections of solutions of the Na⁺ salts should be placed deeply into large muscles to avoid the pain and possible necrosis that can result at more superficial sites. The intravenous route usually is reserved for the management of status epilepticus (phenobarbital sodium) or for the induction and/or maintenance of general anesthesia (e.g., thiopental or methohexital).

Barbiturates are distributed widely, and they readily cross the placenta. The highly lipid-soluble barbiturates, led by those used to induce anesthesia, undergo redistribution after intravenous injection. Uptake into less vascular tissues, especially muscle and fat, leads to a decline in the concentration of barbiturate in the plasma and brain. With thiopental and methohexital, this results in the awakening of patients within 5–15 minutes of the injection of the usual anesthetic doses (Chapter 19).

Except for the less lipid-soluble aprobarbital and phenobarbital, nearly complete metabolism and/or conjugation of barbiturates in the liver precedes their renal excretion. The oxidation of radicals at C5 is the most important biotransformation that terminates biological activity. Oxidation results in the formation of alcohols, ketones, phenols, or carboxylic acids, which may appear in the urine as such or as glucuronic acid conjugates. In some instances (e.g., phenobarbital), *N*-glycosylation is an important metabolic pathway. Other biotransformations include *N*-hydroxylation, desulfuration of thiobarbiturates to oxybarbiturates, opening of the barbituric acid ring, and *N*-dealkylation of *N*-alkyl barbiturates to active metabolites (e.g., mephobarbital to phenobarbital). About 25% of phenobarbital and nearly all of aprobarbital are excreted unchanged in the urine. Their renal excretion can be increased greatly by osmotic diuresis and/or alkalinization of the urine.

The metabolic elimination of barbiturates is more rapid in young people than in the elderly and infants, and $t_{1/2}$ are increased during pregnancy partly because of the expanded volume of distribution. Chronic liver disease, especially cirrhosis, often increases the $t_{1/2}$ of the biotransformable barbiturates. Repeated administration, especially of phenobarbital, shortens the $t_{1/2}$ of barbiturates that are metabolized as a result of the induction of microsomal enzymes.

None of the barbiturates used for hypnosis in the U.S. appears to have an elimination $t_{1/2}$ that is short enough for elimination to be virtually complete in 24 hours (Table 17–4). However, the relationship between duration of action and $t_{1/2}$ of elimination is complicated by the fact that enantiomers of optically active barbiturates often differ in both biological potencies and rates of biotransformation. *All of these barbiturates will accumulate during repetitive administration unless appropriate adjustments in dosage are made.*

Furthermore, the persistence of the drug in plasma during the day favors the development of tolerance and abuse.

Therapeutic Uses

The major uses of individual barbiturates are listed in Table 17–4. As with the benzodiazepines, the selection of a particular barbiturate for a given therapeutic indication is based primarily on pharmacokinetic considerations.

CNS Uses. Benzodiazepines and other compounds for sedation have largely replaced barbiturates. Barbiturates, especially butabarbital and phenobarbital, are used sometimes to antagonize unwanted CNS-stimulant effects of various drugs, such as ephedrine, dextroamphetamine, and theophylline, although a preferred approach is adjustment of dosage or substitution of alternative therapy for the primary agents (see Chapter 24).

Untoward Effects

After-Effects. Drowsiness may last for only a few hours after a hypnotic dose of barbiturate, but residual CNS depression sometimes is evident the following day, and subtle distortions of mood and impairment of judgment and fine motor skills may be demonstrable. For example, a 200-mg dose of secobarbital has been shown to impair performance of driving or flying skills for 10–22 hours. Residual effects also may take the form of vertigo, nausea, vomiting, or diarrhea, or sometimes may be manifested as overt excitement. The user may awaken slightly intoxicated and feel euphoric and energetic; later, as the demands of daytime activities challenge possibly impaired faculties, the user may display irritability and temper.

Paradoxical Excitement. In some persons, barbiturates produce excitement rather than depression, and the patient may appear to be inebriated. This type of idiosyncrasy is relatively common among geriatric and debilitated patients and occurs most frequently with phenobarbital and *N*-methylbarbiturates. Barbiturates may cause restlessness, excitement, and even delirium when given in the presence of pain and may worsen a patient's perception of pain.

Hypersensitivity. Allergic reactions occur, especially in persons with asthma, urticaria, angioedema, or similar conditions. Hypersensitivity reactions include localized swellings, particularly of the eyelids, cheeks, or lips, and erythematous dermatitis. Rarely, exfoliative dermatitis may be caused by phenobarbital and can prove fatal; the skin eruption may be associated with fever, delirium, and marked degenerative changes in the liver and other parenchymatous organs.

Drug Interactions. Barbiturates combine with other CNS depressants to cause severe depression; ethanol is the most frequent offender, and interactions with first-generation antihistamines also are common. Isoniazid, methylphenidate, and monoamine oxidase inhibitors also increase the CNS-depressant effects.

Barbiturates competitively inhibit the metabolism of certain other drugs; however, the greatest number of drug interactions results from induction of hepatic CYPs and the accelerated disappearance of many drugs and endogenous substances. The metabolism of vitamins D and K is accelerated, which may hamper bone mineralization and lower Ca²⁺ absorption in patients taking phenobarbital and may be responsible for the reported coagulation defects in neonates whose mothers had been taking phenobarbital. Hepatic

enzyme induction enhances metabolism of endogenous steroid hormones, which may cause endocrine disturbances, as well as of oral contraceptives, which may result in unwanted pregnancy. Barbiturates also induce the hepatic generation of toxic metabolites of chlorocarbons (chloroform, trichloroethylene, carbon tetrachloride) and consequently promote lipid peroxidation, which facilitates periportal necrosis of the liver caused by these agents.

Other Untoward Effects. Because barbiturates enhance porphyrin synthesis, they are absolutely contraindicated in patients with acute intermittent porphyria or porphyria variegata. In hypnotic doses, the effects of barbiturates on the control of respiration are minor; however, in the presence of pulmonary insufficiency, serious respiratory depression may occur, and the drugs thus are contraindicated. Rapid intravenous injection of a barbiturate may cause cardiovascular collapse before anesthesia ensues, so the CNS signs of depth of anesthesia may fail to give an adequate warning of impending toxicity. Blood pressure can fall to shock levels; even slow intravenous injection of barbiturates often produces apnea and occasionally laryngospasm, coughing, and other respiratory difficulties.

Barbiturate Poisoning. The incidence of barbiturate poisoning has declined markedly, largely as a result of their decreased use as sedative-hypnotic agents. Nevertheless, poisoning with barbiturates is a significant clinical problem, and death occurs in a few percent of cases (Gary and Tresznewksy, 1983). Most of the cases are the result of deliberate attempts at suicide, but some are from accidental poisonings in children or in drug abusers. The lethal dose of barbiturate varies, but severe poisoning is likely to occur when >10 times the full hypnotic dose has been ingested at once. If alcohol or other depressant drugs also are present, the concentrations that can cause death are lower.

In severe intoxication, the patient is comatose; respiration is affected early. Breathing may be either slow or rapid and shallow. Eventually, blood pressure falls because the effect of the drug and of hypoxia on medullary vasomotor centers; depression of cardiac contractility and sympathetic ganglia also contributes. Pulmonary complications (e.g., atelectasis, edema, and bronchopneumonia) and renal failure are likely to be the fatal complications of severe barbiturate poisoning.

The treatment of acute barbiturate intoxication is based on general supportive measures, which are applicable in most respects to poisoning by any CNS depressant. Hemodialysis or hemoperfusion is necessary only rarely, and the use of CNS stimulants is contraindicated because they increase the mortality rate. If renal and cardiac functions are satisfactory, and the patient is hydrated, forced diuresis and alkalization of the urine will hasten the excretion of phenobarbital. Measures to prevent or treat atelectasis should be taken, and mechanical ventilation should be initiated when indicated. See Chapter 4, *Drug Toxicity and Poisoning*.

In severe acute barbiturate intoxication, circulatory collapse is a major threat. Often the patient is admitted to the hospital with severe hypotension or shock, and dehydration frequently is severe. Hypovolemia must be corrected, and if necessary, the blood pressure can be supported with dopamine. Acute renal failure consequent to shock and hypoxia accounts for perhaps one-sixth of the deaths. In the event of renal failure, hemodialysis should be instituted.

MISCELLANEOUS SEDATIVE-HYPNOTIC DRUGS

Many drugs with diverse structures have been used for their sedative-hypnotic properties, including ramelteon, paraldehyde, chloral hydrate, and meprobamate. With the exception of ramelteon and meprobamate, the pharmacological actions of these drugs generally resemble those of the barbiturates: they all are general CNS depressants that can produce profound hypnosis with little or no analgesia; their effects on the stages of sleep are similar to those of the barbiturates; their therapeutic index is limited, and acute intoxication, which produces respiratory depression and hypotension, is managed similarly to barbiturate poisoning; their chronic use can result in tolerance and physical dependence; and the syndrome after chronic use can be severe and life-threatening. The properties of meprobamate bear some resemblance to those of the benzodiazepines, but the drug has a distinctly higher potential for abuse and has less selective anti-anxiety effects.

The clinical use of these agents has decreased markedly, and deservedly so. Some of them may be useful in certain settings, particularly in hospitalized patients. The chemical structures and major pharmacological properties of paraldehyde, ethchlorvynol (PLACIDYL, others), chloral hydrate (NOCTEC, others), meprobamate, glutethimide, methyprylon, and ethinamate can be found in previous editions of this book.

Paraldehyde. Paraldehyde is a polymer of acetaldehyde, basically a cyclic polyether. It has a strong odor and a disagreeable taste. Orally, it is irritating to the throat and stomach, and it is not administered parenterally because of its injurious effects on tissues. Use of paraldehyde has been discontinued in the U.S.

Chloral Hydrate. Chloral hydrate is formed by adding one molecule of water to the carbonyl group of chloral (2,2,2-trichloroacetaldehyde). Chloral hydrate may be used to treat patients with paradoxical reactions to benzodiazepines. Chloral hydrate is reduced rapidly to the active compound, trichloroethanol ($\text{CCl}_3\text{CH}_2\text{OH}$), largely by hepatic alcohol dehydrogenase; significant amounts of chloral hydrate are not found in the blood after its oral administration. Therefore, its pharmacological effects probably are caused by trichloroethanol. Indeed, the latter compound can exert barbiturate-like effects on GABA_A receptor channels *in vitro* (Lovinger et al., 1993).

Chloral hydrate is best known in the U.S. as a literary poison, the “knock-out drops” added to a strong alcoholic beverage to produce a “Mickey Finn” or “Mickey,” a cocktail given to an unwitting imbiber to render him malleable or unconscious, most famously Sam Spade in Dashiell Hammett’s 1930 novel, *The Maltese Falcon*. Now that detectives drink wine rather than whiskey, this off-label use of chloral hydrate has waned.

Meprobamate. Meprobamate a *bis*-carbamate ester, was introduced as an anti-anxiety agent and this remains its only approved use in the U.S. However, it also became popular as a sedative-hypnotic drug and is discussed here mainly because of its continued use for such purposes. The question of whether the sedative and anti-anxiety actions of meprobamate differ is unanswered, and clinical proof for the efficacy of meprobamate as a selective anti-anxiety agent in humans is lacking.

The pharmacological properties of meprobamate resemble those of the benzodiazepines in a number of ways. Meprobamate can release suppressed behaviors in experimental animals at doses that cause little impairment of locomotor activity, and although it can cause widespread depression of the CNS, it cannot produce anesthesia. However, ingestion of large doses of meprobamate alone can cause severe or even fatal respiratory depression, hypotension, shock, and heart failure. Meprobamate appears to have a mild analgesic effect in patients with musculoskeletal pain, and it enhances the analgesic effects of other drugs.

Meprobamate is well absorbed when administered orally. Nevertheless, an important aspect of intoxication with meprobamate is the formation of gastric bezoars consisting of undissolved meprobamate tablets; hence treatment may require endoscopy, with mechanical removal of the bezoar. Most of the drug is metabolized in the liver, mainly to a side-chain hydroxy derivative and a glucuronide; the kinetics of elimination may depend on the dose. The $t_{1/2}$ of meprobamate may be prolonged during its chronic administration, even though the drug can induce some hepatic CYPs.

The major unwanted effects of the usual sedative doses of meprobamate are drowsiness and ataxia; larger doses produce considerable impairment of learning and motor coordination and prolongation of reaction time. Like the benzodiazepines, meprobamate enhances the CNS depression produced by other drugs.

The abuse of meprobamate has continued despite a substantial decrease in the clinical use of the drug. Carisoprodol (SOMA), a skeletal muscle relaxant whose active metabolite is meprobamate, also has abuse potential and has become a popular “street drug” (Reeves et al., 1999). Meprobamate is preferred to the benzodiazepines by subjects with a history of drug abuse. After long-term medication, abrupt discontinuation evokes a withdrawal syndrome usually characterized by anxiety, insomnia, tremors, and, frequently, hallucinations; generalized seizures occur in ~10% of cases. The intensity of symptoms depends on the dosage ingested.

Other Agents. Etomidate (AMIDATE, generic) is used in the U.S. and other countries as an intravenous anesthetic, often in combination with fentanyl. It is advantageous because it lacks pulmonary and vascular depressant activity, although it has a negative inotropic effect on the heart. Its pharmacology and anesthetic uses are described in Chapter 13. It also is used in some countries as a sedative-hypnotic drug in intensive care units, during intermittent positive-pressure breathing, in epidural anesthesia, and in other situations. Because it is administered only intravenously, its use is limited to hospital settings. The myoclonus commonly seen after anesthetic doses is not seen after sedative-hypnotic doses.

Clomethiazole has sedative, muscle relaxant, and anticonvulsant properties. It is used outside the U.S. for hypnosis in elderly

and institutionalized patients, for preanesthetic sedation, and especially in the management of withdrawal from ethanol (Symposium, 1986b). Given alone, its effects on respiration are slight, and the therapeutic index is high. However, deaths from adverse interactions with ethanol are relatively frequent.

Propofol (DIPRIVAN) is a rapidly acting and highly lipophilic diisopropylphenol used in the induction and maintenance of general anesthesia (Chapter 19), as well as in the maintenance of long-term sedation. Propofol sedation is of a similar quality to that produced by midazolam. Emergence from sedation occurs quickly owing to its rapid clearance (McKeage and Perry, 2003). Propofol has found use in intensive care sedation in adults (McKeage and Perry, 2003), as well as for sedation during gastrointestinal endoscopy procedures (Heuss and Inauen, 2004) and transvaginal oocyte retrieval (Dell and Cloote, 1998). Although its mechanism of action is not understood completely, propofol is believed to act primarily through enhancement of GABA_A receptor function. Effects on other ligand-gated channels and GPCRs also have been reported (Trapani et al., 2000).

Nonprescription Hypnotic Drugs. As part of the ongoing systematic review of over-the-counter (OTC) drug products, the FDA has ruled that diphenhydramine is the only antihistamine that is recognized as generally safe and effective for use in nonprescription sleep aids. Despite the prominent sedative side effects encountered during the use of doxylamine and pyrilamine, these agents subsequently were eliminated as ingredients in the OTC nighttime sleep aids marketed in the U.S.. In 2004, doxylamine regained FDA approval as an OTC sleep aid and re-entered the market as Unisom Nighttime Sleep Aid (doxylamine 25-mg tablets). With elimination $t_{1/2}$ of ~9 hours (diphenhydramine) and 10 hours (doxylamine), these antihistamines can be associated with prominent residual daytime sleepiness when taken the prior evening as a sleep aid.

MANAGEMENT OF INSOMNIA

Insomnia is one of the most common complaints in general medical practice, and its treatment is predicated on proper diagnosis. Although the precise function of sleep is not known, adequate sleep improves the quality of daytime wakefulness, and hypnotics should be used judiciously to avoid its impairment.

A number of pharmacological agents are available for the treatment of insomnia. The “perfect” hypnotic would allow sleep to occur with normal sleep architecture rather than produce a pharmacologically altered sleep pattern. It would not cause next-day effects, either of rebound anxiety or of continued sedation. It would not interact with other medications. It could be used chronically without causing dependence or rebound insomnia on discontinuation. Regular moderate exercise meets these criteria but often is not effective by itself, and many patients may not be able to exercise. However, even small amounts of exercise often are effective in promoting sleep.

Controversy in the management of insomnia revolves around two issues:

- Pharmacological versus nonpharmacological treatment
- Use of short-acting versus long-acting hypnotics

The side effects of hypnotic medications must be weighed against the sequelae of chronic insomnia, which include a 4-fold increase in serious accidents (Balter and Uhlenhuth, 1992). In addition to appropriate pharmacological treatment, the management of insomnia should correct identifiable causes, address inadequate sleep hygiene, eliminate performance anxiety related to falling asleep, provide entrainment of the biological clock so that maximum sleepiness occurs at the hour of attempted sleep, and suppress the use of alcohol and OTC sleep medications (Nino-Murcia, 1992).

Categories of Insomnia. The National Institute of Mental Health Consensus Development Conference (1984) divided insomnia into three categories:

- *Transient insomnia* lasts <3 days and usually is caused by a brief environmental or situational stressor. It may respond to attention to sleep hygiene rules. If hypnotics are prescribed, they should be used at the lowest dose and for only 2-3 nights. However, benzodiazepines given acutely before important life events, such as examinations, may result in impaired performance (James and Savage, 1984).
- *Short-term insomnia* lasts from 3 days to 3 weeks and usually is caused by a personal stressor such as illness, grief, or job problems. Again, sleep hygiene education is the first step. Hypnotics may be used adjunctively for 7-10 nights. Hypnotics are best used intermittently during this time, with the patient skipping a dose after 1-2 nights of good sleep.
- *Long-term insomnia* is insomnia that has lasted for >3 weeks; no specific stressor may be identifiable. A more complete medical evaluation is necessary in these patients, but most do not need an all-night sleep study.

Insomnia Accompanying Major Psychiatric Illnesses. The insomnia caused by major psychiatric illnesses often responds to specific pharmacological treatment for that illness. In major depressive episodes with insomnia, e.g., the selective serotonin reuptake inhibitors, which may cause insomnia as a side effect, usually will result in improved sleep because they treat the depressive syndrome. In patients whose depression is responding to the serotonin reuptake

inhibitor but who have persistent insomnia as a side effect of the medication, judicious use of evening trazodone may improve sleep (Nierenberg et al., 1994), as well as augment the antidepressant effect of the reuptake inhibitor. However, the patient should be monitored for priapism, orthostatic hypotension, and arrhythmias.

Adequate control of anxiety in patients with anxiety disorders often produces adequate resolution of the accompanying insomnia. Sedative use in the anxiety disorders is decreasing because of a growing appreciation of the effectiveness of other agents, such as β adrenergic receptor antagonists (Chapter 12) for performance anxiety and serotonin reuptake inhibitors for obsessive-compulsive disorder and perhaps generalized anxiety disorder. The profound insomnia of patients with acute psychosis owing to schizophrenia or mania usually responds to dopamine-receptor antagonists (Chapters 13 and 16). Benzodiazepines often are used adjunctively in this situation to reduce agitation; their use also will result in improved sleep.

Insomnia Accompanying Other Medical Illnesses. For long-term insomnia owing to other medical illnesses, adequate treatment of the underlying disorder, such as congestive heart failure, asthma, or COPD, may resolve the insomnia.

Adequate pain management in conditions of chronic pain, including terminal cancer pain, will treat both the pain and the insomnia and may make hypnotics unnecessary.

Many patients simply manage their sleep poorly. *Adequate attention to sleep hygiene, including reduced caffeine intake, avoidance of alcohol, adequate exercise, and regular sleep and wake times, often will reduce the insomnia.*

Conditioned (Learned) Insomnia. In those who have no major psychiatric or other medical illness and in whom attention to sleep hygiene is ineffective, attention should be directed to conditioned (learned) insomnia. These patients have associated the bedroom with activities consistent with wakefulness rather than sleep. In such patients, the bed should be used only for sex and sleep. All other activities associated with waking, even such quiescent activities as reading and watching television, should be done outside the bedroom.

Sleep-State Misperception. Some patients complain of poor sleep but have been shown to have no objective polysomnographic evidence of insomnia. They are difficult to treat.

Long-Term Insomnia. Nonpharmacological treatments are important for all patients with long-term insomnia. These include education about sleep hygiene, adequate exercise (where possible), relaxation training, and behavioral-modification approaches, such as sleep-restriction and stimulus-control therapies. In sleep-restriction therapy, the patient keeps a diary of the amount of time spent in bed and then chooses a time in bed of 30-60 minutes less than this time. This induces a mild sleep debt, which aids sleep onset. In stimulus-control therapy, the patient is instructed to go to bed only when sleepy, to use the bedroom only for sleep and sex, to get up and leave the bedroom if sleep does not occur within 15-20 minutes, to return to bed again only when sleepy, to arise at the same time each morning regardless of sleep quality the preceding night, and to avoid daytime naps. Nonpharmacological treatments for insomnia have been found to be particularly effective in reducing sleep-onset latency and time awake after sleep onset (Morin et al., 1994).

Side effects of hypnotic agents may limit their usefulness for insomnia management. The use of hypnotics for long-term insomnia is problematic for many reasons. Long-term hypnotic use leads to a decrease in effectiveness and may produce rebound insomnia on discontinuance. Almost all hypnotics change sleep architecture. The barbiturates reduce REM sleep; the benzodiazepines reduce slow-wave non-REM sleep and, to a lesser extent, REM sleep. While the significance of these findings is not clear, there is an emerging consensus that slow-wave sleep is particularly important for physical restorative processes. REM sleep may aid in the consolidation of learning. The blockade of slow-wave sleep by benzodiazepines may partly account for their diminishing effectiveness over the long term, and it also may explain their effectiveness in blocking sleep terrors, a disorder of arousal from slow-wave sleep.

Long-acting benzodiazepines can cause next-day confusion, with a concomitant increase in falls, whereas shorter-acting agents can produce rebound next-day anxiety. Paradoxically, the acute amnesic effects of benzodiazepines may be responsible for the patient's subsequent report of restful sleep. Triazolam has been postulated to induce cognitive changes that blur the subjective distinction between waking and sleeping (Mendelson, 1993). Anterograde amnesia may be more common with triazolam. While the performance-disruptive effects of alcohol and diphenhydramine are reduced after napping, those of triazolam are not (Roehrs et al., 1993).

Benzodiazepines may worsen sleep apnea. Some hypersomnia patients do not feel refreshed after a night's sleep and so may ask for sleeping pills to improve the quality of their sleep. The consensus is that hypnotics should not be given to patients with sleep apnea, especially of the obstructive type, because these agents decrease upper airway muscle tone while also decreasing the arousal response to hypoxia (Robinson and Zwillich, 1989). These individuals benefit from all-night sleep studies to guide treatment.

Insomnia in Older Patients. The elderly, like the very young, tend to sleep in a *polyphasic* (multiple sleep episodes per day) pattern rather than the *monophasic* pattern characteristic of younger adults. They may have single or multiple daytime naps in addition to nighttime sleep. This pattern makes assessment of adequate sleep time difficult. Anyone who naps regularly will have shortened nighttime sleep without evidence of impaired daytime wakefulness, regardless of age. This pattern is exemplified in "siesta" cultures and probably is adaptive.

Changes in the pharmacokinetic profiles of hypnotic agents occur in the elderly because of reduced body water, reduced renal function, and increased body fat, leading to a longer $t_{1/2}$ for benzodiazepines. A dose that produces pleasant sleep and adequate daytime wakefulness during week 1 of administration may produce daytime confusion and amnesia by week 3 as the level continues to rise, particularly with long-acting hypnotics. For example, the benzodiazepine diazepam is highly lipid soluble and is excreted by the kidney. Because of the increase in body fat and the decrease in renal excretion that typically occur from age 20-80, the $t_{1/2}$ of the drug may increase 4-fold over this span.

Elderly people who are living full lives with relatively unimpaired daytime wakefulness may complain of insomnia because they are not sleeping as long as they did when they were younger.

Injudicious use of hypnotics in these individuals can produce daytime cognitive impairment and so impair overall quality of life.

Once an older patient has been taking benzodiazepines for an extended period, whether for daytime anxiety or for nighttime sedation, terminating the drug can be a long, involved process. Since attempts at drug withdrawal may not be successful, it may be necessary to leave the patient on the medication, with adequate attention to daytime side effects.

Management of Patients After Long-Term Treatment with Hypnotic Agents. Patients who have been taking hypnotics for many months or even years pose a special problem (Fleming, 1993). If a benzodiazepine has been used regularly for >2 weeks, it should be tapered rather than discontinued abruptly. In some patients on hypnotics with a short $t_{1/2}$, it is easier to switch first to a hypnotic with a long $t_{1/2}$ and then to taper. The onset of withdrawal symptoms from medications with a long $t_{1/2}$ may be delayed. Consequently, the patient should be warned about the symptoms associated with withdrawal effects.

Prescribing Guidelines for the Management of Insomnia. Hypnotics that act at GABA_A receptors, including the benzodiazepine hypnotics and the newer agents zolpidem, zopiclone, and zaleplon, are preferred to barbiturates because they have a greater therapeutic index, are less toxic in overdose, have smaller effects on sleep architecture, and have less abuse potential. Compounds with a shorter $t_{1/2}$ are favored in patients with sleep-onset insomnia but without significant daytime anxiety who need to function at full effectiveness during the day. These compounds also are appropriate for the elderly because of a decreased risk of falls and respiratory depression. However, the patient and physician should be aware that early-morning awakening, rebound daytime anxiety, and amnesic episodes also may occur. These undesirable side effects are more common at higher doses of the benzodiazepines.

Benzodiazepines with longer $t_{1/2}$ are favored for patients who have significant daytime anxiety and who may be able to tolerate next-day sedation but would be impaired further by rebound daytime anxiety. These benzodiazepines also are appropriate for patients receiving treatment for major depressive episodes because the short-acting agents can worsen early-morning awakening. However, longer-acting benzodiazepines can be associated with next-day cognitive impairment or delayed daytime cognitive impairment (after 2-4 weeks of treatment) as a result of drug accumulation with repeated administration.

Older agents such as barbiturates, chloral hydrate, and meprobamate should be avoided for the management of insomnia. They have high abuse potential and are dangerous in overdose.

chapter

Opioids, Analgesia, and Pain Management

Tony L. Yaksh
and Mark S. Wallace

Pain is a component of virtually all clinical pathologies, and management of pain is a primary clinical imperative. Opioids are a mainstay of pain treatment, but rational therapy may involve, depending upon the pain state, one or more drug classes, such as NSAIDs, anticonvulsants, and antidepressants. The properties of these non-opioid agents are presented in Chapters 34, 21, and 15. This chapter focuses first on the biochemical, pharmacological, and functional nature of the opioid system that defines the effects of opioids on pain processing, gastrointestinal-endocrine-autonomic functions, and reward-addiction circuits. Subsequently, the chapter presents principles that guide the use of opioid and non-opioid agents in the management of clinical pain states.

The term *opiate* refers to compounds structurally related to products found in opium, a word derived from *opos*, the Greek word for “juice,” natural opiates being derived from the resin of the opium poppy, *Papaver somniferum*. Opiates include the natural plant alkaloids, such as morphine, codeine, thebaine, and many semi-synthetic derivatives. An opioid is any agent, regardless of structure, that has the functional and pharmacological properties of an opiate. Endogenous opioids, many of which are peptides, are naturally occurring ligands for opioid receptors found in animals. The term *endorphin* is used synonymously with *endogenous opioid peptides* but also refers to a specific endogenous opioid, β -endorphin. The term *narcotic* was derived from the Greek word *narkotikos*, for “benumbing” or “stupor.” Although narcotic originally referred to any drug that induced narcosis or sleep, the word has become associated with opioids and is often used in a legal context to refer to a variety of substances with abuse or addictive potential.

History. The first undisputed reference to opium is found in the writings of Theophrastus in the third century B.C. Arab physicians were

well-versed in the uses of opium; Arab traders introduced the drug to the Orient, where it was employed mainly for the control of dysentery. By 1680, Sydenham was lauding opium: “Among the remedies which it has pleased Almighty God to give to man to relieve his sufferings, none is so universal and so efficacious as opium.”

Opium contains >20 distinct alkaloids. In 1806, Frederick Sertürner, a pharmacist’s assistant, reported the isolation by crystallization of a pure substance in opium that he named morphine, after Morpheus, the Greek god of dreams. By the middle of the 19th century, the use of pure alkaloids in place of crude opium preparations began to spread throughout the medical world, an event that coincided with the development of the hypodermic syringe and hollow needle, permitting direct delivery of such water-soluble formulations “under the skin” into the body.

In addition to the remarkable beneficial effects of opioids, the side effects and addictive potential of these drugs also have been known for centuries. In the civil war in the U.S., the administration of “soldier’s joy” often led to “soldier’s disease,” the opiate addiction brought about by medication of chronic pain states arising from war wounds. These problems stimulated a search for potent synthetic opioid analgesics free of addictive potential and other side effects. The early discovery of the synthetic product heroin by C.R. Alder Wright in 1874 was followed by its widespread utilization as a purportedly non-addictive cough suppressant and sedative. Unfortunately, heroin and all subsequent synthetic compounds that have been introduced into clinical use share the liabilities of classical opioids, including their addictive properties. However, the search for new opioid agonists led to the synthesis of opioid antagonists and compounds with mixed agonist–antagonist properties, which expanded therapeutic options and provided important tools for exploring mechanisms of opioid actions.

Until the early 1970s, the effects of morphine, heroin, and other opioids as anti-nociceptive and addictive agents, were well described, but mechanisms mediating the interaction of the opioid alkaloids with biological systems were unknown. *In vivo* and *in vitro* physiological studies investigating the pharmacology of opiate agonists, their antagonists, and cross-tolerance led to the hypothesis of three separate opioid receptors: mu (μ), kappa (κ), and delta (δ) (Martin et al., 1976). These results were paralleled by work showing multiple radioligand binding sites for opiates on brain cell membranes (Goldstein et al., 1971; Pert et al., 1973). The three-receptor hypothesis was confirmed by subsequent cloning, which indicated

the existence of three main receptor types with an opioid pharmacology (Waldhoer et al., 2004). In 2000, the Committee on Receptor Nomenclature and Drug Classification of the International Union of Pharmacology adopted the terms MOP, DOP, and KOP receptors (**mu** **opi** **oid** **pe**ptide receptor, etc). In concert with identification of these opioid receptors, Kostelitz and associates (Hughes et al., 1975) identified an endogenous opiate-like factor that they called *enkephalin* (“from the head”). Soon afterward, two more classes of endogenous opioid peptides were isolated, the endorphins and dynorphins (Akil et al., 1984).

In the early work by Martin, a sigma (σ) receptor was identified and was thought to represent a site that accounted for the paradoxical excitatory effects of opiates; this site is now thought to be the phencyclidine binding site and is not strictly speaking an opiate receptor or an opiate site.

ENDOGENOUS OPIOID SYSTEMS: AGONISTS AND RECEPTORS

An agent found within the brain that acts through an opioid receptor is an endogenous opioid. Several distinct families of endogenous opioid peptides have been identified: principally the enkephalins, endorphins, and dynorphins. These families have several common properties:

- Each derives from a distinct large precursor protein, prepro-opiomelanocortin (POMC), preproenkephalin, and prodynorphin, respectively, encoded by a corresponding gene.
- Each precursor is subject to complex cleavages by distinct trypsin-like enzymes, typically at sites designated by pairs of dibasic amino acids, and to a variety of post-translational modifications resulting in the synthesis of multiple peptides, some of which are active.
- Most opioid peptides with activity at a receptor share the common amino-terminal sequence of Tyr-Gly-Gly-Phe-(Met or Leu) followed by various C-terminal extensions yielding peptides ranging from a few (5) to many residues (Table 18–1; the endomorphins, with different terminal sequences, are exceptions).

The POMC sequence contains a variety of non-opioid peptides including adrenocorticotrophic hormone (ACTH), melanocyte-stimulating hormone (α MSH), and β -lipotropin (β -LPH), all of which are generated by proteolytic cleavage of POMC. The major opioid peptide derived from further cleavage of β -lipotropin is the potent opioid agonist, β -endorphin. Although β -endorphin contains the sequence for met-enkephalin at its amino terminus, it is not converted to this peptide. The anatomical distribution of POMC-producing cells is relatively limited within the CNS, occurring mainly in the arcuate nucleus of the hypothalamus and the nucleus tractus solitarius. These neurons project widely to limbic and brainstem areas and to the spinal cord. POMC expression also occurs in the anterior and intermediate lobes of the pituitary and also are contained

in pancreatic islet cells. Circulating β -endorphin derives primarily from the pituitary, from which it and other pituitary hormones are released (Chapter 38).

Proenkephalin contains multiple copies of met-enkephalin, as well as a single copy of leu-enkephalin. Proenkephalin peptides are present in areas of the CNS believed to be related to the processing of pain information (e.g., laminae I and II of the spinal cord, the spinal trigeminal nucleus, and the periaqueductal gray), to the modulation of affective behavior (e.g., amygdala, hippocampus, locus ceruleus, and the frontal cerebral cortex), to the modulation of motor control (e.g., caudate nucleus and globus pallidus), to the regulation of the autonomic nervous system (e.g., medulla oblongata), and to neuroendocrinological functions (e.g., median eminence). Although there are a few long enkephalinergic fiber tracts, these peptides are contained primarily in interneurons with short axons. The peptides from proenkephalin also are found in chromaffin cells of the adrenal medulla and in nerve plexuses and exocrine glands of the stomach and intestine. Circulating proenkephalin products are considered to be largely derived from these sites.

Prodynorphin contains three peptides of differing lengths that all begin with the leu-enkephalin sequence: dynorphin A, dynorphin B, and neoendorphin (Figure 18–1). The peptides derived from prodynorphin are distributed widely in neurons and to a lesser extent in astrocytes throughout the brain and spinal cord and are frequently found co-expressed with other opioid peptide precursors.

Nociceptin peptide is present in neurons widely distributed throughout brain (cortex, hippocampus, brainstem, and to a lesser degree, hypothalamus, thalamus, raphe nuclei, and periaqueductal gray matter) and spinal cord structures. It has been observed in neurons as well as astrocytes and neutrophils.

More recently, a family of peptides has been identified and named endomorphins, endomorphin-1 (Tyr-Pro-Trp-Phe-NH₂) and endomorphin-2 (Tyr-Pro-Phe-Phe-NH₂) (Zadina et al., 1997). By comparison with other opioid peptides, endomorphins have an atypical structure and display selectivity towards the μ opioid receptor (Fichna et al., 2007).

Several points should be stressed:

- Not all cells that make a given opioid pro-hormone precursor store and release the same mixture of opioid peptides; this results from differential processing secondary to variations in the cellular complement of peptidases that produce and degrade the active opioid fragments (Hook et al., 2008).
- Processing of these peptides is altered by physiological demands, leading to the release of a different mix of post-translationally derived peptides by a given cell under different conditions.
- Opioid peptides are found in plasma and reflect release from secretory systems such as the pituitary and the adrenals that do not reflect neuraxial release. Conversely, levels of these peptides in brain/spinal cord and in CSF arise from neuraxial systems and not from peripheral systems.

OPIOID RECEPTORS

Principal Receptor Classes; Distribution

The three opioid receptors— δ , μ , and κ —belong to the rhodopsin family of GPCRs (Chapter 3) and share

extensive sequence homologies (55–58%). The greatest diversity is found in their extracellular loops. In addition, all opioid receptors possess two conserved cysteine residues in the first and second extracellular loops forming a disulfide bridge.

μ , δ , and κ opioid receptors are widely distributed and this distribution has been examined in detail using immunohistochemistry, *in situ* hybridization, and more recently by noninvasive imaging techniques. The profound and diverse effects on CNS function are consistent with the density and diverse distribution of receptors in the brain and spinal cord (Henriksen et al., 2008). In addition, these receptors are expressed in a wide variety of peripheral tissues, including vascular, cardiac, airway/lung, gut, and many resident and circulating immune/inflammatory cells (discussed subsequently).

Following the cloning of the classical opioid receptors, the G-protein coupled opiate receptor-like protein (ORL1 or NOP) was cloned based on its structural homology (48–49% identity) to other members of the opioid receptor family; it has an endogenous ligand, nociceptin/orphanin (FQ: N/OFQ) (Stevens, 2009). See Figure 18–2. Since this system does not display an opioid pharmacology (Fioravanti et al., 2008), it will not be discussed in detail in this chapter.

N/OFQ binding sites have been found to be largely in the CNS and to be densely distributed in cortical regions, ventral fore-brain, hippocampus, brainstem, and spinal cord, as well as in a number of peripheral cells including basophils, endothelial cells, and macrophages.

Opiate Receptor Subtypes

The existence of three classes of opiate receptors (MOR, DOR, and KOR) is widely accepted. The opioid receptors appear early in vertebrate evolution, being already present with the appearance of jawed vertebrates. The human opiate receptors have been mapped to chromosome 1p355-33 (DOR), chromosome 8q11.23-21 (KOR), chromosome 6q25-26 (MOR), and chromosome 20q13.33 (NOR) (Dreborg et al., 2008). Low-stringency hybridization procedures have identified no opioid receptor types other than the cloned opioid receptors. Nevertheless, pharmacological studies have suggested the possible existence of at least two subtypes of each receptor. While cloning studies have not supported the existence of these subtypes as distinct classes, the modified specificity for opioid ligands may result from several underlying events.

Heterodimerization. In the membrane, opiate receptors can form both homo- and heterodimers. Dimerization can alter the pharmacological properties of the respective receptors. For example, DORs form heterodimers with both MORs and KORs. Thus, MOR-DOR and DOR-KOR heterodimers show less affinity for highly selective agonists, reduced agonist-induced receptor trafficking, and mutual synergy between receptor-selective agonists in binding to the

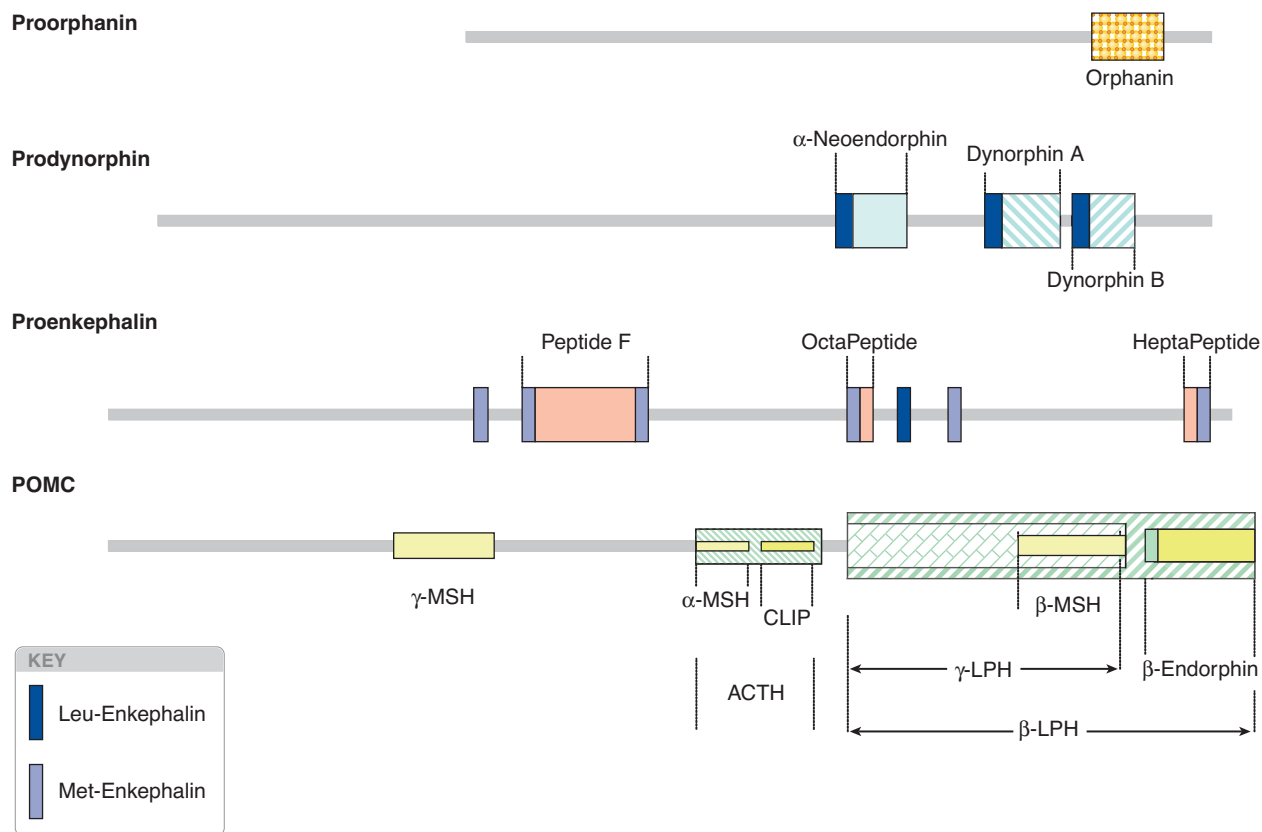

Figure 18–1. Peptide precursors. (Reproduced with permission from Akil et al, 1998. Copyright © Elsevier.)

respective agonists and also in the agonist-induced intracellular signaling (Gupta et al., 2006).

Alternative Splicing of Receptor RNA

Alternative splicing of receptor heteronuclear RNA (e.g., exon skipping and intron retention) is thought to play an important role in producing *in vivo* diversity within many members of the GPCR superfamily (Chapter 3). Splice variants exist within each of the three opioid receptor families, and this alternative splicing of receptor transcripts may be crucial for the diversity of opioid receptors. As an example, the human *Oprm* gene has at least two promoters, multiple exons, with many exons generating at least 11 splice variants that encode multiple morphine-binding isoforms, varying largely at their carboxy (intracellular) terminus. Given the functional importance of the intracellular components of the GPCRs, it is not surprising that significant differences exist for the receptor isoforms in terms of agonist-induced G protein activation and receptor internalization. Importantly, these splice variants have been found expressed *in vivo* (Pan, 2005).

Receptor Subtype Agonists/Antagonists

Studies on the presence and function of these receptors have depended upon the convergence between agonist/antagonist structure-activity studies and a variety of functional assays in biological and cloned receptor systems. Highly selective agonists have

been developed that show specific affinity for the respective binding site and G-protein coupled reporter activation in cloned expression systems (e.g., DAMGO for MOR, DPDPE for DOR, and U-50,488, and U-69,593 for KOR) (Table 18–1). The study of the biological functions of opioid receptors *in vivo* has been aided by synthesis of selective antagonists. Among the most commonly used antagonists are cyclic analogs of somatostatin such as CTOP as a MOR antagonist, a derivative of naloxone called naltrindole as a DOR-receptor antagonist, and a bivalent derivative of naltrexone called nor-binaltorphimine (nor-BNI) as a KOR antagonist. These tools have made possible the characterization of the distribution of binding which, in conjunction with immunohistochemistry using antibodies derived from cloned receptors, has served to define the anatomical distribution of the receptors and the roles of the respective receptors in biological functions. Positron emission tomography (PET) has been used to characterize *in vivo* binding in brain with selective isotopically labeled ligands (Henriksen and Willoch, 2008). *In vivo* delivery of selective antagonists and agonists into specific brain regions has established the receptor types and anatomical distribution involved in mediating various opioid effects (see below).

Receptor Structure

Each receptor consists of an extracellular N-terminus, seven transmembrane helices, three extra- and intracellular loops, and an intracellular C-terminus characteristic of the GPCRs. The opioid receptors

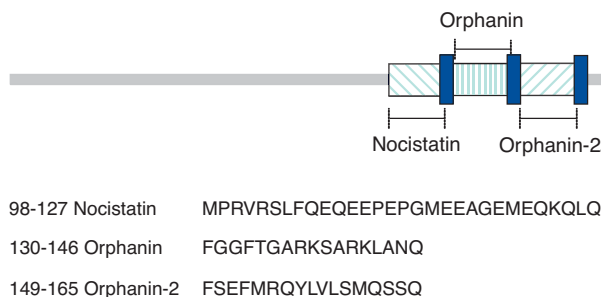

Figure 18–2. Human pro-orphanin-derived peptides.

also possess two conserved cysteine residues in the first and second extracellular loops, which form a disulfide bridge.

Structural Correlates of Binding/Coupling Requirements for Opiate Ligands

Opiate Receptor Structures. Studies of chimeric receptors and site-directed mutagenesis of cloned receptors have provided definitive insights into structural determinants of opioid ligand–receptor interaction. Though there is significant complexity (Kane et al., 2006), several general principles define binding and selectivity. First, all opioid receptors display a binding pocket formed by TM₃–TM₇. Second, the pocket in the respective receptor is partially covered by the extracellular loops, which together with the extracellular termini of the TM segments, provide a gate conferring selectivity, allowing ligands, particularly peptides, to be differentially accessible to the different receptor types. Thus, alkaloids (e.g., morphine) bind in the core of the transmembrane portion of the receptor, whereas large peptidyl ligands bind at the extracellular loops. As noted, it is the extracellular loops that show the greatest structural diversity across receptors. Third, selectivity has been attributed to extracellular loops: first and third for the MOR, second for the KOR, and third for the DOR (Waldhoer et al., 2004). Alkaloid antagonists are thought to bind deeper into the pocket sterically hindering conformational changes leading to a functional antagonism.

Structure-Activity Relationships. Receptor selectivity by the various opiate agonists is commonly explained in terms of the “message-address” concept (Takemori and Portoghese, 1992). Thus, elements shared by all structures (reflecting agents that bind at all sites, such as naltrexone) represent the “message,” while elements associated with a ligand binding at a specific receptor represent the structural “address.” The common structural features constituting the message are:

- a protonated nitrogen
- a phenolic ring (that, with the protonated nitrogen, forms tyramine)
- a hydrophobic domain

To this “message” are added a variable “linker” region and the “address” that specifies opiate receptor selectivity (Figure 18–3). Refinements of this message-linker-address model have led to the synthesis of new compounds with the predicted specificity. For the KOR and DOR, elements constituting the address have been defined. Thus, for the KOR, a second basic hydrophobic group is implicated

in forming a specific salt bridge; for the DOR, a hydrophobic group such as an indole forms the address. MOR ligands such as morphine lack a common chemical moiety and thus other elements are thought to contribute to ligand specificity at that receptor (Kane et al., 2006).

Opiate Receptor Coupling to Membrane Function

Agonist binding results in conformational changes in the GPCR, initiating the G protein activation/inactivation cycle (Chapter 3). The μ , δ , and κ receptors largely couple through pertussis toxin-sensitive, G_i/G_o proteins (but occasionally to G_s or G₁₂). Upon receptor activation, the G_i/G_o coupling results in a large number of intracellular events, including:

- Inhibition of adenylyl cyclase activity
- Reduced opening of voltage-gated Ca²⁺ channels
- Stimulation of K⁺ current through several channels including G protein-activated inwardly rectifying K⁺ channels (GIRKs)
- Activation of PKC and PLC β

As with other GPCRs, the second intracellular loop is involved in the efficacy of G-protein activation while the third loop defines the α subunit that is activated (Gether, 2000).

Regulation of Opiate Receptor Disposition

Like other GPCRs, MOR and DORs can undergo rapid agonist-mediated internalization via a classic endocytic, β -arrestin-mediated pathway, whereas KORs do not internalize after prolonged agonist exposure (Chu et al., 1997). Internalization of the MOR and DORs apparently occurs via partially distinct endocytic pathways, suggesting receptor-specific interactions with different mediators of intracellular trafficking. These processes may be induced differentially as a function of the structure of the ligand. For example, certain agonists, such as etorphine and enkephalins, cause rapid internalization of the receptor, whereas morphine does not cause MOR internalization, even though it decreases adenylyl cyclase activity equally well. In addition, a truncated receptor with normal G-protein coupling recycles constitutively from the membrane to the cytosol (Segredo et al., 1997), suggesting that activation of signal transduction and internalization are controlled by distinct molecular mechanisms. These studies also support the hypothesis that different ligands induce different conformational changes in the receptor that result in divergent intracellular events, and they may provide an explanation for differences in the spectrum of effects of various opioids.

Functional Consequences of Acute and Chronic Opiate Receptor Activation

The loss of effect with exposure to opiates occurs over short- and long-term intervals.

Desensitization. Acute agonist occupancy of the opiate receptors results in activation of the intracellular signaling outlined previously. In the face of a transient activation (minutes to hours), a phenomenon called acute tolerance or desensitization can be observed that is specific for that receptor and disappears with a time course parallel to the clearance of the agonist. Short-term desensitization probably involves phosphorylation of the receptors resulting in an uncoupling of the receptor from its G-protein and/or internalization of the receptor.

Tolerance. Sustained administration of an opiate agonist (days to weeks) leads to progressive loss of drug effect. Here tolerance refers to a decrease in the apparent effectiveness of a drug with continuous

Figure 18–3. Structural features of opioid ligands contribute to receptor selectivity. The “message-linker-address” formulation (Takemore and Portoghese, 1992) has been refined and used to synthesize non-peptide ligands that exhibit predicted opiate receptor specificity. The ligands pictured above demonstrate some of the common (message) and variable (linker and address) features thought to contribute to ligand-receptor interactions for both opiate receptor agonists and antagonists.

or repeated agonist administration, and with the removal of the agonist disappears over several weeks. This tolerance is reflected by a reduction in the maximum achievable effect or a right shift in the dose-effect curve. This phenomenon can be manifested at the level of the intracellular cascade (e.g., reduced inhibition of adenylyl cyclase) and at the organ system level (e.g., loss of sedative and analgesic effects).

This loss of effect with persistent exposure to an opiate agonist has several key properties:

- Changes in response are time-dependent, with changes occurring over short-term (minutes to hours, as with desensitization) and long-term intervals (weeks to months).
- Tolerance to drug effect is surmountable with higher doses of the opioid.
- Tolerance is reversible over time after termination of the drug.
- Different physiological responses develop tolerance at different rates. Thus, at the organ system level, some end points show little or no tolerance development (pupillary miosis), some show moderate tolerance (constipation, emesis, analgesia, sedation), and some show rapid tolerance (euphorogenic).
- In general, opiate agonists of a given class will typically show a reduced response in a system rendered tolerant to another agent of that class (e.g., cross-tolerance between the μ agonists, such as morphine and fentanyl).

The completeness of this cross-tolerance is not consistent and forms the basis for the switching between opioid drugs used in clinical therapy. This incomplete cross-tolerance has been hypothesized to reflect small but important differences in the receptors with which the different opiates of the same class bind (Pasternak, 2005).

Dependence. During the state of tolerance, the phenomenon of dependence is observed. Dependence represents a state of adaptation manifested by receptor/drug class-specific withdrawal syndrome produced by cessation of drug exposure (e.g., by drug abstinence) or administration of an antagonist (e.g., naloxone). The withdrawal is manifested by the exaggerated appearance of enhanced signs of cellular activation. In the CNS, increased adenylyl cyclase, release of excitatory amino acids and cytokines, activation of microglia and astrocytes, and the initiation of apoptotic processes have been reported. Such indices of hyperexcitability are also noted in peripheral plexi such as are present in the GI tract and in autonomic ganglia (discussed later). At the organ system level, withdrawal is manifested by significant somatomotor and autonomic outflow (reflected by agitation, hyperalgesia, hyperthermia, hypertension, diarrhea, pupillary dilation, and release of virtually all pituitary and adrenomedullary hormones) and by affective symptoms (dysphoria, anxiety, and depression) (Kreek et al., 1998). These phenomena are considered to be highly aversive and motivate the drug recipient to make robust efforts to avoid the withdrawal state. Consistent with

the receptor selectivity of the effects, the withdrawal signs observed in an animal tolerant to a given opiate can be suppressed by application of another drug from the same class.

Addiction. Addiction is a behavioral pattern characterized by compulsive use of a drug and overwhelming involvement with its procurement and use. The positive, rewarding effects of opiates are considered to be the driving component for initiating the recreational use of opiates. This positive reward property in humans and animals is subject to the development of tolerance. Given the aversive nature of withdrawal symptoms, in the dependent organism, it is not surprising that avoidance and alleviation of withdrawal symptoms may become a primary motivation for compulsive drug taking (Kreek and Koob, 1998). When the drive to acquire the drug leads to drug-seeking behaviors that occur in spite of the physical, emotional, or societal damage suffered by the drug seeker, then the obsession or compulsion to acquire and use the drug is considered to reflect an addicted state. In animals, this may be manifest by willingness to tolerate very stressful conditions to acquire drug delivery. In humans, aberrant behaviors considered to be signs of addiction include prescription forgery, stealing drugs from others, and obtaining prescription drugs from nonmedical sources; these behaviors are considered indicators of an addiction disorder. Note that drug dependence is *not* synonymous with drug addiction. Any individual who is exposed for some period to opiates will display some degree of tolerance and should the drug be removed abruptly, there will be an expression of withdrawal signs, the severity of which will depend upon the dose and duration of drug exposure. Such a condition does not itself indicate an addicted state. Thus, tolerance and dependence are physiological responses seen in all patients but are not predictors of addiction (Chapter 24). For example, cancer pain often requires prolonged treatment with high doses of opioids, leading to tolerance and dependence. Yet abuse in this setting is considered to be unusual (Foley, 1993).

Mechanisms of Tolerance/Dependence-Withdrawal

The mechanisms underlying chronic tolerance and dependence/withdrawal are controversial. Several types of events are considered to contribute.

Receptor Disposition. With chronic opiate exposure, the general consensus is that the loss of effect is not related to the density of membrane receptors. As noted, acute desensitization or receptor internalization may play a role in the initiation of chronic tolerance but is not sufficient to explain persistent changes observed with chronic exposure. Thus, morphine, unlike other μ agonists, does not promote μ receptor internalization or receptor phosphorylation and desensitization (Koch et al., 2005; von Zastrow et al., 2003). These studies suggest that receptor desensitization and down-regulation are agonist specific. Other studies of GPCRs indicate that endocytosis and sequestration of receptors do not invariably lead to receptor degradation but can also result in receptor dephosphorylation and recycling to the surface of the cell (Krupnick and Benovic, 1998). Accordingly, opioid tolerance may not be related to receptor desensitization but rather to a lack of desensitization. Agonists that rapidly internalize opioid receptors also would rapidly desensitize signaling, but this desensitization would be at least partially reset by recycling of “reactivated” opioid receptors. The lack of desensitization caused by morphine may result in prolonged receptor signaling, which even though less efficient than that observed with other agonists, would lead to

further downstream cellular adaptations that increase tolerance development. The measurement of relative agonist signaling versus endocytosis (RAVE) for opioid agonists could be predictive of the potential for tolerance development (Waldhoer et al., 2004).

Adaptation of Intracellular Signaling Mechanisms in the Opioid Receptor-Bearing Neurons. Coupling of MOR to cellular effectors, such as inhibition of adenylyl cyclase, activation of inwardly rectifying K^+ channels, inhibition of Ca^{2+} currents, and inhibition of terminal release of transmitters demonstrates functional uncoupling of receptor occupancy from effector function (Williams et al., 2001). Importantly, the chronic opioid effect initiates adaptive counterregulatory change. The best example of such cellular counterregulatory processes is the rebound increase in cellular cyclic AMP levels produced by “superactivation” of adenylyl cyclase and up-regulation of the amount of enzyme. Such superactivation leads to an induction of an excitatory state mediated by an increased cation current through activation of PKA. Terminal transmitter release is thus commonly enhanced during opioid withdrawal (Bailey and Connor, 2005).

System Level Counteradaptation. In the face of chronic opiate exposure, an evident loss of drug effect is noted. An important line of speculation is that the apparent loss of inhibitory effect may reflect an enhanced excitability of the regulated link. Thus, tolerance to the analgesic action of chronically administered μ opiates may result in an activation of bulbospinal pathways that increases the excitability of spinal dorsal horn pain transmission linkages. Similarly, in the face of chronic opiate exposure, opiate receptor occupancy will lead to the activation of PKC, which can phosphorylate and, accordingly, enhance the activation of local glutamate receptors of the N-methyl-D-aspartate (NMDA) type (Chapter 14). These receptors are known to mediate a facilitated state leading to enhanced spinal pain processing. Blocking of these receptors can at least partially attenuate the loss of analgesic efficacy with continued opiate exposure (Trujillo and Akil, 1991). These system level counteradaptation hypotheses may represent mechanisms that apply to specific systems (e.g., pain modulation) but not necessarily to others (e.g., sedation or miosis) (Christie, 2008).

Differential Tolerance Development and Fractional Occupancy Requirements. An interesting problem posed in explaining tolerance relates to the differential rates of tolerance development noted earlier. Why responses such as miosis show no tolerance over extended exposure (indeed, it is considered symptomatic in drug overdose of highly tolerant patients) while analgesia and sedation are more likely to show a reduction is not clear. One possibility is that tolerance represents a functional uncoupling of some fraction of the receptor population and that different physiological end points may require activation of different fractions of their coupled receptors to produce a given physiological effect. Accordingly, it would be consistent that receptors in the miosis pathways need to activate a small fraction of their receptors, relative to those systems mediating pain control to produce a significant physiological action (e.g., the systems mediating miosis have a greater functional receptor reserve).

Effect Profile of Clinically Used Opioids

Opiates, depending upon their receptor preferences, produce a variety of effects consistent with the role

played by the organ systems with which the receptors are associated. Whereas the primary clinical use of opioids is for their pain-relieving properties, opioids produce a host of other effects. This is not surprising in view of the wide distribution of opioid receptors in the brain and the periphery. Within the nervous systems, these effects range from analgesia to effects upon motivation and higher-order affect (euphoria), arousal, and a number of autonomic, hormonal, and motor processes. In the periphery, opiates can influence a variety of visceromotor systems, including those related to GI motility and smooth muscle tone. The next sections consider these class actions and their mechanisms.

Analgesia. In humans, morphine-like drugs produce analgesia, drowsiness, changes in mood, and mental clouding. When therapeutic doses of morphine are given to patients with pain, they report the pain to be less intense or entirely gone. Patients frequently report that the pain, though still present, is tolerable and that they feel more comfortable. In addition to relief of distress, some patients may experience euphoria. A significant feature of the analgesia is that it often occurs without loss of consciousness, though drowsiness commonly occurs (see “Respiration” later in the chapter). Morphine at these doses does not have anticonvulsant activity and usually does not cause slurred speech, emotional lability, or significant motor uncoordination.

When morphine in an analgesic dose is given to normal, pain-free individuals, the patients may report the drug experience to be frankly unpleasant. There may be drowsiness, difficulty in mentation, apathy, and lessened physical activity. As the dose is increased, the subjective, analgesic, and toxic effects, including respiratory depression, become more pronounced.

Specificity of Analgesic Effects. The relief of pain by morphine-like opioids is selective in that other somatosensory modalities, such as light touch, proprioception, and the sense of moderate temperatures, are unaffected. Systematic psychophysical studies have shown that low doses of morphine produce reductions in the affective but not the perceived intensity of pain whereas higher (clinically effective) doses reduced both reported perceived intensity and the affective response otherwise evoked by acute experimental pain stimuli (Price et al., 1985). In general, continuous dull pain (as generated by tissue injury and inflammation) is relieved more effectively than sharp intermittent (incident) pain, such as that associated with the movement of an inflamed joint, but with sufficient amounts of opioid it is possible to relieve even the severe piercing pain associated with acute renal or biliary colic.

Pain States and Mechanisms Underlying Different Pain States. Any meaningful discussion of the action of analgesic agents must include the appreciation that all pain is not the same and that a number of variables contribute to the patient’s pain report and therefore to the effect

of the analgesic. Heuristically, one may think mechanistically of pain as several distinct sets of events, described in the next sections.

Acute Nociception. Acute activation of small high-threshold sensory afferents (A δ and C fibers) generates transient input into the spinal cord, which in turn leads to activation of neurons that project contralaterally to the thalamus and thence to the somatosensory cortex. A parallel spinofugal projection is to the medial thalamus and from there to the anterior cingulate cortex, part of the limbic system. The output produced by acutely activating this ascending system is sufficient to evoke pain reports. Examples of such stimuli include a hot coffee cup, a needle stick, or an incision.

Tissue Injury. Following tissue injury or local inflammation (e.g., local skin burn, toothache, rheumatoid joint), an ongoing pain state arises that is characterized by burning, throbbing, or aching and an abnormal pain response (hyperalgesia) and can be evoked by otherwise innocuous or mildly aversive stimuli (tepid bathwater on a sunburn; moderate extension of an injured joint). This pain typically reflects the effects of active factors (such as prostaglandins, bradykinin, cytokines, and H⁺ ions, among many mediators) released into the injury site, which have the ability to activate the terminal of small high-threshold afferents (A δ and C fibers) and to reduce the stimulus intensity required to activate these sensory afferents (peripheral sensitization). In addition, the ongoing afferent traffic initiated by the injury leads to the activation of spinal facilitatory cascades, yielding a greater output to the brain for any given input. This facilitation is thought to underlie the hyperalgesic states. Such tissue injury-evoked pain is often referred to as “nociceptive” pain (Figure 18–4)

Figure 18–4. Mechanistic flow diagram of tissue injury–evoked nociception.

Nerve Injury. Injury to the peripheral nerve yields complex anatomical and biochemical changes in the nerve and spinal cord that induce spontaneous dysesthesias (shooting, burning pain) and allodynia (light touch hurts). This nerve injury pain state may not depend upon the activation of small afferents, but may be initiated by low-threshold sensory afferents (e.g., A β fibers). Such nerve injuries result in the development of ectopic activity arising from neuromas formed by nerve injury and the dorsal root ganglia of the injured axons as well as a dorsoal horn reorganization, such that low-threshold afferent input carried by A β fibers evokes a pain state. This dorsal horn reorganization reflects changes in ongoing inhibition and in the excitability of dorsal horn projection neurons (Latremoliere and Woolf, 2009). Examples of such nerve injury-inducing events include nerve trauma or compression (carpal tunnel syndrome), chemotherapy (as for cancer), diabetes, and in the post-herpetic state (shingles). These pain states are said to be neuropathic (Figure 18–5). Many clinical pain syndromes, such as found in cancer, typically represent a combination of these inflammatory and neuropathic mechanisms. Although nociceptive pain usually is responsive to opioid analgesics, neuropathic pain is typically considered to respond less well to opioid analgesics (McQuay, 1988).

Sensory Versus Affective Dimensions. Information generated by a high intensity peripheral stimulus initiates activity in defined pathways that activate higher-order systems that reflect the aversive magnitude of the stimulus. This reflects the *sensory-discriminative* dimension of the pain experience (such as the ability to accurately estimate and characterize the pain state). Painful stimuli have the certain ability to generate strong emotional components that reflect a distinction between pain as a specific sensation subserved by distinct neurophysiological structures, and pain such as suffering (the original sensation plus the reactions evoked by the sensation; the *affective motivational* dimension) (Melzack and Casey, 1968). When pain does not evoke its usual responses (anxiety, fear, panic, and suffer-

ing), a patient’s ability to tolerate the pain may be markedly increased, even when the capacity to perceive the sensation is relatively unaltered. It is clear, however, that alteration of the emotional reaction to painful stimuli is not the sole mechanism of analgesia. Thus, intrathecal administration of opioids can produce profound segmental analgesia without causing significant alteration of motor or sensory function or subjective effects (Yaksh, 1988).

Mechanisms of Opioid-Induced Analgesia. The analgesic actions of opiates after systemic delivery are believed to represent actions in the brain, spinal cord, and in some instances in the periphery.

Supraspinal Actions. The microinjection of opiates through chronically placed microinjection cannulae targeted at specific brain sites has shown that opiate agonists will, in a manner consistent with their respective activity at a MOR, block pain behavior after delivery into a number of highly circumscribed brain regions and that these analgesic effects are naloxone reversible. The best characterized of these sites is the mesencephalic periaqueductal gray (PAG) matter. Microinjections of morphine into this region will block nociceptive responses in every species examined from rodents to primates; naloxone will reverse these effects.

Several mechanisms exist whereby opiates with an action limited to the PAG may act to alter nociceptive transmission. These are summarized in Figure 18–6. MOR agonists block release of the inhibitory transmitter GABA from tonically active PAG systems that regulate activity in projections to the medulla. PAG projections to the medulla activate medullospinal release of NE and 5-HT at the level of the spinal dorsal horn. This release can attenuate dorsal horn excitability (Yaksh, 1997). Interestingly, this PAG organization can also serve to increase excitability of dorsal raphe and locus coeruleus from which ascending serotonergic and noradrenergic projections to the limbic forebrain originate (the role of forebrain 5-HT and NE in mediating emotional tone is discussed in Chapter 15). In humans, it is not feasible to routinely access the site of action within the brain where opiates may act to alter nociceptive transmission as is done in preclinical models. However, intracerebroventricular opioids have been employed in humans for pain relief in cancer patients. Accordingly, it seems probable that the supraspinal site of opiate action in the human, as in other animal models, lies close to the ventricular lumen (Karavelis et al., 1996).

Spinal Opiate Action. A local action of opiates in the spinal cord will selectively depress the discharge of spinal dorsal horn neurons evoked by small (high-threshold) but not large (low-threshold) afferent nerve fibers. Intrathecal administration of opioids in animals ranging from mouse to human will reliably attenuate the response of the organism to a variety of somatic and visceral stimuli that otherwise evoke pain states. Specific opiate binding and receptor protein are limited for the most part to the substantia gelatinosa of the superficial dorsal horn, the region in which small, high-threshold sensory afferents show their principal termination. A significant proportion of these opiate receptors are associated with small peptidergic primary afferent C fibers and the remainder are on local dorsal horn neurons. This finding is consistent with the presence of opioid receptor protein being synthesized in and transported from small dorsal root ganglion cells.

Confirmation of the presynaptic action is provided by the observation that spinal opiates reduce the release of primary afferent

Figure 18–5. Mechanistic flow diagram of nerve injury–evoked nociception.

Figure 18–6. Mechanisms of opiate action in producing analgesia. Top left: Schematic of organization of opiate action in the periaqueductal gray. Top right: Opiate-sensitive pathways in PAG. Mu opiate actions block the release of GABA from tonically active systems that otherwise regulate the projections to the medulla (1) leading to an activation of PAG outflow resulting and activation of forebrain (2) and spinal (3) monoamine receptors that regulate spinal cord projections (4) which provide sensory input to higher centers and mood.

Bottom left: Schematic of primary afferent synapse with second order dorsal horn spinal neuron, showing pre- and post-synaptic opiate receptors coupled to Ca^{2+} and K^{+} channels, respectively. Opiate receptor binding is highly expressed in the superficial spinal dorsal horn (substantia gelatinosa). These receptors are located presynaptically on the terminals of small primary afferents (C fibers) and postsynaptically on second order neurons. Presynaptically, activation of MOR blocks the opening of the voltage sensitive Ca^{2+} channel, which otherwise initiates transmitter release. Postsynaptically, MOR activation enhances opening of K^{+} channels, leading to hyperpolarization. Thus, an opiate agonist acting at these sites jointly serves to attenuate the afferent-evoked excitation of the second order neuron.

peptide transmitters such as substance P contained in small afferents (Yaksh et al., 1980). The presynaptic action corresponds to the ability of opiates to prevent the opening of voltage-sensitive Ca^{2+} channels, thereby preventing transmitter release. A postsynaptic action is demonstrated by the ability of opiates to block excitation of dorsal horn neurons directly evoked by glutamate, reflecting a direct activation of dorsal horn projection neurons. The activation of K^{+} channels in these postsynaptic neurons, leading to hyperpolarization, is consistent with a direct postsynaptic inhibition. The joint capacity of spinal opiates to reduce the release of excitatory neurotransmitters from C fibers and to decrease the excitability of dorsal horn neurons is believed to account for the powerful and selective

effect of opiates on spinal nociceptive processing. In humans, there is extensive literature indicating that a variety of opiates delivered spinally (intrathecally or epidurally) can induce a powerful analgesia that is reversed by low doses of systemic naloxone (Yaksh, 1997).

Peripheral Action. It has been a principal tenet of opiate action that these agents act “centrally.” Direct application of opiates to a peripheral nerve can, in fact, produce a local anesthetic-like action at high concentrations, but this is not naloxone reversible and is believed to reflect a “nonspecific” action. Moreover, in studies examining normal animals, it can be demonstrated that the analgesic actions are limited if the agent does not readily penetrate the brain. Alternately, studies employing the direct injection of these agents into peripheral sites have demonstrated that under conditions of inflammation, where there is an increased terminal sensitivity leading to an exaggerated pain response (e.g., hyperalgesia), the local action of opiates can exert a normalizing effect upon the exaggerated thresholds. This has been demonstrated for the response to mechanical stimulation applied to inflamed paw or inflamed knee joints. In the absence of inflammation, there is no local peripheral effect. This action is believed to be mediated by opiate receptors on the peripheral terminals of small primary afferents. Local opiates in the knee joint and in the skin can reduce the firing of spontaneously active afferents observed when these tissues are inflamed. Whether the effects are uniquely on the afferent terminal, whether the opiate acts upon inflammatory cells that release products that sensitize the nerve terminal, or both, is not known (Stein and Lang, 2009).

Mood Alterations and Rewarding Properties. The mechanisms by which opioids produce euphoria, tranquility, and other alterations of mood (including rewarding properties) are complex and not entirely clear. Neural systems thought to mediate opioid reinforcement overlap with, but are distinct from, those involved in physical dependence and analgesia (Koob et al., 1988). Behavioral and pharmacological data point to a pivotal role of the mesocorticolimbic (MCL) dopamine system, a basal forebrain circuit long implicated in reward and motivation (Figure 18–7).

The mesolimbic dopamine system originates in the ventral segmental area (VTA) and projects to the nucleus accumbens (NAc) in the forebrain. Dopamine and glutamate projections from the VTA and prefrontal cortex (PFC), respectively, synapse on NAc GABAergic neurons. These cells project to the ventral pallidum (VP). In the NAc, ionotropic glutamate receptors activate, while dopamine D_2 -like receptors inhibit GABAergic neurons. In general, interventions that suppress the NAc-VP GABA pathway leading to increased dopamine release are considered to be positively rewarding, supporting, for example, self-administration. Thus, dopamine delivered directly into the NAc, mimicking increased extracellular release, is powerfully reinforcing. Opiates increase DA release in the NAc, and catheterized animals will activate administration of opiates directly into their VTA and into the NAc, emphasizing the importance of that system in opiate reward. In the NAc, MORs are present postsynaptically on GABAergic neurons. The reinforcing effects of opiates in the VTA are thought to be mediated through

Figure 18–7. Schematic pathways underlying rewarding properties of opiates.

Upper panel: This sagittal section of rat brain displays simplified DA and GABA inputs from the ventral tegmental area (VTA) and prefrontal cortex (PFC), respectively, into the nucleus accumbens (NAc).

Lower panel: Neurons are labeled with their primary neurotransmitters. At a cellular level, MOR agonists reduce excitability and transmitter release at the sites indicated by inhibiting Ca^{2+} influx and enhancing K^{+} current (see Figure 18-6). Thus, opiate-induced inhibition in the VTA on GABA-ergic interneurons or in the NAc reduce GABA-mediated inhibition and increase outflow from the ventral pallidum (VP), which appears to correlate with a positive reinforcing state (enhanced reward).

inhibition of local GABAergic neuronal activity, which otherwise acts to inhibit DA outflow (Xi and Stein, 2002).

Respiration. Although effects on respiration are readily demonstrated, clinically significant respiratory depression rarely occurs with standard analgesic doses in the absence of other contributing variables (discussed in

the next sections). It should be stressed, however, that *respiratory depression represents the primary cause of morbidity secondary to opiate therapy*. In humans, death from opiate poisoning is nearly always due to respiratory arrest or obstruction (Pattinson, 2008). Opiates depress all phases of respiratory activity (rate, minute volume, and tidal exchange) and produce irregular and aperiodic breathing. The diminished respiratory volume is due primarily to a slower rate of breathing; with toxic amounts of opioids, the rate may fall to 3–4 breaths per minute. The respiratory depression is discernible even with doses too small to disturb consciousness and increases progressively as the dose is increased. After large doses of morphine or other agonists, patients will breathe if instructed to do so, but without such instruction, they may remain relatively apneic. Thus, opioids must be used with caution in patients with asthma, COPD, cor pulmonale, decreased respiratory reserve, preexisting respiratory depression, hypoxia, or hypercapnia to avoid apnea due to a decrease in respiratory drive coinciding with an increase airway resistance. While respiratory depression is not considered to be a favorable therapeutic effect of opiates, their ability to suppress respiratory drive is used to therapeutic advantage to treat dyspnea resulting, for example, in patients with chronic obstructive pulmonary disease (COPD), where air hunger leads to extreme agitation, discomfort, and gasping; similarly, opiates find use in patients who require artificial ventilation (Clemens and Klaschik, 2007).

Mechanisms Underlying Respiratory Depression. Respiratory rate and tidal volume depend upon intrinsic rhythm generators located in the ventrolateral medulla. These systems generate a “respiratory” rhythm that is driven by afferent input reflecting the partial pressure of arterial O_2 as measured by chemosensors in the carotid and aortic bodies and CO_2 as measured by chemosensors in the brainstem. Morphine-like opioids depress respiration through MOR and DOR receptors in part by a direct depressant effect on rhythm generation, with changes in respiratory pattern and rate observed at lower doses than changes in tidal volume. A key property of opiate effects on respiration is the depression of the ventilatory response to increased CO_2 . This effect is mediated by opiate depression of the excitability of brainstem chemosensory neurons. In addition to the effects on the CO_2 response, opiates will depress ventilation otherwise driven by hypoxia though an effect upon carotid and aortic body chemosensors. Importantly, with opiates, hypoxic stimulation of chemoreceptors still may be effective when opioids have decreased the responsiveness to CO_2 , and inhalation of O_2 may remove the residual drive resulting from the elevated PO_2 and produce apnea (Pattinson, 2008). In addition to the effect upon respiratory rhythm and chemosensitivity, opiates can have mechanical effects on airway function by increasing chest wall rigidity and diminishing upper airway patency (Lalley, 2008).

Factors Exacerbating Opiate-Induced Respiratory Depression. A number of factors are recognized as increasing the risk of opiate-related respiratory depression even at therapeutic doses:

- **Other medications.** The combination of opiates with other depressant medications, such as general anesthetics, tranquilizers, alcohol, or sedative-hypnotics, produces additive depression of respiratory activity.
- **Sleep.** Natural sleep produces a decrease in the sensitivity of the medullary center to CO₂, and the depressant effects of morphine and sleep are at least additive. Obstructive sleep apnea is considered to be an important risk factor for increasing the likelihood of fatal respiratory depression.
- **Age.** Newborns can show significant respiratory depression and desaturation; and this may be evident in lower Apgar scores if opioids are administered parenterally to women within 2-4 hours of delivery because of transplacental passage of opioids. Elderly patients are at greater risk of depression because of reduced lung elasticity, chest wall stiffening, and decreased vital capacity.
- **Disease.** Opiates may cause a greater depressant action in patients with chronic cardiopulmonary or renal diseases because they can manifest a desensitization of their response to increased CO₂.
- **COPD.** Enhanced depression can also be noted in patients with chronic obstructive pulmonary disease (COPD) and sleep apnea secondary to diminished hypoxic drive.
- **Relief of Pain.** Because pain stimulates respiration, removal of the painful condition (as with the analgesia resulting from the therapeutic use of the opiate) will reduce the ventilatory drive and lead to apparent respiratory depression.

Sedation. Opiates can produce drowsiness and cognitive impairment. Such depression can augment respiratory impairment. These effects are most typically noted following initiation of opiate therapy or after dose incrementation. Importantly, these effects upon arousal resolve over a few days. As with respiratory depression, the degree of drug effect can be enhanced by a variety of predisposing patient factors including dementia, encephalopathies, or brain tumors as well as other depressant medications, including sleep aids, antihistamines, antidepressants, and anxiolytics (Cherny, 1996).

Different Opiates. Numerous studies have compared morphine and morphine-like opioids with respect to their ratios of analgesic to respiratory-depressant activities, and most have found that when equianalgesic doses are used, there is no significant difference. Maximal respiratory depression occurs within 5-10 minutes of intravenous administration of morphine or within 30-90 minutes of intramuscular or subcutaneous administration. Maximal respiratory depressant effects occur more rapidly with more lipid-soluble agents. After therapeutic doses, respiratory minute volume may be reduced for as long as 4-5 hours. Agents that have persistent kinetics, such as methadone, must be carefully monitored, particularly after dose incrementation.

Management of Opiate Depression. Life-threatening respiratory depression produced by any opiate agonist can be readily reversed by delivery of an opiate antagonist. Conversely, the ability to reverse the somnolent patient is considered to be indicative of an opiate-mediated effect. It is important to remember that most opiate antagonists have a relatively short duration of action as compared to an agonist such as morphine or methadone and fatal “re-narcotization” can occur if vigilance is not exercised.

Neuroendocrine Effects. The regulation of the release of hormones and factors from the pituitary is under complex regulation by opiate receptors in the hypothalamic-pituitary-adrenal (HPA) axis. Broadly considered, morphine-like opioids block the release of a large number of HPA hormones.

Sex Hormones. In males, acute opiate therapy reduces plasma cortisol, testosterone, and gonadotrophins. Inhibition of adrenal function is reflected by reduced cortisol production and reduced adrenal androgens (dehydroepiandrosterone, DHEA). In females, morphine will additionally result in lower LH and FSH release. In both males and females, chronic therapy can result in endocrinopathies, including hypogonadotropic hypogonadism. In men, this may result in decreased libido and, with extended exposure, reduced secondary sex characteristics. In women these exposures are associated with menstrual cycle irregularities. Importantly, these changes are reversible with removal of the opiate.

The mechanisms of the opiate regulation of gonadotrophin release may reflect a direct effect upon secreting pituicytes and an indirect action, through an effect on receptors present on hypothalamic neurons, to block release of gonadotropin-releasing hormone (GnRH) and corticotropin-releasing hormone (CRH). This reduction of the releasing factors leads to reduced release of luteinizing hormone (LH), follicle-stimulating hormone (FSH), ACTH, and β -endorphin. This series of events leads to reduced circulating testosterone and cortisol. Secretion of thyrotropin is relatively unaffected.

Prolactin. Prolactin release from lactotrope cells in the anterior pituitary is under inhibitory control by dopamine released from tuberoinfundibulum neurons of the arcuate nucleus. MOR agonists act presynaptically on these dopamine-releasing terminals to inhibit DA release and thereby increase plasma prolactin.

Growth Hormone. Growth hormone (GH) is released in a pulsatile fashion from somatotrophs in the anterior pituitary. GH-releasing hormone (GHRH) neurons in the hypothalamic arcuate nucleus and inhibitory input from somatostatin (SST) cells in the periventricular nucleus regulate this. Although some opioids increase GH release, possibly by inhibiting SST release, acute morphine has little effect on plasma GH concentration (Bluet-Pajot et al., 2001).

Antidiuretic Hormone and Oxytocin. The effects of opiates on ADH and oxytocin release are complex. These hormones are synthesized in the perikarya of the magnocellular neurons in the paraventricular and supraoptic nuclei of the hypothalamus and released from the posterior pituitary (Chapter 38). ADH (vasopressin) release can occur secondary to surgical stress, hypovolemia, hypotension, and low osmolarity, while oxytocin release typically is released with afferent stimuli related to the milk ejection pathway. KOR agonists inhibit the release of oxytocin and antidiuretic hormone (and cause prominent diuresis). In humans, the administration of MOR agonists has little effect or tends to produce antidiuretic effects. Morphine reduces oxytocin secretion in nursing women (Lindow et al., 1999). It should be noted that agents such as morphine may yield a hypotension secondary to histamine release and this would, by itself, promote ADH release. Based on electrophysiology and localization of opiate receptors, these effects upon vasopressin and oxytocin release may reflect both a direct effect upon terminal secretion as well as

indirect effects upon dopaminergic and noradrenergic modulatory projections into the paraventricular and supraoptic hypothalamus (Gimpl and Fahrenholz, 2001).

Miosis. Illumination of the pupil activates a reflex arc, which through local circuitry in the Edinger Westphal nucleus, activates parasympathetic outflow through the ciliary ganglion to the pupil, producing constriction. MOR opiates induce pupillary constriction (miosis) in the awake state and block pupillary reflex dilation during anesthesia. The parasympathetic outflow is locally regulated by GABAergic interneurons. Opiates are believed to block the GABAergic interneuron-mediated inhibition (Larson, 2008). At high doses of agonists, the miosis is marked, and pinpoint pupils are pathognomonic; however, marked mydriasis will occur with the onset of asphyxia. While some tolerance to the miotic effect develops, addicts with high circulating concentrations of opioids continue to have constricted pupils. Therapeutic doses of morphine increase accommodative power and lower intraocular tension in normal and glaucomatous eyes.

Seizures and Convulsions. In older children and adults, moderately higher doses of opiates produce EEG slowing. In the newborn, morphine has been shown to produce epileptiform activity (Young and da Silva, 2000) and occasionally seizure activity. While increased jaw and chest wall rigidity routinely occur at doses used for anesthesia induction, frank seizures and convulsions typically occur only at doses far in excess of those required to produce even profound analgesia. Myoclonus and seizures have been reported particularly in opioid tolerant patients on high doses of morphine-like opiates, including fentanyl, as encountered in hospice and terminal stages of pain therapy (Vella-Brincat and Macleod., 2007). However, seizures that are produced by some agents such as meperidine may occur at doses only moderately higher than those required for analgesia, especially in children, particularly with repeated delivery.

Several mechanisms are most certainly involved in these excitatory actions:

- **Inhibition of inhibitory interneurons.** Morphine-like drugs excite certain groups of neurons, especially hippocampal pyramidal cells, probably from inhibition of the release of GABA by interneurons (McGinty, 1988).
- **Direct stimulatory effects.** Opiates may interact with receptors coupled through both inhibitory and stimulatory G-protein, with the inhibitory coupling but not the excitatory coupling showing tolerance with continued exposure (King et al., 2005).
- **Actions mediated by non-opioid receptors.** The metabolites of several opiates have been implicated in seizure activity, notably morphine-3-glucuronide (from morphine) and normeperidine (from meperidine) (Seifert and Kenedy, 2004; Smith, 2000).

A special case is the withdrawal syndrome from an opiate-dependent state in the adult and in the infant born to an opiate-dependent mother. Withdrawal in these circumstances, either by antagonists or abstinence, can lead to prominent EEG activation, tremor, and rigidity. Approaches to the management of such activation are controversial. Re-narcotization with a tapering dose and management of symptoms with anticonvulsants and anesthetics has been suggested (Farid et al., 2008). Anticonvulsant agents may not always be effective in suppressing opioid-induced seizures (Chapter 21).

Cough. Morphine and related opioids depress the cough reflex at least in part by a direct effect on a cough center in the medulla and this can be achieved without altering the protective glottal function. There is no obligatory relationship between depression of respiration and depression of coughing, and effective antitussive agents are available that do not depress respiration (antitussives are discussed later in the chapter). Suppression of cough by such agents appears to involve receptors in the medulla that are less sensitive to naloxone (an opioid antagonist) than those responsible for analgesia (Chung and Pavord, 2008).

Cough is a protective reflex evoked by airway stimulation. It involves rapid expression of air against a transiently closed glottis. The reflex is complex, involving the central and peripheral nervous systems as well as the smooth muscle of the bronchial tree. Irritation of the bronchial mucosa causes bronchoconstriction, which in turn stimulates cough receptors (which probably represent a specialized type of stretch receptor) located in tracheobronchial passages. Afferent conduction from these receptors is via fibers in the vagus nerve; central components of the reflex probably include several mechanisms or centers that are distinct from the mechanisms involved in the regulation of respiration.

Nauseant and Emetic Effects. Nausea is the prodromal sensation that is a common feature of gastric upset that is associated with reduced gastric motility and increased secretions. Vomiting, the motor sequela of nausea, is a complex reflex characterized by simultaneous contractions of inspiratory-expiratory respiratory muscle, increased stomach pressure, relaxation of the esophageal sphincter, and retrograde reflex propulsion of gastric contents. Nausea and vomiting produced by morphine-like drugs are side-effects caused by direct stimulation of the chemoreceptor trigger zone for emesis in the area postrema of the medulla. Apomorphine is a structural analog of morphine that has no opioid action but has prominent emetogenic actions.

Nausea and vomiting are relatively uncommon in recumbent patients given therapeutic doses of morphine, but nausea occurs in ~40% and vomiting in 15% of ambulatory patients given 15 mg of the drug subcutaneously. This suggests that a vestibular component is also operative. Indeed, the nauseant and emetic effects of morphine are markedly enhanced by vestibular stimulation, and morphine and related synthetic analgesics produce an increase in vestibular sensitivity. A component of nausea is likely due to the gastric stasis that occurs postoperatively and that is exacerbated by analgesic doses of morphine (Greenwood-Van Meerveld, 2007). All clinically useful agonists produce some degree of nausea and vomiting. Careful, controlled clinical studies usually demonstrate that, in equianalgesic dosage, the incidence of such side effects is not significantly lower than that seen with morphine. Antagonists to the 5-HT₃ receptor have supplanted phenothiazines and drugs used for motion sickness as the drugs of choice for the treatment of opioid-induced nausea and vomiting. Gastric prokinetic agents such as metoclopramide also are use-

ful anti-nausea and anti-emetic drugs (Cameron et al., 2003); however, caution is warranted due to the propensity of metoclopramide to cause tardive dyskinesia (Chapter 46).

Cardiovascular System. In the supine patient, therapeutic doses of morphine-like opioids have no major effect on blood pressure or cardiac rate and rhythm. Such doses can, however, produce peripheral vasodilation, reduced peripheral resistance, and an inhibition of baroreceptor reflexes. Thus, when supine patients assume the head-up position, orthostatic hypotension and fainting may occur. The peripheral arteriolar and venous dilation produced by morphine involves several mechanisms:

- morphine-induced release of histamine from mast cells, leading to vasodilation (reversed by naloxone only partially blocked by H_1 antagonists)
- blunting of the reflex vasoconstriction caused by increased P_{CO_2}

High doses of MOR agonists, such as fentanyl and sufentanil, used as anesthetic induction agents, have only modest effects upon hemodynamic stability, in part because they do not cause release of histamine (Monk et al., 1988).

Effects on the myocardium are not significant in normal individuals. In patients with coronary artery disease but no acute medical problems, 8-15 mg morphine administered intravenously produces a decrease in O_2 consumption, left ventricular end-diastolic pressure, and cardiac work; effects on cardiac index usually are slight. In patients with acute myocardial infarction, the cardiovascular responses to morphine may be more variable than in normal subjects, and the magnitude of changes (e.g., the decrease in blood pressure) may be more pronounced (Roth et al., 1988). Anesthetic induction doses (described later) of the MOR result in a centrally mediated increase in vagal outflow to the heart, leading to an atropine-sensitive bradycardia.

Morphine may exert its well-known therapeutic effect in the treatment of angina pectoris and acute myocardial infarction by decreasing preload, inotropy, and chronotropy, thus favorably altering determinants of myocardial O_2 consumption and helping to relieve ischemia. It is not clear whether the analgesic properties of morphine in this situation are due to the reversal of acidosis that may stimulate local acid-sensing ion channels (McCleskey and Gold, 1999) or to a direct analgesic effect on nociceptive afferents from the heart.

When administered before experimental ischemia, morphine has been shown to produce cardioprotective effects. Morphine can mimic the phenomenon of ischemic preconditioning, where a short ischemic episode paradoxically protects the heart against further ischemia. This effect appears to be mediated through receptors signaling through a mitochondrial ATP-sensitive K^+ channel in cardiac myocytes; the effect also is produced by other GPCRs signaling through G_i (Fryer et al., 2000). Some researchers suggest that

opioids can be anti-arrhythmic and anti-fibrillatory during and after periods of ischemia (Fryer et al., 2000), although other data suggest that opioids can be arrhythmogenic (McIntosh et al., 1992).

Morphine-like opioids should be used with caution in patients who have decreased blood volume because these agents can aggravate hypovolemic shock. Morphine should be used with great care in patients with cor pulmonale because deaths after ordinary therapeutic doses have been reported. The concurrent use of certain phenothiazines may increase the risk of morphine-induced hypotension.

Cerebral circulation is not affected directly by therapeutic doses of opiates. However, opioid-induced respiratory depression and CO_2 retention can result in cerebral vasodilation and an increase in cerebrospinal fluid pressure. This pressure increase does not occur when PCO_2 is maintained at normal levels by artificial ventilation. Nevertheless, opioids produce changes in arousal that can obscure the clinical course of patients with head injuries.

Motor Tone. At therapeutic doses required for analgesia, opiates have little effect upon motor tone or function. However, high doses of opioids, as used for anesthetic induction, produce muscular rigidity in humans. Thus, rigidity of the chest wall and masseter severe enough to compromise respiration and intubation is not uncommon during anesthesia and routinely requires the use muscle relaxants.

Myoclonus, ranging from mild twitching to generalized spasm, is an occasional side-effect, which has been reported with all clinical opiate agonists; while it may be observed at lower therapeutic doses, it is particularly prevalent in hospice patients receiving high doses (Lyss et al., 1997). The increased muscle tone is certainly mediated by a central effect although the mechanisms of its effects are not clear. High doses of spinal opiates can increase motor tone, possibly through an inhibition of inhibitory interneurons in the ventral horn of the spinal cord. Alternately, intracranial delivery can initiate rigidity in animal models possibly reflecting on increased extrapyramidal activity. As already indicated, both actions are reversed by opiate antagonists.

GI Tract. Opiates have important effects upon all aspects of GI function. It is estimated that 40-95% of patients treated with opioids develop constipation and that changes in bowel function can be demonstrated even with acute dosing (Benyamin et al., 2008). Opioid receptors are densely distributed in enteric neurons between the myenteric and submucosal plexi and on a variety of secretory cells. The more prominent expression of the action mediated by these receptors will be reviewed in the next sections. Importantly, the presence of opioids can obscure recognition of the diagnosis or clinical course in patients with acute abdominal conditions.

Esophagus. The esophageal sphincter is under control by brainstem reflexes that activate cholinergic motor neurons originating in the esophageal myenteric plexus. This system regulates passage of material from the esophagus to the stomach and prevents regurgitation; conversely, it allows relaxation in the act of emesis. Morphine inhibits lower esophageal sphincter relaxation induced by swallowing and by esophageal distension. This effect is believed to be centrally mediated, as peripherally restricted opiates such as loperamide do not alter esophageal sphincter tone (Sidhu and Triadafilopoulos, 2008).

Stomach. Movement of a meal though the stomach reflects the coordinated contractions of the antrum and the resting tone of the gastric

reservoir. Relatively low doses of morphine result in an increase in tonic contracture of the antral musculature (secondary to an inhibition of local inhibitory neurons) and upper duodenum and reduced resting tone in the musculature of the gastric reservoir (secondary to inhibition of the motor neurons to the reservoir musculature), thereby prolonging gastric emptying time and increasing the likelihood of esophageal reflux. Passage of the gastric contents through the duodenum may be delayed by as much as 12 hours, and the absorption of orally administered drugs is retarded. Morphine and other agonists usually decrease secretion of hydrochloric acid, although stimulation sometimes is evident. Activation of opioid receptors on parietal cells enhances secretion, but indirect effects, including increased secretion of somatostatin from the pancreas and reduced release of acetylcholine, appear to be dominant in most circumstances (Kromer, 1988).

Intestine. Morphine reduces propulsive activity in the small and large intestine and diminishes intestinal secretions.

Propulsive Activity. Opiate agonists suppress local neurogenic networks that provide a rhythmic inhibition of muscle tone leading to concurrent increases in basal tone in the circular muscle of the small and large intestine. This results in enhanced high-amplitude phasic contractions, which are nonpropulsive. The upper part of the small intestine, particularly the duodenum, is affected more than the ileum. A period of relative atony may follow the hypertonicity. The reduced rate of passage of the intestinal contents, along with reduced intestinal secretion, leads to increased water absorption, increasing viscosity of the bowel contents, and constipation. The tone of the anal sphincter is augmented greatly, and reflex relaxation in response to rectal distension is reduced. These actions, combined with inattention to the normal sensory stimuli for defecation reflex owing to the central actions of the drug, contribute to morphine-induced constipation (Wood and Galligan, 2004).

The clinical relevance of the role of the peripheral opioid receptors in regulating GI motility after systemic opioids is supported by:

- The efficacy of peripherally limited opiate agonists such as loperamide as anti-diarrheals
- The ability of peripherally limited opiate antagonists such as methylnaltrexone to reverse the constipatory actions of systemic opiate agonists

Direct delivery of opioids into the cerebral ventricles or into the spinal intrathecal space could also inhibit GI propulsive activity as long as the extrinsic innervation to the bowel is intact. Although some tolerance develops to the effects of opioids on GI motility, patients who take opioids chronically remain constipated.

Intestinal Secretions. In the presence of intestinal hypersecretion that may be associated with diarrhea, morphine-like drugs inhibit the transfer of fluid and electrolytes into the lumen by naloxone-sensitive actions on the intestinal mucosa and within the CNS (Kromer, 1988). Intestinal secretion arises from activation of enterocytes by local cholinergic submucosal plexus secretomotor neurons. Opioids act through μ/δ receptors on these secretomotor neurons to inhibit their excitatory output to the enterocytes and thereby reduce intestinal secretion.

Biliary Tract. Bile flow is regulated by the periodic contractions of the sphincter of Oddi, which is relaxed by inhibitory innervation. This

inhibitory innervation is suppressed by opiates. After the subcutaneous injection of 10 mg morphine sulfate, the sphincter of Oddi constricts, and the pressure in the common bile duct may rise >10-fold within 15 minutes; this effect may persist for 2 hours or more. Fluid pressure also may increase in the gallbladder and produce symptoms that may vary from epigastric distress to typical biliary colic.

Some patients with biliary colic experience exacerbation rather than relief of pain when given opioids. Spasm of the sphincter of Oddi probably is responsible for elevations of plasma amylase and lipase that occur sometimes after morphine administration. All opioids can cause biliary spasm. Atropine only partially prevents morphine-induced biliary spasm, but opioid antagonists prevent or relieve it. Papaverine, another alkaloid of the poppy that lacks opioid activity, produces smooth muscle relaxation and is used therapeutically for GI, urethral, and biliary colic and for other nonvisceral conditions (e.g., embolism and angina pectoris) accompanied by smooth muscle spasm.

Other Smooth Muscle

Ureter and Urinary Bladder. Voiding is a highly organized response initiated by afferents activated by bladder filling and spinobulbospinal reflex arcs, which lead to contraction of the bladder and a reflex relaxation of the external urinary sphincter (Fowler et al., 2008). Morphine inhibits the urinary voiding reflex and increases the tone of the external sphincter with a resultant increase in the volume of the bladder. In animal models, this effect is mediated by MOR and DOR agonists. Stimulation of either receptor type in the brain or in the spinal cord exerts similar actions on bladder motility (Dray and Nunan, 1987). Tolerance develops to these effects of opioids on the bladder. Clinically, opiate-mediated inhibition of micturition can be of such clinical severity that catheterization sometimes is required after therapeutic doses of morphine, particularly with spinal drug administration. Importantly, in humans, the inhibition of systemic opiate effects on micturition is reversed by peripherally restricted antagonists (Rosow et al., 2007).

Uterus. If the uterus has been made hyperactive by oxytocics, morphine tends to restore the tone, frequency, and amplitude of contractions to normal.

Skin. Therapeutic doses of morphine cause dilation of cutaneous blood vessels. The skin of the face, neck, and upper thorax frequently becomes flushed. These changes may be due in part to the release of histamine and may be responsible for the sweating and some of the pruritus that commonly follow the systemic administration of morphine (described later). Histamine release probably accounts for the urticaria commonly seen at the site of injection. Though controversial, it is not blocked by naloxone and thought not to be mediated by opioid receptors. Itching is readily seen with morphine and meperidine but to a much lesser extent with oxymorphone, methadone, fentanyl, or sufentanil. This pruritus is a common and potentially disabling complication of opioid use. It can be caused by systemic as well as intraspinal injections of therapeutic doses of opioids, but it appears to be more intense after epidural or intrathecal administration (Ballantyne et al., 1988). The spinal effect, which is reversible by naloxone, may reflect a disinhibition of itch-specific neurons that have been identified in the spinal dorsal horn (Schmelz, 2002).

Immune System. The effects of opioids on the immune system are complex. Opioids modulate immune function by direct effects on

cells of the immune system and indirectly through centrally mediated neuronal mechanisms (Sharp and Yaksh, 1997). The acute central immunomodulatory effects of opioids may be mediated by activation of the sympathetic nervous system; the chronic effects of opioids may involve modulation of the hypothalamic-pituitary-adrenal (HPA) axis (Mellon and Bayer, 1998).

Direct effects on immune cells may involve unique, incompletely characterized variants of the classical neuronal opioid receptors, with MOR variants being most prominent (Sharp and Yaksh, 1997). Atypical receptors could account for the fact that it has been very difficult to demonstrate significant opioid binding on immune cells despite the observance of robust functional effects. In contrast, morphine-induced immune suppression largely is abolished in knockout mice lacking the receptor gene, suggesting that the receptor is a major target of morphine's actions on the immune system (Gaveriaux-Ruff et al., 1998). A proposed mechanism for the immune suppressive effects of morphine on neutrophils is through a nitric oxide–dependent inhibition of NF- κ B activation (Welters et al., 2000). Others have proposed that the induction and activation of MAP kinase also may play a role (Chuang et al., 1997).

Overall, the effects of opioids appear to be modestly immunosuppressive, and increased susceptibility to infection and tumor spread have been observed. In some situations, immune effects appear more prominent with acute administration than with chronic administration, which could have important implications for the care of the critically ill (Sharp and Yaksh, 1997). In contrast, opioids have been shown to reverse pain-induced immunosuppression and increase tumor metastatic potential in animal models (Page and Ben-Eliyahu, 1997). Therefore, opioids may either inhibit or augment immune function depending on the context in which they are used. These studies also indicate that withholding opioids in the presence of pain in immunocompromised patients actually could worsen immune function. Taken together, these studies indicate that opioid-induced immune suppression may be clinically relevant both to the treatment of severe pain and in the susceptibility of opioid addicts to infection (e.g., human immunodeficiency virus (HIV) infection and tuberculosis). Different opioid agonists also may have unique immunomodulatory properties. Better understanding of these properties eventually should help to guide the rational use of opioids in patients with cancer or at risk for infection or immune compromise.

Temperature Regulation. Opioids alter the equilibrium point of the hypothalamic heat-regulatory mechanisms such that body temperature usually falls slightly. Systematic studies have shown that MOR agonists such as alfentanil and meperidine, acting in the CNS, will result in slightly increased thresholds for sweating and significantly lower the threshold temperatures for evoking vasoconstriction and shivering (Sessler, 2008). In precipitated withdrawal, elevated body temperatures are observed, an observation consistent with the report that chronic high dosage may increase body temperature (Martin, 1983).

FUNCTIONAL OPIOID DRUG TYPES

Most of the clinically used opioid agonists presented below are relatively selective for MOR. They produce analgesia, affect mood and rewarding behavior, and alter respiratory, cardiovascular, GI, and neuroendocrine

function. KOR agonists, with few exceptions (e.g., butorphanol), are not typically employed for long-term therapy since they may produce dysphoric and psychotomimetic effects. DOR agonists, while analgesic in animal models, have not found clinical utility, and NOR agonists have largely proven to lack analgesic effects. Opiates that are relatively receptor selective at lower doses will interact with additional receptor types when given at high doses. This is especially true as doses are escalated to overcome tolerance.

The mixed agonist–antagonist agents frequently interact with more than one receptor class at usual clinical doses. The actions of these drugs are particularly interesting because they may act as an agonist at one receptor and as an antagonist at another. Mixed agonist–antagonist compounds were developed with the hope that they would have less addictive potential and less respiratory depression than morphine and related drugs. In practice, however, for the same degree of analgesia, the same intensity of side effects occurs. A “ceiling effect” limiting the amount of analgesia attainable often is seen with these drugs, such as buprenorphine, which is approved for the treatment of opioid dependence. Some mixed agonist–antagonist drugs, such as pentazocine and nalorphine (not available in the U.S.), can precipitate withdrawal in opioid-tolerant patients. For these reasons, except for the sanctioned use of buprenorphine to manage opioid addiction, the clinical use of these mixed agonist–antagonist drugs is generally limited.

The dosing guidelines and duration of action for the numerous drugs that are part of opioid therapy are summarized in Table 18–2.

MORPHINE AND STRUCTURALLY RELATED AGONISTS

Even though there are many compounds with pharmacological properties similar to those of morphine, morphine remains the standard against which new analgesics are measured.

Source and Composition of Opium

Because the synthesis of morphine is difficult, the drug still is obtained from opium or extracted from poppy straw. Opium is obtained from the unripe seed capsules of the poppy plant, *Papaver somniferum*. The milky juice is dried and powdered to make powdered opium, which contains a number of alkaloids. Only a few—morphine, codeine, and papaverine—have clinical utility. These alkaloids can be divided into two distinct chemical classes, phenanthrenes and benzylisoquinolines. The principal phenanthrenes are morphine (10% of opium), codeine (0.5%), and thebaine (0.2%).

Table 18-2

Dosing Data for Clinically Employed Opioid Analgesics

DRUG	APPROXIMATE EQUI-ANALGESIC	APPROXIMATE EQUI-ANALGESIC	RECOMMENDED STARTING DOSE (adults >50 kg)		RECOMMENDED STARTING DOSE (children and adults <50 kg) ^a	
	ORAL DOSE	PARENTERAL DOSE	ORAL	PARENTERAL	ORAL	PARENTERAL
Opioid Agonists						
Morphine ^b	30 mg q3-4h (around-the-clock dosing) 60 mg q3-4h (single dose or intermittent dosing)	10 mg q3-4h	15 mg q3-4h	5 mg q3-4h	0.3 mg/kg q3-4h	0.1 mg/kg q3-4h
Codeine ^c	130 mg q3-4h	75 mg q3-4h	30 mg q3-4h	30 mg q2h (IM/SC)	1 mg/kg q3-4h ^d	Not recommended
Hydromorphone (DILAUDID) ^b	7.5 mg q3-4h	1.5 mg q3-4h	4 mg q3-4h	1 mg q3-4h	0.06 mg/kg q3-4h	0.015 mg/kg q3-4h

Published tables vary in the suggested doses that are equi-analgesic to morphine. Clinical response is the criterion that must be applied for each patient; titration to clinical response is necessary. Because there is not complete cross-tolerance among these drugs, it is usually necessary to use a lower than equianalgesic dose when changing drugs and to retitrate to response. *Caution:* Recommended doses do not apply to patients with renal or hepatic insufficiency or other conditions affecting drug metabolism and kinetics. *Caution:* Doses listed for patients with body weight less than 50 kg cannot be used as initial starting doses in babies less than 6 months of age. Consult the *Clinical Practice Guideline for Acute Pain Management: Operative or Medical Procedures and Trauma* section on management of pain in neonates for recommendations. ^bFor morphine, hydromorphone, and oxymorphone, rectal administration is an alternate route for patients unable to take oral medications, but equianalgesic doses may differ from oral and parenteral doses because of pharmacokinetic differences. ^cCaution: Codeine doses above 65 mg often are not appropriate due to diminishing incremental analgesia with increasing doses but continually increasing constipation and other side effects. ^dCaution: Doses of aspirin and acetaminophen in combination opioid/NSAID preparations must also be adjusted to the patient's body weight. Maximum acetaminophen dose: 4 g/day in adults, 90 mg/kg/day in children. ^eDoses for moderate pain not necessarily equivalent to 30 mg oral or 10 mg parenteral morphine. ^fRisk of seizures: parenteral formulation not available in the U.S. ^gOxycontin is an extended-release preparation containing up to 160 mg of oxycodone per tablet and recommended for use every 12 hours. It has been subject to substantial abuse. Modified from Agency for Healthcare Policy and Research, 1992.

The principal benzylisoquinolines are papaverine (1%) (a smooth muscle relaxant) and noscapine (6%).

Chemistry of Morphine and Its Congeners

The structure of morphine is shown in Figure 18–8. Many semisynthetic derivatives are made by relatively simple modifications of morphine or thebaine. Codeine is methylmorphine, the methyl substitution being on the phenolic hydroxyl group. Thebaine differs from morphine only in that both hydroxyl groups are methylated and that the ring has two double bonds (6,7; 8,14). Thebaine has little analgesic action but is a precursor of several important 14-OH compounds, such as oxycodone and naloxone. Certain derivatives of thebaine are >1000 times as potent as morphine (e.g., etorphine). Diacetylmorphine, or heroin, is made from morphine by acetylation at the 3 and 6 positions. Apomorphine, which also can be prepared from morphine, is a potent emetic and dopaminergic D1 and D2 agonist, has no opiate receptor interactions, and displays no analgesic actions (Chapters 22 and 46). Hydromorphone, oxycodone, hydrocodone, and oxycodone also are made by modifying the morphine molecule. The structural relationships between morphine and some of its surrogates and antagonists are shown in Figure 18–8.

Structure-Activity Relationship of the Morphine-Like Opioids.

In addition to morphine, codeine, and the semisynthetic derivatives of the natural opium alkaloids, a number of other structurally distinct chemical classes of drugs have pharmacological actions similar to those of morphine. Clinically useful compounds include the morphinans, benzomorphanes, methadones, phenylpiperidines, and propionanilides. Although the two-dimensional representations of these chemically diverse compounds appear to be quite different, molecular models show certain common characteristics, as indicated by the heavy lines in the structure of morphine shown in Figure 18–8. Among the important properties of the opioids that can be altered by structural modification are their affinities for various types of opioid receptors, their activities as agonists versus antagonists, their lipid solubilities, and their resistance to metabolic breakdown. For example, blockade of the phenolic hydroxyl at position 3, as in codeine and heroin, drastically reduces binding to receptors; these compounds are converted *in vivo* to the potent analgesics morphine and 6-acetyl morphine, respectively.

Absorption, Distribution, Metabolism, and Excretion

Absorption. In general, the opioids are modestly absorbed from the GI tract; absorption through the rectal mucosa is adequate and a few agents (e.g., morphine, hydromorphone) are available in suppositories. The more lipophilic opioids are absorbed readily through the nasal or buccal mucosa. Those with the greatest lipid solubility also can be absorbed transdermally. Opioids, particularly morphine, have been widely used for spinal delivery to produce analgesia though a spinal action. These agents display useful transdural movement adequate to permit their use epidurally.

With most opioids, including morphine, the effect of a given dose is less after oral than after parenteral administration because of variable but significant first-pass metabolism in the liver. For example, the bioavailability of oral preparations of morphine is only ~25%. The shape of the time-effect curve also varies with the route of administration, so the duration of action often is somewhat longer with the oral route. If adjustment is made for variability of first-pass metabolism and clearance, adequate relief of pain can be achieved with oral administration of morphine. Satisfactory analgesia in cancer patients is associated with a very broad range of steady-state concentrations of morphine in plasma (16–364 ng/mL) (Neumann et al., 1982).

When morphine and most opioids are given intravenously, they act promptly. However, the more lipid-soluble compounds (e.g., fentanyl) act more rapidly than morphine after subcutaneous administration because of differences in the rates of absorption and entry into the CNS. Compared with more lipid-soluble opioids such as codeine, heroin, and methadone, morphine crosses the blood-brain barrier at a considerably lower rate.

Distribution and Metabolism. About one-third of morphine in the plasma is protein-bound after a therapeutic dose. Morphine itself does not persist in tissues, and 24 hours after the last dose, tissue concentrations are low.

The major pathway for the metabolism of morphine is conjugation with glucuronic acid. The two major metabolites formed are morphine-6-glucuronide and morphine-3-glucuronide. Small amounts of morphine-3,6-diglucuronide also may be formed. Although the 3- and 6-glucuronides are quite polar, both still can cross the blood-brain barrier to exert significant clinical effects (Christrup, 1997).

Morphine-6-glucuronide has pharmacological actions indistinguishable from those of morphine. Morphine-6-glucuronide given systemically is approximately twice as potent as morphine in animal models (Paul et al., 1989) and in humans (Osborne et al., 1988). With chronic administration, the 6-glucuronide accounts for a significant portion of morphine's analgesic actions (Osborne et al., 1988). Indeed, with chronic oral dosing, the blood levels of morphine-6-glucuronide typically exceed those of morphine. Given its greater MOR potency and its higher concentration, morphine-6-glucuronide may be responsible for most of morphine's analgesic activity in patients receiving chronic oral morphine. Morphine-6-glucuronide is excreted by the kidney. In renal failure, the levels of morphine-6-glucuronide can accumulate, perhaps explaining morphine's potency and long duration in patients with compromised renal function. In adults, the $t_{1/2}$ of morphine is ~2 hours; the $t_{1/2}$ of morphine-6-glucuronide is somewhat longer. Children achieve adult renal function values by 6 months of age. In elderly patients, lower doses of morphine are recommended based on a smaller volume of distribution (Owen et al., 1983) and the general decline in renal function in the elderly.

Morphine-3-glucuronide, another important metabolite, has little affinity for opioid receptors but may contribute to excitatory effects of morphine (Smith, 2000). N-Demethylation of morphine to normorphine is a minor metabolic pathway in humans but is more prominent in rodents (Yeh et al., 1977). N-Dealkylation also is important in the metabolism of some congeners of morphine.

Excretion. Morphine is eliminated by glomerular filtration, primarily as morphine-3-glucuronide; 90% of the total excretion takes place during the first day. Very little morphine is excreted unchanged. Enterohepatic circulation of morphine and its glucuronides occurs,

Figure 18–8. Structures of morphine-related opiate agonists and antagonists.

which accounts for the presence of small amounts of morphine in feces and urine for several days after the last dose.

In contrast to morphine, codeine is ~60% as effective orally as parenterally as an analgesic and as a respiratory depressant. Codeine analogs such as levorphanol, oxycodone, and methadone have a high

ratio of oral-to-parenteral potency. The greater oral efficacy of these drugs reflects lower first-pass metabolism in the liver. Once absorbed, codeine is metabolized by the liver, and its metabolites are excreted chiefly as inactive forms in the urine. A small fraction (~10%) of administered codeine is O-demethylated to morphine, and free and

conjugated morphine can be found in the urine after therapeutic doses of codeine. Codeine has an exceptionally low affinity for opioid receptors, and the analgesic effect of codeine is due to its conversion to morphine. However, codeine's antitussive actions may involve distinct receptors that bind codeine itself, and codeine is commonly employed for the management of cough. The $t_{1/2}$ of codeine in plasma is 2-4 hours.

CYP2D6 catalyzes the conversion of codeine to morphine. Well-characterized genetic polymorphisms in CYP2D6 lead to the inability to convert codeine to morphine, thus making codeine ineffective as an analgesic for ~10% of the Caucasian population (Eichelbaum and Evert, 1996). Other polymorphisms (e.g., the CYP2D6*2x2 genotype) can lead to ultra-rapid metabolism and thus increased sensitivity to codeine's effects due to higher than expected serum morphine levels in 4-5% of the US population and 16-28% of North Africans, Ethiopians, and Arabs (Eichelbaum and Evert, 1996). Other variations in metabolic efficiency among ethnic groups are apparent. For example, Chinese produce less morphine from codeine than do Caucasians and also are less sensitive to morphine's effects. The reduced sensitivity to morphine may be due to decreased production of morphine-6-glucuronide (Caraco et al., 1999). Thus, it is important to consider the possibility of metabolic enzyme polymorphism in any patient who experiences toxicity or does not receive adequate analgesia from codeine or other opioid prodrugs (e.g., hydrocodone and oxycodone).

Heroin (diacetylmorphine) is rapidly hydrolyzed to 6-monoacetylmorphine (6-MAM), which in turn is hydrolyzed to morphine. Heroin and 6-MAM are more lipid soluble than morphine and enter the brain more readily. Evidence suggests that morphine and 6-MAM are responsible for the pharmacological actions of heroin. Heroin is excreted mainly in the urine largely as free and conjugated morphine.

Therapeutic Actions and Precautions

Morphine and related opioids produce a wide spectrum of unwanted effects, including respiratory depression, nausea, vomiting, dizziness, mental clouding, dysphoria, pruritus, constipation, increased pressure in the biliary tract, urinary retention, and hypotension. The bases of these effects were described earlier. Rarely, a patient may develop delirium. Increased sensitivity to pain after analgesia has worn off and between-dose withdrawal also may occur.

A number of factors may alter a patient's sensitivity to opioid analgesics, including the integrity of the blood-brain barrier. For example, when morphine is administered to a newborn infant in weight-appropriate doses extrapolated from adults, unexpectedly profound effects (analgesia and respiratory depression) may be observed. This is due to the immaturity of the blood-brain barrier in neonates. As mentioned previously, morphine is hydrophilic, so proportionately less morphine normally crosses into the CNS than with more lipophilic opioids. In neonates or when the blood-brain barrier is compromised, lipophilic opioids may give more predictable clinical results than morphine. In adults, the duration of the analgesia produced by morphine increases progressively with age; however, the degree of analgesia that is obtained with a given dose changes little.

Changes in pharmacokinetic parameters only partially explain these observations. The patient with severe pain may tolerate larger doses of morphine. However, as the pain subsides, the patient may exhibit sedation and even respiratory depression as the stimulatory effects of pain are diminished.

All opioid analgesics are metabolized by the liver and should be used with caution in patients with hepatic disease because increased bioavailability after oral administration or cumulative effects may occur. Renal disease also significantly alters the pharmacokinetics of morphine, codeine, dihydrocodeine, meperidine, and propoxyphene. Although single doses of morphine are well tolerated, the active metabolite, morphine-6-glucuronide, may accumulate with continued dosing, and symptoms of opioid overdose may result (Chan and Matzke, 1987). This metabolite also may accumulate during repeated administration of codeine to patients with impaired renal function. When repeated doses of meperidine are given to such patients, the accumulation of normeperidine may cause tremor and seizures. Similarly, the repeated administration of propoxyphene may lead to naloxone-insensitive cardiac toxicity caused by the accumulation of norpropoxyphene (Chan and Matzke, 1987).

Morphine and related opioids must be used cautiously in patients with compromised respiratory function (e.g., emphysema, kyphoscoliosis, severe obesity). In patients with cor pulmonale, death has occurred after therapeutic doses of morphine. Although many patients with such conditions seem to be functioning within normal limits, they are already using compensatory mechanisms, such as increased respiratory rate. Many have chronically elevated levels of plasma CO_2 and may be less sensitive to the stimulating actions of CO_2 . The further imposition of the depressant effects of opioids can be disastrous. The respiratory-depressant effects of opioids and the related capacity to elevate intracranial pressure must be considered in the presence of head injury or an already elevated intracranial pressure. While head injury *per se* does not constitute an absolute contraindication to the use of opioids, the possibility of exaggerated depression of respiration and the potential need to control ventilation of the patient must be considered. Finally, since opioids may produce mental clouding and side effects such as miosis and vomiting, which are important signs in following the clinical course of patients with head injuries, the advisability of their use must be weighed carefully against these risks.

Patients with reduced blood volume are considerably more susceptible to the vasodilating effects of morphine and related drugs, and these agents must be used cautiously in patients with hypotension from any cause.

Morphine causes histamine release, which can cause bronchoconstriction and vasodilation. Morphine has the potential to precipitate or exacerbate asthmatic attacks and should be avoided in patients with a history of asthma. Other receptor agonists associated with a lower incidence of histamine release, such as the fentanyl derivatives, may be better choices for such patients.

Aside from their ability to release histamine, opioid analgesics may evoke allergic phenomena, but a true allergic response is uncommon. The effects usually are manifested as urticaria and other types of skin rashes such as fixed eruptions; contact dermatitis in nurses and pharmaceutical workers also occurs. Wheals at the site of injection of morphine, codeine, and related drugs are likely secondary to histamine release. Anaphylactoid reactions have been reported after intravenous administration of codeine and morphine, but such

502 reactions are rare. Such reactions may contribute to sudden death, episodes of pulmonary edema, and other complications that occur among addicts who use heroin intravenously (Chapter 24).

LEVORPHANOL

Levorphanol (LEVO-DROMORAN) is the principal available opioid agonist of the morphinan series (see structure in Figure 18–8). The D-isomer (dextrophan) is devoid of analgesic action but has inhibitory effects at NMDA receptors. It has affinity at the MOR, KOR, and DORs and is available for IV, IM, and PO administration. The pharmacological effects of levorphanol closely parallel those of morphine. However, clinical reports suggest that it may produce less nausea and vomiting.

Levorphanol is metabolized less rapidly than morphine and has a $t_{1/2}$ of 12–16 hours; repeated administration at short intervals may thus lead to accumulation of the drug in plasma. Other agents in this class include nalbuphine (NUBAIN, others) and butorphanol (STADOL, others), which are discussed in the section “Opioid Agonists/Antagonists and Partial Agonists” later in the chapter.

MEPERIDINE, DIPHENOXYLATE, LOPERAMIDE

The structural formulas of meperidine, a phenylpiperidine, and some of its congeners, are shown in Figure 18–9. Two important congeners are diphenoxylate and loperamide. These agents are MOR agonists with principal pharmacological effects on the CNS and neural elements in the bowel.

Meperidine

Meperidine is predominantly a MOR agonist that produces a pattern of effects similar but not identical to those already described for morphine.

Effects on Organ Systems

CNS Actions. Meperidine is a potent MOR agonist yielding strong analgesic actions. Peak respiratory depression is observed within 1 hour of intramuscular administration, and there is a return toward normal starting at ~2 hours. Like other opioids, meperidine causes pupillary constriction, increases the sensitivity of the labyrinthine apparatus, and has effects on the secretion of pituitary hormones similar to those of morphine. Meperidine sometimes causes CNS excitation, characterized by tremors, muscle twitches, and seizures; these effects are

due largely to accumulation of a metabolite, normeperidine. Meperidine has well known local anesthetic properties, particularly noted after epidural administration. As with morphine, respiratory depression is responsible for an accumulation of CO_2 , which in turn leads to cerebrovascular dilation, increased cerebral blood flow, and elevation of cerebrospinal fluid pressure.

Cardiovascular System. The effects of meperidine on the cardiovascular system generally resemble those of morphine, including the ability to release histamine following parenteral administration. Intramuscular administration of meperidine does not affect heart rate significantly, but intravenous administration frequently produces a marked increase in heart rate.

Smooth Muscle. Meperidine has effects on certain smooth muscles qualitatively similar to those observed with other opioids. Meperidine does not cause as much constipation as does morphine, even when given over prolonged periods of time; this may be related to its greater ability to enter the CNS, thereby producing analgesia at lower systemic concentrations. As with other opioids, clinical doses of meperidine slow gastric emptying sufficiently to delay absorption of other drugs significantly.

The uterus of a nonpregnant woman usually is mildly stimulated by meperidine. Administered before an oxytocic, meperidine does not exert any antagonistic effect. Therapeutic doses given during active labor do not delay the birth process; in fact, the frequency, duration, and amplitude of uterine contraction sometimes may be increased (Zimmer et al., 1988). The drug does not interfere with normal postpartum contraction or involution of the uterus, and it does not increase the incidence of postpartum hemorrhage. See also “Therapeutic Uses” later in the chapter.

Absorption, Distribution, Metabolism, and Excretion.

Meperidine is absorbed by all routes of administration, but the rate of absorption may be erratic after intramuscular injection. The peak plasma concentration usually occurs at ~45 minutes, but the range is wide. After oral administration, only ~50% of the drug escapes first-pass metabolism to enter the circulation, and peak concentrations in plasma usually are observed in 1–2 hours.

In humans, meperidine is hydrolyzed to meperidinic acid, which in turn is partially conjugated. Meperidine also is N-demethylated to normeperidine, which then may be hydrolyzed to normeperidinic acid and subsequently conjugated. The clinical significance of the formation of normeperidine is discussed later. Meperidine is metabolized chiefly in the liver, with a $t_{1/2} \approx 3$ hours. In patients with cirrhosis, the bioavailability of meperidine is increased to as much as 80%, and the $t_{1/2}$ of both meperidine and normeperidine are prolonged. Approximately 60% of meperidine in plasma is protein bound. Only a small amount of meperidine is excreted unchanged.

Untoward Effects, Precautions, and Contraindications. The pattern and overall incidence of untoward effects that follow the use of meperidine are similar to those observed after equianalgesic doses of morphine, except that constipation and urinary retention may be less common. Patients who experience nausea and vomiting with morphine

may not do so with meperidine; the converse also may be true. As with other opioids, tolerance develops to some of these effects. The contraindications generally are the same as for other opioids. In patients or addicts who are tolerant to the depressant effects of meperidine, large doses repeated at short intervals may produce an excitatory syndrome including hallucinations, tremors, muscle twitches, dilated pupils, hyperactive reflexes, and convulsions. These excitatory symptoms are due to the accumulation of normeperidine, which has a $t_{1/2}$ of 15-20 hours, compared to 3 hours for meperidine. Since normeperidine is eliminated by the kidney and the liver, decreased renal or hepatic function increases the likelihood of toxicity. As a result of these properties, meperidine is not recommended for the treatment of chronic pain because of concerns over metabolic toxicity. It should not be used for longer than 48 hours or in doses >600 mg/day (see www.ahrq.gov).

Interactions with Other Drugs. Severe reactions may follow the administration of meperidine to patients being treated with MAO inhibitors. Two basic types of interactions can be observed. The most prominent is an excitatory reaction (“serotonin syndrome”) with delirium, hyperthermia, headache, hyper- or hypotension, rigidity, convulsions, coma, and death. This reaction may be due to the ability of meperidine to block neuronal reuptake of 5-HT, resulting in serotonergic overactivity (Stack et al., 1988). Conversely, the MAO inhibitor interaction with meperidine may resemble acute narcotic overdose owing to the inhibition of hepatic CYPs. Therefore, meperidine and its congeners are contraindicated in patients taking MAO inhibitors or within 14 days after discontinuation of an MAO inhibitor. Similarly, dextromethorphan (an analog of levorphanol used as a non-narcotic cough suppressant) also inhibits neuronal 5-HT uptake and must be avoided in these patients. In addition, tramadol and tapentadol (centrally acting synthetic opioid analgesics, described later) inhibit the uptake of norepinephrine and 5-HT and should not be used concomitantly with MAO inhibitors or selective serotonin reuptake inhibitors (SSRIs).

Chlorpromazine increases the respiratory-depressant effects of meperidine, as do tricyclic antidepressants; this is not true of diazepam. Concurrent administration of drugs such as promethazine or chlorpromazine also may greatly enhance meperidine-induced sedation without slowing clearance of the drug. Treatment with phenobarbital or phenytoin increases systemic clearance and decreases oral bioavailability of meperidine; this is associated with an elevation of the concentration of normeperidine in plasma (Edwards et al., 1982). As with morphine, concomitant administration of amphetamine has been reported to enhance the analgesic effects of meperidine and its congeners while counteracting sedation.

Therapeutic Uses. The major use of meperidine is for analgesia. Unlike morphine and its congeners, meperidine is not used for the treatment of cough or diarrhea. The analgesic effects of meperidine are detectable ~15 minutes after oral administration, peak in 1-2 hours, and subside gradually. The onset of analgesic effect is faster (within 10 minutes) after subcutaneous or intramuscular administration, and the effect reaches a peak in ~1 hour, corresponding closely to peak concentrations in plasma. In clinical use, the duration of effective

analgesia is ~1.5-3 hours. In general, 75-100 mg meperidine hydrochloride (pethidine, DEMEROL, others) given parenterally is approximately equivalent to 10 mg morphine, and in equianalgesic doses, meperidine produces as much sedation, respiratory depression, and euphoria as does morphine. In terms of total analgesic effect, meperidine is about one-third as effective when given orally as when administered parenterally. A few patients may experience dysphoria.

Single doses of meperidine also appear to be effective in the treatment of postanesthetic shivering. Meperidine, 25-50 mg, is used frequently with antihistamines, corticosteroids, acetaminophen, or nonsteroidal anti-inflammatory drugs (NSAIDs) to prevent or ameliorate infusion-related rigors and shaking chills that accompany the intravenous administration of agents such as amphotericin B, aldesleukin (interleukin-2), trastuzumab, and alemtuzumab.

Meperidine crosses the placental barrier and even in reasonable analgesic doses causes a significant increase in the percentage of babies who show delayed respiration, decreased respiratory minute volume, or decreased O_2 saturation or who require resuscitation. Fetal and maternal respiratory depression induced by meperidine can be treated with naloxone. The fraction of drug that is bound to protein is lower in the fetus; concentrations of free drug thus may be considerably higher than in the mother. Nevertheless, meperidine produces less respiratory depression in the newborn than does an equianalgesic dose of morphine or methadone (Fishburne, 1982).

Diphenoxylate

Diphenoxylate is a meperidine congener that has a definite constipating effect in humans. Its only approved use is in the treatment of diarrhea (Chapter 46). Although single doses in the therapeutic range (see below) produce little or no morphine-like subjective effects, at high doses (40-60 mg) the drug shows typical opioid activity, including euphoria, suppression of morphine abstinence syndrome, and a morphine-like physical dependence after chronic administration. Diphenoxylate is unusual in that even its salts are virtually insoluble in aqueous solution, thus obviating the possibility of abuse by the parenteral route.

Diphenoxylate hydrochloride is available only in combination with atropine sulfate (LOMOTIL, others). The recommended daily dosage of diphenoxylate for the treatment of diarrhea in adults is 20 mg in divided doses. Diarrhea refractory to maximal doses of diphenoxylate for 10 days is unlikely to be controlled by further therapy. Difenoxin, a metabolite of diphenoxylate, has actions similar to those of the parent compound. Like diphenoxylate, difenoxin is marketed in a fixed dose with atropine (MOTOFEN) for the management of diarrhea.

Loperamide

Loperamide (IMODIUM, others), like diphenoxylate, is a piperidine derivative (Figure 18–3). It slows GI motility

by effects on the circular and longitudinal muscles of the intestine, presumably as a result of its interactions with opioid receptors in the intestine. Some part of its antidiarrheal effect may be due to a reduction of gastrointestinal secretion (described earlier) (Kromer, 1988). In controlling chronic diarrhea, loperamide is as effective as diphenoxylate. In clinical studies, the most common side effect was abdominal cramps. Little tolerance develops to its constipating effect.

In human volunteers taking large doses of loperamide, concentrations of drug in plasma peak ~4 hours after ingestion; this long latency may be due to inhibition of GI motility and to enterohepatic circulation of the drug. The apparent elimination $t_{1/2}$ is 7-14 hours. Loperamide is poorly absorbed after oral administration and, in addition, apparently does not penetrate well into the brain due to the exporting activity of P-glycoprotein, which is widely expressed in the brain endothelium (Sadeque et al., 2000). Mice with deletions of one of the genes encoding the P-glycoprotein transporter have much higher brain levels and significant central effects after administration of loperamide (Schinkel et al., 1996). Inhibition of P-glycoprotein by many clinically used drugs, such as quinidine and verapamil, possibly could lead to enhanced central effects of loperamide.

In general, loperamide is unlikely to be abused parenterally because of its low solubility; large doses of loperamide given to human volunteers do not elicit pleasurable effects typical of opioids. The usual dosage is 4-8 mg/day; the daily dose should not exceed 16 mg.

FENTANYL AND CONGENERS

Fentanyl

Fentanyl is a synthetic opioid related to the phenylpiperidines (Figure 18–9). The actions of fentanyl and its congeners, sufentanil, remifentanil, and alfentanil, are similar to those of other MOR agonists. Alfentanil (ALFENTA, others) is seldom used. Fentanyl and sufentanil, are very important drugs in anesthetic practice because of their relatively short time to peak analgesic effect, rapid termination of effect after small bolus doses, minimal direct depressant effects on the myocardium, and their ability to significantly reduce the dosing requirement for the volatile agents (“MAC-sparing”; see Chapter 19). In addition to a role in anesthesia, fentanyl also is used in the management of severe pain states.

Pharmacological Properties

CNS Effects. Fentanyl and its congeners are all extremely potent analgesics and typically exhibit a very short duration of action when given parenterally. As with other opioids, nausea, vomiting, and itching can be observed. Muscle rigidity, while possible after all narcotics, appears to be more common after the high doses used in anesthetic induction. Rigidity can be treated with depolarizing or non-depolarizing neuromuscular blocking agents while controlling

the patient’s ventilation. Care must be taken to make sure that the patient is not simply immobilized but aware. Respiratory depression is similar to that observed with other receptor agonists, but the onset is more rapid. As with analgesia, respiratory depression after small doses is of shorter duration than with morphine but of similar duration after large doses or long infusions. As with morphine and meperidine, delayed respiratory depression also can be seen after the use of fentanyl or sufentanil, possibly owing to enterohepatic circulation. High doses of fentanyl can cause neuroexcitation and, rarely, seizure-like activity in humans (Bailey and Stanley, 1994). Fentanyl has minimal effects on intracranial pressure when ventilation is controlled and the arterial CO_2 concentration is not allowed to rise.

Cardiovascular System. Fentanyl and its derivatives decrease heart rate and mildly decrease blood pressure. However, these drugs do not release histamine and direct depressant effects on the myocardium are minimal. For this reason, high doses of fentanyl or sufentanil are commonly used as the primary anesthetic for patients undergoing cardiovascular surgery or for patients with poor cardiac function.

Absorption, Distribution, Metabolism, and Excretion. These agents are highly lipid soluble and rapidly cross the blood-brain barrier. This is reflected in the $t_{1/2}$ for equilibration between the plasma and cerebrospinal fluid of ~5 minutes for fentanyl and sufentanil. The levels in plasma and cerebrospinal fluid decline rapidly owing to redistribution of fentanyl from highly perfused tissue groups to other tissues, such as muscle and fat. As saturation of less well-perfused tissue occurs, the duration of effect of fentanyl and sufentanil approaches the length of their elimination $t_{1/2}$, 3-4 hours. Fentanyl and sufentanil undergo hepatic metabolism and renal excretion. With the use of higher doses or prolonged infusions, the drugs accumulate, these clearance mechanisms become progressively saturated, and fentanyl and sufentanil become longer acting.

Therapeutic Uses. Fentanyl citrate (SUBLIMAZE, others) and sufentanil citrate (SUFENTA, others) have widespread popularity as anesthetic adjuvants (Chapter 19). They are used commonly either intravenously, epidurally, or intrathecally. The analgesic effects of fentanyl and sufentanil are similar to those of morphine and other opioids. Fentanyl is ~100 times more potent than morphine, and sufentanil is ~1000 times more potent than morphine. The time to peak analgesic effect after intravenous administration of fentanyl and sufentanil (~5 minutes) is notably less than that for morphine and meperidine (~15 minutes). Recovery from analgesic effects also occurs more quickly. However, with larger doses or prolonged infusions, the effects of these drugs become more lasting, with durations of action becoming similar to those of longer-acting opioids (described later). Intravenous use of fentanyl and sufentanil for postoperative pain has been popular.

Epidural use of fentanyl and sufentanil for postoperative or labor analgesia has significant popularity. A combination of epidural opioids with local anesthetics permits reduction in the dosage of both components, minimizing the side effects of the local anesthetic (i.e., motor blockade) and the opioid (i.e., urinary retention, itching, and delayed respiratory depression in the case of morphine). An important caveat to their spinal use is that because of their rapid clearance, these agents at analgesic spinal doses can produce blood levels that are similar to those producing effects after systemic administration (Bernards, 2004).

The use of fentanyl and sufentanil in chronic pain treatment has become more widespread. The development of novel, minimally invasive routes of administration for fentanyl has facilitated the use of these compounds in chronic pain management. Transdermal patches (DURAGESIC, others) that provide sustained release of fentanyl for 48–72 hours are available. However, factors promoting increased absorption (e.g., fever) can lead to relative overdosage and increased side effects (see “Routes of Analgesic Drug Administration” later in the chapter). Transbuccal absorption by the use of buccal tablets, soluble buccal film, and lollipop-like lozenges permits rapid absorption and has found use in the management of acute incident pain (FENTORA, ACTIQ, ONSOLIS, others) and for the relief of breakthrough cancer pain. As fentanyl is poorly absorbed in the GI tract, the optimal absorption is through buccal absorption. Accordingly, there is little opportunity for overdosing by that route.

Remifentanyl

This compound was developed in an effort to create an analgesic with a more rapid onset and predictable termination of effect. The potency of remifentanyl is approximately equal to that of fentanyl. The pharmacological properties of remifentanyl are similar to those of fentanyl and sufentanil. They produce similar incidences of nausea, vomiting, and dose-dependent muscle rigidity. Nausea, vomiting, itching, and headaches have been reported when remifentanyl has been used for conscious analgesia for painful procedures. Intracranial pressure changes are minimal when ventilation is controlled. Seizures after remifentanyl administration have been reported (Beers and Camporesi, 2004).

Absorption, Fate, and Excretion. Remifentanyl has a more rapid onset of analgesic action than fentanyl or sufentanil. Analgesic effects occur within 1–1.5 minutes following intravenous administration. Peak respiratory depression after bolus doses of remifentanyl occurs after 5 minutes (Patel and Spencer, 1996). Remifentanyl is metabolized by plasma esterases, with a $t_{1/2}$ of 8–20 minutes (Burkle et al., 1996); thus, elimination is independent of hepatic metabolism or renal excretion. There is no prolongation of effect with repeated dosing or prolonged infusion. Age and weight can affect clearance of remifentanyl, requiring that dosage be reduced in the elderly and based on lean body mass. However, neither of these conditions causes major changes in duration of effect. After 3- to 5-hour infusions of remifentanyl, recovery of respiratory function can be seen within 3–5 minutes; full recovery from all effects of remifentanyl is observed within 15 minutes (Glass et al., 1999). The primary metabolite, remifentanyl acid, has 0.05–0.025% of the potency of the parent compound, and is excreted renally.

Therapeutic Uses. Remifentanyl hydrochloride (ULTIVA) is useful for short, painful procedures that require intense analgesia and blunting of stress responses; the drug is routinely given by continuous intravenous infusion because its short duration of action makes bolus administration impractical. The titratability of remifentanyl and its consistent, rapid offset make it ideally suited for short surgical procedures where rapid recovery is desirable. Remifentanyl also has

been used successfully for longer neurosurgical procedures, where rapid emergence from anesthesia may be important. However, in cases where postprocedural analgesia is required, remifentanyl alone is a poor choice. In this situation, either a longer-acting opioid or another analgesic modality should be combined with remifentanyl for prolonged analgesia, or another opioid should be used. Remifentanyl is not used intraspinally because of its formulation with glycine, an inhibitory transmitter in the spinal dorsal horn.

METHADONE AND PROPOXYPHENE

Methadone

Methadone (Figure 18–9) is a long-acting MOR agonist with pharmacological properties qualitatively similar to those of morphine. The analgesic activity of methadone, a racemate, is almost entirely the result of its content of L-methadone, which is 8–50 times more potent than the D isomer. D-methadone also lacks significant respiratory depressant action and addiction liability but possesses antitussive activity.

CNS Effects. The outstanding properties of methadone are its analgesic activity, its efficacy by the oral route, its extended duration of action in suppressing withdrawal symptoms in physically dependent individuals, and its tendency to show persistent effects with repeated administration. Miotic and respiratory-depressant effects can be detected for >24 hours after a single dose; on repeated administration, marked sedation is seen in some patients. Effects on cough, bowel motility, biliary tone, and the secretion of pituitary hormones are qualitatively similar to those of morphine.

Absorption, Distribution, Metabolism, and Excretion. Methadone is absorbed well from the GI tract and can be detected in plasma within 30 minutes of oral ingestion; it reaches peak concentrations at ~4 hours. After therapeutic doses, ~90% of methadone is bound to plasma proteins. Peak concentrations occur in brain within 1–2 hours of subcutaneous or intramuscular administration, and this correlates well with the intensity and duration of analgesia. Methadone also can be absorbed from the buccal mucosa.

Methadone undergoes extensive biotransformation in the liver. The major metabolites, the results of N-demethylation and cyclization to form pyrrolidines and pyrroline, are excreted in the urine and the bile along with small amounts of unchanged drug. The amount of methadone excreted in the urine is increased when the urine is acidified. The $t_{1/2}$ of methadone is long, 15–40 hours.

Methadone appears to be firmly bound to protein in various tissues, including brain. After repeated administration, there is gradual accumulation in tissues. When administration is discontinued, low concentrations are maintained in plasma by slow release from extravascular binding sites; this process probably accounts for the relatively mild but protracted withdrawal syndrome.

Side Effects, Toxicity, Drug Interactions, and Precautions. Side effects, toxicity, and conditions that alter sensitivity, as well as the

treatment of acute intoxication, are similar to those described for morphine. During long-term administration, there may be excessive sweating, lymphocytosis, and increased concentrations of prolactin, albumin, and globulins in the plasma. Rifampin and phenytoin accelerate the metabolism of methadone and can precipitate withdrawal symptoms. Unlike other opioids, methadone is associated with the prolonged QT syndrome and is additive with agents known to prolong the QT interval. Serious cardiac arrhythmias, including torsades de pointes, have been observed during treatment with methadone.

Therapeutic Uses. The primary uses of methadone hydrochloride (DOLOPHINE, others) are relief of chronic pain, treatment of opioid abstinence syndromes, and treatment of heroin users. In the U.S., prescribing methadone for abstinence syndrome and maintenance of heroin users is regulated by Federal Opioid Treatment Standards (42 CFR 8.12). The onset of analgesia occurs 10-20 minutes after parenteral administration and 30-60 minutes after oral medication. The average minimal effective analgesic concentration in blood is ~30 ng/mL (Gourlay et al., 1986). The typical oral dose is 2.5-10 mg repeated every 8-12 hours as needed depending on the severity of the pain and the response of the patient. Care must be taken when escalating the dosage because of the prolonged $t_{1/2}$ of the drug and its tendency to accumulate over a period of several days with repeated dosing. Iatrogenic overdoses have occurred during initiation of therapy and dosing titration with methadone because of too-rapid titration or the concomitant use of depressant drugs. The peak respiratory depressant effects of methadone typically occur later and persist longer than the peak analgesic effects so it is necessary to exercise vigilance and strongly caution patients against self-medicating with CNS depressants, particularly during treatment initiation and dose titration. Methadone is not used widely as an antiperistaltic agent and should not be used in labor.

Despite its longer plasma $t_{1/2}$, the duration of the analgesic action of single doses is essentially the same as that of morphine. With repeated use, cumulative effects are seen, so either lower dosages or longer intervals between doses become possible. In contrast to morphine, methadone and many of its congeners retain a considerable degree of their effectiveness when given orally. In terms of total analgesic effects, methadone given orally is ~50% as effective as the same dose administered intramuscularly; however, the oral-parenteral potency ratio is considerably lower when peak analgesic effect is considered. In equianalgesic doses, the pattern and incidence of untoward effects caused by methadone and morphine are similar.

Because of its oral bioavailability and long $t_{1/2}$, methadone has been widely implemented as a replacement modality to treat heroin dependence. Methadone, like other opiates, will produce tolerance and dependence. Thus, addicts who receive daily subcutaneous or oral therapy develop partial tolerance to the nauseant, anorectic, miotic, sedative, respiratory-depressant, and cardiovascular effects of methadone. Many former heroin users treated with oral methadone show virtually no overt behavioral effects (Mattick et al., 2009). Development of physical dependence during the long-term administration of methadone can be demonstrated following abrupt drug withdrawal or by administration of an opioid antagonist. Likewise, subcutaneous administration of methadone to former opioid addicts produces euphoria equal in duration to that caused by morphine, and its overall abuse potential is comparable with that of morphine.

Propoxyphene

Propoxyphene is structurally related to methadone (Figure 18-9). Its analgesic effect resides in the D-isomer. However, L-propoxyphene seems to have some anti-tussive activity. D-propoxyphene may be combined with a number of adjuvants including acetaminophen or acetylsalicylic acid. A variant on propoxyphene is formulation as the napsylate salt, which slows absorption and reduces solubility (to diminish diversion for IV delivery).

Pharmacological Actions. Although slightly less selective than morphine, propoxyphene binds primarily to μ opioid receptors and produces analgesia and other CNS effects that are similar to those seen with morphine-like opioids. It is likely that at equianalgesic doses the incidence of side effects such as nausea, anorexia, constipation, abdominal pain, and drowsiness are similar to those of codeine.

As an analgesic, propoxyphene is about one-half to two-thirds as potent as codeine given orally. A dose of 90-120 mg of propoxyphene hydrochloride administered orally would equal the analgesic effects of 60 mg of codeine, a dose that usually produces about as much analgesia as 600 mg aspirin. Combinations of propoxyphene and aspirin, like combinations of codeine and aspirin, afford a higher level of analgesia than does either agent given alone (Beaver, 1988).

Absorption, Distribution, Metabolism, and Excretion. After oral administration, concentrations of propoxyphene in plasma reach their highest values at 1-2 hours. There is great variability between subjects in the rate of clearance and the plasma concentrations that are achieved. The average $t_{1/2}$ of propoxyphene in plasma after a single dose is 6-12 hours, which is longer than that of codeine. In humans, the major route of metabolism is N-demethylation to yield norpropoxyphene. The $t_{1/2}$ of norpropoxyphene is ~30 hours, and its accumulation with repeated doses may be responsible for some of the observed toxicity (Chan and Matzke, 1987).

Toxicity. Given orally, propoxyphene is approximately one-third as potent as orally administered codeine in depressing respiration. Moderately toxic doses usually produce CNS and respiratory depression, but with still larger doses the clinical picture may be complicated by convulsions in addition to respiratory depression. Delusions, hallucinations, confusion, cardiotoxicity, and pulmonary edema also have been noted. Respiratory-depressant effects are significantly enhanced when ethanol or sedative-hypnotics are ingested concurrently. Naloxone antagonizes the respiratory-depressant, convulsant, and some of the cardiotoxic effects of propoxyphene. A second aspect of propoxyphene toxicity is liver or renal toxicity that arises when the combination medication containing acetaminophen or acetylsalicylate, respectively, is employed in conjunction with intake of those medications separately, leading to a frank overdose of these adjuvants.

Tolerance and Dependence. Very large doses (800 mg propoxyphene hydrochloride [DARVON, others] or 1200 mg of the napsylate [DARVON-N] per day) reduce the intensity of the morphine withdrawal syndrome somewhat less effectively than do 1500 mg doses of codeine. Maximal tolerated doses are equivalent to daily

doses of 20–25 mg morphine given subcutaneously. The use of higher doses of propoxyphene is accompanied by untoward effects including toxic psychoses. Very large doses produce some respiratory depression in morphine-tolerant addicts, suggesting that cross-tolerance between propoxyphene and morphine is incomplete. Abrupt discontinuation of chronically administered propoxyphene hydrochloride (up to 800 mg/day given for almost 2 months) results in mild abstinence phenomena, and large oral doses (300–600 mg) produce subjective effects that are considered pleasurable by postaddicts. The drug is quite irritating when administered either intravenously or subcutaneously, so abuse by these routes results in severe damage to veins and soft tissues.

Therapeutic Uses. In 2009, the European Medicines Agency completed a review of the safety and effectiveness of dextro-propoxyphene-containing medicines and concluded that the benefits do not outweigh the risks and recommended a gradual withdrawal of marketing authorization throughout the EU (European Medicines Agency, 2009). The conclusion reached by the agency included an assessment that dextropropoxyphene-containing medicines are weak painkillers with a limited effectiveness in the treatment of pain and a narrow therapeutic index. Furthermore, the agency judged acetaminophen (paracetamol) containing combinations with dextro-propoxyphene to be no more effective than acetaminophen alone. In the U.S., propoxyphene has been approved for mild to moderate pain since 1957. Recently the drug has been labeled with additional warnings related to the risk of rapidly fatal effects in the event of an overdose (FDA, 2009). Thus, in the U.S., propoxyphene should not be prescribed to patients who are suicidal or have a history of suicidal ideation. In addition, higher than expected serum levels of propoxyphene should be anticipated from the concomitant administration of strong CYP3A4 inhibitors such as ritonavir, ketoconazole, itraconazole, clarithromycin, nelfinavir, nefazadone, amiodarone, amprenavir, aprepitant, diltiazem, erythromycin, fluconazole, fosamprenavir, grapefruit juice, and verapamil. Propoxyphene alternatives should be considered for patients receiving a strong CYP3A4 inhibitor and others at risk for overdose, particularly those with pre-existing heart disease.

Other Opioid Agonists

Tramadol. Tramadol (ULTRAM) is a synthetic codeine analog that is a weak MOR agonist. Part of its analgesic effect is produced by inhibition of uptake of norepinephrine and serotonin. In the treatment of mild to moderate pain, tramadol is as effective as morphine or meperidine. However, for the treatment of severe or chronic pain, tramadol is less effective. Tramadol is as effective as meperidine in the treatment of labor pain and may cause less neonatal respiratory depression.

Pharmacokinetics. Tramadol is 68% bioavailable after a single oral dose and 100% available when administered intramuscularly. Its affinity for the μ opioid receptor is only 1/6000 that of morphine. However, the primary O-demethylated metabolite of tramadol is two to four times as potent as the parent drug and may account for part of the analgesic effect. Tramadol is supplied as a racemic mixture, which is more effective than either enantiomer alone. The (+)-enantiomer binds to the receptor and inhibits serotonin uptake. The (–)-enantiomer inhibits norepinephrine uptake and stimulates α_2 adrenergic receptors (Lewis and Han, 1997). Tramadol undergoes

extensive hepatic metabolism by a number of pathways, including CYP2D6 and CYP3A4, as well as by conjugation with subsequent renal excretion. The rate of formation of the active metabolite is dependent on CYP2D6 and therefore is subject to both metabolic induction and inhibition. The elimination $t_{1/2}$ is 6 hours for tramadol and 7.5 hours for its active metabolite. Analgesia begins within an hour of oral dosing and peaks within 2–3 hours. The duration of analgesia is ~6 hours. The maximum recommended daily dose is 400 mg.

Side Effects and Adverse Effects. Common side effects of tramadol include nausea, vomiting, dizziness, dry mouth, sedation, and headache. Respiratory depression appears to be less than with equianalgesic doses of morphine, and the degree of constipation is less than that seen after equivalent doses of codeine (Duthie, 1998). Tramadol can cause seizures and possibly exacerbate seizures in patients with predisposing factors. While tramadol-induced analgesia is not entirely reversible by naloxone, tramadol-induced respiratory depression is reversed by naloxone. However, the use of naloxone increases the risk of seizure in patients exposed to tramadol. Misuse, diversion, physical dependence, abuse, addiction, and withdrawal have been reported in conjunction with the use of tramadol. Tramadol has been shown to reinstate physical dependence in some patients who have previously been dependent on other opioids, thus it should be avoided in patients with a history of addiction. Precipitation of withdrawal necessitates that tramadol be tapered prior to discontinuation. Tramadol should not be used in patients taking MAO inhibitors (Lewis and Han, 1997), SSRIs, or other drugs that lower the seizure threshold (described earlier).

Tapentadol. Tapentadol (NUCYNTA) is structurally and mechanistically similar to tramadol. It displays a mild opioid activity and possesses monoamine reuptake inhibitor activity. It is considered similar to tramadol in activity, efficacy, and side-effect profile. Like tramadol, it should not be used concurrently with agents that enhance monoamine activity or lower the seizure threshold, such as MAO inhibitors and SSRIs. The major pathway of tapentadol metabolism is conjugation with glucuronic acid; ~70% of the dose is excreted in urine in the conjugated form.

OPIOID AGONISTS/ANTAGONISTS AND PARTIAL AGONISTS

The drugs described in this section differ from clinically used μ opioid receptor agonists. Drugs such as nalbuphine and butorphanol are competitive MOR antagonists but exert their analgesic actions by acting as agonists at KOR receptors. Pentazocine qualitatively resembles these drugs, but it may be a weaker MOR receptor antagonist or partial agonist while retaining its KOR agonist activity. Buprenorphine, on the other hand, is a partial agonist at MOR. The stimulus for the development of mixed agonist–antagonist drugs was a desire for analgesics with less respiratory depression and addictive potential. However, the clinical use of these compounds is limited by undesirable side-effects and limited analgesic effects.

Pentazocine

Pentazocine was synthesized as part of a deliberate effort to develop an effective analgesic with little or no abuse potential. It has agonistic actions and weak opioid antagonistic activity.

Pharmacological Actions and Side Effects. The pattern of CNS effects produced by pentazocine generally is similar to that of the morphine-like opioids, including analgesia, sedation, and respiratory depression. The analgesic effects of pentazocine are due to agonistic actions at opioid receptors. Higher doses of pentazocine (60–90 mg) elicit dysphoric and psychotomimetic effects. The mechanisms responsible for these side effects are not known but might involve activation of supraspinal receptors because it has been suggested that these untoward effects may be reversible by naloxone.

The cardiovascular responses to pentazocine differ from those seen with typical receptor agonists, in that high doses cause an increase in blood pressure and heart rate. Pentazocine acts as a weak antagonist or partial agonist at opioid receptors. Pentazocine does not antagonize the respiratory depression produced by morphine. However, when given to patients dependent on morphine or other MOR agonists, pentazocine may precipitate withdrawal. Ceiling effects for analgesia and respiratory depression are observed at doses above 50–100 mg of pentazocine (Bailey and Stanley, 1994).

Therapeutic Uses. Pentazocine lactate (TALWIN) injection is indicated for the relief of moderate to severe pain and is also used as a preoperative medication and as a supplement to anesthesia. Pentazocine tablets for oral use are only available in fixed-dose combinations with acetaminophen (TALACEN, others) or naloxone (TALWIN NX). Combination of pentazocine with naloxone reduces the potential misuse of tablets as a source of injectable pentazocine by producing undesirable effects in subjects dependent on opioids. After oral ingestion, naloxone is destroyed rapidly by the liver. An oral dose of ~50 mg pentazocine results in analgesia equivalent to that produced by 60 mg of orally administered codeine.

Nalbuphine

Nalbuphine is related structurally to naloxone and oxymorphone (Figure 18–8). It is generally considered to be a KOR agonist-MOR antagonist opioid with a spectrum of effects that qualitatively resembles that of pentazocine; however, nalbuphine is considered to be less likely to produce dysphoric side effects than is pentazocine.

Pharmacological Actions and Side Effects. An intramuscular dose of 10 mg nalbuphine is equianalgesic to 10 mg morphine, with similar onset and duration of analgesic and subjective effects. Nalbuphine depresses respiration as much as do equianalgesic doses of morphine; however, nalbuphine exhibits a ceiling effect such that increases in dosage beyond 30 mg produce no further respiratory depression as well as no further analgesia. In contrast to pentazocine and butorphanol, 10 mg nalbuphine given to patients with stable coronary artery disease does not produce an increase in cardiac index, pulmonary arterial pressure, or cardiac work, and systemic blood pressure is not significantly altered; these indices also are

relatively stable when nalbuphine is given to patients with acute myocardial infarction (Roth et al., 1988); nevertheless, morphine is generally considered a first-line agent for use during acute cardiac events to relieve chest pain and anxiety. The GI effects of nalbuphine probably are similar to those of pentazocine. Nalbuphine produces few side effects at doses of 10 mg or less; sedation, sweating, and headache are the most common. At much higher doses (70 mg), psychotomimetic side effects (e.g., dysphoria, racing thoughts, and distortions of body image) can occur. Nalbuphine is metabolized in the liver and has a plasma $t_{1/2}$ of 2–3 hours. Nalbuphine is 20–25% as potent when administered orally as when given intramuscularly. No oral dosage forms are commercially available in the U.S.

Tolerance and Physical Dependence. In subjects dependent on low doses of morphine (60 mg/day), nalbuphine precipitates an abstinence syndrome. Prolonged administration of nalbuphine can produce physical dependence. The withdrawal syndrome is similar in intensity to that seen with pentazocine. The potential for abuse of parenteral nalbuphine in subjects not dependent on receptor agonists probably is similar to that for parenteral pentazocine.

Therapeutic Use. Nalbuphine hydrochloride (NUBAIN, others) is used to produce analgesia. Because it is an agonist–antagonist, administration to patients who have been receiving morphine-like opioids may create difficulties unless a brief drug-free interval is interposed. The usual adult dose is 10 mg parenterally every 3–6 hours; this may be increased to 20 mg in nontolerant individuals. A caveat: agents that act through the KOR have been reported to be relatively more effective in women than in men (Gear et al., 1999).

Butorphanol

Butorphanol is a morphinan congener with a profile of actions similar to those of pentazocine and nalbuphine: KOR agonist-MOR antagonist opioid. The structural formula of butorphanol is shown in Figure 18–8.

Therapeutic Use. In general, butorphanol tartrate (STADOL, others) is considered to be best suited for the relief of acute pain (e.g., postoperative), and because of its potential for antagonizing MOR agonists should not be used in combination. Because of its side effects on the heart, it is less useful than morphine or meperidine in patients with congestive heart failure or myocardial infarction. The usual dose is 1–4 mg of the tartrate given intramuscularly, or 0.5–2 mg given intravenously, every 3–4 hours. A nasal formulation is available and has proven to be effective in pain relief, including migraine pain. This formulation may be particularly useful for patients with severe headaches who are unresponsive to other forms of treatment.

Pharmacological Actions and Side Effects. In postoperative patients, a parenteral dose of 2–3 mg butorphanol produces analgesia and respiratory depression approximately equal to that produced by 10 mg morphine or 80–100 mg meperidine; the onset, peak, and duration of action are similar to those that follow the administration of morphine. The plasma $t_{1/2}$ of butorphanol is ~3 hours. Like pentazocine, analgesic doses of butorphanol produce an increase in pulmonary arterial pressure and in the work of the heart; systemic arterial pressure is slightly decreased (Popio et al., 1978).

The major side effects of butorphanol are drowsiness, weakness, sweating, feelings of floating, and nausea. While the incidence

510 of psychotomimetic side effects is lower than that with equianalgesic doses of pentazocine, they are qualitatively similar. Nasal administration is associated with drowsiness and dizziness. Physical dependence can occur.

Buprenorphine

Buprenorphine is a highly lipophilic MOR agonist derived from thebaine (Figure 18–8). It is 25–50 times more potent than morphine, though it is considered to be a partial MOR agonist (e.g., has limited intrinsic activity) and accordingly can display antagonism when used in conjunction with a full agonist (see below).

Pharmacological Actions and Side Effects. Buprenorphine produces analgesia and other CNS effects that are qualitatively similar to those of morphine. About 0.4 mg buprenorphine is equianalgesic with 10 mg morphine given intramuscularly (Wallenstein et al., 1986). Although variable, the duration of analgesia usually is longer than that of morphine. Some of the subjective and respiratory-depressant effects are unequivocally slower in onset and last longer than those of morphine. For example, peak miosis occurs ~6 hours after intramuscular injection, whereas maximal respiratory depression is observed at ~3 hours.

Because buprenorphine is a partial MOR agonist, it may cause symptoms of abstinence in patients who have been receiving receptor agonists for several weeks. It antagonizes the respiratory depression produced by anesthetic doses of fentanyl about as well as naloxone without completely reversing opioid pain relief (Boysen and Hertel, 1988). Although respiratory depression has not been a major problem, it is not clear whether there is a ceiling for this effect (as seen with nalbuphine and pentazocine). The respiratory depression and other effects of buprenorphine can be prevented by prior administration of naloxone, but they are not readily reversed by high doses of naloxone once the effects have been produced. This suggests that buprenorphine dissociates very slowly from opioid receptors. The $t_{1/2}$ for dissociation from the receptor is 166 minutes for buprenorphine, as opposed to 7 minutes for fentanyl (Boas and Villiger, 1985). Therefore, plasma levels of buprenorphine may not parallel clinical effects. Cardiovascular and other side effects (e.g., sedation, nausea, vomiting, dizziness, sweating, and headache) appear to be similar to those of morphine-like opioids.

Buprenorphine is relatively well absorbed by most routes. Administered sublingually, the drug (0.4–0.8 mg) produces satisfactory analgesia in postoperative patients. Concentrations in blood peak within 5 minutes of intramuscular injection and within 1–2 hours of oral or sublingual administration. While the plasma $t_{1/2}$ in plasma is ~3 hours, this value bears little relationship to the rate of disappearance of effects (discussed earlier). Both N-dealkylated and conjugated metabolites are detected in the urine, but most of the drug is excreted unchanged in the feces. About 96% of the circulating drug is bound to protein.

Physical Dependence. When buprenorphine is discontinued, a withdrawal syndrome develops that is delayed in onset for 2–14 days; this consists of typical but generally not very severe morphine-like withdrawal signs and symptoms, and it persists for 1–2 weeks (Fudala et al., 1989).

Therapeutic Uses. Buprenorphine (BUPRENEX) injection is indicated for use as an analgesic. In the U.S., use of the oral formulations of

buprenorphine (SUBUTEX) and buprenorphine in fixed-dose combination with naloxone (SUBOXONE) is limited to the treatment of opioid dependence by the Drug Addiction Treatment Act (DATA) of 2000 [21 U.S.C. 823(g)]. This act created an opportunity for clinicians with special training to be exempted from the requirement to obtain a special DEA license when using buprenorphine to treat opioid addicts. The usual intramuscular or intravenous dose for analgesia is 0.3 mg given every 6 hours. Buprenorphine is metabolized to norbuprenorphine by CYP3A4. Thus, care should be taken in treating patients who also are taking known inhibitors of CYP3A4 (e.g., azole antifungals, macrolide antibiotics, and HIV protease inhibitors), as well as drugs that induce CYP3A4 activity (e.g., certain anticonvulsants and rifampin).

Buprenorphine for the treatment of opioid addiction is initiated with sublingual drug, followed by maintenance therapy with a fixed-dose combination formulation of buprenorphine and naloxone. The partial agonist properties of buprenorphine limit its utility in the treatment of addicts who require high maintenance doses of opioids (Kreek et al., 2002).

OPIOID ANTAGONISTS

A variety of agents bind competitively to one or more of the opioid receptors, display little or no intrinsic activity, and robustly antagonize the effects of receptor agonists. These agents have obvious therapeutic utility in the treatment of opioid overdose. Under ordinary circumstances, these opioid antagonists produce few effects in the absence of an exogenous agonist. However, under certain conditions (e.g., shock), when the endogenous opioid systems are activated, the administration of an opioid antagonist alone may have visible consequences.

Chemistry. Relatively minor changes in the structure of an opioid can convert a drug that is primarily an agonist into one with antagonistic actions at one or more types of opioid receptors. The most common such substitution is that of a larger moiety (e.g., an allyl or methylcyclopropyl group) for the N-methyl group that is typical of the MOR agonists. Such substitutions transform morphine to nalorphine, levorphanol to levallorphan, and oxymorphone to naloxone (NARCAN, others) or naltrexone (REVIA, VIVITROL, others) (Figure 18–8). In some cases, congeners are produced that are competitive antagonists at MOR but that also have agonistic actions at KORs. Nalorphine and levallorphan have such properties. Other congeners, especially naloxone and naltrexone, appear to be devoid of agonistic actions and interact with all types of opioid receptors, albeit with somewhat different affinities (Martin, 1983). Nalmefene (no longer marketed in the U.S.) is a relatively pure MOR antagonist that is more potent than naloxone (Dixon et al., 1986). A number of other non-peptide antagonists have been developed that are relatively selective for individual types of opioid receptors. These include cyprodime and β funaltrexamine, for MOR; naltrindole for DOR; and norbinaltorphimine for KOR (Portoghese, 1989), though these agents are not in clinical use.

The majority of the agents noted above are relatively lipid soluble and have excellent CNS bioavailability after systemic delivery. A recognition that there was a need for antagonism limited to

peripheral sites led to the development of agents that have poor CNS bioavailability such as methylnaltrexone (RELISTOR).

Pharmacological Properties

If endogenous opioid systems have not been activated, the profile of opioid antagonist effects depend the presence or absence of the exogenous opioid agonist and on the degree to which physical dependence on an opioid has developed.

Effects in the Absence of Opioid Agonists. Subcutaneous doses of naloxone up to 12 mg produce no discernible subjective effects in humans, and 24 mg causes only slight drowsiness. Naltrexone also appears to be a relatively pure antagonist but with higher oral efficacy and a longer duration of action.

The effects of opiate receptor antagonists are usually both subtle and limited. Most likely this reflects the low levels of tonic activity and organizational complexity of the opioid systems in various physiologic systems (Drolet et al., 2001). In the face of a variety of physical (pain) or psychological stressors, an increased release of a variety of opioid peptides occurs. Many stressors will activate central circuits. Changes in circulating levels of endorphins in plasma are often cited in events such as runner's high, yet such peripheral changes have little significance to central systems, given the minimal ability of these peptides to penetrate the blood-brain barrier.

Pain. Opiate antagonism in humans is associated with variable effects ranging from no effect to a mild hyperalgesia and even hypoalgesia as measured in a variety of well-controlled experimental pain paradigms (France et al., 2007). A number of studies have, however, suggested that agents such as naloxone appear to attenuate the analgesic effects of placebo medications and acupuncture (Benedetti and Amanzio, 1997).

Stress. Even at high doses of different antagonists, normal subjects typically show modest changes in blood pressure or heart rate. In laboratory animals, the administration of naloxone will reverse or attenuate the hypotension associated with shock of diverse origins, including that caused by anaphylaxis, endotoxin, hypovolemia, and injury to the spinal cord; opioid agonists aggravate these conditions (Amir, 1988; Faden, 1988).

Affect. High doses of naltrexone appeared to cause mild dysphoria in one study but little or no subjective effects in others (Gonzalez and Brogden, 1988).

Endocrine Effects. Endogenous opioid peptides participate in the regulation of pituitary secretion apparently by exerting tonic inhibitory effects on the release of certain hypothalamic hormones (Chapter 38). Thus, the administration of naloxone or naltrexone increases the secretion of gonadotropin-releasing hormone and corticotropin-releasing hormone and elevates the plasma concentrations of LH, FSH, and ACTH, as well as the steroid hormones produced by their target organs. Antagonists do not consistently alter basal or stress-induced concentrations of prolactin in plasma in men; paradoxically, naloxone stimulates the release of prolactin in women. Opioid antagonists augment the increases in plasma concentrations of cortisol and catecholamines that normally accompany stress or exercise.

Endogenous opioid peptides probably have some role in the regulation of feeding or energy metabolism: in laboratory models, opioid antagonists increase energy expenditure, interrupt hibernation in appropriate species, induce weight loss, and prevent stress-induced overeating and obesity. These observations have led to the experimental use of opioid antagonists in the treatment of human obesity, especially that associated with stress-induced eating disorders. However, naltrexone does not accelerate weight loss in very obese subjects, even though short-term administration of opioid antagonists reduces food intake in lean and obese individuals (Atkinson, 1987).

Even after prolonged administration of high doses of the antagonist alone, discontinuation of naloxone is not followed by any recognizable withdrawal syndrome, and the withdrawal of naltrexone, another relatively pure antagonist, produces very few signs and symptoms. However, long-term administration of antagonists increases the density of opioid receptors in the brain and causes a temporary exaggeration of responses to the subsequent administration of opioid agonists (Yoburn et al., 1988). Naltrexone and naloxone have no known potential for abuse.

Effects in the Presence of Opioid Agonists

Actions on Acute Opioid Effects. Small doses (0.4-0.8 mg) of naloxone given intramuscularly or intravenously prevent or *promptly* reverse the effects of receptor agonists. In patients with respiratory depression, an increase in respiratory rate is seen within 1-2 minutes. Sedative effects are reversed, and blood pressure, if depressed, returns to normal. Higher doses of naloxone are required to antagonize the respiratory-depressant effects of buprenorphine; 1 mg naloxone intravenously completely blocks the effects of 25 mg heroin. Naloxone reverses the psychotomimetic and dysphoric effects of agonist-antagonist agents such as pentazocine, but much higher doses (10-15 mg) are required. The duration of antagonistic effects depends on the dose but usually is 1-4 hours. Antagonism of opioid effects by naloxone often is accompanied by an "overshoot" phenomenon. For example, respiratory rate depressed by opioids transiently becomes higher than that before the period of depression. Rebound release of catecholamines may cause hypertension, tachycardia, and ventricular arrhythmias. Pulmonary edema also has been reported after naloxone administration.

Effects in Opioid-Dependent Patients. In subjects who are dependent on morphine-like opioids, small subcutaneous doses of naloxone (0.5 mg) precipitate a moderate to severe withdrawal syndrome that is very similar to that seen after abrupt withdrawal of opioids, except that the syndrome appears within minutes of administration and subsides in ~2 hours. The severity and duration of the syndrome are related to the dose of the antagonist and to the degree and type of dependence. Higher doses of naloxone will precipitate a withdrawal

512 syndrome in patients dependent on pentazocine, butorphanol, or nalbuphine. Naloxone produces overshoot phenomena suggestive of early acute physical dependence 6-24 hours after a single dose of an μ agonist (Heishman et al., 1989). In dependent patients, peripheral side-effects, notably reduced GI motility and constipation, can be reversed by methylnaltrexone with doses of 0.15 mg/kg subcutaneously, producing reliable bowel movements and no evidence of centrally mediated withdrawal signs (Thomas et al., 2008).

Absorption, Distribution, Metabolism, and Excretion

Although absorbed readily from the GI tract, naloxone is almost completely metabolized by the liver before reaching the systemic circulation and thus must be administered parenterally. The drug is absorbed rapidly from parenteral sites of injection and is metabolized in the liver primarily by conjugation with glucuronic acid; other metabolites are produced in small amounts. The $t_{1/2}$ of naloxone is ~1 hour, but its clinically effective duration of action can be even less.

Compared with naloxone, naltrexone retains much more of its efficacy by the oral route, and its duration of action approaches 24 hours after moderate oral doses. Peak concentrations in plasma are reached within 1-2 hours and then decline with an apparent $t_{1/2}$ of ~3 hours; this value does not change with long-term use. Naltrexone is metabolized to 6-naltrexol, which is a weaker antagonist but has a longer $t_{1/2}$, ~13 hours. Naltrexone is much more potent than naloxone, and 100 mg oral doses given to patients addicted to opioids produce concentrations in tissues sufficient to block the euphoric effects of 25-mg intravenous doses of heroin for 48 hours (Gonzalez and Brogden, 1988). Methylnaltrexone is handled similarly to naltrexone. It is converted to methyl-6-naltrexol isomers and is largely eliminated primarily as the unchanged drug with significant active renal secretion. The terminal disposition $t_{1/2}$ of methylnaltrexone is ~8 hours.

Therapeutic Uses

Treatment of Opioid Overdose. Opioid antagonists, particularly naloxone, have an established use in the treatment of opioid-induced toxicity, especially respiratory depression. Its specificity is such that reversal by this agent is virtually diagnostic for the contribution of an opiate to the depression. Naloxone acts rapidly to reverse the respiratory depression associated with high doses of opioids. It should be used cautiously because it also can precipitate withdrawal in dependent subjects and cause undesirable cardiovascular side effects. By carefully titrating the dose of naloxone, it usually is possible to rapidly antagonize the respiratory-depressant actions without eliciting a fully expressed withdrawal syndrome. The duration of action of naloxone is relatively short, and it often must be given repeatedly or by continuous infusion. Opioid antagonists also have been employed effectively to decrease neonatal respiratory depression

secondary to the intravenous or intramuscular administration of opioids to the mother. In the neonate, the initial dose is 10 μ g/kg given intravenously, intramuscularly, or subcutaneously.

Management of Constipation. The peripherally limited antagonists such as methylnaltrexone have a very important role in the management of the constipation and the reduced GI motility present in the patient undergoing chronic opioid therapy (as for chronic pain or methadone maintenance) and have been approved by the FDA for that use. With distribution restricted to the periphery, these agents do not alter central opioid agonist actions. Worrisome reports of GI perforation in this setting are under review by FDA. Other strategies for the management of opioid-induced constipation are described in Chapter 46.

Management of Abuse Syndromes. There is considerable interest in the use of opiate antagonists such as naltrexone as an adjuvant in treating a variety of non-opioid dependency syndromes such as alcoholism (Chapters 23 and 24), where an opiate antagonist decreases the chance of relapse (Anton, 2008). Interestingly, patients with a single nucleotide polymorphism (SNP) in the MOR gene have significantly lower relapse rates to alcoholism when treated with naltrexone (Haile et al., 2008). Naltrexone is FDA-approved for treatment of alcoholism.

Trauma. The potential utility of opiate antagonists in the treatment of shock, stroke, spinal cord and brain trauma, and other disorders that may involve mobilization of endogenous opioid peptides has been reported; but opioid antagonists have failed to demonstrate neuroprotective benefits and their study in trauma has been largely abandoned (Hawryluk et al., 2008).

CENTRALLY ACTIVE ANTITUSSIVES

Cough is a useful physiological mechanism that serves to clear the respiratory passages of foreign material and excess secretions. It should not be suppressed indiscriminately. There are, however, many situations in which cough does not serve any useful purpose but may, instead, annoy the patient, prevent rest and sleep, or hinder adherence to otherwise beneficial medication regimens (e.g., angiotension-converting enzyme (ACE) inhibitor-induced cough). Chronic cough can contribute to fatigue, especially in elderly patients. In such situations, the physician should try to substitute a drug with a different side effect profile (e.g., an AT_1 antagonist in place of an ACE inhibitor) or add an antitussive agent that will reduce the frequency or intensity of the coughing (Chapters 12 and 36).

A number of drugs reduce cough as a result of their central actions, including opioid analgesics (codeine, hydrocodone, and dihydrocodeine are the opioids most commonly used to suppress cough). Cough suppression often occurs with lower doses of opioids than those needed for analgesia. A 10- or 20-mg oral dose of codeine, although ineffective for analgesia,

produces a demonstrable antitussive effect, and higher doses produce even more suppression of chronic cough. A few other antitussive agents are noted below.

Dextromethorphan

Dextromethorphan (D-3-methoxy-N-methylmorphinan) is the D-isomer of the codeine analog methorphan; however, unlike the L-isomer, it has no analgesic or addictive properties and does not act through opioid receptors. The drug acts centrally to elevate the threshold for coughing. Its effectiveness in patients with pathological cough has been demonstrated in controlled studies; its potency is nearly equal to that of codeine. Compared with codeine, dextromethorphan produces fewer subjective and GI side effects (Matthys et al., 1983). In therapeutic dosages, the drug does not inhibit ciliary activity, and its antitussive effects persist for 5-6 hours. Its toxicity is low, but extremely high doses may produce CNS depression.

Sites that bind dextromethorphan with high affinity have been identified in membranes from various regions of the brain (Craviso et al., 1983). Although dextromethorphan is known to function as an NMDA-receptor antagonist, the dextromethorphan binding sites are not limited to the known distribution of NMDA receptors (Elliott et al., 1994). Thus, the mechanism by which dextromethorphan exerts its antitussive effect still is not clear.

The average adult dosage of dextromethorphan hydrobromide is 10-30 mg three to six times daily, not to exceed 120 mg daily. The drug is marketed for over-the-counter sale in liquids, syrups, capsules, soluble strips, lozenges, and freezer pops or in combinations with antihistamines, bronchodilators, expectorants, and decongestants. An extended-release dextromethorphan suspension (DELSYM) is approved for twice daily administration.

Two other antitussives not currently recognized as generally safe and effective (GRAS/E) by the FDA, carbetapentane (pentoxiverine) and caramiphen, are known to bind avidly to the dextromethorphan binding sites; codeine, levopropoxyphene, and other antitussive opioids (as well as naloxone) do not bind. Although noscapine (discussed later) enhances the affinity of dextromethorphan, it appears to interact with distinct binding sites (Karlsson et al., 1988). The relationship of these binding sites to antitussive actions is not known; however, these observations, coupled with the ability of naloxone to antagonize the antitussive effects of codeine but not those of dextromethorphan, indicate that cough suppression can be achieved by a number of different mechanisms.

Other Antitussives

Pholcodine [3-O-(2-morpholinoethyl) morphine] is used clinically in many countries outside the U.S. Although structurally related to the opioids, pholcodine has no opioid-like actions because the substitution at the 3-position is not removed by metabolism. Pholcodine is at least as effective as codeine as an antitussive; it has a long $t_{1/2}$ and can be given once or twice daily.

Benzonatate (TESSALON, others) is a long-chain polyglycol derivative chemically related to procaine and believed to exert its antitussive action on stretch or cough receptors in the lung, as well as by a central mechanism. It is available in oral capsules and the dosage is 100 mg three times daily; doses as high as 600 mg daily have been used safely.

ROUTES OF ANALGESIC DRUG ADMINISTRATION

In addition to the traditional oral and parenteral formulations for opioids, many other methods of administration have been developed in an effort to improve therapeutic efficacy while minimizing side effects. These alternative routes generally improve the ease of use of opioids and some increase patient satisfaction.

Patient-Controlled Analgesia (PCA)

With this modality, the patient has limited control of the dosing of opioid from an infusion pump programmed within tightly mandated parameters. PCA can be used for intravenous, epidural, or intrathecal administration of opioids. This technique avoids delays inherent in administration by a caregiver and generally permits better alignment between pain control and individual differences in pain perception and responsiveness to opioids. The PCA technique also gives the patient a greater sense of control over the pain. With shorter-acting opioids, serious toxicity or excessive use rarely occurs; however, caution is warranted due to the potential for serious medication errors associated with this delivery method. PCA is suitable for adults and children capable of understanding the principles involved. It is generally conceded that PCA is preferred over intramuscular injections for postoperative pain control.

Spinal Delivery

Administration of opioids into the epidural or intrathecal space provides more direct access to the first pain-processing synapse in the dorsal horn of the spinal cord. This permits the use of doses substantially lower than those required for oral or parenteral administration (Table 18-3). Systemic side effects of opioid administration thus are decreased. In postoperative pain management sustained release epidural injections are accomplished through the incorporation of morphine into a liposomal formulation (DEPODUR), providing up to 48 hours of pain relief (Hartrick and Hartrick, 2008). The management of chronic pain with spinal opiates has been addressed by the use of chronically implanted intrathecal catheters connected to subcutaneously implanted refillable pumps (Wallace and Yaksh, 2000).

Though they have important therapeutic uses, epidural and intrathecal opioids have their own dose-dependent side effects, such as pruritis, nausea, vomiting, respiratory depression, and urinary retention. Hydrophilic opioids such as morphine (DURAMORPH, others)

Table 18–3

Epidural or Intrathecal Opioids for the Treatment of Acute (Bolus) or Chronic (Infusion) Pain

DRUG	SINGLE DOSE (mg) ^a	INFUSION RATE (mg/h) ^b	ONSET (min)	DURATION OF EFFECT OF A SINGLE DOSE (h) ^c
Epidural				
Morphine	1-6	0.1-1.0	30	6-24
Meperidine	20-150	5-20	5	4-8
Methadone	1-10	0.3-0.5	10	6-10
Hydromorphone	1-2	0.1-0.2	15	10-16
Fentanyl	0.025-0.1	0.025-0.10	5	2-4
Sufentanil	0.01-0.06	0.01-0.05	5	2-4
Alfentanil	0.5-1	0.2	15	1-3
Subarachnoid (Intrathecal)				
Morphine	0.1-0.3		15	8-24+
Fentanyl	0.005-0.025		5	3-6

^aLow doses may be effective when administered to the elderly or when injected in the thoracic region.

^bIf combining with a local anesthetic, consider using 0.0625% bupivacaine. ^cDuration of analgesia varies widely; higher doses produce longer duration. With the exception of epidural/intrathecal morphine or epidural sufentanil, all other spinal opioid use is considered to be off label.

Adapted from International Association for the Study of Pain, 1992.

have a longer residence times in the cerebrospinal fluid; as a consequence, after intrathecal or epidural morphine, delayed respiratory depression can be observed for as long as 24 hours after a bolus dose. While the risk of delayed respiratory depression is reduced with more lipophilic opioids, it is not eliminated. Extreme vigilance and appropriate monitoring are required for all opioid-naïve patients receiving intraspinal narcotics. Use of intraspinal opioids in the opioid-naïve patient is reserved for postoperative pain control in an inpatient monitored setting. Epidural administration of opioids has become popular in the management of postoperative pain and for providing analgesia during labor and delivery. Lower systemic opioid levels are achieved with epidural opioids, leading to less placental transfer and less potential for respiratory depression of the newborn (Shnider and Levinson, 1987). Many opioids and other adjuvants are commonly used for neuraxial administration in adults and children; however, the majority of agents employed have not undergone appropriate preclinical safety evaluation and approval for these clinical indications; thus, such uses are “off-label”. Thus, at this time, those agents approved for spinal delivery are certain preservative-free formulations of morphine sulfate (DURAMORPH, DEPODUR, others) and sufentanil (SUFENTA). It is important to remember that the spinal route of delivery represents a novel environment wherein the neuraxis may be exposed to exceedingly high concentrations of an agent for an extended period of time and safety by another route (e.g., PO, IV) may not translate to safety after spinal delivery (Yaksh and Allen, 2004).

Patients on chronic spinal opioid therapy are less likely to experience respiratory depression. Selected patients who fail conservative therapies for chronic pain may receive intraspinal opioids chronically through an implanted programmable pump.

Analogous to the relationship between systemic opioids and NSAIDs, intraspinal narcotics often are combined with other agents that include local anesthetics, N-type Ca²⁺ channel blockers (e.g., ziconotide), α₂ adrenergic agonists, and GABA_B agonists. This permits synergy between drugs with different mechanisms allowing the use

of lower concentrations of both agents, minimizing side-effects and the opioid-induced complications (Wallace and Yaksh, 2000).

Local Drug Action

Opioid receptors on peripheral sensory nerves respond to locally applied opioids during inflammation (Stein, 1993). Peripheral analgesia permits the use of lower doses, applied locally, than those necessary to achieve a systemic effect. The pain relief generated by this route of delivery is limited but the technique has been demonstrated to have some efficacy in postoperative pain (Stein, 1993). Development of such compounds and expansion of clinical applications of this technique are active areas of research.

Rectal Administration

This route is an alternative for patients with difficulty swallowing or other oral pathology and who prefer a less invasive route than parenteral administration. This route is not well tolerated by most children. Onset of action is within 10 minutes. In the U.S., only morphine and hydromorphone are available in rectal suppository formulations.

Inhalation

Opioids can be delivered by nebulizer. However, this delivery method is rarely used due to erratic absorption from the lung and highly variable therapeutic effect.

Oral Transmucosal Administration

Opioids can be absorbed through the oral mucosa more rapidly than through the stomach. Bioavailability is greater owing to avoidance of first-pass metabolism, and lipophilic opioids are absorbed better by this route than are hydrophilic compounds such as morphine. A transmucosal delivery system that suspends fentanyl in a dissolvable sugar-based lollipop (ACTIQ, others) or rapidly dissolving buccal tablet (FENTORA) have been approved for the treatment of cancer pain; in this setting, transmucosal fentanyl relieves pain within 15 minutes, and patients easily can titrate the appropriate dose.

A buccal fentanyl “film” is FDA-approved for the treatment of cancer pain (ONSOLIS). The film is applied to the buccal mucosa and slowly dissolves releasing the fentanyl to cross the mucosa into the bloodstream. A New Drug Application has been filed with the FDA for a sublingual tablet (ABSTRAL, formerly RAPINYL). Transmucosal fentanyl also has been studied as a premedicant for children; however, this technique has been largely abandoned owing to undesirable side effects such as respiratory depression, sedation, nausea, vomiting, and pruritus.

Transnasal Administration

Butorphanol, a KOR agonist/MOR antagonist has been employed intranasally. A transnasal pectin-based fentanyl spray is currently in clinical trials for the treatment of cancer related pain. Administration is well tolerated and pain relief occurs within 10 minutes of delivery (Kress et al., 2009).

Transdermal and Iontophoretic Administration

Transdermal fentanyl patches are approved for use in sustained pain. The opioid permeates the skin, and a “depot” is established in the stratum corneum layer. Unlike other transdermal systems (i.e., transdermal scopolamine), anatomic position of the patch does not affect absorption. However, fever and external heat sources (heating pads, hot baths) can increase absorption of fentanyl and potentially lead to an overdose (Rose et al., 1993). This modality is well suited for cancer pain treatment because of its ease of use, prolonged duration of action, and stable blood levels (Portenoy et al., 1993). It may take up to 12 hours to develop analgesia and up to 16 hours to observe full clinical effect. Plasma levels stabilize after two sequential patch applications, and the kinetics do not appear to change with repeated applications (Portenoy et al., 1993). However, there may be a great deal of variability in plasma levels after a given dose. The plasma $t_{1/2}$ after patch removal is ~17 hours. Thus, if excessive sedation or respiratory depression is experienced, antagonist infusions may need to be maintained for an extended period. Dermatological side effects from the patches, such as rash and itching, usually are mild.

Iontophoresis is the transport of soluble ions through the skin by using a mild electric current. This technique has been employed with morphine (Ashburn et al., 1992). Unlike transdermal opioids, a drug reservoir does not build up in the skin, thus limiting the duration of both desired and undesired effects. Patient-controlled iontophoretic transdermal fentanyl systems have been developed, but none is currently marketed.

THERAPEUTIC USE OF OPIATES IN PAIN CONTROL

Management of pain is an important element in any therapeutic intervention. Failure to adequately manage pain can have important negative consequences on physiological function such as autonomic hyper-reactivity (increased blood pressure, heart rate, suppression of gastrointestinal motility, reduced secretions), reduced mobility leading to deconditioning, muscle wasting, joint stiffening, and decalcification, and can contribute to deleterious changes in the psychological state (depression, helplessness syndromes, anxiety). By many hospital accrediting organizations, and by law in many states, appropriate pain assessment and adequate pain management are considered to be standard of care, with pain being considered the “fifth vital sign.”

The comments included here are only a general orientation to the principles in pain management. Extensive efforts by many individuals and organizations have resulted in the publication of many useful guidelines for the management of pain states including acute pain, cancer pain, and neuropathic pain (Table 18–4). In the case of cancer pain, adherence to standardized protocols has been shown to improve pain management

516 significantly (Du Pen et al., 1999). The next sections provide guidelines for rational drug selection, discuss routes of administration other than the standard oral and parenteral methods, and outline general principles for the use of opioids in acute and chronic pain states.

Guidelines for Opiate Dosing

Whereas the World Health Organization three-step ladder was initially targeted at the treatment of cancer pain, it is accepted practice to use this three-step ladder to treat chronic noncancer pain (Table 18–5). The three-step ladder encourages the use of more conservative therapies before initiating opioid therapy. However, in the presence of severe pain, the opioids should be considered sooner rather than later.

Numerous societies and agencies have published guidelines for the use of strong opioids in treating pain, including the American Academy of Pain Medicine, the American Pain Society, the Federation of State Medical Boards (FSMB), and the Drug Enforcement Agency. While slightly different in particulars, all guidelines to date share the criteria established by the FSMB (Table 18–6).

Table 18–5

World Health Organization Analgesic Ladder^a

Step 1 Mild to Moderate Pain

Non-opioid ± adjuvant agent

- Acetaminophen or an NSAID should be used, unless contraindicated. Adjuvant agents are those that enhance analgesic efficacy, treat concurrent symptoms that exacerbate pain, and/or provide independent analgesic activity for specific types of pain.

Step 2 Mild to Moderate Pain or Pain Uncontrolled after Step 1

Short-acting opioid as required ± non-opioid around the clock (ATC) ± adjuvant agent

- Morphine, oxycodone, or hydromorphone should be added to acetaminophen or an NSAID for maximum flexibility of opioid dose.

Step 3 Moderate to Severe Pain or Pain Uncontrolled after Step 2

Sustained release/long-acting opioid ATC or continuous infusion + short-acting opioid as required ± non-opioid ± adjuvant agent

- Sustained release oxycodone, morphine, oxymorphone or transdermal fentanyl is indicated.

^a<http://www.who.int/cancer/palliative/painladder/en/>

Guidelines for the oral and parenteral dosing of commonly used opioids are presented in Table 18–2. *Tables such as those presented here are only guidelines.* They are typically constructed with the use of these agents in the management of acute (e.g., post-operative) pain in opioid-naïve patients. A number of factors will contribute to the dosing requirement (described in subsequent sections).

Methadone is considered separately in Table 18–7 as updated safety information has emerged more recently. In 2006, the FDA notified health care professionals of reports of death and life-threatening adverse events, such as respiratory depression and cardiac arrhythmias in patients receiving methadone. Methadone is thought to be involved in about one-third of all prescription opioid-related deaths, exceeding hydrocodone and oxycodone, despite being prescribed one-tenth as often. This has led to revisions in the labeled dosing recommendations.

Variables Modifying the Therapeutic Response to Opiates

There is substantial individual variability in responses to opioids. A standard intramuscular dose of 10 mg morphine sulfate will relieve severe pain adequately in only 2 of 3 patients. The minimal effective analgesic concentration for opioids, such as morphine, meperidine (pethidine), alfentanil, and sufentanil, varies among patients by factors of 5–10 (Woodhouse and Mather, 2000). Adjustments will have to be made based on clinical response. Appropriate therapeutics typically involve undertaking a treatment strategy that most efficiently addresses the pain state, minimizes the potential for undesired drug effects, and accounts for the variables that can influence an individual patient's response to opiate analgesia.

Pain Intensity. Increased pain intensity may require titrating doses to produce acceptable analgesia with tolerable side effects.

Type of Pain State. Systems underlying a pain state may be broadly categorized as being mediated by events secondary to injury and inflammation and by injury to the sensory afferent or nervous system. Neuropathic conditions may be less efficaciously managed by opiates than pain secondary to tissue injury and inflammation. Such pain states are more efficiently managed by combination treatment modalities.

Acuity and Chronicity of Pain. The pain state in any given clinical condition is not typically constant and will vary over time. In chronic pain states, the daily course of the pain may fluctuate, e.g., being greater in the morning hours or upon awakening. Arthritic states display flares that are associated with an exacerbated pain condition. Changes in the magnitude of pain occur during the daily routine resulting in “breakthrough pain” during episodic events such as

Table 18–6

Guidelines for the Use of Opioids to Treat Chronic Pain

- *Evaluation of the patient:* A complete medical history and physical must be conducted and documented in the medical record.
- *Treatment plan:* The treatment plan should state objectives that are used to determine treatment success.
- *Informed consent and agreement:* The physician should discuss the risks, benefits, and alternatives to chronic opioid therapy with the patient. Many practitioners have developed an “opioid contract” that outlines the responsibilities of the physician and the patient for continued prescription of controlled substances.
- *Periodic review:* At reasonable intervals, the patient should be seen by the physician to review the course of treatment and document results of consultation, diagnostic, testing, laboratory results, and the success of treatment.
- *Consultation:* The physician should refer the patient for consultation when appropriate.
- *Documentation/medical records:* The physician should keep actual and complete medical records that include: (a) medical history and physical examination; (b) diagnostic, therapeutic, and laboratory results; (c) evaluations and consultations; (d) treatment objectives; (e) discussion of risks and benefits; (f) treatment; (g) medications including date, type, dosage, and quantity prescribed; (h) instructions and agreements; and (i) periodic reviews.
- *Compliance with controlled substances law and regulations:* To prescribe, dispense or administer controlled substances, the physician must be licensed in the state and comply with applicable state and federal regulations.

ressing changes (incident pain). These examples emphasize the need for individualized management of increased or decreased pain levels with baseline analgesic dosing supplemented with the use of short-acting “rescue” medications as required. In the face of ongoing severe pain, analgesics should be dosed in continuous or “around-the-clock” fashion rather than on an as-needed basis. This provides more consistent analgesic levels and avoids unnecessary suffering (Vashi et al., 2005).

Opioid Tolerance. Chronic exposure to one opiate agonist typically leads to a reduction in the efficacy of other opiate agonists. The degree of tolerance can be remarkable. For example, 10 mg of an oral opioid (such as morphine) is considered a high dose for a treatment-naïve individual whereas 100 mg IV may produce only minor sedation in severely tolerant individual.

Patient Physical State and Genetic Variables. Codeine, hydrocodone, and oxycodone are weak analgesic prodrugs that are

metabolized into the much more effective analgesic drugs morphine, hydromorphone, and oxymorphone, respectively, by CYP2D6 (Supernaw, 2001). The analgesic properties of morphine, hydromorphone, oxymorphone, propoxyphene, and fentanyl are largely due to their direct influence on opioid receptors and do not require additional metabolism, although the first metabolite of propoxyphene, norpropoxyphene, is also an effective analgesic with a very long $t_{1/2}$. CYP2D6 activity is genetically diminished in 7% of whites, 3% of blacks, and 1% of Asians (Eichelbaum and Gross, 1990); rendering oxycodone, hydrocodone, and codeine relatively ineffective analgesics in these “poor metabolizers” and potentially toxic for “ultra-rapid” metabolizers.

The activity of CYP2D6 is inhibited by selective serotonin reuptake inhibitors, including fluoxetine, fluvoxamine, paroxetine, sertraline, and bupropion, medications that are commonly administered to pain patients. The CYP2D6 inhibition resulting from these interacting medications may render opioids less effective as analgesics in some patients. Whereas diminished activity of the CYP2D6 isoenzyme will lead to less efficacy of prodrug opioids, the opposite occurs with methadone. Although methadone is primarily metabolized through the CYP3A4 isoenzyme, genetic polymorphisms involving deficiencies in the CYP2C9, CYP2C19, and CYP2D6 isoenzymes may lead to surprisingly high methadone plasma concentrations resulting in overdose.

Opioids are highly protein bound and factors such as plasma pH may dramatically change binding. In addition, α_1 -acid glycoprotein (AAG) is an acute-phase reactant protein that is elevated in cancer patients and has a high affinity for basic drugs such as methadone and meperidine. Morphine and meperidine should be avoided in patients with renal impairment since morphine-6-glucuronide (a metabolite of morphine) and normeperidine (a metabolite of meperidine) are excreted by the kidney and will accumulate and lead to toxicity. Other states that may increase the risk of adverse effects of the opioids include chronic obstructive pulmonary disease, sleep apnea, dementia, benign prostatic hypertrophy, unstable gait, and pretreatment constipation.

Table 18–7

Oral Morphine to Methadone Conversion Guidelines

DAILY MORPHINE DOSE(mg/24 h, ORALLY)	CONVERSION RATIOS	
	MORPHINE (oral)	METHADONE (oral)
< 100	3	1
101-300	5	1
301-600	10	1
601-800	12	1
801-1000	15	1
> 1001	20	1

Routes of Administration Available. The aim in chronic pain states is to prefer to employ the least invasive routes of drug administration, which include oral, buccal, or transdermal delivery. IV routes are more useful in perioperative in-hospital pain management and during end-of-life care. Patients with chronic pain states where side effects from systemic drug exposure are intolerable and are candidates for spinal drug delivery; however, this may require surgery for indwelling catheterization and pump placement.

Dose Selection/Titration. The conservative approach to the initiation of chronic opioid therapy suggests starting with low doses that may be incremented on the basis of the pharmacokinetics of the drug. In chronic pain states, the aim would be the use of long-acting medications to permit once or twice daily dosing (e.g., controlled release formulations or methadone). Such agents reach steady-state slowly. Rapid incrementation is to be avoided and rescue medication should be made available for breakthrough pain during initial dosing titration.

Opiate Rotation. Opioid rotation is the practice of changing to a different opioid when the patient either fails to achieve benefit or side effects are reached before analgesia is sufficient. In a retrospective review, it was found that the first opioid prescribed was effective for 36% of patients, was stopped because of side effects in 30%, and was stopped for ineffectiveness in 34% (Quang-Cantagrel et al., 2000). Of the remaining patients, the second opioid prescribed after the failure of the first was effective in 31%, the third in 40%, the fourth in 56%, and the fifth in 14%. Thus, if it is necessary to change the opioid prescription because of intolerable side effects or ineffectiveness, the cumulative percentage of efficacy increases with each new opioid tested. Failure or intolerance of one opioid cannot necessarily predict the patient's response or acceptance to another. Practically, opioid rotation involves incrementing the dose of a given opioid, e.g. morphine, to one limited by side-effect and insufficient analgesia. At this point an alternate opioid medication at an equieffective dose may be substituted for the first medication. Agents typically involved in such rotation sequences are various oral opioids such as morphine, methadone, dilaudid, and oxycodone and the fentanyl patch systems. Care must be taken to titrate the doses and monitor the patient closely during such drug transitions.

Combination Therapy. In general, the use of combinations of drugs with the same pharmacological kinetic profile is not warranted (e.g., morphine plus methadone). Nor if the drugs have overlapping targets and opposing effects (e.g., combining a MOR agonist with an agent having mixed agonist/antagonist properties). On the other hand, certain opiate combinations are useful. For example, in a chronic pain state with periodic incident or breakthrough pain, the patient might receive a slow-release formulation of morphine for baseline pain relief and the acute incident pain may be managed with a rapid-onset/short-lasting formulation such as buccal fentanyl.

For inflammatory or nociceptive pain, it is routinely recommended that opioids be combined with other analgesic agents, such as NSAIDs or acetaminophen. In this way, one can take advantage of the analgesic effects produced by the adjuvant and minimize the dose requirement of the opioid. In some situations, NSAIDs can provide analgesia equal to that produced by 60 mg codeine. The analgesic synergism between opioids and aspirin-like drugs is discussed below and in Chapter 34. In the case of neuropathic pain, other drug classes may be useful in combination with the opiate. For example,

antidepressants that block amine reuptake, such as amitriptyline or duloxetine, and anticonvulsants such as gabapentin, may enhance the analgesic effect and may be synergistic in some pain states. Different classes of drug may have distinguishable efficacy in different models of pain processing (Table 18–8).

The “opioid-sparing” strategy is the backbone of the “analgesic ladder” for pain management proposed by the World Health Organization. Weaker opioids can be supplanted by stronger opioids in cases of moderate and severe pain. Antidepressants such as duloxetine and amitriptyline are used in the treatment of chronic neuropathic pain but have limited intrinsic analgesic actions in acute pain. However, antidepressants may enhance morphine-induced analgesia (Levine et al., 1986).

NON-ANALGESIC THERAPEUTIC USES OF OPIOIDS

Dyspnea

Morphine is used to alleviate the dyspnea of acute left ventricular failure and pulmonary edema, and the response to intravenous morphine may be dramatic. The mechanism underlying this relief is not clear. It may involve an alteration of the patient's reaction to impaired respiratory function and an indirect reduction of the work of the heart owing to reduced fear and apprehension. However, it is more probable that the major benefit is due to cardiovascular effects, such as decreased peripheral resistance and an increased capacity of the peripheral and splanchnic vascular compartments. Nitroglycerin, which also causes vasodilation, may be superior to morphine in this condition (Hoffman and Reynolds, 1987). In patients with normal blood gases but severe breathlessness owing to chronic obstruction of airflow (“pink puffers”), dihydrocodeine, 15 mg orally before exercise, reduces the feeling of breathlessness and increases exercise tolerance (Johnson et al., 1983). Nonetheless, opioids generally are contraindicated in pulmonary edema unless severe pain also is present.

Anesthetic Adjuvants

High doses of opioids, notably fentanyl and sufentanil, are widely used as the primary anesthetic agents in many surgical procedures. They have powerful “MAC-sparing” effects¹, e.g., they reduce the concentrations of volatile anesthetic otherwise required to produce an adequate anesthetic depth. Although respiration is so depressed that physical assistance is required, patients can retain consciousness. Therefore, when using opioids as the primary anesthetic agent, it is important to use in conjunction with an agent that results in unconsciousness and produces amnesia such as the benzodiazepines or low concentrations of volatile anesthetics. High doses of opiate also result in prominent rigidity of the chest wall and masseters requiring concurrent treatment with muscle relaxants to permit intubations and ventilation.

TREATMENT OF ACUTE OPIOID TOXICITY

Acute opioid toxicity may result from clinical overdose, accidental overdose, or attempts at suicide. Occasionally, a delayed type of toxicity may occur from

Table 18–8

Summary of Drug Target and Site of Action of Common Drug Classes and Relative Efficacy by Pain State

DRUG CLASS (REPRESENTATIVE AGENTS IN PARENTHESES)	DRUG ACTION	SITE OF ACTION ^a	RELATIVE EFFICACY IN PAIN STATES ^b
NSAIDs (ibuprofen, aspirin acetaminophen)	Nonspecific COX inhibitors	Peripheral and spinal	Tissue injury >> acute stimuli = nerve injury = 0 (Hamza and Dionne, 2009, Svensson and Yaksh, 2002)
COX 2 inhibitor (celecoxib)	COX2-selective inhibitor	Peripheral and spinal	Tissue injury >> acute stimuli = nerve injury = 0 (Hamza and Dionne, 2009)
Opioids (morphine)	μ receptor agonist	Supraspinal and spinal	Tissue injury = acute stimuli ≥ nerve injury > 0 (see this chapter)
Anticonvulsants (gabapentin)	Na ⁺ channel block, α ₂ δ subunit of Ca ²⁺ channel	Supraspinal and spinal	Nerve injury > tissue injury = acute stimuli = 0 (Lai et al., 2004; Taylor, 2009)
Tricyclic antidepressants (amitriptyline)	Inhibit uptake of 5-HT/NE	Supraspinal and spinal	Nerve injury ≥ tissue injury >> acute stimuli = 0 (Mochizucki, 2004)

^aStudies based on local delivery in preclinical models, e.g., intracranial microinjection or intraventricular injections, lumbar intrathecal delivery or topical/sq application at injury site. ^bPain states are defined by preclinical models: acute: hot plate/tail flick/acute mechanical compression; tissue injury: intraplantar injections of irritants, focal thermal injury; nerve injury: compression/ligation of sciatic nerve or its branches or of nerve roots; systemic delivery of chemotherapeutics. See Mogil, 2009.

the injection of an opioid into chilled skin areas or in patients with low blood pressure and shock. The drug is not fully absorbed, and therefore, a subsequent dose may be given. When normal circulation is restored, an excessive amount may be absorbed suddenly. It is difficult to define the exact amount of any opioid that is toxic or lethal to humans. Recent experiences with methadone indicate that in nontolerant individuals, serious toxicity may follow the oral ingestion of 40-60 mg. Older literature suggests that in the case of morphine, a normal, opiate-naïve, pain-free adult is not likely to die after oral doses <120 mg or to have serious toxicity with <30 mg parenterally.

Symptoms and Diagnosis

The patient who has taken an overdose of an opioid usually is stuporous or, if a large overdose has been taken, may be in a profound coma. The respiratory rate will be very low, or the patient may be apneic, and cyanosis may be present. As respiratory exchange decreases, blood pressure, at first likely to be near normal, will fall progressively. If adequate oxygenation is restored early, the blood pressure will improve; if hypoxia persists untreated, there may be capillary damage, and measures to combat shock may be required. The pupils will be symmetrical and pinpoint in size; however, if hypoxia is severe, they may be dilated. Urine formation is depressed. Body temperature falls, and the skin becomes cold and clammy. The skeletal muscles are flaccid, the jaw is relaxed, and the tongue may fall back and block the airway. Frank convulsions occasionally may be

noted in infants and children. When death occurs, it is nearly always from respiratory failure. Even if respiration is restored, death still may occur as a result of complications that develop during the period of coma, such as pneumonia or shock. Noncardiogenic pulmonary edema is seen commonly with opioid poisoning. It probably is not due to contaminants or to anaphylactic reactions, and it has been observed after toxic doses of morphine, methadone, propoxyphene, and pure heroin.

The triad of coma, pinpoint pupils, and depressed respiration strongly suggests opioid poisoning. The finding of needle marks suggestive of addiction further supports the diagnosis. Mixed poisonings, however, are not uncommon. Examination of the urine and gastric contents for drugs may aid in diagnosis, but the results usually become available too late to influence treatment.

Treatment

The first step is to establish a patent airway and ventilate the patient. Opioid antagonists can produce dramatic reversal of the severe respiratory depression, and the antagonist naloxone is the treatment of choice. However, care should be taken to avoid precipitating withdrawal in dependent patients, who may be extremely sensitive to antagonists. The safest approach is to dilute the standard naloxone dose (0.4 mg) and slowly administer it intravenously, monitoring arousal and respiratory function. With care, it usually is possible to reverse the respiratory depression without precipitating a major withdrawal syndrome. If no response is seen with the first dose, additional doses can be given. Patients should be observed for rebound increases in sympathetic nervous system activity, which may result in cardiac arrhythmias and pulmonary edema. For reversing opioid poisoning in children, the initial dose of naloxone is 0.01 mg/kg. If no effect is seen after a total dose of 10 mg, one can reasonably

question the accuracy of the diagnosis. Pulmonary edema sometimes associated with opioid overdose may be countered by positive-pressure respiration. Tonic-clonic seizures, occasionally seen as part of the toxic syndrome with meperidine, propoxyphene, and tramadol, are ameliorated by treatment with naloxone.

The presence of general CNS depressants does not prevent the salutary effect of naloxone, and in cases of mixed intoxications, the situation will be improved largely owing to antagonism of the respiratory-depressant effects of the opioid. However, some evidence indicates that naloxone and naltrexone also may antagonize some of the depressant actions of sedative-hypnotics. One need not attempt to restore the patient to full consciousness. The duration of action of the available antagonists is shorter than that of many opioids; hence patients can slip back into coma. This is particularly important when the overdose is due to methadone. The depressant effects of these drugs may persist for 24-72 hours, and fatalities have occurred as a result of premature discontinuation of naloxone. In cases of overdoses of these drugs, a continuous infusion of naloxone should be considered. Toxicity owing to overdose of pentazocine and other opioids with mixed actions may require higher doses of naloxone.

CLINICAL SUMMARY

Opioid analgesics provide symptomatic relief of pain, but the underlying disease remains. The clinician must weigh the benefits of this relief against any potential risk to the patient, which may be quite different in an acute compared with a chronic disease.

In acute problems, opioids will reduce the intensity of pain. However, physical signs (such as abdominal rigidity with an acute abdomen) generally will remain. Relief of pain can facilitate history taking and examination in the emergency room, and the patient's ability to tolerate diagnostic procedures. In most cases analgesics should not be withheld for fear of obscuring the progression of underlying disease.

The problems that arise in the relief of pain associated with chronic conditions are more complex. Repeated daily administration of opioid analgesics eventually will produce tolerance and some degree of physical dependence. The degree will depend on the particular drug, the frequency of administration, the quantity administered, the genetic predisposition, and the psychosocial status of the patient. The decision to control any chronic symptom, especially pain, by the repeated administration of an opioid must be made carefully. When pain is due to chronic nonmalignant disease, conservative measures using non-opioid drugs should be tried before resorting to the opioids. Such measures include the use of NSAIDs, local nerve blocks, antidepressant drugs, electrical stimulation, acupuncture, hypnosis, and behavioral modification.

Selected subpopulations of chronic nonmalignant pain patients can clearly be maintained adequately

on opioids for extended periods of time. Careful patient selection is important before starting chronic opioid therapy. All patients should have a risk assessment for drug abuse, diversion, and noncompliance using a validated assessment questionnaire. Chronic pain patients at a higher risk of abuse should not necessarily be denied opioids; however, these patients will require a higher level of monitoring (i.e., random urine drug testing, limited supplies, pill counting) and perhaps referral to a specialist in pain or addiction to assist with therapy.

In the usual doses, morphine-like drugs relieve suffering by altering the emotional component of the painful experience, as well as by producing analgesia. Control of pain, especially chronic pain, must include attention to both psychological factors and the social impact of the illness that sometimes play dominant roles in determining the suffering experienced by the patient. The physician must consider the substantial variabilities in patients' capacities to tolerate pain and in their responses to opioids. Some clinicians, out of an exaggerated concern for the possibility of inducing addiction, tend to prescribe initial doses of opioids that are too small or given too infrequently to alleviate pain and then respond to the patient's continued complaints with an even more exaggerated concern about drug dependence despite the high probability that the request for more drug is only the expected consequence of the inadequate dosage initially prescribed. Infants and children probably are more apt to receive inadequate treatment for pain than are adults owing to communication challenges, physician's lack of familiarity with appropriate pain assessment methodologies in this population, and inexperience with the use of strong opioids in children. If an illness or procedure causes pain for an adult, there is no reason to assume that it will produce less pain for a child (Yaster and Deshpande, 1988).

Pain of Terminal Illness and Cancer Pain

Opioids are not indicated in all cases of terminal illness, but the analgesia, tranquility, and even euphoria afforded by the use of opioids can make the final days of life far less distressing for the patient and family. Although physical dependence and tolerance may develop, this possibility should not prevent physicians from fulfilling their primary obligation to ease the patient's discomfort. The physician should not wait until the pain becomes agonizing; no patient should ever wish for death because of a physician's reluctance to use adequate amounts of effective opioids. This sometimes may entail the regular use of opioid analgesics in substantial doses. Such patients,

while they may be physically dependent, are not “addicts” even though they may need large doses on a regular basis. Physical dependence is not equivalent to addiction (Chapter 24).

Most clinicians who are experienced in the management of chronic pain associated with malignant disease or terminal illness recommend that a baseline long-acting opioid be administered around the clock so that pain is continually under control and patients do not dread its return (Foley, 1993). For breakthrough pain episodes, a fast-onset, short-acting opioid can be administered. Less drug is needed to prevent the recurrence of pain than to relieve it initially. Morphine remains the opioid of choice in most of these situations, and the route and dose should be adjusted to the needs of the individual patient. Oral morphine is adequate in most situations. Sustained-release preparations of oral morphine and oxycodone are available that can be administered at 8-, 12-, or 24-hour intervals (morphine) or 8- to 12-hour intervals (oxycodone); thus, superior control of pain often can be achieved with fewer side effects using the same daily dose; a decrease in the fluctuation of plasma concentrations of morphine may be partially responsible.

Constipation is an exceedingly common problem when opioids are used, and the use of stool softeners and laxatives should be initiated early; newer modalities include the use of peripheral opiate antagonists such as methylnaltrexone. Amphetamines have demonstrable mood-elevating and analgesic effects, enhance opioid-induced analgesia, and can reverse opioid induced sedation. However, not all terminal patients require the euphoriant effects of amphetamine, and some experience side effects, such as anorexia. Controlled studies demonstrate no superiority of oral heroin over oral morphine. Similarly, after adjustment is made for potency, parenteral heroin is not superior to morphine in terms of analgesia, effects on mood, or side effects (Sawynok, 1986). Although tolerance does develop to oral opioids, many patients obtain relief from the same dosage for weeks or months. In cases where one opioid loses effectiveness, switching to another may provide better pain relief. “Cross-tolerance” among opioids exists, but clinically and experimentally, cross-tolerance among related receptor agonists is not complete. The reasons for this are not clear but may relate to differences between agonists in receptor-binding characteristics and subsequent cellular signaling interactions.

When oral opioids and other analgesics are no longer satisfactory, subcutaneous or intravenous opioids, nerve blocks, or neurolysis may be required if the

nature of the disease permits. Epidural or intrathecal administration of opioids may be useful when administration of opioids by usual routes no longer yields adequate relief of pain.

chapter

General Anesthetics and Therapeutic Gases

Piyush M. Patel, Hemal H. Patel,
and David M. Roth

General Anesthetics

General anesthetics depress the central nervous system to a sufficient degree to permit the performance of surgery and other noxious or unpleasant procedures. Inevitably, anesthetics also suppress normal homeostatic reflexes. Not surprisingly, general anesthetics have low therapeutic indices and thus require great care in administration. While all general anesthetics produce a relatively similar anesthetic state, they are quite dissimilar in their secondary actions (side effects) on other organ systems. The selection of specific drugs and routes of administration to produce general anesthesia is based on their pharmacokinetic properties and on the secondary effects of the various drugs, in the context of the proposed diagnostic or surgical procedure and with the consideration of the individual patient's age, associated medical condition, and medication use. Anesthesiologists also employ sedatives (Chapter 17), neuromuscular blocking agents (Chapter 11), and local anesthetics (Chapter 20) as the situation requires.

Historical Perspectives. Crawford Long, a physician in rural Georgia, first used ether anesthesia in 1842. William T.G. Morton, a Boston dentist and medical student, performed the first public demonstration of general anesthesia using diethyl ether in 1846 when Gilbert Abbott underwent surgical excision of a neck tumor at the Massachusetts General Hospital in the operating room now known as "the ether dome." The era of modern anesthesia and a revolution in the medical care of the surgical patient had begun.

Ether was the ideal "first" anesthetic. A liquid at room temperature, it readily vaporized, and was easy to administer. Ether, unlike nitrous oxide, was potent and could produce anesthesia without diluting room air to hypoxic levels. It was relatively nontoxic and produced limited respiratory or circulatory compromise. Ether maintained a role in clinical anesthesia until the 1950s.

Horace Wells, a dentist, noted at a stage show that an injured participant under the influence of nitrous oxide felt no pain. The next day Wells had a tooth extracted while breathing nitrous oxide. An attempt in 1845 by Wells to demonstrate his discovery at the Massachusetts General Hospital in Boston ended in failure when the patient cried out and nitrous oxide fell into disuse. In 1868, Edmond Andrews, a Chicago surgeon, described the co-administration of nitrous oxide and oxygen, a practice that continues to this day.

The Scottish obstetrician James Simpson introduced chloroform in 1847. Chloroform had a more pleasant odor than ether and was nonflammable. It was, however, a hepatotoxin and a severe cardiovascular depressant, which limited its ultimate utility. Despite incidents of intraoperative and postoperative deaths associated with chloroform, its use continued, especially in Great Britain, for nearly 100 years.

The anesthetic properties of cyclopropane were discovered accidentally in 1929 by chemists analyzing impurities in propylene. Cyclopropane is a pleasant-smelling gas that produces rapid anesthetic induction and recovery, and was widely used as a general anesthetic for over 30 years. However, cyclopropane is explosive when mixed with air, oxygen, or nitrous oxide. In 1956 came the introduction of halothane, a nonflammable volatile halogenated alkane that quickly became the dominant anesthetic.

In 1935, Lundy demonstrated the clinical usefulness of thiopental, a rapidly acting agent that could be administered intravenously; however, anesthetic doses of thiopental resulted in serious depression of the circulatory, respiratory, and nervous systems. The further development of intravenous anesthetic agents such as propofol, combined with other intravenous anesthetic adjuncts such as midazolam, dexmedetomidine, and remifentanyl, has led to the use of total intravenous anesthesia (TIVA) as a clinically useful tool in modern anesthetic practice.

GENERAL PRINCIPLES OF SURGICAL ANESTHESIA

Unlike the practice of every other branch of medicine, anesthesia is usually neither therapeutic nor diagnostic. The exceptions to this, such as treatment of status

asthmaticus with halothane and intractable angina with epidural local anesthetics, should not obscure this critical point that permeates the training and practice of the specialty. Hence, administration of general anesthesia, as well as the development of new anesthetic agents and physiologic monitoring technology, has been driven by three general objectives:

1. *Minimizing the potentially deleterious direct and indirect effects of anesthetic agents and techniques.*
2. *Sustaining physiologic homeostasis during surgical procedures* that may involve major blood loss, tissue ischemia, reperfusion of ischemic tissue, fluid shifts, exposure to a cold environment, and impaired coagulation.
3. *Improving postoperative outcomes* by choosing techniques that block or treat components of the surgical stress response, which may lead to short- or long-term sequelae.

Hemodynamic Effects of General Anesthesia. The most prominent physiological effect of anesthesia induction, associated with the majority of both intravenous and inhalational agents, is a decrease in systemic arterial blood pressure. The causes include direct vasodilation, myocardial depression, or both; a blunting of baroreceptor control; and a generalized decrease in central sympathetic tone. Agents vary in the magnitude of their specific effects (described later in the chapter), but in all cases the hypotensive response is enhanced by underlying volume depletion or preexisting myocardial dysfunction. Even anesthetics that show minimal hypotensive tendencies under normal conditions (e.g., etomidate and ketamine) must be used with caution in trauma victims, in whom intravascular volume depletion is being compensated by intense sympathetic discharge. Smaller-than-normal anesthetic dosages are employed in patients presumed to be sensitive to hemodynamic effects of anesthetics.

Respiratory Effects of General Anesthesia. Airway maintenance is essential following induction of anesthesia, as nearly all general anesthetics reduce or eliminate both ventilatory drive and the reflexes that maintain airway patency. Therefore, ventilation generally must be assisted or controlled for at least some period during surgery. The gag reflex is lost, and the stimulus to cough is blunted. Lower esophageal sphincter tone also is reduced, so both passive and active regurgitation may occur. Endotracheal intubation, introduced by Kuhn in the early 1900s, has been a major reason for a

decline in the number of aspiration deaths during general anesthesia. Muscle relaxation is valuable during the induction of general anesthesia where it facilitates management of the airway, including endotracheal intubation. Neuromuscular blocking agents commonly are used to effect such relaxation (Chapter 11), reducing the risk of coughing or gagging during laryngoscopic-assisted instrumentation of the airway, and thus reducing the risk of aspiration prior to secure placement of an endotracheal tube. Alternatives to an endotracheal tube include a facemask and a laryngeal mask, an inflatable mask placed in the oropharynx forming a seal around the glottis. The choice of airway management is based on the type of procedure and characteristics of the patient.

Hypothermia. Patients commonly develop hypothermia (body temperature $< 36^{\circ}\text{C}$) during surgery. The reasons for the hypothermia include low ambient temperature, exposed body cavities, cold intravenous fluids, altered thermoregulatory control, and reduced metabolic rate. General anesthetics lower the core temperature set point at which thermoregulatory vasoconstriction is activated to defend against heat loss. Furthermore, vasodilation produced by both general and regional anesthesia offsets cold-induced peripheral vasoconstriction, thereby redistributing heat from central to peripheral body compartments, leading to a decline in core temperature (Sessler, 2000). Metabolic rate and total body oxygen consumption decrease with general anesthesia by $\sim 30\%$, reducing heat generation.

Even small drops in body temperatures may lead to an increase in perioperative morbidity, including cardiac complications, wound infections, and impaired coagulation. Prevention of hypothermia has emerged as a major goal of anesthetic care. Modalities to maintain normothermia include using warm intravenous fluids, heat exchangers in the anesthesia circuit, forced-warm-air covers, and new technology involving water-filled garments with microprocessor feedback control to a core temperature set point.

Nausea and Vomiting. Nausea and vomiting in the postoperative period continue to be significant problems following general anesthesia and are caused by an action of anesthetics on the chemoreceptor trigger zone and the brainstem vomiting center, which are modulated by serotonin (5-HT), histamine, acetylcholine (ACh), and dopamine (DA). The 5-HT₃-receptor antagonists, ondansetron and dolasetron (Chapters 13 and 46), are very effective in suppressing nausea and vomiting. Common treatments also include droperidol, metoclopramide, dexamethasone, and avoidance of N₂O. The use of propofol as an induction agent and the

nonsteroidal anti-inflammatory drug ketorolac as a substitute for opioids may decrease the incidence and severity of postoperative nausea and vomiting.

Other Emergence and Postoperative Phenomena. Hypertension and tachycardia are common as the sympathetic nervous system regains its tone and is enhanced by pain. Myocardial ischemia can appear or markedly worsen during emergence in patients with coronary artery disease. Emergence excitement occurs in 5-30% of patients and is characterized by tachycardia, restlessness, crying, moaning, and thrashing. A variety of neurologic signs, including delirium, spasticity, hyperreflexia, and Babinski sign, are often manifest in the patient emerging from anesthesia. Postanesthesia shivering occurs frequently because of core hypothermia. A small dose of meperidine (12.5 mg) lowers the shivering trigger temperature and effectively stops the activity. The incidence of all of these emergence phenomena is greatly reduced when opioids and α_2 agonists (dexmedetomidine) are employed as part of the intraoperative regimen.

Airway obstruction may occur during the postoperative period because residual anesthetic effects continue to partially obtund consciousness and reflexes (especially in patients who normally snore or who have sleep apnea). Strong inspiratory efforts against a closed glottis can lead to negative-pressure pulmonary edema. Pulmonary function is reduced postoperatively following all types of anesthesia and surgery, and hypoxemia may occur. Hypertension can be prodigious, often requiring aggressive treatment.

Pain control can be complicated in the immediate postoperative period. The respiratory suppression associated with opioids can be problematic among postoperative patients who still have a substantial residual anesthetic effect. Patients can alternate between states of excruciating pain to somnolence with airway obstruction, all in a matter of moments. The nonsteroidal anti-inflammatory agent ketorolac (30-60 mg intravenously) frequently is effective, and the development of injectable cyclooxygenase-2 inhibitors (Chapter 34) holds promise for analgesia without respiratory depression. In addition, regional anesthetic techniques are an important part of a perioperative multimodal approach that employs local anesthetic wound infiltration; epidural, spinal, and plexus blocks; and nonsteroidal anti-inflammatory drugs, opioids, α_2 adrenergic receptor agonists, and NMDA-receptor antagonists. Patient-controlled administration of intravenous and epidural analgesics makes use of small, computerized pumps activated on demand but programmed with safety limits to prevent overdose. The agents used are opioids (frequently morphine) by the intravenous route, and an opioid, local anesthetic, or both by the epidural route. These techniques have revolutionized postoperative pain management, can be continued for hours or days, and promote ambulation and improved bowel function until oral pain medications are initiated.

ACTIONS AND MECHANISMS OF GENERAL ANESTHETICS

The Anesthetic State

General anesthetics are a structurally diverse class of drugs that produce a common end point—a behavioral

state referred to as *general anesthesia*. In the broadest sense, general anesthesia can be defined as a global but reversible depression of CNS function resulting in the loss of response to and perception of all external stimuli. While this definition is appealing in its simplicity, it is not useful for two reasons: First, it is inadequate because anesthesia is not simply a deafferented state; e.g., amnesia is an important aspect of the anesthetic state. Second, not all general anesthetics produce identical patterns of deafferentation. Barbiturates, e.g., are very effective at producing amnesia and loss of consciousness, but are not effective as analgesics.

An alternative way of defining the anesthetic state is to consider it as a collection of “component” changes in behavior or perception. The components of the anesthetic state include:

- *amnesia*
- *immobility* in response to noxious stimulation
- *attenuation of autonomic responses* to noxious stimulation
- *analgesia*
- *unconsciousness*

It is important to remember that general anesthesia is useful only insofar as it facilitates the performance of surgery or other noxious procedures. The performance of surgery usually requires an immobilized patient who does not have an excessive autonomic response to surgery (blood pressure and heart rate) and who has amnesia for the procedure. Indeed, if an anesthetic produces profound amnesia, it can be difficult in principle to determine if it also produces either analgesia or unconsciousness.

Measurement of Anesthetic Potency

The potency of general anesthetic agents usually is measured by determining the concentration of general anesthetic that prevents movement in response to surgical stimulation. For inhalational anesthetics, anesthetic potency is measured in MAC units, with 1 MAC defined as the minimum alveolar concentration that prevents movement in response to surgical stimulation in 50% of subjects.

The strengths of MAC as a measurement are that:

- alveolar concentrations can be monitored continuously by measuring end-tidal anesthetic concentration using infrared spectroscopy or mass spectrometry
- it provides a direct correlate of the free concentration of the anesthetic at its site(s) of action in the CNS
- it is a simple-to-measure end point that reflects an important clinical goal

End points other than immobilization also can be used to measure anesthetic potency. For example, the ability to respond to verbal commands (MAC_{awake}) and the ability to form memories also have been correlated with alveolar anesthetic concentration. Interestingly, verbal response and memory formation both are suppressed at a fraction

Table 19–1

Properties of Inhalational Anesthetic Agents

ANESTHETIC AGENT	MAC ^a (vol %)	MAC _{AWAKE} ^b (vol %)	EC ₅₀ ^c FOR SUPPRESSION OF MEMORY (vol %)	VAPOR PRESSURE (mm Hg at 20°C)	PARTITION COEFFICIENT AT 37°C			RECOVERED AS METABOLITES (%)
					Blood:Gas	Brain:Blood	Fat:Blood	
Halothane	0.75	0.41	—	243	2.3	2.9	51	20
Isoflurane	1.2	0.4	0.24	250	1.4	2.6	45	0.2
Enflurane	1.6	0.4	—	175	1.8	1.4	36	2.4
Sevoflurane	2	0.6	—	160	0.65	1.7	48	3
Desflurane	6	2.4	—	664	0.45	1.3	27	0.02
Nitrous oxide	105	60.0	52.5	Gas	0.47	1.1	2.3	0.004
Xenon	71	32.6	—	Gas	0.12	—	—	0

^aMAC (minimum alveolar concentration) values are expressed as vol %, the percentage of the atmosphere that is anesthetic. A value of MAC greater than 100% means that hyperbaric conditions would be required.

^bMAC_{awake} is the concentration at which appropriate responses to commands are lost.

^cEC₅₀ is the concentration that produces memory suppression in 50% of patients. —, Not available.

of MAC. Furthermore, the ratio of the anesthetic concentrations required to produce amnesia and immobility vary significantly among different inhalational anesthetic agents (nitrous oxide versus isoflurane) (Table 19–1), suggesting that anesthetic agents may produce these behavioral end points through different cellular and molecular mechanisms. The potency of intravenous anesthetic agents is somewhat more difficult to measure; we lack methods to measure blood or plasma anesthetic concentration continuously, and we cannot determine the free concentration of the drug at its site of action. Generally, the potency of intravenous agents is defined as the free plasma concentration (at equilibrium) that produces loss of response to surgical incision (or other end points) in 50% of subjects.

Mechanisms of Anesthesia

The molecular and cellular mechanisms by which general anesthetics produce their effects have remained one of the great mysteries of pharmacology. For most of the 20th century, it was theorized that all anesthetics act by a common mechanism (the unitary theory of anesthesia). The leading unitary theory was that anesthesia is produced by perturbation of the physical properties of cell membranes. This thinking was based largely on the observation that the anesthetic potency of a gas correlated with its solubility in olive oil. This correlation, referred to as the Meyer-Overton rule, was interpreted as implicating the lipid bilayer as the likely target of anesthetic action. Clear exceptions to the Meyer-Overton rule have now been noted (Franks, 2006). For example, inhalational and intravenous anesthetics can be enantioselective in their action as anesthetics (etomidate, steroids, isoflurane). The fact that enantiomers

with identical physical properties have unique actions indicates that properties other than bulk solubility are important in determining anesthetic action. Consequently, the lipid theory of anesthesia has largely been discarded (Franks, 2006). This realization has focused thinking on identification of specific protein binding sites for anesthetics.

A substantial body of work indicates that an anesthetic agent produces different components of the anesthetic state by means of actions at different anatomic loci in the nervous system and may produce these component effects through different cellular and molecular actions. Moreover, increasing evidence supports the hypothesis that different anesthetic agents produce specific components of anesthesia by actions at different molecular targets. Given these insights, the unitary theory of anesthesia has been largely discarded.

Cellular Mechanisms of Anesthesia. General anesthetics produce two important physiologic effects at the cellular level.

First, the inhalational anesthetics can hyperpolarize neurons. This may be an important effect on neurons serving a pacemaker role and on pattern-generating circuits. It also may be important in synaptic communication, since reduced excitability in a postsynaptic neuron may diminish the likelihood that an action potential will be initiated in response to neurotransmitter release.

Second, at anesthetizing concentrations, both inhalational and intravenous anesthetics have substantial effects on synaptic transmission and much smaller effects on action-potential generation or propagation.

The inhalational anesthetics inhibit excitatory synapses and enhance inhibitory synapses in various preparations. These effects likely are produced by both pre- and postsynaptic actions of the inhalational anesthetics. The inhalational anesthetic isoflurane clearly can inhibit neurotransmitter release, while the small reduction in presynaptic action potential amplitude produced by isoflurane (3% reduction at MAC concentration) substantially inhibits neurotransmitter release (Wu et al., 2004b). The latter effect occurs because the reduction in the presynaptic action potential is amplified into a much larger reduction in presynaptic Ca^{2+} influx, which in turn is amplified into an even greater reduction in transmitter release. This effect may account for the majority of the reduction in transmitter release by inhalational anesthetics at some excitatory synapses. Inhalational anesthetics also can act postsynaptically, altering the response to released neurotransmitter. These actions are thought to be due to specific interactions of anesthetic agents with neurotransmitter receptors.

The intravenous anesthetics produce a narrower range of physiological effects. Their predominant actions are at the synapse, where they have profound and relatively specific effects on the postsynaptic response to released neurotransmitter. Most of the intravenous agents act predominantly by enhancing inhibitory neurotransmission, whereas ketamine predominantly inhibits excitatory neurotransmission at glutamatergic synapses.

Molecular Actions of General Anesthetics. A variety of ligand-gated ion channels, receptors and signal transduction proteins are modulated by general anesthetics. Of these, the strongest evidence for a direct effect of anesthetics exists for the GABA_A and NMDA receptors and the two-pore K^+ channels, as described later in this section.

Chloride channels gated by the inhibitory GABA_A receptors (Chapters 14 and 17) are sensitive to clinical concentrations of a wide variety of anesthetics, including the halogenated inhalational agents and many intravenous agents (propofol, barbiturates, etomidate, and neurosteroids). At clinical concentrations, general anesthetics increase the sensitivity of the GABA_A receptor to GABA, thus enhancing inhibitory neurotransmission and depressing nervous system activity. The action of anesthetics on the GABA_A receptor probably is mediated by binding of the anesthetics to specific sites on the GABA_A -receptor protein, since point mutations of the receptor can eliminate the effects of the anesthetic on ion channel function (Rudolph and Antkowiak, 2004). Judging from the capacity of mutations in various regions (and subunits) of the GABA_A receptor to selectively affect the actions of various anesthetics, there likely are specific binding sites for at least several classes of anesthetics (Belelli et al., 1997). Notably, none of the general anesthetics competes with GABA for its binding site on the receptor. The capacity of propofol and etomidate to inhibit the response to

noxious stimuli is mediated by a specific site on the β_3 subunit of the GABA_A receptor, whereas the sedative effects of these anesthetics are mediated by the same site on the β_2 subunit (Reynolds et al., 2003). These results indicate that two components of anesthesia *can* be mediated by GABA_A receptors. For anesthetics other than propofol and etomidate, which components of anesthesia *are* produced by actions on GABA_A receptors remains a matter of conjecture.

Structurally related to the GABA_A receptors are other ligand-gated ion channels including glycine receptors and neuronal nicotinic acetylcholine receptors. Glycine receptors may play a role in mediating inhibition by anesthetics of responses to noxious stimuli. Clinical concentrations of inhalational anesthetics enhance the capacity of glycine to activate glycine-gated chloride channels (glycine receptors), which play an important role in inhibitory neurotransmission in the spinal cord and brainstem. Propofol, neurosteroids, and barbiturates also potentiate glycine-activated currents, whereas etomidate and ketamine do not. Subanesthetic concentrations of the inhalational anesthetics inhibit some classes of neuronal nicotinic acetylcholine receptors (Violet et al., 1997). However, these actions do not appear to mediate anesthetic immobilization (Eger et al., 2002); rather, neuronal nicotinic receptors could mediate other components of anesthesia such as analgesia or amnesia.

The only general anesthetics that do not have significant effects on GABA_A or glycine receptors are ketamine, nitrous oxide, cyclopropane, and xenon. These agents inhibit a different type of ligand-gated ion channel, the *N*-methyl-D-aspartate (NMDA) receptor (Chapter 14). NMDA receptors are glutamate-gated cation channels that are somewhat selective for calcium and are involved in long-term modulation of synaptic responses (long-term potentiation) and glutamate-mediated neurotoxicity. Ketamine inhibits NMDA receptors by binding to the phencyclidine site on the NMDA-receptor protein, and the NMDA receptor is thought to be the principal molecular target for ketamine's anesthetic actions. Nitrous oxide (Jevtovic-Todorovic et al., 1998), cyclopropane (Raines et al., 2001), and xenon (de Sousa et al., 2000) are potent and selective inhibitors of NMDA-activated currents, suggesting that these agents also may produce unconsciousness by means of actions on NMDA receptors.

Inhalational anesthetics have two other known molecular targets that may mediate some of their actions. Halogenated inhalational anesthetics activate some members of a class of K^+ channels known as

532 two-pore domain channels (Patel et al., 1999); other two-pore domain channel family members are activated by xenon, nitrous oxide, and cyclopropane (Franks, 2006). These channels are located in both pre-synaptic and post-synaptic sites. The post-synaptic channels are important in setting the resting membrane potential of neurons and may be the molecular locus through which these agents hyperpolarize neurons. Activation of pre-synaptic channels can lead to hyperpolarization of the pre-synaptic terminal, thereby reducing neurotransmitter release. Modulation of neurotransmitter release can also be modulated by interaction of anesthetics with the molecular machinery involved in neurotransmitter release. The action of inhalational anesthetics requires a protein complex (syntaxin, SNAP-25, synaptobrevin) involved in synaptic neurotransmitter release (van Swinderen et al., 1999). These molecular interactions may explain, in part, the capacity of inhalational anesthetics to cause presynaptic inhibition in the hippocampus and could contribute to the amnesic effect of inhalational anesthetics.

Anatomic Sites of Anesthetic Action. In principle, general anesthetics could interrupt nervous system function at myriad levels, including peripheral sensory neurons, the spinal cord, the brainstem, and the cerebral cortex. Delineation of the precise anatomic sites of action is difficult because many anesthetics diffusely inhibit electrical activity in the CNS. For example, isoflurane at 2 MAC can cause electrical silence in the brain. However, *in vitro* studies show that specific cortical pathways exhibit markedly different sensitivities to both inhalational and intravenous anesthetics (MacIver and Roth, 1988), suggesting that anesthetics produce specific components of the anesthetic state through actions at specific sites in the CNS. Consistent with this possibility, inhalational anesthetics produce immobilization in response to a surgical incision (the end point used in determining MAC) by action on the spinal cord (Rampil, 1994). Given that amnesia or unconsciousness cannot result from anesthetic actions in the spinal cord, one concludes that different components of anesthesia are produced at different sites in the CNS. Indeed, recent studies show that the sedative effects of pentobarbital and propofol (GABA-ergic anesthetics) are mediated by GABA_A receptors in the tuberomammillary nucleus (Nelson et al., 2002), and the sedative effects of the intravenous anesthetic dexmedetomidine (an α_2 adrenergic receptor agonist) are produced by actions in the locus ceruleus (Mizobe et al., 1996). These findings suggest that the sedative actions of some anesthetics share the neuronal pathways involved in endogenous sleep.

Functional imaging studies of the awake and anesthetized brain have revealed that most anesthetics cause, with some exceptions, a global reduction in cerebral metabolic rate (CMR) and in cerebral blood flow (CBF); agent-specific effects on CMR and CBF will be described later in the chapter. A consistent feature of general anesthesia is a suppression of metabolism in the thalamus (Alkire et al., 2008). This is not surprising given the demonstration that inhalational anesthetics depress the excitability of thalamic neurons. The

thalamus serves as a major relay by which sensory input from the periphery ascends to the cortex. Suppression of thalamic activity might isolate the cortex from ascending input. Thus, the thalamus may serve as a switch between the awake and anesthetized states (Franks, 2008). In addition, general anesthesia results in the suppression of activity in specific regions of the cortex, including the mesial parietal cortex, posterior cingulate cortex, precuneus, and inferior parietal cortex. Of interest is the recent observation that electrical activity in the cortex is suppressed before that in the thalamus. This suggests that it is cortical suppression that, via the corticothalamic fibers, leads to thalamic suppression, thereby making the cortex the primary target of anesthetics (Alkire et al., 2008). However, the temporal relationships between thalamus and cortical activity (and deactivation) under general anesthesia need further clarification before the relative importance of each site to anesthetic induced loss of consciousness is known (Franks, 2008).

The similarities between natural sleep and the anesthetized state suggest that anesthetics might also modulate endogenous sleep regulating pathways, which include ventrolateral preoptic (VLPO) and tuberomammillary nuclei. VLPO projects inhibitory GABA-ergic fibers to ascending arousal nuclei, which in turn project to the cortex, forebrain, and subcortical areas; release of histamine, 5-HT, orexin, NE, and ACh mediate wakefulness (Sanders and Maze, 2007). Intravenous and inhalational agents with activity at GABA_A receptors can increase the inhibitory effects of VLPO, thereby suppressing consciousness. Dexmedetomidine, an α_2 agonist, also increases VLPO-mediated inhibition by suppressing the inhibitory effect of locus ceruleus neurons on VLPO (Sanders et al., 2007). Finally, both intravenous and inhalational anesthetics depress hippocampal neurotransmission (Kendig et al., 1991), a probable locus for their amnesic effects.

Summary. Current evidence supports the view that most intravenous general anesthetics act predominantly through GABA_A receptors and perhaps through some interactions with other ligand-gated ion channels such as NMDA receptors and two-pore K⁺ channels. The halogenated inhalational agents have a variety of molecular targets, consistent with their status as complete (all components) anesthetics. Nitrous oxide, ketamine, and xenon constitute a third category of general anesthetics that are likely to produce unconsciousness by inhibition of the NMDA receptor and/or activation of two-pore-domain K⁺ channels.

PARENTERAL ANESTHETICS

Pharmacokinetic Principles

Parenteral anesthetics are small, hydrophobic, substituted aromatic or heterocyclic compounds (Figure 19–1). Hydrophobicity is the key factor governing their pharmacokinetics. After a single intravenous bolus, these drugs preferentially partition into the highly perfused and lipophilic tissues of the brain and spinal cord where they produce anesthesia within a single circulation

Figure 19-1. Structures of some parenteral anesthetics.

time. Subsequently blood levels fall rapidly, resulting in drug redistribution out of the CNS back into the blood. The anesthetic then diffuses into less perfused tissues such as muscle and viscera, and at a slower rate into the poorly perfused but very hydrophobic adipose tissue. Termination of anesthesia after single boluses of parenteral anesthetics primarily reflects redistribution out of the CNS rather than metabolism (Figure 19-2). After redistribution, anesthetic blood levels fall according to a complex interaction between the metabolic rate and the amount and lipophilicity of the drug stored in the peripheral compartments. Thus, parenteral anesthetic half-life are “context-sensitive,” and the degree to which a $t_{1/2}$ is contextual varies greatly from drug to drug, as might be predicted based on their differing hydrophobicities and metabolic clearances (Table 19-2 and Figure 19-3). For example, after a single bolus of thiopental, patients usually emerge from anesthesia within 10 minutes; however, a patient may require more than a day to awaken from a prolonged thiopental infusion.

Most individual variability in sensitivity to parenteral anesthetics can be accounted for by pharmacokinetic factors. For example, in patients with lower cardiac output, the relative perfusion of the brain and the fraction of anesthetic dose delivered to the brain are higher; thus, patients in septic shock or with cardiomyopathy usually require lower doses of anesthetic. The elderly also typically require a smaller anesthetic dose, primarily because of a smaller initial volume of

Figure 19-2. Thiopental serum levels after a single intravenous induction dose. Thiopental serum levels after a bolus can be described by two time constants, $t_{1/2\alpha}$ and $t_{1/2\beta}$. The initial fall is rapid ($t_{1/2\alpha} < 10$ min) and is due to redistribution of drug from the plasma and the highly perfused brain and spinal cord into less well-perfused tissues such as muscle and fat. During this redistribution phase, serum thiopental concentration falls to levels at which patients awaken (AL, awakening level; see inset—the average thiopental serum concentration in 12 patients after a 6-mg/kg intravenous bolus of thiopental). Subsequent metabolism and elimination is much slower and is characterized by a half-life ($t_{1/2\beta}$) of more than 10 hours. (Adapted with permission from Burch PG, and Stanski DR, The role of metabolism and protein binding in thiopental anesthesia. *Anesthesiology*, 1983, 58:146–152. Copyright Lippincott Williams & Wilkins. <http://lww.com>.)

distribution. As described later in the chapter, similar principles govern the pharmacokinetics of the hydrophobic inhalational anesthetics, with the added complexity of drug uptake by inhalation.

SPECIFIC PARENTERAL AGENTS

Barbiturates

Chemistry and Formulations. Barbiturates are derivatives of barbituric acid (2,4,6-trioxohexahydropyrimidine), with either an oxygen or a sulfur at the 2-position (Figure 19-1). The three barbiturates most commonly used in clinical anesthesia are sodium thiopental, thiamylal, and methohexital. Sodium thiopental (PENTOTHAL, others) has been used most frequently for inducing anesthesia. Thiamylal (SURITAL) is licensed in the U.S. only for veterinary use. Barbiturates are supplied as racemic mixtures despite enantioselectivity in their anesthetic potency. Barbiturates are formulated as the sodium salts with 6% sodium carbonate and

Table 19-2

Pharmacological Properties of Parenteral Anesthetics

Figure 19-3. Context-sensitive half-time of general anesthetics. The duration of action of single intravenous doses of anesthetic/hypnotic drugs is similarly short for all and is determined by redistribution of the drugs away from their active sites (see Figure 19-2). However, after prolonged infusions, drug half-lives and durations of action are dependent on a complex interaction between the rate of redistribution of the drug, the amount of drug accumulated in fat, and the drug's metabolic rate. This phenomenon has been termed the *context-sensitive half-time*; that is, the $t_{1/2}$ of a drug can be estimated only if one knows the context—the total dose and over what time period it has been given. Note that the half-times of some drugs such as etomidate, propofol, and ketamine increase only modestly with prolonged infusions; others (e.g., diazepam and thiopental) increase dramatically. (Reproduced with permission from Reves JG, Glass PSA, Lubarsky DA, et al: *Intravenous anesthetics*, in Miller RD et al, (eds): *Miller's Anesthesia*, 7th ed. Philadelphia: Churchill Livingstone, 2010, p 718. Copyright © Elsevier.)

reconstituted in water or isotonic saline to produce 2.5% (thiopental), 2% (thiamylal), or 1% (methohexital) alkaline solutions ($10 \leq \text{pH} \leq 11$). *Mixing barbiturates with drugs in acidic solutions during anesthetic induction can result in precipitation of the barbiturate as the free acid; thus, standard practice is to delay the administration of other drugs until the barbiturate has cleared the intravenous tubing.*

Dosages and Clinical Use. Recommended intravenous dosing for parenteral anesthetics in a healthy young adult is given in Table 19-2.

The typical induction dose (3-4 mg/kg) of thiopental produces unconsciousness in 10-30 seconds with a peak effect in 1 minute and duration of anesthesia of 5-8 minutes. Neonates and infants usually require a higher induction dose (5-8 mg/kg), whereas elderly and pregnant patients require less (1-3 mg/kg) (Gin et al., 1997). Dosage calculation based on lean body mass reduces individual variation in dosage requirements. Doses can be reduced by 10-50% after premedication with benzodiazepines, opiates, or α_2 adrenergic agonists, because of their additive hypnotic effect

(Nishina et al., 1994; Short et al., 1991; Wang et al., 1996). Thiamylal is approximately equipotent with and in all aspects similar to thiopental. Methohexital (BREVITAL) is 3-fold more potent but otherwise similar to thiopental in onset and duration of action. Thiopental and thiamylal produce little to no pain on injection; methohexital elicits mild pain. Veno-irritation can be reduced by injection into larger non-hand veins and by prior intravenous injection of lidocaine (0.5-1 mg/kg). For induction of pediatric patients without IV access, any of the three drugs can be given off-label per rectum at ~10-fold the IV dose.

Pharmacokinetics and Metabolism. Pharmacokinetic parameters for parenteral anesthetics are given in Table 19-2. As already discussed, the principal mechanism limiting anesthetic duration after single doses is redistribution of these hydrophobic drugs from the brain to other tissues. However, after multiple doses or infusions, the duration of action of the barbiturates varies considerably depending on their clearances.

Methohexital differs from the other two intravenous barbiturates in its much more rapid clearance; thus, it accumulates less during prolonged infusions. Because of their slow elimination and large volumes of distribution, prolonged infusions or very large doses of thiopental and thiamylal can produce unconsciousness lasting several days. Even single induction doses of thiopental and to a lesser degree methohexital can produce psychomotor impairment lasting up to 8 hours (Beskow et al., 1995). Propofol has largely supplanted methohexital for outpatient procedures that require a rapid return to an alert state (see "Propofol" later in the chapter).

All three barbiturates are primarily eliminated by hepatic metabolism and renal excretion of inactive metabolites; a small fraction of thiopental undergoes desulfuration to the longer-acting hypnotic pentobarbital. In patients with cirrhosis, a larger volume of distribution combined with a reduction in clearance can result in prolongation of the clinical action of barbiturates. These drugs are highly protein bound (Table 19-2). Hepatic disease or other conditions that reduce serum protein concentration will increase the initial free concentration and hypnotic effect of an induction dose; this is noted in patients with advanced cirrhosis in whom the protein synthesis capacity of the liver is greatly compromised.

Side Effects

Nervous System. Barbiturates suppress the EEG and can produce burst suppression of the EEG. They reduce the cerebral metabolic rate, as measured by cerebral O_2 consumption (CMRO_2), in a dose-dependent manner. Induction doses of thiopental reduce CMRO_2 by 25-30%, with a maximal decrease of 55% occurring at two to five times that dose (Stullken et al., 1977). As a consequence of the decrease in CMRO_2 , cerebral blood flow and intracranial pressure are similarly reduced.

Because it markedly lowers cerebral metabolism, thiopental has been used as a protectant against cerebral ischemia; however, the large doses required and the subsequent prolonged sedation have precluded its use clinically for this purpose. Thiopental also reduces intraocular pressure. Presumably in part due to their CNS depressant activity, barbiturates are effective anticonvulsants. Thiopental in particular is a proven medication in the treatment of status epilepticus. Methohexital can increase ictal activity, and seizures have been described in patients who received doses sufficient to produce burst

536 suppression of the EEG (Todd et al., 1984). This property makes methohexital a good choice for anesthesia in patients who undergo electroconvulsive therapy.

Cardiovascular System. The anesthetic barbiturates produce dose-dependent decreases in blood pressure. The effect is due primarily to vasodilation, particularly venodilation, and to a lesser degree to a direct decrease in cardiac contractility. Typically, heart rate increases as a compensatory response to a lower blood pressure, although barbiturates also blunt the baroreceptor reflex. Thiopental maintains the ratio of myocardial O₂ supply to demand in patients with coronary artery disease within a normal blood pressure range.

Hypotension can be severe in patients with an impaired ability to compensate for venodilation such as those with hypovolemia, cardiomyopathy, valvular heart disease, coronary artery disease, cardiac tamponade, or β adrenergic blockade. None of the barbiturates has been shown to be arrhythmogenic.

Respiratory System. Barbiturates are respiratory depressants. Induction doses of thiopental decrease minute ventilation and tidal volume, with a smaller and inconsistent decrease in respiratory rate (Grounds et al., 1987). Reflex responses to hypercarbia and hypoxia are diminished by anesthetic barbiturates (Hirshman et al., 1975); and at higher doses or in the presence of other respiratory depressants such as opiates, apnea can result. With the exception of uncommon anaphylactoid reactions, these drugs have little effect on bronchomotor tone (Kingston and Hirshman, 1984). Compared to propofol, barbiturates produce a higher incidence of wheezing in asthmatics, attributed to histamine release from mast cells, during induction of anesthesia (Pizov et al., 1995).

Other Side Effects. Short-term administration of barbiturates has no clinically significant effect on the hepatic, renal, or endocrine systems. A single induction dose of thiopental does not alter tone of the gravid uterus, but may produce mild transient depression of newborn activity. True allergies to barbiturates are rare; however, direct drug-induced histamine release is occasionally seen (Sprung et al., 1997).

Barbiturates can induce fatal attacks of porphyria in patients with acute intermittent or variegate porphyria and are contraindicated in such patients. The abnormal synthesis of protoporphyrin (important in hemoglobin production) results in excess porphobilinogen. Barbiturates induce aminolevulinic acid synthase, an enzyme responsible for phorphobilinogen synthesis. This leads to excessive porphobilinogen levels and can precipitate acute porphyric crises that are manifested by severe abdominal pain, nausea, vomiting, psychiatric disorders, and neurologic abnormalities.

Methohexital can produce pain on injection to a greater degree than thiopental. Inadvertent intra-arterial injection of thiobarbiturates can induce a severe inflammatory and potentially necrotic reaction that can threaten limb survival. Methohexital and to a lesser degree other barbiturates can produce excitatory symptoms on induction such as cough, hiccup, muscle tremors, twitching, and hypertonus.

Unlike inhalational anesthetics and succinylcholine, barbiturates and all other parenteral anesthetics apparently do not trigger malignant hyperthermia (Rosenberg et al., 1997).

Propofol

Propofol is the most commonly used parenteral anesthetic in the U.S. Fospropofol is a prodrug form that

is converted to propofol *in vivo*. The clinical pharmacological properties of propofol are summarized in Table 19–2.

Chemistry and Formulations. The active ingredient in propofol, 2,6-diisopropylphenol, is an oil at room temperature and insoluble in aqueous solutions. Propofol is formulated for IV administration as a 1% (10 mg/mL) emulsion in 10% soybean oil, 2.25% glycerol, and 1.2% purified egg phosphatide. In the U.S., disodium EDTA (0.05 mg/mL) or sodium metabisulfite (0.25 mg/mL) is added to inhibit bacterial growth. Nevertheless, significant bacterial contamination of open containers has been associated with serious patient infections; propofol should be administered within 4 hours of its removal from sterile packaging; unused drug should be discarded.

The lipid emulsion formulation of propofol is associated with significant pain on injection and hyperlipidemia. A new aqueous formulation of propofol, fospropofol, which is not associated with these adverse effects, has recently been approved for use for sedation in patients undergoing diagnostic procedures. Fospropofol, which itself is inactive, is a phosphate ester prodrug of propofol that is hydrolyzed by endothelial alkaline phosphatases to yield propofol, phosphate, and formaldehyde. The formaldehyde is rapidly converted to formic acid, which then is metabolized by tetrahydrofolate dehydrogenase to CO₂ and water (Fechner et al., 2008).

Dosage and Clinical Use. The induction dose of propofol (DIPRIVAN, others) in a healthy adult is 2–2.5 mg/kg and it has an onset and duration of anesthesia similar to thiopental (Table 19–2). As with barbiturates, dosages should be reduced in the elderly and in the presence of other sedatives and increased in young children. Because of its reasonably short elimination $t_{1/2}$, propofol often is used for maintenance of anesthesia as well as for induction. For short procedures, small boluses (10–50% of the induction dose) every 5 minutes or as needed are effective. An infusion of propofol produces a more stable drug level (100–300 μ g/kg per minute) and is better suited for longer-term anesthetic maintenance. Infusion rates should be tailored to patient response and the levels of other hypnotics. Sedating doses of propofol are 20–50% of those required for general anesthesia. However, even at these lower doses, caregivers should be vigilant and prepared for all of the side effects of propofol discussed below, particularly airway obstruction and apnea.

Fospropofol produces dose-dependent sedation and can be administered in otherwise healthy individuals at 2–8 mg/kg intravenously (delivered either as a bolus or by a short infusion over 5–10 min). The optimum dose for sedation is ~6.5 mg/kg. This results in a loss of consciousness in ~10 minutes. The duration of the sedative effect is ~45 min.

Pharmacokinetics and Metabolism. The pharmacokinetics of propofol are governed by the same principles that apply to barbiturates. Onset and duration of anesthesia after a single bolus are similar to thiopental. Recovery after multiple doses or continuous infusion has been shown to be much faster after propofol than after thiopental or even methohexital. Propofol has a context-sensitive $t_{1/2}$ of ~10 min with an infusion lasting 3 hours and ~40 minutes for infusions lasting up to 8 hours (Figure 19–3). Propofol's shorter duration of action after infusion can be explained by its very high clearance, coupled with the slow diffusion of drug from the peripheral to the central compartment (Figure 19–3). The rapid clearance of propofol explains the more rapid emergence from anesthesia in comparison to barbiturates; this facilitates a more rapid discharge from the recovery room.

Propofol is metabolized in the liver by conjugation to sulfate and glucuronide to less active metabolites that are renally excreted; however, its clearance exceeds hepatic blood flow, and anhepatic metabolism, particularly in the lungs and kidneys, has been demonstrated (Veroli et al., 1992). In patients with moderate cirrhosis, the volume of distribution of propofol is increased significantly. However, terminal elimination $t_{1/2}$ and emergence from propofol anesthesia is not substantially different from healthy patients (Servin et al., 1990). Propofol is highly protein bound, and its pharmacokinetics, like those of the barbiturates, may be affected by conditions that alter serum protein levels.

Clearance of propofol is reduced in the elderly; given that the central volume of distribution of propofol is also reduced, the required dose of propofol for both induction and maintenance of anesthesia may be decreased. In neonates, propofol clearance is also reduced (Allegaert et al., 2007). Infusion of propofol in neonates therefore has the potential for substantial accumulation and a consequent delay in emergence from anesthesia or sedation. By contrast, in young children, a more rapid clearance in combination with a larger central volume may necessitate larger doses of propofol for induction and maintenance of anesthesia (Kataria et al., 1994).

The $t_{1/2}$ for hydrolysis of fospropofol is 8 min. Fospropofol has a small volume of distribution and a terminal $t_{1/2}$ ~46 min. The currently published pharmacokinetic data on fospropofol were derived using an analytical method that has now been shown to be inaccurate; correct pharmacokinetic data are not yet available (Fechner et al., 2008).

Pharmacology and Side Effects

Nervous System. The sedation and hypnotic actions of propofol are mediated by its action on GABA_A receptors; agonism at these receptors results in an increased chloride conduction and hyperpolarization of neurons. Propofol suppresses the EEG, and in sufficient doses, can produce burst suppression of the EEG. Propofol decreases CMRO₂, cerebral blood flow, and intracranial and intraocular pressures by about the same amount as thiopental. Like thiopental, propofol has been used in patients at risk for cerebral ischemia; however, no human outcome studies have been performed to determine its efficacy as a neuroprotectant. Excitatory phenomena, such as choreiform movements and opisthotonus, have been observed after propofol injection with the same frequency as that seen with thiopental but less than with methohexital. These movements, which are transient, are *not* associated with seizure activity. Results from studies on the anticonvulsant effects of propofol have been mixed; some

data even suggest it has proconvulsant activity when combined with other drugs. However, propofol has been shown to suppress seizure activity in experimental models and has been used for the treatment of status epilepticus in humans (Parviainen et al., 2007).

Cardiovascular System. Propofol produces a dose-dependent decrease in blood pressure that is significantly greater than that produced by thiopental. The fall in blood pressure can be explained by both vasodilation and possibly mild depression of myocardial contractility. Propofol appears to blunt the baroreceptor reflex and reduce sympathetic nerve activity (Ebert and Muzi, 1994). As with thiopental, propofol should be used with caution in patients at risk for or intolerant of decreases in blood pressure; these include patients with significant blood loss and hypovolemia.

Respiratory System. At equipotent doses, propofol produces a slightly greater degree of respiratory depression than thiopental (Blouin et al., 1991). Patients given propofol should be monitored to ensure adequate oxygenation and ventilation. Propofol appears to be less likely than barbiturates to provoke bronchospasm and may be the induction agent of choice in asthmatics (Pizov et al., 1995). The bronchodilator properties of propofol may be attenuated by the metabisulfite preservative in some propofol formulations (Brown et al., 2001).

Other Side Effects. Propofol has no clinically significant effects on hepatic, renal, or endocrine organ systems. Unlike thiopental, propofol does not have an anti-analgesic effect. It has a significant anti-emetic action. Propofol elicits pain on injection that can be reduced with lidocaine and the use of larger arm and antecubital veins. Propofol provokes anaphylactoid reactions at about the same low frequency as thiopental; the histamine release (in the absence of anaphylactic or anaphylactoid reactions) that occurs with thiopental administration is greater than that with propofol. Although propofol does cross placental membranes, it is considered safe for use in pregnant women; like thiopental, propofol only transiently depresses activity in the newborn (Abboud et al., 1995). Propofol does not trigger malignant hyperthermia.

A rare but potentially fatal complication, termed propofol infusion syndrome (PRIS), has been described primarily in prolonged, higher-dose infusions of propofol in young or head-injured patients. The syndrome is characterized by metabolic acidosis, hyperlipidemia, rhabdomyolysis, and an enlarged liver. While the precise mechanisms by which PRIS occurs are not clear, alterations in mitochondrial metabolism and electron transport chain function have been described (Kam and Cardone, 2007).

The side-effect profile of fospropofol is similar to that of propofol. Fospropofol's slower onset of sedation (due to the need for hydrolysis of the prodrug) results in a lower incidence of hypotension, respiratory depression, apnea, and loss of airway patency. Nonetheless, unintended deep levels of sedation can occur with fospropofol, and the drug should therefore be used only by individuals who can maintain an adequate airway and support cardiorespiratory function.

Whether fospropofol can also cause PRIS is not currently known (Fechner et al., 2008). A metabolic byproduct of fospropofol is formic acid. This is degraded to CO₂ and water by tetrahydrofolate dehydrogenase, an enzyme that requires folate as a co-factor. In patients who have a folate deficiency, there is a theoretical risk of formic acid accumulation; to date, such an adverse event has not been reported.

Etomidate is a substituted imidazole that is supplied as the active d-isomer (Figure 19–1). Etomidate is poorly soluble in water and is formulated as a 2 mg/mL solution in 35% propylene glycol. An aqueous solution of etomidate using sulfobutyl ether-7 β -cyclodextrin as a solubilizing agent has been developed; this formulation is not currently available for clinical use in the U.S.. Unlike thiopental, etomidate does not induce precipitation of neuromuscular blockers or other drugs frequently given during anesthetic induction. Etomidate's clinical pharmacological properties are listed in Table 19–2.

Dosage and Clinical Use. Etomidate (AMIDATE, others) is primarily used for anesthetic induction of patients at risk for hypotension.

Induction doses of etomidate (0.2–0.6 mg/kg) have a rapid onset and short duration of action (Table 19–2) and are accompanied by a high incidence of pain on injection and myoclonic movements. Lidocaine effectively reduces the pain of injection, while myoclonic movements can be reduced by premedication with either benzodiazepines or opiates. These myoclonic movements, which are similar to seizures, are not associated with convulsive activity on the EEG. Etomidate is pharmacokinetically suitable for off-label infusion for anesthetic maintenance (10 μ g/kg per minute) or sedation (5 μ g/kg per minute); however, long-term infusions are not recommended (see below, under “Respiratory and Other Side Effects”). Etomidate also may be given rectally (6.5 mg/kg) with an onset of ~5 minutes.

Pharmacokinetics and Metabolism. An induction dose of etomidate has a rapid onset; redistribution limits the duration of action (Table 19–2). Metabolism occurs in the liver, primarily to inactive compounds. Elimination is both renal (78%) and biliary (22%). Compared to thiopental, the duration of action of etomidate increases less with repeated doses (Figure 19–3). The plasma protein binding of etomidate is high but less than that of barbiturates and propofol (Table 19–2).

Side Effects

Nervous System. Etomidate produces hypnosis and has no analgesic effects. The effects of etomidate on cerebral blood flow, metabolism, and intracranial and intraocular pressures are similar to those of thiopental (without dropping mean arterial blood pressure) (Modica and Tempelhoff, 1992). Etomidate has been used as a protectant against cerebral ischemia; however, animal studies have failed to show a consistent beneficial effect (Drummond et al., 1995), and no controlled human trials have been performed. Etomidate produces increased EEG activity in epileptogenic foci and has been associated with seizures (Ebrahim et al., 1986).

Cardiovascular System. Cardiovascular stability after induction is a major advantage of etomidate over either barbiturates or propofol. Induction doses of etomidate typically produce a small increase in heart rate and little or no decrease in blood pressure or cardiac output. Etomidate has little effect on coronary perfusion pressure while reducing myocardial O₂ consumption (Kettler et al., 1974). Thus, of

all induction agents, etomidate is best suited to maintain cardiovascular stability in patients with coronary artery disease, cardiomyopathy, cerebral vascular disease, or hypovolemia.

Respiratory and Other Side Effects. The degree of respiratory depression due to etomidate appears to be less than that due to thiopental. Like methohexital, etomidate may induce hiccups but does not significantly stimulate histamine release. Despite minimal cardiac and respiratory effects, etomidate does have two major drawbacks. Etomidate has been associated with nausea and vomiting. The drug also inhibits adrenal biosynthetic enzymes required for the production of cortisol and some other steroids. Single induction doses of etomidate may mildly and transiently reduce cortisol levels but no significant differences in outcome after short-term administration have been found, even for variables specifically known to be associated with adrenocortical suppression (Wagner et al., 1984). Thus, while etomidate is not recommended for long-term infusion, it appears safe for anesthetic induction and has some unique advantages in patients prone to hemodynamic instability. A rapidly metabolized and ultra-short-acting analog, methoxycarbonyl-etomidate, has been developed that retains the favorable pharmacological properties of etomidate but does not produce adrenocortical suppression after bolus dosing (Cotton and Claing, 2009).

Ketamine

Ketamine is an arylcyclohexylamine, a congener of phencyclidine (Figure 19–1). Clinical pharmacokinetic data for ketamine appear in Table 19–2.

Ketamine is supplied as a mixture of the R+ and S- isomers even though the S- isomer is more potent with fewer side effects. Although more lipophilic than thiopental, ketamine is water soluble and available as 10-, 50-, and 100-mg/mL solutions in sodium chloride plus the preservative benzethonium chloride.

Dosage and Clinical Use. Ketamine (KETALAR, others) has unique properties that make it useful for anesthetizing patients at risk for hypotension and bronchospasm and for certain pediatric procedures. However, significant side effects limit its routine use. Ketamine rapidly produces a hypnotic state quite distinct from that of other anesthetics. Patients have profound analgesia, unresponsiveness to commands, and amnesia, but may have their eyes open, move their limbs involuntarily, and breathe spontaneously. This cataleptic state has been termed *dissociative anesthesia*. The administration of ketamine has been shown to reduce the development of tolerance to long-term opioid use. Low-dose ketamine infusion for this purpose has been advocated in patients who have developed significant tolerance to opioids (Himmelseher and Durieux, 2005).

Ketamine typically is administered intravenously but also is effective by intramuscular, oral, and rectal routes. The induction doses are 0.5–1.5 mg/kg IV, 4–6 mg/kg IM, and 8–10 mg/kg PR. Onset of action after an intravenous dose is similar to that of the other parental anesthetics, but the duration of anesthesia of a single dose is longer (Table 19–2). For anesthetic maintenance, ketamine occasionally is continued as an infusion (25–100 μ g/kg per minute). Ketamine does not elicit pain on injection or true excitatory behavior as described for methohexital, although involuntary movements produced by ketamine can be mistaken for anesthetic excitement.

Pharmacokinetics and Metabolism. The onset and duration of an induction dose of ketamine are determined by the same distribution/redistribution mechanisms operant for all the other parenteral anesthetics.

Ketamine is hepatically metabolized to norketamine, which has reduced CNS activity; norketamine is further metabolized and excreted in urine and bile. Ketamine has a large volume of distribution and rapid clearance that make it suitable for continuous infusion without the lengthening in duration of action seen with thiopental (Table 19–2 and Figure 19–3). Protein binding is much lower with ketamine than with the other parenteral anesthetics (Table 19–2).

Side Effects

Nervous System. Ketamine has indirect sympathomimetic activity and can support blood pressure on anesthetic induction in patients who are at risk of developing significant hypotension. Ketamine's behavioral effects are distinct from those of other anesthetics. The ketamine-induced cataleptic state is accompanied by nystagmus with pupillary dilation, salivation, lacrimation, and spontaneous limb movements with increased overall muscle tone. Although ketamine does not produce the classic anesthetic state, patients are amnesic and unresponsive to painful stimuli. Ketamine produces profound analgesia, a distinct advantage over other parenteral anesthetics.

Unlike other parenteral anesthetics, ketamine increases cerebral blood flow and intracranial pressure (ICP) with minimal alteration of cerebral metabolism. The racemic mixture of ketamine can increase cerebral metabolic rate (CMR) and cerebral blood flow (CBF), particularly in the anterior cingulate and frontal cortex, thalamus, and putamen (Langsjo et al., 2004). S ketamine produces similar changes in CBF and CMR whereas R+ ketamine reduces both CMR and CBF (Vollenweider et al., 1997). These properties of ketamine have raised a concern that ICP can increase in patients with compromised intracranial compliance. However, ketamine does not increase ICP in patients with intracranial hypertension (Bourgoin et al., 2005). Moreover, the effects of ketamine on CBF can be readily attenuated by the simultaneous administration of sedative hypnotics (propofol, midazolam, barbiturates). In aggregate, the available data suggest that the contraindication of ketamine in patients with intracranial pathology or cerebral ischemia needs re-evaluation (Himmelseher et al., 2005).

In some studies, ketamine increased intraocular pressure, and its use for induction of patients with open eye injuries is controversial (Whitacre and Ellis, 1984). The effects of ketamine on seizure activity appear mixed, without either strong pro- or anticonvulsant activity. Emergence delirium, characterized by hallucinations, vivid dreams, and delusions, is a frequent complication of ketamine that can result in serious patient dissatisfaction and can complicate postoperative management. Delirium symptoms are most frequent in the first hour after emergence and appear to occur less frequently in children. Benzodiazepines reduce the incidence of emergence delirium (Dundee and Lilburn, 1978).

Cardiovascular System. Unlike other anesthetics, induction doses of ketamine typically increase blood pressure, heart rate, and cardiac output. The cardiovascular effects are indirect and are most likely mediated by inhibition of both central and peripheral catecholamine reuptake. Ketamine has direct negative inotropic and vasodilating activity, but these effects usually are overwhelmed by the indirect

sympathomimetic action (Pagel et al., 1992). Thus, ketamine is a useful drug, along with etomidate, for patients at risk for hypotension during anesthesia. While not arrhythmogenic, ketamine increases myocardial O₂ consumption and is not an ideal drug for patients at risk for myocardial ischemia.

Respiratory System. The respiratory effects of ketamine are perhaps the best indication for its use. Induction doses of ketamine produce small and transient decreases in minute ventilation, but respiratory depression is less severe than with other general anesthetics. Ketamine is a potent bronchodilator due to its indirect sympathomimetic activity and perhaps some direct bronchodilating activity. Thus, ketamine is particularly well-suited for anesthetizing patients at high risk for bronchospasm. Increased salivation that attends ketamine administration can be effectively prevented by anticholinergic agents such as glycopyrrolate.

Summary of Parenteral Anesthetics

Parenteral anesthetics are the most common drugs used for anesthetic induction of adults. Their lipophilicity, coupled with the relatively high perfusion of the brain and spinal cord, results in rapid onset and short duration after a single bolus dose. However, these drugs ultimately accumulate in fatty tissue, prolonging recovery if multiple doses are given, particularly for drugs with lower rates of clearance. Each anesthetic has its own unique set of properties and side effects (Table 19–3). Propofol and thiopental are the two most commonly used parenteral agents. Propofol is advantageous for procedures where rapid return to a preoperative mental status is desirable. Thiopental has a long-established track record of safety. Etomidate usually is reserved for patients at risk for hypotension and/or myocardial ischemia. Ketamine is best suited for patients with asthma or for children undergoing short, painful procedures.

INHALATIONAL ANESTHETICS

Introduction

A wide variety of gases and volatile liquids can produce anesthesia. The structures of the currently used inhalational anesthetics are shown in Figure 19–4. One of the troublesome properties of the inhalational anesthetics is their low safety margin. The inhalational anesthetics have therapeutic indices (LD₅₀/ED₅₀) that range from 2 to 4, making these among the most dangerous drugs in clinical use.

The toxicity of these drugs is largely a function of their side effects, and each of the inhalational anesthetics has a unique side-effect profile. Hence, the selection of an inhalational anesthetic often is based on matching a patient's pathophysiology with drug side-effect profiles. The specific adverse effects of each of

Table 19–3

Some Pharmacological Effects of Parenteral Anesthetics^a

the inhalational anesthetics are emphasized in the following sections.

Table 19–1 lists the widely varying physical properties of the inhalational agents in clinical use. These properties are important because they govern the pharmacokinetics of the inhalational agents. Ideally, an inhalational agent would produce a rapid induction of anesthesia and a rapid recovery following discontinuation.

Pharmacokinetic Principles

The inhalational agents are some of the very few pharmacological agents administered as gases. The fact that

these agents behave as gases rather than as liquids requires that different pharmacokinetic constructs be used in analyzing their uptake and distribution.

It is essential to understand that inhalational anesthetics distribute between tissues (or between blood and gas) such that equilibrium is achieved when the partial pressure of anesthetic gas is equal in the two tissues. When a person has breathed an inhalational anesthetic for a sufficiently long time that all tissues are equilibrated with the anesthetic, the partial pressure of the anesthetic in all tissues will be equal to the partial pressure of the anesthetic in inspired gas. Note, however, that while the partial pressure of the anesthetic may be equal in all tissues, the concentration of anesthetic in each tissue will be different. Indeed, anesthetic partition coefficients are defined as the ratio of anesthetic concentration in two tissues when the partial pressures of anesthetic are equal in the two tissues. Blood:gas, brain:brain, and fat:fat partition coefficients for the various inhalational agents are listed in Table 19–1. These partition coefficients show that inhalational anesthetics are more soluble in some tissues (e.g., fat) than they are in others (e.g., blood), and that there is significant range in the solubility of the various inhalational agents in such tissues.

In clinical practice, one can monitor the equilibration of a patient with anesthetic gas. Equilibrium is achieved when the partial pressure in inspired gas is equal to the partial pressure in end-tidal (alveolar) gas. In other words, equilibrium is the point at which there is no *net* uptake of anesthetic from the alveoli into the blood. For inhalational agents that are not very soluble in blood or any other tissue, equilibrium is achieved quickly, as illustrated for nitrous oxide in Figure 19–5. If an agent is more soluble in a tissue such as fat, equilibrium may take many hours to reach. This occurs

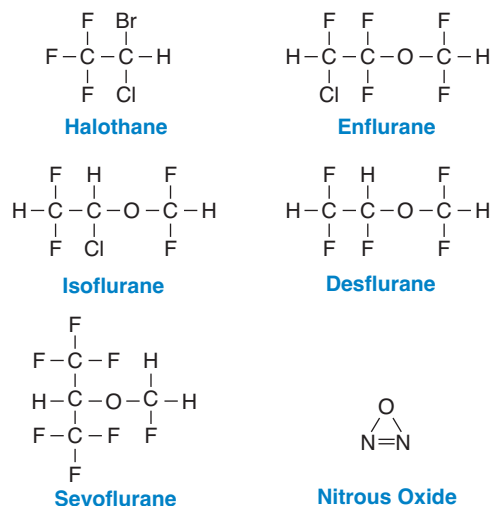

Figure 19–4. Structures of inhalational general anesthetics. Note that all inhalational general anesthetic agents except nitrous oxide and halothane are ethers, and that fluorine progressively replaces other halogens in the development of the halogenated agents. All structural differences are associated with important differences in pharmacological properties.

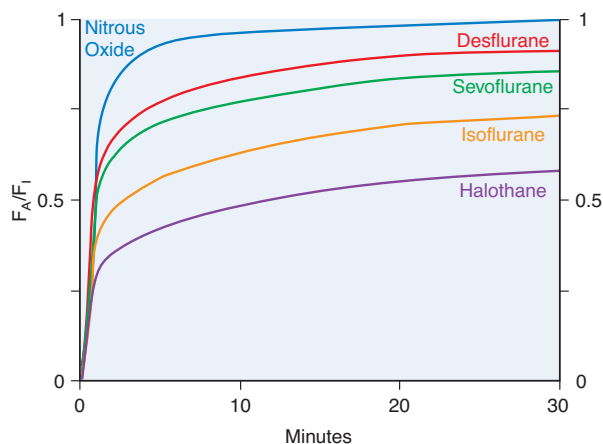

Figure 19–5. Uptake of inhalational general anesthetics. The rise in end-tidal alveolar (F_A) anesthetic concentration toward the inspired (F_I) concentration is most rapid with the least soluble anesthetics, nitrous oxide and desflurane, and slowest with the most soluble anesthetic, halothane. All data are from human studies. (Reproduced with permission from Eger EI, II: Inhaled anesthetics: Uptake and distribution, in Miller RD et al, (eds): *Miller's Anesthesia*, 7th ed. Philadelphia: Churchill Livingstone, 2010, p 540. Copyright © Elsevier.)

because fat represents a huge anesthetic reservoir that will be filled only slowly because of the modest blood flow to fat. This is illustrated by the slow approach of halothane alveolar partial pressure to inspired partial pressure of halothane in Figure 19–5.

In considering the pharmacokinetics of anesthetics, one important parameter is the speed of anesthetic induction. Anesthesia is produced when anesthetic partial pressure in brain is equal to or greater than MAC. Because the brain is well perfused, anesthetic partial pressure in brain becomes equal to the partial pressure in alveolar gas (and in blood) over the course of several minutes. Therefore, anesthesia is achieved shortly after alveolar partial pressure reaches MAC. While the rate of rise of alveolar partial pressure will be slower for anesthetics that are highly soluble in blood and other tissues, this limitation on speed of induction can be overcome largely by delivering higher inspired partial pressures of the anesthetic.

Elimination of inhalational anesthetics is largely the reverse process of uptake. For agents with low blood and tissue solubility, recovery from anesthesia should mirror anesthetic induction, regardless of the duration of anesthetic administration. For inhalational agents with high blood and tissue solubility, recovery will be a function of the duration of anesthetic administration. This occurs because the accumulated amounts

of anesthetic in the fat reservoir will prevent blood (and therefore alveolar) partial pressures from falling rapidly. Patients will be arousable when alveolar partial pressure reaches MAC_{awake} , a partial pressure somewhat lower than MAC (Table 19–1).

Halothane

Halothane is 2-bromo-2-chloro-1,1,1-trifluoroethane (Figure 19–4). Halothane is a volatile liquid at room temperature and must be stored in a sealed container. Because halothane is a light-sensitive compound that also is subject to spontaneous breakdown, it is marketed in amber bottles with thymol added as a preservative. Mixtures of halothane with O_2 or air are neither flammable nor explosive.

Pharmacokinetics. Halothane has a relatively high blood:gas partition coefficient and high fat:blood partition coefficient (Table 19–1). Induction with halothane therefore is relatively slow, and the alveolar halothane concentration remains substantially lower than the inspired halothane concentration for many hours of administration. Because halothane is soluble in fat and other body tissues, it will accumulate during prolonged administration. Therefore, the speed of recovery from halothane is lengthened as a function of duration of administration.

Approximately 60–80% of halothane taken up by the body is eliminated unchanged by the lungs in the first 24 hours after its administration. A substantial amount of the halothane not eliminated in exhaled gas is biotransformed by hepatic CYPs. The major metabolite of halothane is trifluoroacetic acid, which is formed by removal of bromine and chlorine ions. Trifluoroacetic acid, bromine, and chlorine all can be detected in the urine. Trifluoroacetylchloride, an intermediate in oxidative metabolism of halothane, can trifluoroacetylate several proteins in the liver. An immune reaction to these altered proteins may be responsible for the rare cases of fulminant halothane-induced hepatic necrosis. A minor reductive pathway accounts for ~1% of halothane metabolism that generally is observed only under hypoxic conditions.

Clinical Use. Halothane, introduced in 1956, was the first modern, halogenated inhalational anesthetic used in clinical practice. It is a potent agent that usually is used for maintenance of anesthesia. It is not pungent and is therefore well tolerated for inhalation induction of anesthesia. This is most commonly done in children, in whom preoperative placement of an intravenous catheter can be difficult. Anesthesia is produced by halothane at end-tidal concentrations of 0.7–1%. The use of halothane in the U.S. has diminished substantially in the past decade because of the introduction of newer inhalational agents with better pharmacokinetic

542 and side-effect profiles. Halothane continues to be extensively used in children because it is well tolerated for inhalation induction and because the serious side effects appear to be diminished in children. Halothane has a low cost and therefore is still widely used in developing countries.

Side Effects

Cardiovascular System. The most predictable side effect of halothane is a dose-dependent reduction in arterial blood pressure. Mean arterial pressure typically decreases ~20-25% at MAC concentrations of halothane. This reduction in blood pressure is primarily the result of direct myocardial depression leading to reduced cardiac output (Figure 19-6). Myocardial depression is thought to result from attenuation of depolarization-induced intracellular calcium transients. Halothane-induced hypotension usually is accompanied by either bradycardia or a normal heart rate. Attenuation of baroreceptor reflex function decreases the chronotropic and inotropic responses to a reduction in blood pressure (Constant et al., 2004). Heart rate can be increased during halothane anesthesia by exogenous catecholamine or by sympathoadrenal stimulation. Halothane-induced reductions in blood pressure and heart rate generally disappear after

several hours of constant halothane administration, presumably because of progressive sympathetic stimulation.

Halothane does not cause a significant change in systemic vascular resistance. Nonetheless, it does alter the resistance and autoregulation of specific vascular beds, leading to redistribution of blood flow. The vascular beds of the skin and brain are dilated directly by halothane, leading to increased cerebral blood flow and skin perfusion. Conversely, autoregulation of renal, splanchnic, and cerebral blood flow is inhibited by halothane, leading to reduced perfusion of these organs in the face of reduced blood pressure. Coronary autoregulation is largely preserved during halothane anesthesia. Finally, halothane inhibits hypoxic pulmonary vasoconstriction, leading to increased perfusion to poorly ventilated regions of the lung and an increased alveolar:arterial O_2 gradient.

Halothane also has significant effects on cardiac rhythm. Sinus bradycardia and atrioventricular rhythms occur frequently during halothane anesthesia but usually are benign. These rhythms result mainly from a direct depressive effect of halothane on sinoatrial node discharge. Halothane also can sensitize the myocardium to the arrhythmogenic effects of epinephrine (Sumikawa et al., 1983). Premature ventricular contractions and sustained ventricular tachycardia can be observed during halothane anesthesia when exogenous administration or endogenous adrenal production elevates plasma epinephrine levels.

Respiratory System. Spontaneous respiration is rapid and shallow during halothane anesthesia. The decreased alveolar ventilation results in an elevation in arterial CO_2 tension from 40 mm Hg to >50 mm Hg at 1 MAC (Figure 19-7). The elevated CO_2 does not provoke a compensatory increase in ventilation, because halothane causes a concentration-dependent inhibition of the ventilatory response to CO_2 . This action of halothane is thought to be mediated by depression of central chemoreceptor mechanisms. Halothane also inhibits peripheral chemoreceptor responses to arterial hypoxemia. Thus, neither hemodynamic (tachycardia and hypertension) nor ventilatory responses to hypoxemia are observed during halothane anesthesia, making it prudent to monitor arterial O_2 directly. Halothane also is an effective bronchodilator (Yamakage, 1992) and has been effectively used as a treatment of last resort in patients with status asthmaticus (Gold and Helrich, 1970).

Nervous System. Halothane dilates the cerebral vasculature, increasing cerebral blood flow and cerebral blood volume. This can result in an increase in intracranial pressure, especially in patients with space-occupying intracranial masses, brain edema, or preexisting intracranial hypertension. Halothane attenuates autoregulation of cerebral blood flow in a dose-dependent manner. Hence, cerebral blood flow can increase even with a modest reduction in arterial pressure. With a reduction of arterial pressure that is below the lower limit of autoregulation, cerebral blood flow can decrease significantly. Halothane suppresses cerebral metabolism and cerebral metabolic rate is decreased.

Muscle. Halothane causes some relaxation of skeletal muscle by its central depressant effects. Halothane also potentiates the actions of non-depolarizing muscle relaxants (curariform drugs; Chapter 11), increasing both their duration of action and the magnitude of their effect. Halothane and the other halogenated inhalational anesthetics can trigger malignant hyperthermia, a syndrome characterized by

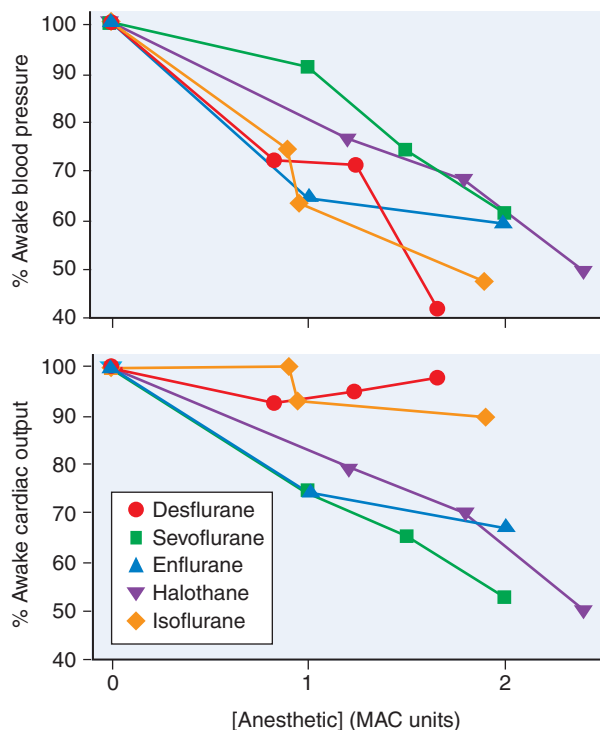

Figure 19-6. Influence of inhalational general anesthetics on the systemic circulation. While all of the inhalational anesthetics reduce systemic blood pressure in a dose-related manner (top), the lower figure shows that cardiac output is well preserved with isoflurane and desflurane, and therefore that the causes of hypotension vary with the agent. (Data from Bahlman et al., 1972; Calverley et al., 1978; Cromwell et al., 1971; Stevens et al., 1971; Weiskopf et al., 1991).

Figure 19-7. Respiratory effects of inhalational anesthetics. Spontaneous ventilation with all of the halogenated inhalational anesthetics reduces minute volume of ventilation in a dose-dependent manner (*lower panel*). This results in an increased arterial carbon dioxide tension (*top panel*). Differences among agents are modest. (Data from Calverley et al., 1978; Doi and Ikeda, 1987; Fourcade et al., 1971; Lockhart et al., 1991; Munson et al., 1966.)

severe muscle contraction, rapid development of hyperthermia, and a massive increase in metabolic rate in genetically susceptible patients. This syndrome frequently is fatal and is treated by immediate discontinuation of the anesthetic and administration of dantrolene.

Uterine smooth muscle is relaxed by halothane. This is a useful property for manipulation of the fetus (version) in the prenatal period and for delivery of retained placenta postnatally. However, halothane inhibits uterine contractions during parturition, prolonging labor and increasing blood loss, and therefore is not used as an analgesic or anesthetic for labor and vaginal delivery.

Kidney. Patients anesthetized with halothane usually produce a small volume of concentrated urine. This is the consequence of halothane-induced reduction of renal blood flow and glomerular filtration rate, which may be reduced by 40-50% at 1 MAC. Halothane-induced changes in renal function are fully reversible and are not associated with long-term nephrotoxicity.

Liver and GI Tract. Halothane reduces splanchnic and hepatic blood flow as a consequence of reduced perfusion pressure, as discussed above. This reduced blood flow has not been shown to produce detrimental effects on hepatic or GI function.

Halothane can produce fulminant hepatic necrosis in a small number of patients. This syndrome generally is characterized by

fever, anorexia, nausea, and vomiting, developing several days after anesthesia and can be accompanied by a rash and peripheral eosinophilia. There is a rapid progression to hepatic failure, with a fatality rate of ~50%. This syndrome occurs in ~1 in 10,000 patients receiving halothane and is referred to as *halothane hepatitis* (Study, 1966). Current thinking is that halothane hepatitis is the result of an immune response to hepatic proteins that become trifluoroacetylated as a consequence of halothane metabolism (see the “Pharmacokinetics” section for halothane earlier in the chapter).

Isoflurane

Isoflurane (FORANE, others) is 1-chloro-2,2,2-trifluoroethyl difluoromethyl ether (Figure 19-4). It is a volatile liquid at room temperature and is neither flammable nor explosive in mixtures of air or oxygen.

Pharmacokinetics. Isoflurane has a blood:gas partition coefficient substantially lower than that of halothane or enflurane (Table 19-1). Consequently, induction with isoflurane and recovery from isoflurane are faster than with halothane. Changes in anesthetic depth also can be achieved more rapidly with isoflurane than with halothane or enflurane.

More than 99% of inhaled isoflurane is excreted unchanged by the lungs. Approximately 0.2% of absorbed isoflurane is metabolized by CYP2E1. This small amount of isoflurane degradation products produced is insufficient to produce any renal, hepatic, or other organ toxicity. Isoflurane does not appear to be a mutagen, teratogen, or carcinogen.

Clinical Use. Isoflurane is a commonly used inhalational anesthetic worldwide.

It is typically used for maintenance of anesthesia *after induction* with other agents because of its pungent odor, but induction of anesthesia can be achieved in < 10 minutes with an inhaled concentration of 3% isoflurane in O₂; this concentration is reduced to 1-2% (~1-2 MAC) for maintenance of anesthesia. The use of other drugs such as opioids or nitrous oxide reduces the concentration of isoflurane required for surgical anesthesia.

Side Effects

Cardiovascular System. Isoflurane produces a concentration-dependent decrease in arterial blood pressure. Unlike halothane, cardiac output is well maintained with isoflurane, and hypotension is the result of decreased systemic vascular resistance (Figure 19-6). Isoflurane produces vasodilation in most vascular beds, with particularly pronounced effects in skin and muscle. Isoflurane is a potent coronary vasodilator, simultaneously producing increased coronary blood flow and decreased myocardial O₂ consumption. In theory, this makes isoflurane a particularly safe anesthetic to use for patients with ischemic heart disease. Concern that isoflurane might produce myocardial ischemia by inducing “coronary steal” has not been substantiated in animal and human studies. Isoflurane significantly attenuates baroreceptor function. Patients anesthetized with isoflurane generally have mildly elevated heart rates as a compensatory

response to reduced blood pressure; however, rapid changes in isoflurane concentration can produce both transient tachycardia and hypertension due to isoflurane-induced sympathetic stimulation.

Respiratory System. Isoflurane produces concentration-dependent depression of ventilation. Patients spontaneously breathing isoflurane have a normal respiration rate but a reduced tidal volume, resulting in a marked reduction in alveolar ventilation and an increase in arterial CO₂ tension (Figure 19–7). Isoflurane is particularly effective at depressing the ventilatory response to hypercapnia and hypoxia (Hirshman et al., 1977). While isoflurane is an effective bronchodilator, it also is an airway irritant and can stimulate airway reflexes during induction of anesthesia, producing coughing and laryngospasm.

Nervous System. Isoflurane dilates the cerebral vasculature, producing increased cerebral blood flow; this vasodilating activity is less than that of either halothane or enflurane (Drummond et al., 1983). There is a modest risk of an increase in intracranial pressure in patients with preexisting intracranial hypertension. Isoflurane reduces cerebral metabolic O₂ consumption in a dose dependent manner. At 1.5–2.0 MAC, isoflurane produces burst suppression of the EEG and reduces cerebral metabolic rate by ~50%. The modest effects of isoflurane on cerebral blood flow can be reversed readily by hyperventilation (McPherson et al., 1989).

Muscle. Isoflurane produces some relaxation of skeletal muscle by its central effects. It also enhances the effects of both depolarizing and non-depolarizing muscle relaxants. Isoflurane is more potent than halothane in its potentiation of neuromuscular blocking agents. Like other halogenated inhalational anesthetics, isoflurane relaxes uterine smooth muscle and is not recommended for analgesia or anesthesia for labor and vaginal delivery.

Kidney. Isoflurane reduces renal blood flow and glomerular filtration rate, resulting in a small volume of concentrated urine. Changes in renal function observed during isoflurane anesthesia are rapidly reversed, with no long-term renal sequelae or toxicities.

Liver and Gastrointestinal Tract. Splanchnic and hepatic blood flows are reduced with increasing doses of isoflurane as systemic arterial pressure decreases. Liver function tests are minimally affected by isoflurane, with no reported incidence of hepatic toxicity.

Enflurane

Enflurane (ETHRANE, others) is 2-chloro-1,1,2-trifluoroethyl difluoromethyl ether (Figure 19–4).

It is a clear, colorless liquid at room temperature with a mild, sweet odor. Like other inhalational anesthetics, it is volatile and must be stored in a sealed bottle. It is nonflammable and non-explosive in mixtures of air or oxygen.

Pharmacokinetics. Because of its relatively high blood:gas partition coefficient, induction of anesthesia and recovery from enflurane are relatively slow (Table 19–1).

Enflurane is metabolized to a modest extent, with 2–8% of absorbed enflurane undergoing oxidative metabolism in the liver by CYP2E1. Fluoride ions are a by-product of enflurane metabolism,

but plasma fluoride levels are low and nontoxic. Patients taking isoniazid exhibit enhanced metabolism of enflurane with significantly elevated serum fluoride concentrations (Mazze et al., 1982).

Clinical Use. As with isoflurane, enflurane is primarily utilized for maintenance rather than induction of anesthesia.

Surgical anesthesia can be induced with enflurane in < 10 minutes with an inhaled concentration of 4% in oxygen. Anesthesia can be maintained with concentrations from 1.5–3%. As with other anesthetics, the enflurane concentrations required to produce anesthesia are reduced when it is co-administered with nitrous oxide or opioids. With the advent of new inhalational agents, enflurane is rarely used for clinical anesthesia in developed countries.

Side Effects

Cardiovascular System. Enflurane causes a concentration-dependent decrease in arterial blood pressure. Hypotension is due in part to depression of myocardial contractility, with some contribution from peripheral vasodilation (Figure 19–6). Enflurane has minimal effects on heart rate and produces neither the bradycardia seen with halothane nor the tachycardia seen with isoflurane.

Respiratory System. The respiratory effects of enflurane are similar to those of halothane. Spontaneous ventilation with enflurane produces a pattern of rapid, shallow breathing. Minute ventilation is markedly decreased, and a Pa_{CO2} of 60 mm Hg can be seen with 1 MAC of enflurane (Figure 19–7). Enflurane produces a greater depression of the ventilatory responses to hypoxia and hypercarbia than do either halothane or isoflurane (Hirshman et al., 1977). Enflurane, like other inhalational anesthetics, is an effective bronchodilator.

Nervous System. Enflurane is a cerebral vasodilator and thus can increase intracranial pressure in some patients. Like other inhalational anesthetics, enflurane reduces cerebral metabolic O₂ consumption. Enflurane has an unusual property of producing electrical seizure activity. High concentrations of enflurane or profound hypercarbia during enflurane anesthesia result in a characteristic high-voltage, high-frequency electroencephalographic (EEG) pattern that progresses to spike-and-dome complexes. The spike-and-dome pattern can be punctuated by frank seizure activity that may or may not be accompanied by peripheral motor manifestations of seizure activity. The seizures are self-limited and are not thought to produce permanent damage. Epileptic patients are not particularly susceptible to enflurane-induced seizures. Nonetheless, enflurane generally is not used in patients with seizure disorders.

Muscle. Enflurane produces significant skeletal muscle relaxation in the absence of muscle relaxants. It also significantly enhances the effects of non-depolarizing muscle relaxants. As with other inhalational agents, enflurane relaxes uterine smooth muscle. It is not widely used for obstetric anesthesia.

Kidney. Like other inhalational anesthetics, enflurane reduces renal blood flow, glomerular filtration rate, and urinary output. These effects are rapidly reversed upon drug discontinuation. Enflurane metabolism produces significant plasma levels of fluoride ions (20–40 μmol) and can produce transient urinary-concentrating defects following prolonged administration (Mazze et al., 1977). There is scant evidence of

long-term nephrotoxicity following enflurane use, and it is safe to use in patients with renal impairment, provided that the depth of enflurane anesthesia and the duration of administration are not excessive.

Liver and GI Tract. Enflurane reduces splanchnic and hepatic blood flow in proportion to reduced arterial blood pressure. Enflurane does not appear to alter liver function or to be hepatotoxic.

Desflurane

Desflurane (SUPRANE) is difluoromethyl 1-fluoro-2,2,2-trifluoromethyl ether (Figure 19–4). It is a highly volatile liquid at room temperature (vapor pressure = 681 mm Hg) and thus must be stored in tightly sealed bottles.

Delivery of a precise concentration of desflurane requires the use of a specially heated vaporizer that delivers pure vapor that then is diluted appropriately with other gases (O₂, air, or N₂O). Desflurane is nonflammable and non-explosive in mixtures of air or oxygen.

Pharmacokinetics. Desflurane has a very low blood:gas partition coefficient (0.42) and also is not very soluble in fat or other peripheral tissues (Table 19–1). For this reason, the alveolar (and blood) concentration rapidly rises to the level of inspired concentration.

Indeed, within 5 minutes of administration, the alveolar concentration reaches 80% of the inspired concentration. This provides for a very rapid induction of anesthesia and for rapid changes in depth of anesthesia following changes in the inspired concentration. Emergence from anesthesia also is very rapid with desflurane. The time to awakening following desflurane is shorter than with halothane or sevoflurane and usually does not exceed 5–10 minutes in the absence of other sedative agents (La Colla et al., 2007).

Desflurane is metabolized to a minimal extent, and > 99% of absorbed desflurane is eliminated unchanged through the lungs. A small amount of absorbed desflurane is oxidatively metabolized by hepatic CYPs. Virtually no fluoride ions are detectable in serum after desflurane administration, but low concentrations of trifluoroacetic acid are found in serum and urine (Koblin et al., 1988).

Clinical Use. Desflurane is a widely used anesthetic for outpatient surgery because of its rapid onset of action and rapid recovery. The drug irritates the tracheobronchial tree and can provoke coughing, salivation, and bronchospasm. Anesthesia therefore usually is induced with an intravenous agent, with desflurane subsequently administered for maintenance of anesthesia. Maintenance of anesthesia usually requires inhaled concentrations of 6–8% (~1 MAC). Lower concentrations of desflurane are required if it is co-administered with nitrous oxide or opioids.

Side Effects

Cardiovascular System. Desflurane, like all inhalational anesthetics, causes a concentration-dependent decrease in blood pressure. Desflurane has a very modest negative inotropic effect and produces hypotension primarily by decreasing systemic vascular resistance (Eger, 1994) (Figure 19–6). Thus, cardiac output is well preserved

during desflurane anesthesia, as is blood flow to the major organ beds (splanchnic, renal, cerebral, and coronary). Marked increases in heart rate often are noted during induction of desflurane anesthesia and during abrupt increases in the delivered concentration of desflurane. This transient tachycardia results from desflurane-induced stimulation of the sympathetic nervous system (Ebert and Muzi, 1993). Unlike some inhalational anesthetics, the hypotensive effects of desflurane do not wane with increasing duration of administration.

Respiratory System. Similarly to halothane and enflurane, desflurane causes a concentration-dependent increase in respiratory rate and a decrease in tidal volume. At low concentrations (< 1 MAC) the net effect is to preserve minute ventilation. At desflurane concentrations > 1 MAC, minute ventilation is markedly depressed, resulting in elevated arterial CO₂ tension (Pa_{CO₂}) (Figure 19–7). Patients spontaneously breathing desflurane at concentrations > 1.5 MAC will have extreme elevations of Pa_{CO₂} and may become apneic. Desflurane, like other inhalational agents, is a bronchodilator. However, it also is a strong airway irritant, and can cause coughing, breath-holding, laryngospasm, and excessive respiratory secretions. *Because of its irritant properties, desflurane is not used for induction of anesthesia.*

Nervous System. Desflurane decreases cerebral vascular resistance and cerebral metabolic O₂ consumption. Burst suppression of the EEG is achieved with ~ 2 MAC desflurane; at this level, CMRO₂ is reduced by ~ 50%. Under conditions of normocapnia and normotension, desflurane produces an increase in cerebral blood flow and can increase intracranial pressure in patients with poor intracranial compliance. The vasoconstrictive response to hypocapnia is preserved during desflurane anesthesia, and increases in intracranial pressure thus can be prevented by hyperventilation.

Muscle. Desflurane produces direct skeletal muscle relaxation as well as enhancing the effects of non-depolarizing and depolarizing neuromuscular blocking agents (Caldwell et al., 1991).

Kidney. Consistent with its minimal metabolic degradation, desflurane has no reported nephrotoxicity.

Liver and GI Tract. Desflurane is not known to affect liver function tests or to cause hepatotoxicity.

Desflurane and Carbon Monoxide. Inhaled anesthetics are administered via a circle system circuit that permits unidirectional flow of gas. This system permits rebreathing of exhaled gases that contain CO₂. To prevent rebreathing of CO₂ (which can lead to hypercarbia), CO₂ absorbers are incorporated into the anesthesia delivery circuits. These CO₂ absorbers contained either Ca(OH)₂ or Ba(OH)₂ and smaller quantities of more potent alkalis, NaOH and KOH. Interaction of inhaled anesthetics with these strong alkalis results in the formation of CO. The amount of CO produced is insignificant as long as the CO₂ absorbent is sufficiently hydrated. With almost complete desiccation of the CO₂ absorbents, substantial quantities of CO can be produced. This effect is greatest with desflurane and can be prevented by the use of well-hydrated, fresh CO₂ absorbent.

Sevoflurane

Sevoflurane (ULTANE, others) is fluoromethyl 2,2,2-trifluoro-1-[trifluoromethyl]ethyl ether (Figure 19–4).

It is a clear, colorless, volatile liquid at room temperature and must be stored in a sealed bottle. It is

nonflammable and non-explosive in mixtures of air or oxygen. However, sevoflurane can undergo an exothermic reaction with desiccated CO₂ absorbent (BARALYME) to produce airway burns (Fatheree and Leighton, 2004) or spontaneous ignition, explosion, and fire (Wu et al., 2004a).

Care must be taken to ensure that sevoflurane is not used with an anesthesia machine in which the CO₂ absorbent has been dried by prolonged gas flow through the absorbent. The reaction of sevoflurane with desiccated CO₂ absorbent also can produce CO, which can result in serious patient injury; this effect is less than that with desflurane.

Pharmacokinetics. The low solubility of sevoflurane in blood and other tissues provides for rapid induction of anesthesia, rapid changes in anesthetic depth following changes in delivered concentration, and rapid emergence following discontinuation of administration (Table 19–1).

Approximately 3% of absorbed sevoflurane is biotransformed. Sevoflurane is metabolized in the liver by CYP2E1, with the predominant product being hexafluoroisopropanol (Kharasch et al., 1995). Hepatic metabolism of sevoflurane also produces inorganic fluoride. Serum fluoride concentrations peak shortly after surgery and decline rapidly. Interaction of sevoflurane with soda lime also produces decomposition products. The major product of interest is referred to as compound A, pentafluoroisopropenyl fluoromethyl ether (see “Kidney” under “Side Effects”) (Hanaki et al., 1987).

Clinical Use. Sevoflurane is widely used, particularly for outpatient anesthesia, because of its rapid recovery profile. It is well-suited for inhalation induction of anesthesia (particularly in children) because it is not irritating to the airway. Induction of anesthesia is rapidly achieved using inhaled concentrations of 2–4% sevoflurane.

Side Effects

Cardiovascular System. Sevoflurane, like all other halogenated inhalational anesthetics, produces a concentration-dependent decrease in arterial blood pressure. This hypotensive effect primarily is due to systemic vasodilation, although sevoflurane also produces a concentration-dependent decrease in cardiac output (Figure 19–6). Unlike isoflurane or desflurane, sevoflurane does not produce tachycardia and thus may be a preferable agent in patients prone to myocardial ischemia.

Respiratory System. Sevoflurane produces a concentration-dependent reduction in tidal volume and increase in respiratory rate in spontaneously breathing patients. The increased respiratory frequency does not compensate for reduced tidal volume, with the net effect being a reduction in minute ventilation and an increase in Pa_{CO2} (Doi and Ikeda, 1987) (Figure 19–7). Sevoflurane is not irritating to the airway and is a potent bronchodilator. Because of this combination of properties, sevoflurane is the most effective clinical bronchodilator of the inhalational anesthetics (Rooke et al., 1997).

Nervous System. Sevoflurane produces effects on cerebral vascular resistance, cerebral metabolic O₂ consumption, and cerebral blood

flow that are very similar to those produced by isoflurane and desflurane. Its cerebral vasodilating capacity is less than that of isoflurane, and particularly desflurane. At ~2 MAC anesthesia, sevoflurane produces burst suppression of the EEG, and at this level, CMRO₂ is reduced by ~50%. While sevoflurane can increase intracranial pressure in patients with poor intracranial compliance, the response to hypocapnia is preserved during sevoflurane anesthesia, and increases in intracranial pressure can be prevented by hyperventilation. In children, sevoflurane is associated with delirium upon emergence from anesthesia. This delirium, the causes of which are not clear, is short lived and without any reported adverse long-term sequelae.

Muscle. Sevoflurane produces skeletal muscle relaxation and enhances the effects of non-depolarizing and depolarizing neuromuscular blocking agents. Its effects are similar to those of other halogenated inhalational anesthetics.

Kidney. Controversy has surrounded the potential nephrotoxicity of compound A, the degradation product produced by interaction of sevoflurane with the CO₂ absorbent soda lime. Biochemical evidence of transient renal injury has been reported in human volunteers (Eger et al., 1997). Large clinical studies have shown no evidence of increased serum creatinine, blood urea nitrogen, or any other evidence of renal impairment following sevoflurane administration (Mazze et al., 2000). *The FDA recommends that sevoflurane be administered with fresh gas flows of at least 2 L/min to minimize accumulation of compound A.*

Liver and GI Tract. Sevoflurane is not known to cause hepatotoxicity or alterations of hepatic function tests.

Nitrous Oxide

Nitrous oxide (dinitrogen monoxide; N₂O) is a colorless, odorless gas at room temperature (Figure 19–4).

N₂O is sold in steel cylinders and must be delivered through calibrated flow meters provided on all anesthesia machines. Nitrous oxide is neither flammable nor explosive, but it does support combustion as actively as oxygen does when it is present in proper concentration with a flammable anesthetic or material.

Pharmacokinetics. Nitrous oxide is very insoluble in blood and other tissues (Table 19–1). This results in rapid equilibration between delivered and alveolar anesthetic concentrations and provides for rapid induction of anesthesia and rapid emergence following discontinuation of administration.

The rapid uptake of N₂O from alveolar gas serves to concentrate co-administered halogenated anesthetics; this effect (the “second gas effect”) speeds induction of anesthesia. On discontinuation of N₂O administration, nitrous oxide gas can diffuse from blood to the alveoli, diluting O₂ in the lung. This can produce an effect called *diffusional hypoxia*. *To avoid hypoxia, 100% O₂ rather than air should be administered when N₂O is discontinued.*

Nitrous oxide is almost completely eliminated by the lungs, with some minimal diffusion through the skin. Nitrous oxide is not biotransformed by enzymatic action in human tissue, and 99.9% of absorbed nitrous oxide is eliminated unchanged. N₂O can oxidize

the cobalt I (Co⁺) form of vitamin B₁₂ to Co³⁺ (Sanders et al., 2007), thereby preventing vitamin B₁₂ from acting as a co-factor for methionine synthetase. The latter is important in the synthesis of a number of products including DNA, RNA, and myelin. Indeed, methionine synthetase activity is dramatically reduced after 3-4 hours of N₂O exposure; activity of the enzyme is restored in 3-4 days. Inactivation of methionine synthetase can produce signs of vitamin B₁₂ deficiency, including megaloblastic anemia and peripheral neuropathy. This is of particular concern in patients with malnutrition, vitamin B₁₂ deficiency, or alcoholism. For this reason, N₂O is not used as a chronic analgesic or as a sedative in critical care settings.

Clinical Use. N₂O is a weak anesthetic agent that has significant analgesic effects. Noncompetitive antagonist activity at the NMDA receptor contributes to its anesthetic mechanism. However, surgical anesthetic depth is only achieved under hyperbaric conditions. By contrast, analgesia is produced at concentrations as low as 20%.

The analgesic property of N₂O is a function of the activation of opioidergic neurons in the periaqueductal gray matter (Fang et al., 1997) and the adrenergic neurons in the locus ceruleus (Sawamura et al., 2000). At least part of the activation of the locus ceruleus is due to release of corticotrophin-releasing factor from the hypothalamus as a result of antagonism of the NMDA receptor.

In doses approaching 70-80%, significant sedation is produced. Therefore, N₂O is frequently used in concentrations of ~50% to provide analgesia and mild sedation in outpatient dentistry. Nitrous oxide cannot be used at concentrations > 80% because this limits the delivery of adequate O₂. Because of this limitation, nitrous oxide is used primarily as an adjunct to other inhalational or intravenous anesthetics. Nitrous oxide substantially reduces the requirement for inhalational anesthetics. For example, at 70% nitrous oxide, the MAC for other inhalational agents is reduced by ~60%, allowing for lower concentrations of halogenated anesthetics and a lesser degree of side effects.

One major problem with N₂O is that it will exchange with N₂ in any air-containing cavity in the body. Moreover, because of their differential blood:gas partition coefficients, nitrous oxide will enter the cavity faster than nitrogen escapes, thereby increasing the volume and/or pressure in this cavity. Examples of air collections that can be expanded by nitrous oxide include a pneumothorax, an obstructed middle ear, an air embolus, an obstructed loop of bowel, an intraocular air bubble, a pulmonary bulla, and intracranial air. Nitrous oxide should be avoided in these clinical settings.

Side Effects

Cardiovascular System. Although N₂O produces a negative inotropic effect on heart muscle *in vitro*, depressant effects on cardiac function generally are not observed in patients because of the stimulatory effects of nitrous oxide on the sympathetic nervous system. The cardiovascular effects of nitrous oxide also are heavily influenced by the concomitant administration of other anesthetic agents. When nitrous oxide is co-administered with halogenated inhalational anesthetics, it generally produces an increase in heart rate, arterial blood pressure, and cardiac output. In contrast, when nitrous oxide is co-administered with an opioid, it generally decreases arterial blood pressure and

cardiac output. Nitrous oxide also increases venous tone in both the peripheral and pulmonary vasculature. The effects of N₂O on pulmonary vascular resistance can be exaggerated in patients with pre-existing pulmonary hypertension; thus, the drug generally is not used in these patients.

Respiratory System. N₂O causes modest increases in respiratory rate and decreases in tidal volume in spontaneously breathing patients. The net effect is that minute ventilation is not significantly changed and PaCO₂ remains normal. However, even modest concentrations of nitrous oxide markedly depress the ventilatory response to hypoxia. Thus, it is prudent to monitor arterial O₂ saturation directly in patients receiving or recovering from nitrous oxide.

Nervous System. When administered alone, nitrous oxide can significantly increase cerebral blood flow and intracranial pressure. This cerebral vasodilatory capacity of N₂O is significantly attenuated by the simultaneous administration of intravenous agents such as opiates and propofol. By contrast, the combination of N₂O and inhaled agents results in greater vasodilation than the administration of the inhaled agent alone at equivalent anesthetic depth.

Muscle. Nitrous oxide does not relax skeletal muscle and does not enhance the effects of neuromuscular blocking drugs. Unlike the halogenated anesthetics, nitrous oxide does not trigger malignant hyperthermia.

Kidney, Liver, and GI Tract. Nitrous oxide is not known to produce any changes in renal or hepatic function and is neither nephrotoxic nor hepatotoxic.

Xenon

Xenon is an inert gas that first was identified as an anesthetic agent in 1951. It is not approved for use in the U.S. and is unlikely to enjoy widespread use because it is a rare gas that cannot be manufactured and must be extracted from air. This limits the quantities of available xenon gas and renders xenon very expensive. Recent advances in the manufacturing technology, coupled with development of low-flow circuit systems that permit recycling of xenon, have led to a resurgence in the interest in xenon as an anesthetic agent. Much of this enthusiasm is based on the observation that xenon, unlike other anesthetic agents, has minimal cardiorespiratory side effects (Lynch et al., 2000).

Xenon exerts its analgesic and anesthetic effects at a number of receptor systems in the CNS. Of these, non-competitive antagonism of the NMDA receptor and agonism at the TREK channel (a member of the two-pore K⁺ channel family) are thought to be the central mechanisms of xenon action (Franks and Honore, 2004).

Xenon is extremely insoluble in blood and other tissues, providing for rapid induction and emergence from anesthesia (Table 19-1). It is sufficiently potent to produce surgical anesthesia when administered with 30% oxygen. However, supplementation with an intravenous agent such as propofol appears to be required for clinical

548 anesthesia (Rasmussen et al., 2006). Xenon is well tolerated in patients of advanced age. No long-term side effects from xenon anesthesia have been reported.

Effects on Organ Systems

Cardiovascular System. Xenon has minimal effects on cardiovascular function. Arterial pressure, unlike the situation with other anesthetic agents, is well maintained. Left ventricular contractility is not affected and heart rate and systemic vascular resistance are essentially unchanged. Autonomic function is better maintained under xenon anesthesia than under anesthesia with propofol and inhaled anesthetics (Hanss et al., 2006). Even in patients with significant cardiac disease, xenon maintains a favorable profile (Lockwood et al., 2006).

Respiratory System. Under xenon anesthesia, respiratory rate is reduced slightly. However, an increase in tidal volume maintains minute ventilation, indicating that there is minimal respiratory depression. An increase in airway pressure does occur; this has been attributed to the greater density and viscosity of xenon (compared to oxygen) and not due to changes in bronchomotor tone (Baumert et al., 2002).

Central Nervous System. Like other anesthetic agents, xenon reduces cerebral metabolism by 25-30%. This reduction in metabolism is accompanied by a corresponding reduction in cerebral blood flow. Consequently, xenon is not expected to increase intracranial pressure.

Liver, Kidney, and GI Tract. Xenon is an inert agent and does not undergo metabolism. Hepatic or renal toxicity with its use have not been reported.

ANESTHETIC ADJUNCTS

A general anesthetic is rarely given as the sole agent. Anesthetic adjuncts usually are used to augment specific components of anesthesia, permitting lower doses of general anesthetics with fewer side effects. Because they are such an integral part of general anesthetic drug regimens, their use as anesthetic adjuncts is described briefly here. The detailed pharmacology of each drug is covered in other chapters.

Benzodiazepines

While benzodiazepines (Chapter 17) can produce anesthesia similar to that of barbiturates, they are more commonly used for sedation rather than general anesthesia because prolonged amnesia and sedation may result from anesthetizing doses. As adjuncts, benzodiazepines are used for anxiolysis, amnesia, and sedation prior to induction of anesthesia or for sedation during procedures not requiring general anesthesia. The benzodiazepine most frequently used in the perioperative period is midazolam followed distantly by diazepam (VALIUM, others), and lorazepam (ATIVAN, others).

Midazolam is water soluble and typically is administered intravenously but also can be given orally, intramuscularly, or rectally; oral midazolam is particularly useful for sedation of young children. Midazolam produces minimal venous irritation as opposed to diazepam and lorazepam, which are formulated in propylene glycol and are painful on injection, sometimes producing thrombophlebitis. Midazolam has the pharmacokinetic advantage, particularly over lorazepam, of being more rapid in onset and shorter in duration of effect. Sedative doses of midazolam (0.01-0.05 mg/kg intravenously) reach peak effect in ~2 minutes and provide sedation for ~30 minutes. Elderly patients tend to be more sensitive to and have a slower recovery from benzodiazepines (Jacobs et al., 1995); thus, titration to the desired effect of smaller doses in this age group is prudent. Midazolam is hepatically metabolized with a clearance (6-11 mL/min per kg), similar to that of methohexital and ~20 and 7 times higher than those of diazepam and lorazepam, respectively. Either for prolonged sedation or for general anesthetic maintenance, midazolam is more suitable for infusion than are other benzodiazepines, although its duration of action does significantly increase with prolonged infusions (Figure 19-3). Benzodiazepines reduce both cerebral blood flow and metabolism but at equi-anesthetic doses are less potent in this respect than are barbiturates. They are effective anticonvulsants and sometimes are given to treat status epilepticus. Benzodiazepines modestly decrease blood pressure and respiratory drive, occasionally resulting in apnea. Thus, blood pressure and respiratory rate should be monitored in patients sedated with intravenous benzodiazepines.

α_2 Adrenergic Agonists. Dexmedetomidine (PRECEDEX) is an imidazole derivative that is a highly selective α_2 adrenergic receptor agonist (Kamibayashi and Maze, 2000). Dexmedetomidine is FDA-approved for short-term (< 24 hours) sedation of critically ill adults and sedation prior to and/or during surgical or other medical procedures in non-intubated patients. Activation of the α_{2A} adrenergic receptor by dexmedetomidine produces both sedation and analgesia, but does not reliably provide general anesthesia, even at maximal doses (Lakhlani et al., 1997).

Dexmedetomidine is a sedative-hypnotic that provides analgesia with little respiratory depression and, in most patients, a tolerable decrease in blood pressure and heart rate. The drug is likely to be increasingly used for sedation and as an anesthetic adjunct.

The most common side effects of dexmedetomidine include hypotension and bradycardia, both of which are attributed to decreased catecholamine release by activation peripherally and in the CNS of the α_{2A} receptor (Lakhlani et al., 1997). Nausea and dry mouth also are common untoward reactions. At higher drug concentrations, the α_{2B} subtype is activated, resulting in hypertension and a further decrease in heart rate and cardiac output. Dexmedetomidine has the very useful property of producing sedation and analgesia with minimal respiratory depression (Belleville et al., 1992); thus, it is particularly valuable in sedation of patients who are not endotracheally

intubated and mechanically ventilated. The sedation produced by dexmedetomidine has been noted to be more akin to natural sleep, with patients relatively easy to arouse (Hall et al., 2000). However, dexmedetomidine does not appear to provide reliable amnesia and additional agents may need to be employed if lack of recall is desirable.

Dexmedetomidine is supplied as an aqueous solution of the hydrochloride salt and should be diluted in normal saline to a final concentration of 4 $\mu\text{g}/\text{mL}$ for intravenous delivery, the only approved route of administration. The recommended loading dose is 1 $\mu\text{g}/\text{kg}$ given over 10 minutes, followed by infusion at a rate of 0.2-0.7 $\mu\text{g}/\text{kg}$ per hour. Reduced doses should be considered in patients with risk factors for severe hypotension. The distribution and terminal half-lives are 6 minutes and 2 hours, respectively. Dexmedetomidine is highly protein bound and is primarily hepatically metabolized; the glucuronide and methyl conjugates are excreted in the urine.

Analgesics

With the exception of ketamine, neither parenteral nor currently available inhalational anesthetics are effective analgesics. Thus, analgesics typically are administered with general anesthetics to reduce anesthetic requirement and minimize hemodynamic changes produced by painful stimuli. Nonsteroidal anti-inflammatory drugs, COX-2 inhibitors, and acetaminophen (Chapter 34) sometimes provide adequate analgesia for minor surgical procedures. However, opioids are the primary analgesics used during the perioperative period because of the rapid and profound analgesia they produce.

Fentanyl (SUBLIMAZE, others), sufentanil (SUFENTA, others), alfentanil (ALFENTA, others), remifentanyl (ULTIVA), meperidine (DEMEROL, others), and morphine are the major parenteral opioids used in the perioperative period. The primary analgesic activity of each of these drugs is produced by agonist activity at μ -opioid receptors. Their order of potency (relative to morphine) is: sufentanil (1000 \times), remifentanyl (300 \times), fentanyl (100 \times), alfentanil (15 \times), morphine (1 \times), and meperidine (0.1 \times). These agents are discussed in more detail in Chapter 18.

The choice of a perioperative opioid is based primarily on duration of action, since, at appropriate doses, all produce similar analgesia and side effects. Remifentanyl has an ultrashort duration of action (~10 minutes) and accumulates minimally with repeated doses or infusion; it is particularly well suited for procedures that are briefly painful, but for which little analgesia is required postoperatively. Single doses of fentanyl, alfentanil, and sufentanil all have similar intermediate durations of action (30, 20, and 15 minutes, respectively), but recovery after prolonged administration varies considerably. Fentanyl's duration of action lengthens the most with infusion, sufentanil's much less so, and alfentanil's the least. Except for remifentanyl, all of the above-mentioned opioids are metabolized in

the liver, followed by renal and biliary excretion of the metabolites. Remifentanyl is hydrolyzed by tissue and plasma esterases. Given its rapid elimination, termination of the effects of remifentanyl can result in significant pain in the surgical patient. Consequently, longer-acting opiates are often given prior to discontinuation of remifentanyl.

During the perioperative period, opioids often are given at induction to preempt responses to predictable painful stimuli (e.g., endotracheal intubation and surgical incision). Subsequent doses either by bolus or infusion are titrated to the surgical stimulus and the patient's hemodynamic response. Marked decreases in respiratory rate and heart rate with much smaller reductions in blood pressure are seen to varying degrees with all opioids. Muscle rigidity that can impair ventilation sometimes accompanies larger doses of opioids. The incidence of sphincter of Oddi spasm is increased with all opioids, although morphine appears to be more potent in this regard (Hahn et al., 1988). The frequency and severity of nausea, vomiting, and pruritus after emergence from anesthesia are increased by all opioids to about the same degree. A useful side effect of meperidine is its capacity to reduce shivering, a common problem during emergence from anesthesia (Pauca et al., 1984); other opioids are not as efficacious against shivering, perhaps due to less κ receptor agonism. Finally, opioids often are administered intrathecally and epidurally for management of acute and chronic pain (Chapter 18). Neuraxial opioids with or without local anesthetics can provide profound analgesia for many surgical procedures; however, respiratory depression and pruritus usually limit their use to major operations.

Neuromuscular Blocking Agents

The practical aspects of the use of neuromuscular blockers as anesthetic adjuncts are briefly described here. The detailed pharmacology of this drug class is presented in Chapter 11.

Depolarizing (e.g., succinylcholine) and non-depolarizing muscle relaxants (e.g., vecuronium) often are administered during the induction of anesthesia to relax muscles of the jaw, neck, and airway and thereby facilitate laryngoscopy and endotracheal intubation. Barbiturates will precipitate when mixed with muscle relaxants and should be allowed to clear from the intravenous line prior to injection of a muscle relaxant. Following induction, continued muscle relaxation is desirable for many procedures to aid surgical exposure and to provide additional insurance of immobility. Of course, muscle relaxants are not by themselves anesthetics and should not be used in lieu of adequate anesthetic depth. The action of non-depolarizing muscle relaxants usually is antagonized, once muscle paralysis is no longer desired, with an acetylcholinesterase inhibitor such as neostigmine or edrophonium (Chapter 10) combined with a muscarinic receptor antagonist (e.g., glycopyrrolate or atropine; Chapter 9) to offset the muscarinic activation resulting from esterase inhibition. Other than histamine release by some agents, non-depolarizing muscle relaxants used in this manner have

550 few side effects. However, succinylcholine has multiple serious side effects (bradycardia, hyperkalemia, and severe myalgia) including induction of malignant hyperthermia in susceptible individuals.

ANESTHETIC CYTOPROTECTION AND TOXICITY

The conventional view of general anesthesia is that anesthetics produce a reversible loss of consciousness and that CNS function returns to basal levels upon termination of anesthesia and recovery of consciousness. Recent data, however, have cast doubt upon this notion. Exposure of rodents to anesthetic agents during the period of synaptogenesis (within the first 10 days post birth) results in widespread neurodegeneration in the developing brain (Jevtovic-Todorovic et al., 2003). This neuronal injury, which is apoptotic in nature, results in disturbed electrophysiologic function and cognitive dysfunction in adolescent and adult rodents that were exposed to anesthetics during the neonatal period. A variety of agents, including isoflurane, propofol, midazolam, nitrous oxide, and thiopental, manifest this toxicity (Patel and Sun, 2009).

Although the etiology is not clear, GABA_A agonism and NMDA receptor antagonism play a role. In particular, the combination of a GABA_A agonist and NMDA receptor antagonist produce the greatest toxicity. Until the occurrence of this neurotoxicity during brain development has been established in pre-clinical studies, its relevance to the use of anesthetics in humans will not be clear. To date, there are no data to suggest that the provision of anesthesia to neonates and infants undergoing surgery produces any neurotoxicity. Ongoing clinical trials in humans should clarify this within the next few years.

By contrast, anesthetics reduce ischemic injury to a variety of tissues, including the brain and heart. This protective effect is robust and results in better functional outcomes in comparison to ischemic injury that occurs in unanesthetized awake subjects. With respect to ischemic injury of the brain, anesthetics (inhalational agents, propofol, barbiturates, ketamine, lidocaine, midazolam) suppress excitotoxic injury produced by excessive glutamate release, reduce inflammation, and promote pro-survival signaling (Head et al., 2007). In addition, exposure to anesthesia results in the activation of plasmalemmal and mitochondrial ATP-dependent K⁺ channels, activation of signal transduction pathways (NO synthase, MAP kinases), and protein synthesis that render the brain less vulnerable to subsequent ischemic injury. In a similar fashion, volatile anesthetics and, under some conditions, propofol and barbiturates, reduce myocardial ischemia-reperfusion injury (Frassdorf et al., 2009). The molecular mechanisms leading to cardiac protection by volatile anesthetics

involve activation of “classical” preconditioning signaling pathways (e.g., GPCRs, endothelial NO synthase, survival protein kinases, PKC, reactive oxygen species, ATP-dependent K⁺ channels, and the mitochondrial permeability transition pore) (Hausenloy and Scorrano, 2007). Propofol and barbiturates may induce specific components of the “classical” pathways involved in cardiac protection; however, there is debate as to whether these agents are truly protective or injurious to the ischemic myocardium (Frassdorf et al., 2009).

Therapeutic Gases

OXYGEN

Oxygen (O₂) is essential to life. Hypoxia is a life-threatening condition in which oxygen delivery is inadequate to meet the metabolic demands of the tissues. Since oxygen delivery is the product of blood flow and oxygen content, hypoxia may result from alterations in tissue perfusion, decreased oxygen tension in the blood, or decreased oxygen-carrying capacity. In addition, hypoxia may result from restricted oxygen transport from the microvasculature to cells or impaired utilization within the cell. An inadequate supply of oxygen ultimately results in the cessation of aerobic metabolism and oxidative phosphorylation, depletion of high-energy compounds, cellular dysfunction, and death.

Normal Oxygenation

Oxygen makes up 21% of air, which at sea level represents a partial pressure of 21 kPa (158 mm Hg). While the fraction (percentage) of O₂ remains constant regardless of atmospheric pressure, the partial pressure of O₂ (P_{O₂}) decreases with lower atmospheric pressure. Since the partial pressure drives the diffusion of O₂, ascent to elevated altitude reduces the uptake and delivery of oxygen to the tissues. Conversely, increases in atmospheric pressure (e.g., hyperbaric therapy or breathing at depth) raise the P_{O₂} in inspired air and increase gas uptake. As the air is delivered to the distal airways and alveoli, the P_{O₂} decreases by dilution with CO₂ and water vapor and by uptake into the blood.

Under ideal conditions, when ventilation and perfusion are well matched, the alveolar P_{O₂} will be ~14.6 kPa (110 mm Hg). The corresponding alveolar partial pressures of water and CO₂ are 6.2 kPa (47 mm Hg) and 5.3 kPa (40 mm Hg), respectively. Under normal conditions, there is complete equilibration of alveolar gas and capillary blood, and the P_{O₂} in end-capillary blood is typically within a fraction of a kPa of that in the alveoli. In some diseases, the diffusion barrier

for gas transport may be increased, or, during exercise, when high cardiac output reduces capillary transit time, full equilibration may not occur, and the alveolar–end-capillary PO_2 gradient may be increased.

The PO_2 in arterial blood, however, is further reduced by venous admixture (shunt), the addition of mixed venous blood from the pulmonary artery, which has a PO_2 of ~ 5.3 kPa (40 mm Hg). Together, the diffusional barrier, ventilation–perfusion mismatches, and the shunt fraction are the major causes of the alveolar-to-arterial oxygen gradient, which is normally 1.3–1.6 kPa (10–12 mm Hg) when air is breathed and 4.0–6.6 kPa (30–50 mm Hg) when 100% oxygen is breathed.

Oxygen is delivered to the tissue capillary beds by the circulation and again follows a gradient out of the blood and into cells. Tissue extraction of oxygen typically reduces the PO_2 of venous blood by an additional 7.3 kPa (55 mm Hg). Although the PO_2 at the site of cellular oxygen utilization—the mitochondria—is not known, oxidative phosphorylation can continue at a PO_2 of only a few mm Hg.

In the blood, oxygen is carried primarily in chemical combination with hemoglobin and is to a small extent dissolved in solution. The quantity of oxygen combined with hemoglobin depends on the PO_2 , as illustrated by the sigmoidal oxyhemoglobin dissociation curve (Figure 19–8). Hemoglobin is $\sim 98\%$ saturated with oxygen when air is breathed under normal circumstances, and it binds 1.3 mL of oxygen per gram when fully saturated. The steep slope

Figure 19–8. Oxyhemoglobin dissociation curve for whole blood. The relationship between PO_2 and hemoglobin (Hb) saturation is shown. The P_{50} , or the PO_2 resulting in 50% saturation, is indicated as well. An increase in temperature or a decrease in pH (as in working muscle) shifts this relationship to the right, reducing the hemoglobin saturation at the same PO_2 and thus aiding in the delivery of oxygen to the tissues.

of this curve with falling PO_2 facilitates unloading of oxygen from hemoglobin at the tissue level and reloading when desaturated mixed venous blood arrives at the lung. Shifting of the curve to the right with increasing temperature, increasing PCO_2 , and decreasing pH, as is found in metabolically active tissues, lowers the oxygen saturation for the same PO_2 and thus delivers additional oxygen where and when it is most needed. However, the flattening of the curve with higher PO_2 indicates that increasing blood PO_2 by inspiring oxygen-enriched mixtures can increase the amount of oxygen carried by hemoglobin only minimally. Further increases in blood oxygen content can occur only by increasing the amount of oxygen dissolved in plasma. Because of the low solubility of oxygen (0.226 mL/L per kPa or 0.03 mL/L per mm Hg at 37°C), breathing 100% oxygen can increase the amount of oxygen dissolved in blood by only 15 mL/L, less than one-third of normal metabolic demands. However, if the inspired PO_2 is increased to 3 atm (304 kPa) in a hyperbaric chamber, the amount of dissolved oxygen is sufficient to meet normal metabolic demands even in the absence of hemoglobin (Table 19–4).

Oxygen Deprivation

An understanding of the causes and effects of oxygen deficiency is necessary for the rational therapeutic use of the gas. *Hypoxia* is the term used to denote insufficient oxygenation of the tissues. *Hypoxemia* generally implies a failure of the respiratory system to oxygenate arterial blood.

Pulmonary Mechanisms of Hypoxemia. Classically, there are five causes of hypoxemia: low inspired oxygen fraction ($\text{F}_{\text{I}\text{O}_2}$), increased diffusion barrier, hypoventilation, ventilation–perfusion mismatch, and shunt or venous admixture.

Low $\text{F}_{\text{I}\text{O}_2}$ is a cause of hypoxemia only at high altitude or in the event of equipment failure, such as a gas blender malfunction or a mislabeled compressed-gas tank. An increase in the barrier to diffusion of oxygen within the lung is rarely a cause of hypoxemia in a resting subject, except in end-stage parenchymal lung disease. Both these problems may be alleviated with administration of supplemental oxygen, the former by definition and the latter by increasing the gradient driving diffusion.

Hypoventilation causes hypoxemia by reducing the alveolar PO_2 in proportion to the buildup of CO_2 in the alveoli. During hypoventilation, there is decreased delivery of oxygen to the alveoli, whereas its removal by the blood remains the same, causing its alveolar concentration to fall. The opposite occurs with carbon dioxide. This is described by the alveolar gas equation:

$$\text{P}_{\text{A}\text{O}_2} = \text{P}_{\text{I}\text{O}_2} - (\text{P}_{\text{A}\text{CO}_2}/\text{R})$$

where $\text{P}_{\text{A}\text{O}_2}$ and $\text{P}_{\text{A}\text{CO}_2}$ are the alveolar partial pressures of oxygen and carbon dioxide, $\text{P}_{\text{I}\text{O}_2}$ is the partial pressure of oxygen in the inspired gas, and R the respiratory quotient.

Under normal conditions, breathing room air at sea level (corrected for the partial pressure of water vapor), the $\text{P}_{\text{I}\text{O}_2}$ is ~ 20 kPa (150 mm Hg), the $\text{P}_{\text{A}\text{CO}_2} \sim 5.3$ kPa (40 mm Hg), R is 0.8, and thus the $\text{P}_{\text{A}\text{O}_2}$ is normally around 13.3 kPa (100 mm Hg). It would require

Table 19-4

The Carriage of Oxygen in Blood^a

ARTERIAL P _O ₂ kPa (mmHg)	ARTERIAL O ₂ CONTENT (mL O ₂ /L)			MIXED VENOUS P _O ₂ kPa (mmHg)	MIXED VENOUS O ₂ CONTENT (mL O ₂ /L)			EXAMPLES
	DISSOLVED	BOUND TO HEMOGLOBIN	TOTAL		DISSOLVED	BOUND TO HEMOGLOBIN	TOTAL	
4.0 (30)	0.9	109	109.9	2.7 (20)	0.6	59	59.6	High altitude; respiratory failure breathing air
12.0 (90)	2.7	192	194.7	5.5 (41)	1.2	144	145.2	Normal person breathing air
39.9 (300)	9.0	195	204	5.9 (44)	1.3	153	154.3	Normal person breathing 50% O ₂
79.7 (600)	18	196	214	6.5 (49)	1.5	163	164.5	Normal person breathing 100% O ₂
239 (1800)	54	196	250	20.0 (150)	4.5	196	200.5	Normal person breathing hyperbaric O ₂

^aThis table illustrates the carriage of oxygen in the blood under a variety of circumstances. As arterial O₂ tension increases, the amount of dissolved O₂ increases in direct proportion to the P_O₂, but the amount of oxygen bound to hemoglobin reaches a maximum of 196 mL O₂/liter (100% saturation of hemoglobin at 15 g/dL). Further increases in O₂ content require increases in dissolved oxygen. At 100% inspired O₂, dissolved O₂ still provides only a small fraction of total demand. Hyperbaric oxygen therapy is required to increase the amount of dissolved oxygen to supply all or a large part of metabolic requirements. Note that, during hyperbaric oxygen therapy, the hemoglobin in the mixed venous blood remains fully saturated with O₂. The figures in this table are approximate and are based on the assumptions of 15 g/dL hemoglobin, 50 mL O₂/liter whole-body oxygen extraction, and constant cardiac output. When severe anemia is present, arterial P_O₂ remains the same, but arterial content is lower; oxygen extraction continues, resulting in lower O₂ content and tension in mixed venous blood. Similarly, as cardiac output falls significantly, the same oxygen extraction occurs from a smaller volume of blood and results in lower mixed venous oxygen content and tension.

substantial hypoventilation, with the $P_{A_{CO_2}}$ rising to over 9.8 kPa (72 mm Hg), to cause the $P_{A_{O_2}}$ to fall below 7.8 kPa (60 mm Hg). This cause of hypoxemia is readily prevented by administration of even small amounts of supplemental O_2 .

Shunt and \dot{V}/\dot{Q} mismatch are related causes of hypoxemia but with an important distinction in their responses to supplemental oxygen. Optimal gas exchange occurs when blood flow (\dot{Q}) and ventilation (\dot{V}) are matched quantitatively. However, regional variations in \dot{V}/\dot{Q} matching typically exist within the lung, particularly in the presence of lung disease. As ventilation increases relative to blood flow, the alveolar PO_2 ($P_{A_{O_2}}$) increases; because of the flat shape of the oxyhemoglobin dissociation curve at high PO_2 (Figure 19–8), this increased $P_{A_{O_2}}$ does not contribute much to the oxygen content of the blood. Conversely, as the \dot{V}/\dot{Q} ratio falls and perfusion increases relative to ventilation, the $P_{A_{O_2}}$ of the blood leaving these regions falls relative to regions with better matched ventilation and perfusion. Since the oxyhemoglobin dissociation curve is steep at these lower PO_2 values, the oxygen saturation and content of the pulmonary venous blood falls significantly. At the extreme of low \dot{V}/\dot{Q} ratios, there is no ventilation to a perfused region, and a pure shunt results; thus the blood leaving the region has the same low PO_2 and high $P_{A_{CO_2}}$ as mixed venous blood.

The deleterious effect of \dot{V}/\dot{Q} mismatch on arterial oxygenation is a direct result of the asymmetry of the oxyhemoglobin dissociation curve. Adding supplemental oxygen generally will make up for the fall in $P_{A_{O_2}}$ in low \dot{V}/\dot{Q} units and thereby improve arterial oxygenation. However, since there is no ventilation to units with pure shunt, supplemental oxygen will not be effective in reversing hypoxemia from this cause. Because of the steep oxyhemoglobin dissociation curve at low PO_2 , even moderate amounts of pure shunt will cause significant hypoxemia despite oxygen therapy (Figure 19–9). For the same reason, factors that decrease mixed venous PO_2 , such as decreased cardiac output or increased O_2 consumption, enhance the hypoxemic effects of mismatch and shunt.

Nonpulmonary Causes of Hypoxia. In addition to failure of the respiratory system to oxygenate the blood adequately, a number of other factors can contribute to hypoxia at the tissue level. These may be divided into categories of O_2 delivery and O_2 utilization. Oxygen delivery decreases globally when cardiac output falls or locally when regional blood flow is compromised, such as from a vascular occlusion (e.g., stenosis, thrombosis, or microvascular occlusion) or increased downstream pressure (e.g., compartment syndrome, venous stasis, or venous hypertension). Decreased O_2 -carrying capacity of the blood likewise will reduce oxygen delivery, such as occurs with anemia, CO poisoning, or hemoglobinopathy. Finally, hypoxia may occur when transport of O_2 from the capillaries to the tissues is decreased (edema) or utilization of the O_2 by the cells is impaired (CN^- toxicity).

Effects of Hypoxia. There has been a considerable increase in our understanding of the cellular and biochemical changes that occur after acute and chronic

Figure 19–9. Effect of shunt on arterial oxygenation. The iso-shunt diagram shows the effect of changing inspired oxygen concentration on arterial oxygenation in the presence of different amounts of pure shunt. As shunt fraction increases, even an inspired oxygen fraction ($F_{I_{O_2}}$) of 1.0 is ineffective at increasing the arterial PO_2 . This estimation assumes hemoglobin (Hb) 10–14 g/dL, arterial P_{CO_2} 3.3–5.3 kPa (25–40 mm Hg), and an arterial–venous (a–v) O_2 content difference of 5 mL/100 mL. (Redrawn from Benatar SR, Hewlett AM, Nunn JF. The use of iso-shunt lines for control of oxygen therapy. *Br J Anaesth*, 1973, 45:711–718, with permission. hypoxia. Regardless of the cause, hypoxia produces a marked alteration in gene expression, mediated in part by hypoxia inducible factor-1 α (Brahimi-Horn and Pouyssegur, 2009). Ultimately, hypoxia results in the cessation of aerobic metabolism, exhaustion of high-energy intracellular stores, cellular dysfunction, and death. The time course of cellular demise depends on the tissue's relative metabolic requirements, O_2 and energy stores, and anaerobic capacity. Survival times (the time from the onset of circulatory arrest to significant organ dysfunction) range from 1–2 minutes in the cerebral cortex to around 5 minutes in the heart and 10 minutes in the kidneys and liver, with the potential for some degree of recovery if reperfused. Revival times (the duration of hypoxia beyond which recovery is no longer possible) are ~4 to 5 times longer. Less severe degrees of hypoxia have progressive physiological

554 effects on different organ systems (Nunn, 2005b). Responses of individual organ systems to hypoxia are summarized next.

Respiratory System. Hypoxia stimulates the carotid and aortic baroreceptors to cause increases in both the rate and depth of ventilation. Minute volume almost doubles when normal individuals inspire gas with a P_{O_2} of 6.6 kPa (50 mm Hg). Dyspnea is not always experienced with simple hypoxia but occurs when the respiratory minute volume approaches half the maximal breathing capacity; this may occur with minimum exertion in patients in whom maximal breathing capacity is reduced by lung disease. In general, little warning precedes the loss of consciousness resulting from hypoxia.

Cardiovascular System. Hypoxia causes reflex activation of the sympathetic nervous system by both autonomic and humoral mechanisms, resulting in tachycardia and increased cardiac output. Peripheral vascular resistance, however, decreases primarily through local autoregulatory mechanisms, with the net result that blood pressure generally is maintained unless hypoxia is prolonged or severe. In contrast to the systemic circulation, hypoxia causes pulmonary vasoconstriction and hypertension, an extension of the normal regional vascular response that matches perfusion with ventilation to optimize gas exchange in the lung (hypoxic pulmonary vasoconstriction).

CNS. The CNS is least able to tolerate hypoxia. Hypoxia is manifest initially by decreased intellectual capacity and impaired judgment and psychomotor ability. This state progresses to confusion and restlessness and ultimately to stupor, coma, and death as the arterial P_{O_2} decreases below 4–5.3 kPa (30–40 mm Hg). Victims often are unaware of this progression.

Cellular and Metabolic Effects. When the mitochondrial P_{O_2} falls below ~0.13 kPa (1 mm Hg), aerobic metabolism stops, and the less efficient anaerobic pathways of glycolysis become responsible for the production of cellular energy. End products of anaerobic metabolism, such as lactic acid, are released into the circulation in measurable quantities. Energy-dependent ion pumps slow, and transmembrane ion gradients dissipate. Intracellular concentrations of Na^+ , Ca^{2+} , and H^+ increase, finally leading to cell death. The time course of cellular demise depends on the relative metabolic demands, oxygen storage capacity, and anaerobic capacity of the individual organs. Restoration of perfusion and oxygenation prior to hypoxic cell death paradoxically can result in an accelerated form of cell injury (ischemia–reperfusion syndrome), which is thought to result from the generation of highly reactive oxygen free radicals.

Adaptation to Hypoxia. Long-term hypoxia results in adaptive physiological changes; these have been studied most thoroughly in persons exposed to high altitude. Adaptations include increased numbers of pulmonary alveoli, increased concentrations of hemoglobin in blood and myoglobin in muscle, and a decreased ventilatory response to hypoxia. Short-term exposure to high altitude produces similar adaptive changes. In susceptible individuals, however, acute exposure to high altitude may produce *acute mountain sickness*, a syndrome characterized by headache, nausea, dyspnea, sleep disturbances, and impaired judgment progressing to pulmonary and cerebral edema. Mountain sickness is treated with rest and analgesics when mild or supplemental oxygen, descent to lower altitude, or an increase in ambient pressure when more severe. Acetazolamide

(a carbonic anhydrase inhibitor) and dexamethasone also may be helpful. The syndrome usually can be avoided by a slow ascent to altitude, adequate hydration, and prophylactic use of acetazolamide or dexamethasone.

Certain aspects of fetal and newborn physiology are strongly reminiscent of adaptation mechanisms found in hypoxia-tolerant animals (Mortola, 1999), including shifts in the oxyhemoglobin dissociation curve (fetal hemoglobin), reductions in metabolic rate and body temperature (hibernation-like mode), reductions in heart rate and circulatory redistribution (as in diving mammals), and redirection of energy utilization from growth to maintenance metabolism. These adaptations probably account for the relative tolerance of the fetus and neonate to both chronic (uterine insufficiency) and short-term hypoxia.

Oxygen Inhalation

Physiological Effects of Oxygen Inhalation. Oxygen inhalation is used primarily to reverse or prevent the development of hypoxia; other consequences usually are minor. However, when O_2 is breathed in excessive amounts or for prolonged periods, secondary physiological changes and toxic effects can occur.

Respiratory System. Inhalation of O_2 at 1 atm or above causes a small degree of respiratory depression in normal subjects, presumably as a result of loss of tonic chemoreceptor activity. However, ventilation typically increases within a few minutes of O_2 inhalation because of a paradoxical increase in the tension of CO_2 in tissues. This increase results from the increased concentration of oxyhemoglobin in venous blood, which causes less efficient removal of carbon dioxide from the tissues.

In a small number of patients whose respiratory center is depressed by long-term retention of CO_2 , injury, or drugs, ventilation is maintained largely by stimulation of carotid and aortic chemoreceptors, commonly referred to as the *hypoxic drive*. The provision of too much oxygen can depress this drive, resulting in respiratory acidosis. In these cases, supplemental oxygen should be titrated carefully to ensure adequate arterial saturation. If hypoventilation results, then mechanical ventilatory support with or without tracheal intubation should be provided.

Expansion of poorly ventilated alveoli is maintained in part by the nitrogen content of alveolar gas; nitrogen is poorly soluble and thus remains in the airspaces while oxygen is absorbed. High oxygen concentrations delivered to poorly ventilated lung regions dilute the nitrogen content and can promote absorption atelectasis, occasionally resulting in an increase in shunt and a paradoxical worsening of hypoxemia after a period of oxygen administration.

Cardiovascular System. Aside from reversing the effects of hypoxia, the physiological consequences of oxygen inhalation on the cardiovascular system are of little significance. Heart rate and cardiac output are slightly reduced when 100% O_2 is breathed; blood pressure changes little. While pulmonary arterial pressure changes little in normal subjects with oxygen inhalation, elevated pulmonary artery pressures in patients living at high altitude who have chronic hypoxic pulmonary hypertension may reverse with oxygen therapy or return to sea level. In particular, in neonates with congenital heart disease

and left-to-right shunting of cardiac output, oxygen supplementation must be regulated carefully because of the risk of further reducing pulmonary vascular resistance and increasing pulmonary blood flow.

Metabolism. Inhalation of 100% O₂ does not produce detectable changes in O₂ consumption, CO₂ production, respiratory quotient, or glucose utilization.

Oxygen Administration

Oxygen is supplied as a compressed gas in steel cylinders, and a purity of 99% is referred to as *medical grade*. Most hospitals have oxygen piped from insulated liquid oxygen containers to areas of frequent use. For safety, oxygen cylinders and piping are color-coded (green in the U.S.), and some form of mechanical indexing of valve connections is used to prevent the connection of other gases to oxygen systems. Oxygen concentrators, which employ molecular sieve, membrane, or electrochemical technologies, are available for low-flow home use. Such systems produce 30-95% oxygen depending on the flow rate.

Oxygen is delivered by inhalation except during extracorporeal circulation, when it is dissolved directly into the circulating blood. Only a closed delivery system with an airtight seal to the patient's airway and complete separation of inspired from expired gases can precisely control F_IO₂. In all other systems, the actual delivered F_IO₂ will depend on the ventilatory pattern (i.e., rate, tidal volume, inspiratory–expiratory time ratio, and inspiratory flow) and delivery system characteristics.

Low-Flow Systems. Low-flow systems, in which the oxygen flow is lower than the inspiratory flow rate, have a limited ability to raise the F_IO₂ because they depend on entrained room air to make up the balance of the inspired gas. The F_IO₂ of these systems is extremely sensitive to small changes in the ventilatory pattern. Nasal cannulae—small, flexible prongs that sit just inside each naris—deliver oxygen at 1-6 L/min. The nasopharynx acts as a reservoir for storing the oxygen, and patients may breathe through either the mouth or nose as long as the nasal passages remain patent. These devices typically deliver 24-28% F_IO₂ at 2-3 L/min. Up to 40% F_IO₂ is possible at higher flow rates, although this is poorly tolerated for more than brief periods because of mucosal drying. The simple face mask, a clear plastic mask with side holes for clearance of expiratory gas and inspiratory air entrainment, is used when higher concentrations of oxygen delivered without tight control are desired. The maximum F_IO₂ of a face mask can be increased from around 60% at 6-15 L/min to > 85% by adding a 600- to 1000-mL reservoir bag. With this partial rebreathing mask, most of the inspired volume is drawn from the reservoir, avoiding dilution by entrainment of room air.

High-Flow Systems. The most commonly used high-flow oxygen delivery device is the Venturi-style mask, which uses a specially designed mask insert to entrain room air reliably in a fixed ratio and thus provides a relatively constant F_IO₂ at relatively high flow rates. Typically, each insert is designed to operate at a specific oxygen flow

rate, and different inserts are required to change the F_IO₂. Lower delivered F_IO₂ values use greater entrainment ratios, resulting in higher total (oxygen plus entrained air) flows to the patient, ranging from 80 L/min for 24% F_IO₂ to 40 L/min at 50% F_IO₂. While these flow rates are much higher than those obtained with low-flow devices, they still may be lower than the peak inspiratory flows for patients in respiratory distress, and thus the actual delivered O₂ concentration may be lower than the nominal value. Oxygen nebulizers, another type of Venturi-style device, provide patients with humidified oxygen at 35-100% F_IO₂ at high flow rates. Finally, oxygen blenders provide high inspired oxygen concentrations at very high flow rates. These devices mix high-pressure compressed air and oxygen to achieve any concentration of O₂ from 21-100% at flow rates of up to 100 L/min. These same blenders are used to provide control of F_IO₂ for ventilators, CPAP/BiPAP machines, oxygenators, and other devices with similar requirements. Again, despite the high flows, the delivery of high F_IO₂ to an individual patient also depends on maintaining a tight-fitting seal to the airway and/or the use of reservoirs to minimize entrainment of diluting room air.

Monitoring of Oxygenation. Monitoring and titration are required to meet the therapeutic goal of oxygen therapy and to avoid complications and side effects. Although cyanosis is a physical finding of substantial clinical importance, it is not an early, sensitive, or reliable index of oxygenation. Cyanosis appears when ~5 g/dL of deoxyhemoglobin is present in arterial blood, representing an oxygen saturation of ~67% when a normal amount of hemoglobin (15 g/dL) is present. However, when anemia lowers the hemoglobin to 10 g/dL, then cyanosis does not appear until the arterial blood saturation has decreased to 50%. Invasive approaches for monitoring oxygenation include intermittent laboratory analysis of arterial or mixed venous blood gases and placement of intravascular cannulae capable of continuous measurement of oxygen tension. The latter method, which relies on fiber-optic oximetry, is used frequently for the continuous measurement of mixed venous hemoglobin saturation as an index of tissue extraction of oxygen, usually in critically ill patients.

Noninvasive monitoring of arterial oxygen saturation can be achieved using transcutaneous pulse oximetry, in which oxygen saturation is measured from the differential absorption of light by oxyhemoglobin and deoxyhemoglobin and the arterial saturation determined from the pulsatile component of this signal. Application is simple, and calibration is not required. Pulse oximetry measures hemoglobin saturation and not Po₂. It is not sensitive to increases in Po₂ that exceed levels required to saturate the blood fully. Pulse oximetry is very useful for monitoring the adequacy of oxygenation during procedures requiring sedation or anesthesia, rapid evaluation and monitoring of potentially compromised patients, and titrating oxygen therapy in situations where toxicity from oxygen or side effects of excess oxygen are of concern. Near infrared spectroscopy (NIRS) is a noninvasive technique being used to monitor oxygen content in the cerebral cortex. Unlike pulse oximetry NIRS measures all reflected light in both pulsatile arterial blood and nonpulsatile venous blood, the primary compartment in the cerebral vascular bed. NIRS is useful to monitor cerebral oxygenation in surgical procedures involving cardiopulmonary bypass and circulatory arrest (Guarracino, 2008).

Complications of Oxygen Therapy. Administration of supplemental oxygen is not without potential complications. In addition to the

potential to promote absorption atelectasis and depress ventilation (discussed earlier), high flows of dry oxygen can dry out and irritate mucosal surfaces of the airway and the eyes, as well as decrease mucociliary transport and clearance of secretions. Humidified oxygen thus should be used when prolonged therapy (>1 hour) is required. Finally, any oxygen-enriched atmosphere constitutes a fire hazard, and appropriate precautions must be taken both in the operating room and for patients on oxygen at home.

It is important to realize that hypoxemia still can occur despite the administration of supplemental oxygen. Furthermore, when supplemental oxygen is administered, desaturation occurs at a later time after airway obstruction or hypoventilation, potentially delaying the detection of these critical events. Therefore, whether or not oxygen is administered to a patient at risk for these problems, it is essential that both O_2 saturation and adequacy of ventilation be assessed frequently.

Therapeutic Uses of Oxygen

Correction of Hypoxia. The primary therapeutic use of oxygen is to correct hypoxia. Hypoxia is most commonly a manifestation of an underlying disease, and administration of oxygen thus should be viewed as temporizing therapy. Efforts must be directed at correcting the cause of the hypoxia. For example, airway obstruction is unlikely to respond to an increase in inspired oxygen tension without relief of the obstruction. More important, while hypoxemia owing to hypoventilation after a narcotic overdose can be improved with supplemental oxygen administration, the patient remains at risk for respiratory failure if ventilation is not increased through stimulation, narcotic reversal, or mechanical ventilation. Hypoxia resulting from most pulmonary diseases can be alleviated at least partially by administration of oxygen, allowing time for definitive therapy to reverse the primary process. Thus, administration of oxygen is basic and important treatment for all forms of hypoxia.

Reduction of Partial Pressure of an Inert Gas. Since nitrogen constitutes some 79% of ambient air, it also is the predominant gas in most gas-filled spaces in the body. In situations such as bowel distension from obstruction or ileus, intravascular air embolism, or pneumothorax, it is desirable to reduce the volume of air-filled spaces. Since nitrogen is relatively insoluble, inhalation of high concentrations of oxygen (and thus low concentrations of nitrogen) rapidly lowers the total-body partial pressure of nitrogen and provides a substantial gradient for the removal of nitrogen from gas spaces. Administration of oxygen for air embolism is additionally beneficial because it helps to relieve localized hypoxia distal to the vascular obstruction. In the case of *decompression sickness*, or *bends*, lowering the inert gas tension in blood and tissues by oxygen inhalation prior to or during a barometric decompression reduces the supersaturation that occurs after decompression so that bubbles do not form. If bubbles do form in either tissues or the vasculature, administration of oxygen is based on the same rationale as that described for gas embolism.

Hyperbaric Oxygen Therapy. Oxygen can be administered at greater than atmospheric pressure in hyperbaric chambers (Thom, 2009). Clinical uses of hyperbaric oxygen therapy include the treatment of trauma, burns, radiation damage, infections, non-healing ulcers, skin grafts, spasticity, and other neurological conditions. Hyperbaric chambers can withstand pressures that range from 200 to 600 kPa (2-6 atm), although inhaled oxygen tension that exceeds 300 kPa

(3 atm) rarely is used. Chambers range from single-person units to multiroom establishments housing complex medical equipment.

Hyperbaric oxygen therapy has two components: increased hydrostatic pressure and increased O_2 pressure. Both factors are necessary for the treatment of decompression sickness and air embolism. The hydrostatic pressure reduces bubble volume, and the absence of inspired nitrogen increases the gradient for elimination of nitrogen and reduces hypoxia in downstream tissues. Increased oxygen pressure at the tissue is the primary therapeutic goal for other indications for hyperbaric O_2 . A small increase in P_{O_2} in ischemic areas enhances the bactericidal activity of leukocytes and increases angiogenesis. Repetitive brief exposures to hyperbaric oxygen may enhance therapy for chronic refractory osteomyelitis, osteoradionecrosis, crush injury, or the recovery of compromised skin and tissue grafts. Increased O_2 tension can be bacteriostatic and useful in the treatment for the spread of infection with *Clostridium perfringens* and clostridial myonecrosis (gas gangrene).

Hyperbaric oxygen may be useful in generalized hypoxia. In CO poisoning, hemoglobin (Hb) and myoglobin become unavailable for O_2 binding because of the high affinity of these proteins for CO. Affinity for CO is ~250 times greater than the affinity for O_2 ; thus, an alveolar concentration of CO = 0.4 mm Hg (1/250th that of alveolar O_2 , which is ~100 mm Hg), will compete equally with O_2 for binding sites on Hb. High P_{O_2} facilitates competition of O_2 for Hb binding sites as CO is exchanged in the alveoli. In addition, hyperbaric O_2 increases the availability of dissolved O_2 in the blood (Table 19-4). In a randomized clinical trial (Weaver et al., 2002), hyperbaric O_2 decreased the incidence of long- and short-term neurological sequelae after CO intoxication. The occasional use of hyperbaric oxygen in cyanide poisoning has a similar rationale. Hyperbaric oxygen may be useful in severe short-term anemia since sufficient oxygen can be dissolved in the plasma at 3 atm to meet metabolic demand. Such treatment must be limited because oxygen toxicity depends on increased P_{O_2} , not on the oxygen content of the blood.

Adverse effects of hyperbaric oxygen therapy include middle ear barotrauma, CNS toxicity, seizures, lung toxicity, and aspiration pneumonia. Contraindications to hyperbaric oxygen therapy include pneumothorax and concurrent doxorubicin, bleomycin, or disulfiram therapy. Relative contraindications include respiratory tract infections, severe obstructive lung disease, fever, seizure disorders, optic neuritis, pregnancy, concurrent steroid use, and claustrophobia.

Oxygen Toxicity

Oxygen is used in cellular energy production and is crucial for cellular metabolism. However, oxygen also has deleterious actions at the cellular level. Oxygen toxicity may result from increased production of hydrogen peroxide and reactive agents such as superoxide anion, singlet oxygen, and hydroxyl radicals that attack and damage lipids, proteins, and other macromolecules, especially those in biological membranes. A number of factors limit the toxicity of oxygen-derived reactive agents, including enzymes such as superoxide dismutase, glutathione peroxidase, and catalase, which scavenge toxic oxygen by-products, and reducing agents such as iron, glutathione, and ascorbate. These

factors, however, are insufficient to limit the destructive actions of oxygen when patients are exposed to high concentrations over an extended time period. Tissues show differential sensitivity to oxygen toxicity, which is likely the result of differences in both their production of reactive compounds and their protective mechanisms.

Respiratory Tract. The pulmonary system is usually the first to exhibit toxicity, a function of its continuous exposure to the highest oxygen tensions in the body. Subtle changes in pulmonary function can occur within 8-12 hours of exposure to 100% O₂. Increases in capillary permeability, which will increase the alveolar/arterial oxygen gradient and ultimately lead to further hypoxemia, and decreased pulmonary function can be seen after only 18 hours of exposure (Clark, 1988). Serious injury and death, however, require much longer exposures. Pulmonary damage is directly related to the inspired oxygen tension, and concentrations of < 0.5 atm appear to be safe over long time periods. The capillary endothelium is the most sensitive tissue of the lung. Endothelial injury results in loss of surface area from interstitial edema and leaks into the alveoli.

Decreases of inspired oxygen concentrations remain the cornerstone of therapy for oxygen toxicity. Tolerance also may play a role in protection from oxygen toxicity; animals exposed briefly to high O₂ tensions are subsequently more resistant to toxicity. Sensitivity in humans also can be altered by preexposure to both high and low O₂ concentrations (Clark, 1988). These studies strongly suggest that changes in alveolar surfactant and cellular levels of antioxidant enzymes play a role in protection from oxygen toxicity.

Nervous System. Retinopathy of prematurity (ROP) is an eye disease in premature infants involving abnormal vascularization of the developing retina that can result from oxygen toxicity or relative hypoxia (Lutty et al., 2006). Retinal changes can progress to blindness and are likely caused by fibrovascular proliferation. Central nervous system problems are rare, and toxicity occurs only under hyperbaric conditions where exposure exceeds 200 kPa (2 atm). Symptoms include seizures and visual changes, which resolve when oxygen tension is returned to normal. Increased inspired oxygen concentrations are often administered to patients who have sustained acute ischemic central nervous system injury. In premature neonates and those who have sustained in utero asphyxia, hyperoxia and hypocapnia are associated with worse neurologic outcomes (Klinger et al., 2005). Similarly, in preclinical studies, resuscitation from cardiac arrest with high inspired oxygen concentrations leads to worse outcomes (Balan et al., 2006). These data indicate that oxygen therapy should be titrated to maintain an acceptable Po₂ and that hyperoxemia should be avoided (Sola, 2008).

CARBON DIOXIDE

Transfer and Elimination of CO₂

Carbon dioxide is produced by metabolism at approximately the same rate as O₂ is consumed. At rest, this value is ~3 mL/kg per minute, but it may increase dramatically with exercise. CO₂ diffuses readily from the

cells into the blood, where it is carried partly as bicarbonate ion (HCO₃⁻), partly in chemical combination with hemoglobin and plasma proteins, and partly in solution at a partial pressure of ~6 kPa (46 mm Hg) in mixed venous blood. CO₂ is transported to the lung, where it is normally exhaled at the rate it is produced, leaving a partial pressure of ~5.2 kPa (40 mm Hg) in the alveoli and in arterial blood. An increase in PCO₂ results in a respiratory acidosis and may be due to decreased ventilation or the inhalation of CO₂, whereas an increase in ventilation results in decreased PCO₂ and a respiratory alkalosis. Since CO₂ is freely diffusible, the changes in blood PCO₂ and pH soon are reflected by intracellular changes in PCO₂ and pH.

Effects of Carbon Dioxide

Alterations in PCO₂ and pH have widespread effects in the body, particularly on respiration, circulation, and the CNS. Complete discussions of these and other effects are found in textbooks of respiratory physiology (Nunn, 2005a).

Respiration. CO₂ is a rapid, potent stimulus to ventilation in direct proportion to the inspired CO₂. Inhalation of 10% carbon dioxide can produce minute volumes of 75 L/min in normal individuals. CO₂ stimulates breathing by acidifying central chemoreceptors and the peripheral carotid bodies (Guyenet, 2008). Elevated PCO₂ causes bronchodilation, whereas hypocarbia causes constriction of airway smooth muscle; these responses may play a role in matching pulmonary ventilation and perfusion (Duane et al., 1979).

Circulation. The circulatory effects of CO₂ result from the combination of its direct local effects and its centrally mediated effects on the autonomic nervous system. The direct effect of CO₂ on the heart, diminished contractility, results from pH changes and a decreased myofilament Ca²⁺ responsiveness (van den Bos et al., 1979). The direct effect on systemic blood vessels results in vasodilation. CO₂ causes widespread activation of the sympathetic nervous system and an increase in the plasma concentrations of epinephrine, norepinephrine, angiotensin, and other vasoactive peptides. The results of sympathetic nervous system activation generally are opposite to the local effects of carbon dioxide. The sympathetic effects consist of increases in cardiac contractility, heart rate, and vasoconstriction (Chapter 12).

The balance of opposing local and sympathetic effects, therefore, determines the total circulatory response to CO₂. The net effect of CO₂ inhalation is an increase in cardiac output, heart rate, and blood pressure. In blood vessels, however, the direct vasodilating actions of CO₂ appear more important, and total peripheral resistance decreases when the PCO₂ is increased. CO₂ also is a potent coronary vasodilator. Cardiac arrhythmias associated with increased PCO₂ are due to the release of catecholamines.

Hypocarbia results in opposite effects: decreased blood pressure and vasoconstriction in skin, intestine, brain, kidney, and heart. These actions are exploited clinically in the use of hyperventilation to diminish intracranial hypertension.

558 CNS. Hypercarbia depresses the excitability of the cerebral cortex and increases the cutaneous pain threshold through a central action. This central depression has therapeutic importance. For example, in patients who are hypoventilating from narcotics or anesthetics, increasing P_{CO_2} may result in further CNS depression, which in turn may worsen the respiratory depression. This positive-feedback cycle can have lethal consequences. The inhalation of high concentrations of carbon dioxide (~50%) produces marked cortical and subcortical depression of a type similar to that produced by anesthetic agents.

Methods of Administration. CO_2 is marketed in gray metal cylinders as the pure gas or as CO_2 mixed with oxygen. It usually is administered at a concentration of 5-10% in combination with O_2 by means of a face mask. Another method for the temporary administration of CO_2 is by rebreathing, such as from an anesthesia breathing circuit when the soda lime canister is bypassed or from something as simple as a paper bag. A potential safety issue exists in that tanks containing carbon dioxide plus oxygen are the same color as those containing 100% CO_2 . When tanks containing CO_2 and O_2 have been used inadvertently where a fire hazard exists (e.g., in the presence of electrocautery during laparoscopic surgery), explosions and fires have resulted.

Therapeutic Uses. CO_2 is used for insufflation during endoscopic procedures (e.g., laparoscopic surgery) because it is highly soluble and does not support combustion. Inadvertent gas emboli thus are dissolved and eliminated more easily by the respiratory system. CO_2 can be used to flood the surgical field during cardiac surgery. Because of its density, carbon dioxide displaces the air surrounding the open heart so that any gas bubbles trapped in the heart are carbon dioxide rather than insoluble nitrogen (Nadolny and Svensson, 2000). Similarly, CO_2 is used to de-bubble cardiopulmonary bypass and extracorporeal membrane oxygenation (ECMO) circuits. It is used to adjust pH during cardiopulmonary bypass procedures when a patient is cooled.

Hypocarbica, with its attendant respiratory alkalosis, still has some uses in anesthesia. It constricts cerebral vessels, decreasing brain size slightly, and thus may facilitate the performance of neurosurgical operations. While short-term hypocarbica is effective for this purpose, sustained hypocarbica has been associated with worse outcomes in patients with head injury (Muizelaar et al., 1991). Consequently, hypocarbica should be instituted with a clearly defined indication and normocarbica should be re-established as soon the indication for hypocarbica no longer applies.

NITRIC OXIDE

Nitric oxide (NO) is a free-radical gas long known as an air pollutant and a potential toxin. NO is now known as a critical endogenous cell-signaling molecule with an increasing number of potential therapeutic applications.

Endogenous NO is produced from L-arginine by a family of enzymes called NO synthases (neural, inducible and endothelial). NO is both an intra-cellular and a cell-cell messenger implicated in a wide range of physiological and pathophysiological events in numerous cell types, including the cardiovascular, immune, and nervous systems. NO activates the soluble guanylyl cyclase, increasing

cellular cyclic GMP (Chapter 3). In the vasculature, basal release of NO produced by endothelial cells is a primary determinant of resting vascular tone; NO causes vasodilation when synthesized in response to shear stress or a variety of vasodilating agents (Chapter 27). It also inhibits platelet aggregation and adhesion. Impaired NO production has been implicated in diseases such as atherosclerosis, hypertension, cerebral and coronary vasospasm, and ischemia-reperfusion injury. In the immune system, NO serves as an effector of macrophage-induced cytotoxicity, and overproduction of NO is a mediator of inflammation. In neurons, NO acts as a mediator of long-term potentiation, cytotoxicity resulting from N-methyl-D-aspartate (NMDA), and non-adrenergic non-cholinergic neurotransmission; NO has been implicated in mediating central nociceptive pathways (Chapters 8 and 18).

NO is rapidly inactivated in the circulation by oxyhemoglobin and by the reaction of NO with the heme iron, leading to the formation of nitrosyl-hemoglobin. Small quantities of methemoglobin are also produced and these are converted to the ferrous form of heme iron by cytochrome b5 reductase. The majority of inhaled NO is excreted in the urine in the form of nitrate. Rapid withdrawal of NO can result in a rebound increase in pulmonary pressure; gradual withdrawal should minimize rebound phenomena (Griffiths and Evans, 2005).

Therapeutic Uses. NO when inhaled selectively dilates the pulmonary vasculature with minimal systemic cardiovascular effects due to its rapid inactivation by oxyhemoglobin in the pulmonary circulation (Cooper, 1999). Ventilation-perfusion matching is preserved or improved by NO because inhaled NO is distributed only to ventilated areas of the lung and dilates only those vessels directly adjacent to the ventilated alveoli. Thus, inhaled NO decreases elevated pulmonary artery pressure and pulmonary vascular resistance and often improves oxygenation. The dose of NO that is required for an improvement in oxygenation is lower than that required for a reduction in pulmonary pressure (Griffiths and Evans, 2005).

Inhaled NO (iNO) has potential as a therapy for numerous diseases associated with increased pulmonary vascular resistance. In patients with adult respiratory distress syndrome (ARDS), iNO is more often used to improve oxygenation rather than reducing pulmonary pressure. NO does improve oxygenation but this effect is transient. Moreover, the use of iNO therapy is not associated with either a reduction in the duration of mechanical ventilation or in morbidity or mortality (Taylor et al., 2004). iNO-mediated reductions in pulmonary pressure have prompted its use in patients with pulmonary hypertension in other clinical settings. Transient reduction in pulmonary pressure have been reported in patients undergoing cardiac surgery (Winterhalter et al., 2008) and pulmonary transplantation (Ardehali et al., 2001). Although transient physiologic improvements do occur, long-term outcome is essentially unchanged (Meade et al., 2003). Several small studies and case reports have suggested potential benefits of inhaled NO in a variety of conditions, including pulmonary hypertension and right heart

failure associated with orthotopic heart transplantation, weaning from cardiopulmonary bypass in adult and congenital heart disease patients, ventricular assist device placement, primary pulmonary hypertension, pulmonary embolism, acute chest syndrome in sickle-cell patients, congenital diaphragmatic hernia, high-altitude pulmonary edema, and lung transplantation (Haddad et al., 2000). Larger prospective, randomized studies for these disease conditions either have not yet been performed or have failed to confirm any changes in outcome.

Inhaled NO is FDA-approved for only one indication, persistent pulmonary hypertension of the newborn (Mourani et al., 2004). A recent systematic review of the available data in neonates has shown that in very sick neonates with poor oxygenation, iNO does improve oxygenation but it does not improve mortality, reduce the incidence of bronchopulmonary dysplasia that is common in this population, or reduce the incidence of brain injury (Hintz et al., 2007, Su and Chen, 2008). Whether there are subsets of patients who may have a favorable response to iNO remains to be determined.

Diagnostic Uses. Inhaled NO also is used in several diagnostic applications. Inhaled NO can be used during cardiac catheterization to safely and selectively evaluate the pulmonary vasodilating capacity of patients with heart failure and infants with congenital heart disease. Inhaled NO also is used to determine the diffusion capacity (DL) across the alveolar–capillary unit. NO is more effective than carbon dioxide in this regard because of its greater affinity for hemoglobin and its higher water solubility at body temperature (Haddad et al., 2000).

NO is produced from the nasal passages and from the lungs of normal human subjects and can be detected in exhaled gas. The measurement of fractional exhaled NO (FeNO) is a noninvasive marker for airway inflammation with utility in the assessment of respiratory tract diseases including asthma, respiratory tract infection and chronic lung diseases (Taylor et al., 2006).

Toxicity. Administered at low concentrations (0.1–50 ppm), inhaled NO appears to be safe and without significant side effects. Pulmonary toxicity can occur with levels higher than 50–100 ppm. In the context of NO as an atmospheric pollutant, the Occupational Safety and Health Administration places the 7-hour exposure limit at 50 ppm. Part of the toxicity of NO may be related to its further oxidation to nitrogen dioxide (NO₂) in the presence of high concentrations of O₂. Even low concentrations of NO₂ (2 ppm) have been shown to be highly toxic in animal models, with observed changes in lung histopathology, including loss of cilia, hypertrophy, and focal hyperplasia in the epithelium of terminal bronchioles. It is important, therefore, to keep NO₂ formation during NO therapy at a low level. This can be achieved by the administration of NO at a site in the respiratory circuit as close to the patient as possible and timing the delivery of NO to inspiration. Laboratory studies have suggested potential additional toxic effects of chronic low doses of inhaled NO, including surfactant inactivation and the formation of peroxynitrite by interaction with superoxide. Nitric oxide and peroxynitrite have been implicated in cellular mechanisms of oxygen toxicity in the lung and central nervous system (Allen et al., 2009). The ability of NO to inhibit or alter the function of a number of iron- and heme-containing proteins, including cyclooxygenase, lipoxygenases, and oxidative cytochromes, as well as its interactions with ADP-ribosylation,

suggests a need for further investigation of the toxic potential of NO under therapeutic conditions (Haddad et al., 2000).

The development of methemoglobinemia is a significant complication of inhaled NO at higher concentrations, and rare deaths have been reported with overdoses of NO. The blood content of methemoglobin, however, generally will not increase to toxic levels with appropriate use of inhaled NO. Methemoglobin concentrations should be monitored intermittently during NO inhalation (Haddad et al., 2000).

Inhaled NO can inhibit platelet function and has been shown to increase bleeding time in some clinical studies, although bleeding complications have not been reported.

In patients with impaired function of the left ventricle, NO has a potential to further impair left ventricular performance by dilating the pulmonary circulation and increasing the blood flow to the left ventricle, thereby increasing left atrial pressure and promoting pulmonary edema formation. Careful monitoring of cardiac output, left atrial pressure, or pulmonary capillary wedge pressure is important in this situation.

Despite these concerns, there are limited reports of inhaled NO-related toxicity in humans. The most important requirements for safe NO inhalation therapy include:

- continuous measurement of NO and NO₂ concentrations using either chemiluminescence or electrochemical analyzers
- frequent calibration of monitoring equipment
- intermittent analysis of blood methemoglobin levels
- the use of certified tanks of NO
- administration of the lowest NO concentration required for therapeutic effect

Methods of Administration. Courses of treatment of patients with inhaled NO are highly varied, extending from 0.1 to 40 ppm in dose and for periods of a few hours to several weeks in duration. The minimum effective inhaled NO concentration should be determined for each patient to minimize the chance for toxicity. Given that sensitivity to NO can vary in the patient during the course of administration, the determination of dose response relationship on a frequent basis should assist in the titration of the optimum dose of NO. Commercial NO systems are available that will accurately deliver inspired NO concentrations between 0.1 and 80 ppm and simultaneously measure NO and NO₂ concentrations. A constant inspired concentration of NO is obtained by administering NO in nitrogen to the inspiratory limb of the ventilator circuit in either a pulse or continuous mode. While inhaled NO may be administered to spontaneously breathing patients by a closely fitting mask, it usually is delivered during mechanical ventilation. Nasal prong administration is being employed in therapeutic trials of home administration for treatment of primary pulmonary hypertension (Griffiths et al., 2005).

HELIUM

Helium (He) is an inert gas whose low density, low solubility, and high thermal conductivity provide the basis for its medical and diagnostic uses. Helium is produced by separation from liquefied natural gas and is supplied in brown cylinders. Helium can be mixed with oxygen and administered by mask or endotracheal tube. Under hyperbaric conditions, it can be substituted for the bulk

560 of other gases, resulting in a mixture of much lower density that is easier to breathe.

The primary uses of helium are in pulmonary function testing, the treatment of respiratory obstruction, laser airway surgery, as a label in imaging studies, and for diving at depth. The determinations of residual lung volume, functional residual capacity, and related lung volumes require a highly diffusible non-toxic gas that is insoluble and does not leave the lung by the bloodstream so that, by dilution, the lung volume can be measured. Helium is well suited to these needs. A breath of a known concentration of helium is given, and the concentration of helium is measured in the mixed expired gas, allowing calculation of the other pulmonary volumes.

Pulmonary gas flow normally is laminar. With increased flow rates or a narrowed flow pathway, a component of pulmonary gas flow becomes turbulent. Helium can be added to oxygen to reduce turbulence due to airway obstruction since the density of helium is less than that of air and the viscosity of helium is greater than that of air. Addition of helium reduces the Reynolds number of the mixture (the Reynolds number is proportional to density and inversely proportional to viscosity), thereby reducing turbulence. Mixtures of helium and oxygen reduce the work of breathing. The utility of helium/oxygen mixtures is limited by the fact that oxygenation often accompanies airway obstruction. The need for increased inspired O_2 concentration limits the fraction of helium that can be used. Furthermore, even though helium reduces the Reynolds number of the gas mixture, the viscosity of helium is greater than that of air, and the increased viscosity increases the resistance to flow according to Poiseuille's law, whereby flow is inversely proportional to viscosity.

Helium has high thermal conductivity, making it useful during laser surgery on the airway. This more rapid conduction of heat away from the point of contact of the laser beam reduces the spread of tissue damage and the likelihood that the ignition point of flammable materials in the airway will be reached. Its low density improves the flow through the small endotracheal tubes typically used in such procedures. However, its use for this purpose is rare.

Laser-polarized helium is used as an inhalational contrast agent for pulmonary magnetic resonance imaging. Optical pumping of hyperpolarized helium increases the signal from the gas in the lung to permit detailed imaging of the airways and inspired airflow patterns (Hopkins et al., 2007).

Hyperbaric Applications. The depth and duration of diving activity are limited by oxygen toxicity, inert gas (nitrogen) narcosis, and nitrogen supersaturation when decompressing. Oxygen toxicity is a problem with prolonged exposure to compressed air at 500 kPa (5 atm) or more. This problem can be minimized by dilution of oxygen with helium, which lacks narcotic potential even at very high pressures and is quite insoluble in body tissues. This low solubility reduces the likelihood of bubble formation after decompression, which therefore can be achieved more rapidly. The low density of helium also reduces the work of breathing in the otherwise dense

hyperbaric atmosphere. The lower heat capacity of helium also decreases respiratory heat loss, which can be significant when diving at depth.

HYDROGEN SULFIDE

Hydrogen sulfide (H_2S), which has a characteristic rotten egg smell, is a colorless, flammable, water-soluble gas that is primarily considered a toxic agent due to its ability to inhibit mitochondrial respiration through blockade of cytochrome c oxidase. Recent research has demonstrated that H_2S in low quantities may have the potential to limit cell death (Lefer, 2007). Inhibition of respiration is potentially toxic; however, if depression of respiration occurs in a controlled manner, it may allow non-hibernating species exposed to inhaled H_2S to enter a state akin to suspended animation (i.e., a slowing of cellular activity to a point where metabolic processes are inhibited but not terminal) and thereby increase tolerance to stress. H_2S also may cause activation of ATP-dependent K^+ channels, cause vasodilation properties, and serve as a free radical scavenger. H_2S has been shown to protect against whole-body hypoxia, lethal hemorrhage, and ischemia-reperfusion injury in various organs including the kidney, lung, liver, and heart. Currently, effort is underway for development of gas-releasing molecules that could deliver H_2S and other therapeutic gases to diseased tissue (Bannenberg and Vieira, 2009). Though H_2S has clinical potential, further verification in preclinical models is necessary as is more information regarding the route of delivery, timing, formulation, and concentration of H_2S .

Local Anesthetics

William A. Catterall and
Kenneth Mackie

Local anesthetics bind reversibly to a specific receptor site within the pore of the Na^+ channels in nerves and block ion movement through this pore. When applied locally to nerve tissue in appropriate concentrations, local anesthetics can act on any part of the nervous system and on every type of nerve fiber, reversibly blocking the action potentials responsible for nerve conduction. Thus, a local anesthetic in contact with a nerve trunk can cause both sensory and motor paralysis in the area innervated. These effects of clinically relevant concentrations of local anesthetics are reversible with recovery of nerve function and no evidence of damage to nerve fibers or cells in most clinical applications.

History. The first local anesthetic, cocaine, was serendipitously discovered to have anesthetic properties in the late 19th century. Cocaine occurs in abundance in the leaves of the coca shrub (*Erythroxylon coca*). For centuries, Andean natives have chewed an alkali extract of these leaves for its stimulatory and euphoric actions. Cocaine was first isolated in 1860 by Albert Niemann. He, like many chemists of that era, tasted his newly isolated compound and noted that it caused a numbing of the tongue. Sigmund Freud studied cocaine's physiological actions, and Carl Koller introduced cocaine into clinical practice in 1884 as a topical anesthetic for ophthalmological surgery. Shortly thereafter, Halstead popularized its use in infiltration and conduction block anesthesia.

Chemistry and Structure-Activity Relationship. Cocaine is an ester of benzoic acid and the complex alcohol 2-carbomethoxy, 3-hydroxy-tropane (Figure 20–1). Because of its toxicity and addictive properties (Chapter 24), a search for synthetic substitutes for cocaine began in 1892 with the work of Einhorn and colleagues, resulting in the synthesis of procaine, which became the prototype for local anesthetics for nearly half a century. The most widely used agents today are procaine, lidocaine, bupivacaine, and tetracaine.

The typical local anesthetics contain hydrophilic and hydrophobic moieties that are separated by an intermediate ester or amide linkage (Figure 20–1). A broad range of compounds containing these minimal structural features can satisfy the requirements for action as local anesthetics. The hydrophilic group usually is a

tertiary amine but also may be a secondary amine; the hydrophobic moiety must be aromatic. The nature of the linking group determines some of the pharmacological properties of these agents. For example, local anesthetics with an ester link are hydrolyzed readily by plasma esterases.

The structure-activity relationship and the physicochemical properties of local anesthetics have been reviewed by Courtney and Strichartz (1987). Hydrophobicity increases both the potency and the duration of action of the local anesthetics; association of the drug at hydrophobic sites enhances the partitioning of the drug to its sites of action and decreases the rate of metabolism by plasma esterases and hepatic enzymes. In addition, the receptor site for these drugs on Na^+ channels is thought to be hydrophobic (see *Mechanism of Action*), so that receptor affinity for anesthetic agents is greater for more hydrophobic drugs. Hydrophobicity also increases toxicity, so that the therapeutic index is decreased for more hydrophobic drugs.

Molecular size influences the rate of dissociation of local anesthetics from their receptor sites. Smaller drug molecules can escape from the receptor site more rapidly. This characteristic is important in rapidly firing cells, in which local anesthetics bind during action potentials and dissociate during the period of membrane repolarization. Rapid binding of local anesthetics during action potentials causes the frequency- and voltage-dependence of their action.

Mechanism of Action. Local anesthetics act at the cell membrane to prevent the generation and the conduction of nerve impulses. Conduction block can be demonstrated in squid giant axons from which the axoplasm has been removed.

Local anesthetics block conduction by decreasing or preventing the large transient increase in the permeability of excitable membranes to Na^+ that normally is produced by a slight depolarization of the membrane (Chapters 8, 11, and 14) (Strichartz and Ritchie, 1987). This action of local anesthetics is due to their direct interaction with voltage-gated Na^+ channels. As the anesthetic action progressively develops in a nerve, the threshold for electrical excitability gradually increases, the rate of rise of the action potential declines, impulse

Figure 20–1. Structural formulas of selected local anesthetics. Most local anesthetics consist of a hydrophobic (aromatic) moiety (black), a linker region (orange), and a substituted amine (hydrophilic region, in red). The structures above are grouped by the nature of the linker region. Procaine is a prototypic ester-type local anesthetic; esters generally are well hydrolyzed by plasma esterases, contributing to the relatively short duration of action of drugs in this group. Lidocaine is a prototypic amide-type local anesthetic; these structures generally are more resistant to clearance and have longer durations of action. There are exceptions, including benzocaine (poorly water soluble; used only topically) and the structures with a ketone, an amidine, and an ether linkage. Chlorprocaine has a chlorine atom on C2 of the aromatic ring of procaine.

conduction slows, and the safety factor for conduction decreases. These factors decrease the probability of propagation of the action potential, and nerve conduction eventually fails.

Local anesthetics can bind to other membrane proteins (Butterworth and Strichartz, 1990). In particular, they can block K^+ channels (Strichartz and Ritchie, 1987). However, since the interaction of local anesthetics

with K^+ channels requires higher concentrations of drug, blockade of conduction is not accompanied by any large or consistent change in resting membrane potential.

Quaternary analogs of local anesthetics block conduction when applied internally to perfused giant axons of squid but are relatively ineffective when applied externally. These observations suggest that the site at which local anesthetics act, at least in their charged form, is accessible only from the inner surface of the membrane (Narahashi and Frazier, 1971; Strichartz and Ritchie, 1987). Therefore, local anesthetics applied externally first must cross the membrane before they can exert a blocking action.

Although a variety of physicochemical models have been proposed to explain how local anesthetics achieve conduction block (Courtney and Strichartz, 1987), it now is generally accepted that the major mechanism of action of these drugs involves their interaction with one or more specific binding sites within the Na^+ channel (Butterworth and Strichartz, 1990). The Na^+ channels of the mammalian brain are complexes of glycosylated proteins with an aggregate molecular size in excess of 300,000 Da; the individual subunits are designated α (260,000 Da) and β_1 to β_4 (33,000–38,000 Da). The large α subunit of the Na^+ channel contains four homologous domains (I–IV); each domain is thought to consist of six transmembrane segments in α -helical conformation (S1–S6; Figure 20–2) and an additional, membrane-reentrant pore (*P*) loop. The Na^+ -selective transmembrane pore of the channel presumably resides in the center of a nearly symmetrical structure formed by the four homologous domains. The voltage dependence of channel opening is hypothesized to reflect conformational changes that result from the movement of “gating charges” within the voltage-sensor module of the sodium channel in response to changes in the transmembrane potential. The gating charges are located in the S4 transmembrane helix; the S4 helices are both hydrophobic and positively charged, containing lysine or arginine residues at every third position. It is postulated that these residues move perpendicular to the plane of the membrane under the influence of the transmembrane potential, initiating a series of conformational changes in all four domains, which leads to the open state of the channel (Figure 20–2) (Catterall, 2000; Yu et al., 2005).

The transmembrane pore of the Na^+ channel is thought to be surrounded by the S5 and S6 transmembrane helices and the short membrane-associated segments between them that form the *P* loop. Amino acid residues in these short segments are the most critical determinants of the ion conductance and selectivity of the channel.

After it opens, the Na^+ channel inactivates within a few milliseconds due to closure of an inactivation gate. This functional gate is formed by the short intracellular loop of protein that connects homologous domains III and IV (Figure 20–2). This loop folds over the intracellular mouth of the transmembrane pore during the process of inactivation and binds to an inactivation gate “receptor” formed by the intracellular mouth of the pore.

Amino acid residues important for local anesthetic binding are found in the S6 segments in domains I, III, and IV (Ragsdale et al., 1994; Yarov-Yarovsky et al., 2002). Hydrophobic amino acid residues near the center and the intracellular end of the S6 segment may interact directly with bound local anesthetics (Figure 20–3).

Experimental mutation of a large hydrophobic amino acid residue (isoleucine) to a smaller one (alanine) near the extracellular end of this segment creates a pathway for access of charged local anesthetic drugs from the extracellular solution to the receptor site. These findings place the local anesthetic receptor site within the intracellular half of the transmembrane pore of the Na^+ channel, with part of its structure contributed by amino acids in the S6 segments of domains I, III, and IV.

Frequency- and Voltage-Dependence of Local Anesthetic Action. The degree of block produced by a given concentration of local anesthetic depends on how the nerve has been stimulated and on its resting membrane potential. Thus, a resting nerve is much less sensitive to a local anesthetic than one that is repetitively stimulated; higher frequency of stimulation and more positive membrane potential cause a greater degree of anesthetic block. These frequency- and voltage-dependent effects of local anesthetics occur because the local anesthetic molecule in its charged form gains access to its binding site within the pore only when the Na^+ channel is in an open state and because the local anesthetic binds more tightly to and stabilizes the inactivated state of the Na^+ channel (Butterworth and Strichartz, 1990; Courtney and Strichartz, 1987). Local anesthetics exhibit these properties to different extents depending on their pK_a , lipid solubility, and molecular size. In general, the frequency dependence of local anesthetic action depends critically on the rate of dissociation from the receptor site in the pore of the Na^+ channel. A high frequency of stimulation is required for rapidly dissociating drugs so that drug binding during the action potential exceeds drug dissociation between action potentials. Dissociation of smaller and more hydrophobic drugs is more rapid, so a higher frequency of stimulation is required to yield frequency-dependent block. Frequency-dependent block of ion channels is most important for the actions of antiarrhythmic drugs (Chapter 29).

Differential Sensitivity of Nerve Fibers to Local Anesthetics. Although there is great individual variation, for most patients treatment with local anesthetics causes the sensation of pain to disappear first, followed by loss of the sensations of temperature, touch, deep pressure, and finally motor function (Table 20–1). Classical experiments with intact nerves showed that the δ wave in the compound action potential, which represents slowly conducting, small-diameter myelinated fibers, was reduced more rapidly and at lower concentrations of cocaine than was the α wave, which represents rapidly conducting, large-diameter fibers (Gasser and Erlanger, 1929). In general, autonomic fibers, small

Figure 20–2. Structure and function of voltage-gated Na^+ channels. **A.** A two-dimensional representation of the α (center), β_1 (left), and β_2 (right) subunits of the voltage-gated Na^+ channel from mammalian brain. The polypeptide chains are represented by continuous lines with length approximately proportional to the actual length of each segment of the channel protein. Cylinders represent regions of transmembrane α helices. ψ indicates sites of demonstrated N-linked glycosylation. Note the repeated structure of the four homologous domains (I–IV) of the α subunit. **Voltage Sensing.** The S4 transmembrane segments in each homologous domain of the α subunit serve as voltage sensors. (+) represents the positively charged amino acid residues at every third position within these segments. Electrical field (negative inside) exerts a force on these charged amino acid residues, pulling them toward the intracellular side of the membrane; depolarization allows them to move outward. **Pore.** The S5 and S6 transmembrane segments and the short membrane-associated loop between them (P loop) form the walls of the pore in the center of an approximately symmetrical square array of the four homologous domains (see panel **B**). The amino acid residues indicated by circles in the P loop are critical for determining the conductance and ion selectivity of the Na^+ channel and its ability to bind the extracellular pore-blocking toxins tetrodotoxin and saxitoxin. **Inactivation.** The short intracellular loop connecting homologous domains III and IV serves as the inactivation gate of the Na^+ channel. It is thought to fold into the intracellular mouth of the pore and occlude it within a few milliseconds after the channel opens. Three hydrophobic residues (isoleucine–phenylalanine–methionine; IFM) at the position marked **h** appear to serve as an inactivation gate receptor there. **Modulation.** The gating of the Na^+ channel can be modulated by protein phosphorylation. Phosphorylation of the inactivation gate between homologous domains III and IV by PKC slows inactivation. Phosphorylation of sites in the intracellular loop between homologous domains I and II by either PKC or PKA reduces Na^+ channel activation. (Adapted from Catterall, 2000, with permission. Copyright © Elsevier.). **B.** The four homologous domains of the Na^+ channel α subunit are illustrated as a square array, as viewed looking down on the membrane. The sequence of conformational changes that the Na^+ channel undergoes during activation and inactivation is diagrammed. Upon depolarization, each of the four homologous domains sequentially undergoes a conformational change to an activated state. After all four domains have activated, the Na^+ channel can open. Within a few milliseconds after opening, the inactivation gate between domains III and IV closes over the intracellular mouth of the channel and occludes it, preventing further ion conductance (see Catterall, 2000).

Figure 20-3. *The local anesthetic receptor site.* **A.** A drawing of the pore structure of a bacterial K^+ channel (KcsA), which is related to the sodium channel. The KcsA channel has two transmembrane segments, analogous to the S5 and S6 segments of sodium channels. The S6-like segment forms the walls of the inner pore while the P loop forms the narrow ion selectivity filter at its extracellular (top) end. Four separate KcsA subunits form the pore in their center; only two of the subunits are shown here. **B.** A structural model of the local anesthetic receptor site. The S6 segments from domains I, III, and IV of the sodium channel α subunit are illustrated, based on the structure of the KcsA channel (panel A). The amino acid residues in these three transmembrane segments that contribute to the local anesthetic receptor site are indicated in single letter code and are presented in space-filling representation (light blue). An etidocaine molecule (black) is illustrated bound in the receptor site. Substitutions of the light blue residues with alanine reduce the affinity for local anesthetic block of sodium channels. It therefore is likely that the side chains of these amino acid residues contact bound local anesthetics in their receptor site. I1760 and I409 likely form the outer boundary of the local anesthetic receptor site. Mutations of I1760 allow drug access to the receptor site from the extracellular side. (This figure was originally published in the *Journal of Biological Chemistry*. Yarov-Yarovsky V, McPhee JC, Idsvoog D, Pate C, Scheuer T, Catterall WA: Role of amino acid residues in transmembrane segments IS6 and IIS6 of the Na^+ channel α subunit in voltage-dependent gating and drug block. *J Biol Chem* 2002;277, 35393. © the American Society for Biochemistry and Molecular Biology.)

unmyelinated C fibers (mediating pain sensations), and small myelinated $A\delta$ fibers (mediating pain and temperature sensations) are blocked before the larger myelinated $A\gamma$, $A\beta$, and $A\alpha$ fibers (mediating postural, touch, pressure, and motor information) (Raymond and Gissen, 1987). *The differential rate of block exhibited by fibers mediating different sensations is of considerable practical importance in the use of local anesthetics.*

The precise mechanisms responsible for this apparent specificity of local anesthetic action on pain fibers are not known, but several factors may contribute. The initial hypothesis from the classical work on intact nerves was that sensitivity to local anesthetic block increases with decreasing fiber size, consistent with high sensitivity for pain sensation mediated by small fibers and low sensitivity for motor function mediated by large fibers (Gasser and Erlanger, 1929). However, when nerve fibers are dissected from nerves to allow direct measurement of action potential generation, no clear correlation of the concentration dependence of local anesthetic block with fiber diameter is observed (Fink and Cairns, 1984; Franz and Perry, 1974; Huang et al., 1997). Therefore, it is unlikely that the fiber size *per se* determines the sensitivity to local anesthetic block under steady-state

conditions. However, the spacing of nodes of Ranvier increases with the size of nerve fibers. Because a fixed number of nodes must be blocked to prevent conduction, small fibers with closely spaced nodes of Ranvier may be blocked more rapidly during treatment of intact nerves, because the local anesthetic reaches a critical length of nerve more rapidly (Franz and Perry, 1974). Differences in tissue barriers and location of smaller C fibers and $A\delta$ fibers in nerves also may influence the rate of local anesthetic action.

Effect of pH. Local anesthetics tend to be only slightly soluble as unprotonated amines. Therefore, they generally are marketed as water-soluble salts, usually hydrochlorides. Inasmuch as the local anesthetics are weak bases (typical pK_a values range from 8-9), their hydrochloride salts are mildly acidic. This property increases the stability of the local anesthetic esters and the catecholamines added as vasoconstrictors. Under usual conditions of administration, the pH of the local anesthetic solution rapidly equilibrates to that of the extracellular fluids.

Although the unprotonated species of the local anesthetic is necessary for diffusion across cellular membranes, it is the cationic

Table 20–1

Susceptibility to Block Types of Nerve Fibers

CLASSIFICATION	ANATOMIC LOCATION	MYELIN	DIAMETER, (μm)	CONDUCTION VELOCITY, (m/sec)	FUNCTION	CLINICAL SENSITIVITY TO BLOCK
A fibers						
A α	Afferent to and efferent from muscles and joints	Yes	6–22	10–85	Motor and proprioception	+
A β	Efferent to muscle spindles	Yes	3–6	15–35	Muscle tone	++
A δ	Sensory roots and afferent peripheral nerves	Yes	1–4	5–25	Pain, temperature, touch	+++
B fibers	Preganglionic sympathetic	Yes	<3	3–15	Vasomotor, visceromotor, sudomotor, pilomotor	++++
C fibers						
Sympathetic	Postganglionic sympathetic	No	0.3–1.3	0.7–1.3	Vasomotor, visceromotor, sudomotor, pilomotor	++++
Dorsal root	Sensory roots and afferent peripheral nerves	No	0.4–1.2	0.1–2	Pain, temperature, touch	++++

species that interacts preferentially with Na⁺ channels. The results of experiments on anesthetized mammalian nonmyelinated fibers support this conclusion (Ritchie and Greengard, 1966). In these experiments, conduction could be blocked or unblocked merely by adjusting the pH of the bathing medium to 7.2 or 9.6, respectively, without altering the amount of anesthetic present. The primary role of the cationic form also was demonstrated by Narahashi and Frazier, who perfused the extracellular and axoplasmic surface of the giant squid axon with tertiary and quaternary amine local anesthetics and found that the quaternary amines were active (Narahashi and Frazier, 1971). However, the unprotonated molecular forms also possess some anesthetic activity (Butterworth and Strichartz, 1990). Recent reports indicate that quaternary local anesthetics such as QX-314 can gain access to the cytoplasmic surface of the nerve cell membrane via TRPV1 channels (transient receptor potential vanilloid subtype channels) (reviewed by Butterworth and Oxford, 2009). TRP channels, and possibly other ion channels, appear to lose selectivity and permit permeation of molecules like QX-314 in the face of prolonged or intense activation.

Prolongation of Action by Vasoconstrictors. The duration of action of a local anesthetic is proportional to the time of contact with nerve. Consequently, maneuvers that keep the drug at the nerve prolong the period of anesthesia. For example, cocaine inhibits the neuronal membrane transporters for catecholamines, thereby

potentiating the effect of NE at α adrenergic receptors in the vasculature, resulting in vasoconstriction and reduced cocaine absorption in vascular beds where α adrenergic effects predominate (Chapters 8 and 12). Ropivacaine and bupivacaine also cause vasoconstriction. In clinical practice, a vasoconstrictor, usually epinephrine, is often added to local anesthetics. The vasoconstrictor performs a dual service. By decreasing the rate of absorption, it not only localizes the anesthetic at the desired site, but also allows the rate at which it is destroyed in the body to keep pace with the rate at which it is absorbed into the circulation. This reduces its systemic toxicity. It should be noted, however, that epinephrine also dilates skeletal muscle vascular beds through actions at β₂ adrenergic receptors, and therefore has the potential to increase systemic toxicity of anesthetic deposited in muscle tissue.

Some of the vasoconstrictor agents may be absorbed systemically, occasionally to an extent sufficient to cause untoward reactions (see the next section). There also may be delayed wound healing, tissue edema, or necrosis after local anesthesia. These effects seem to occur partly because sympathomimetic amines increase the oxygen consumption of the tissue; this, together with

the vasoconstriction, leads to hypoxia and local tissue damage. The use of vasoconstrictors in local anesthetic preparations for anatomical regions with limited collateral circulation could produce irreversible hypoxic damage, tissue necrosis, and gangrene, and therefore is contraindicated.

Undesired Effects of Local Anesthetics. In addition to blocking conduction in nerve axons in the peripheral nervous system, local anesthetics interfere with the function of all organs in which conduction or transmission of impulses occurs. Thus, they have important effects on the CNS, the autonomic ganglia, the neuromuscular junction, and all forms of muscle (for a review, see Covino, 1987; Garfield and Gugino, 1987; Gintant and Hoffman, 1987). The danger of such adverse reactions is proportional to the concentration of local anesthetic achieved in the circulation. In general, in local anesthetics with chiral centers, the *S*-enantiomer is less toxic than the *R*-enantiomer (McClure, 1996).

Central Nervous System. Following absorption, local anesthetics may cause CNS stimulation, producing restlessness and tremor that may progress to clonic convulsions. In general, the more potent the anesthetic, the more readily convulsions may be produced. Alterations of CNS activity are thus predictable from the local anesthetic agent in question and the blood concentration achieved. Central stimulation is followed by depression; death usually is caused by respiratory failure.

The apparent stimulation and subsequent depression produced by applying local anesthetics to the CNS presumably is due solely to depression of neuronal activity; a selective depression of inhibitory neurons is thought to account for the excitatory phase *in vivo*. Rapid systemic administration of local anesthetics may produce death with no or only transient signs of CNS stimulation. Under these conditions, the concentration of the drug probably rises so rapidly that all neurons are depressed simultaneously. Airway control, along with ventilatory and circulatory support, are essential features of treatment in the late stage of intoxication. Benzodiazepines or rapidly acting barbiturates administered intravenously are the drugs of choice for both the prevention and arrest of convulsions (Chapter 17).

Although drowsiness is the most frequent complaint that results from the CNS actions of local anesthetics, lidocaine may produce dysphoria or euphoria and muscle twitching. Moreover, both lidocaine and procaine may produce a loss of consciousness that is preceded only by symptoms of sedation (Covino, 1987). Whereas other local anesthetics also show the effect, cocaine has a particularly prominent effect on mood and behavior. These effects of cocaine and its potential for abuse are discussed in Chapter 24.

Cardiovascular System. Following systemic absorption, local anesthetics act on the cardiovascular system (Covino, 1987). The primary site of action is the myocardium, where decreases in electrical excitability, conduction rate, and force of contraction occur. In

addition, most local anesthetics cause arteriolar dilation. Untoward cardiovascular effects usually are seen only after high systemic concentrations are attained and effects on the CNS are produced. However, on rare occasions, lower doses of some local anesthetics will cause cardiovascular collapse and death, probably due to either an action on the pacemaker or the sudden onset of ventricular fibrillation. Ventricular tachycardia and fibrillation are relatively uncommon consequences of local anesthetics other than bupivacaine. The effects of local anesthetics such as lidocaine and procainamide, which also are used as antiarrhythmic drugs, are discussed in Chapter 29. Finally, it should be stressed that untoward cardiovascular effects of local anesthetic agents may result from their inadvertent intravascular administration, especially if epinephrine also is present.

Smooth Muscle. Local anesthetics depress contractions in the intact bowel and in strips of isolated intestine (Zipf and Dittmann, 1971). They also relax vascular and bronchial smooth muscle, although low concentrations initially may produce contraction (Covino, 1987). Spinal and epidural anesthesia, as well as instillation of local anesthetics into the peritoneal cavity, cause sympathetic nervous system paralysis, which can result in increased tone of GI musculature (described under "Clinical Uses"). Local anesthetics may increase the resting tone and decrease the contractions of isolated human uterine muscle; however, uterine contractions are seldom depressed directly during intrapartum regional anesthesia.

Neuromuscular Junction and Ganglionic Synapse. Local anesthetics also affect transmission at the neuromuscular junction. Procaine, e.g., can block the response of skeletal muscle to maximal motor-nerve volleys and to ACh at concentrations at which the muscle responds normally to direct electrical stimulation. Similar effects occur at autonomic ganglia. These effects are due to block of nicotinic ACh receptors by high concentrations of the local anesthetic (Charnet et al., 1990; Neher and Steinbach, 1978).

Hypersensitivity to Local Anesthetics. Rare individuals are hypersensitive to local anesthetics. The reaction may manifest itself as an allergic dermatitis or a typical asthmatic attack (Covino, 1987). It is important to distinguish allergic reactions from toxic side effects and from the effects of co-administered vasoconstrictors. Hypersensitivity seems to occur more frequently with local anesthetics of the ester type and frequently extends to chemically related compounds. For example, individuals sensitive to procaine also may react to structurally similar compounds (e.g., tetracaine) through reaction to a common metabolite. Although allergic responses to agents of the amide type are uncommon, solutions of such agents may contain preservatives

such as methylparaben that may provoke an allergic reaction (Covino, 1987). Local anesthetic preparations containing a vasoconstrictor also may elicit allergic responses due to the sulfite added as an antioxidant for the catecholamine/vasoconstrictor.

Metabolism of Local Anesthetics. The metabolic fate of local anesthetics is of great practical importance, because their toxicity depends largely on the balance between their rates of absorption and elimination. As noted earlier, the rate of absorption of many anesthetics can be reduced considerably by the incorporation of a vasoconstrictor agent in the anesthetic solution. However, the rate of degradation of local anesthetics varies greatly, and this is a major factor in determining the safety of a particular agent. Since toxicity is related to the free concentration of drug, binding of the anesthetic to proteins in the serum and to tissues reduces the concentration of free drug in the systemic circulation, and consequently reduces toxicity. For example, in intravenous regional anesthesia of an extremity, about half of the original anesthetic dose still is tissue-bound 30 minutes after the restoration of normal blood flow (Arthur, 1987).

Some of the common local anesthetics (e.g., tetracaine) are esters. They are hydrolyzed and inactivated primarily by a plasma esterase, probably plasma cholinesterase. The liver also participates in hydrolysis of local anesthetics. Since spinal fluid contains little or no esterase, anesthesia produced by the intrathecal injection of an anesthetic agent will persist until the local anesthetic agent has been absorbed into the circulation.

The amide-linked local anesthetics are, in general, degraded by the hepatic CYPs the initial reactions involving *N*-dealkylation and subsequent hydrolysis (Arthur, 1987). However, with prilocaine, the initial step is hydrolytic, forming *o*-toluidine metabolites that can cause methemoglobinemia. The extensive use of amide-linked local anesthetics in patients with severe hepatic disease requires caution. The amide-linked local anesthetics are extensively (55–95%) bound to plasma proteins, particularly α_1 -acid glycoprotein. Many factors increase (e.g., cancer, surgery, trauma, myocardial infarction, smoking, and uremia) or decrease (e.g., oral contraceptives) the level of this glycoprotein, thereby changing the amount of anesthetic delivered to the liver for metabolism and thus influencing systemic toxicity. Age-related changes in protein binding of local anesthetics also occur. The neonate is relatively deficient in plasma proteins that bind local anesthetics and thereby is more susceptible to toxicity. Plasma proteins are not the sole determinant of local anesthetic availability. Uptake by the lung also may play an important role in the distribution of amide-linked local anesthetics in the body. Reduced cardiac output slows delivery of the amide compounds to the liver, reducing their metabolism and prolonging their plasma half-lives.

COCAINE

Chemistry. Cocaine, an ester of benzoic acid and methylecgonine, occurs in abundance in the leaves of the coca shrub. Ecgonine is an

amino alcohol base closely related to tropine, the amino alcohol in atropine. It has the same fundamental structure as the synthetic local anesthetics (Figure 20–1).

Pharmacological Actions and Preparations. The clinically desired actions of cocaine are the blockade of nerve impulses, as a consequence of its local anesthetic properties, and local vasoconstriction, secondary to inhibition of local NE reuptake. Toxicity and its potential for abuse have steadily decreased the clinical uses of cocaine. Its high toxicity is due to reduced catecholamine uptake in both the central and peripheral nervous systems. Its euphoric properties are due primarily to inhibition of catecholamine uptake, particularly DA, in the CNS. Other local anesthetics do not block the uptake of NE and do not produce the sensitization to catecholamines, vasoconstriction, or mydriasis characteristic of cocaine. Currently, cocaine is used primarily for topical anesthesia of the upper respiratory tract, where its combination of both vasoconstrictor and local anesthetic properties provide anesthesia and shrinking of the mucosa. Cocaine hydrochloride is provided as a 1%, 4%, or 10% solution for topical application. For most applications, the 1% or 4% preparation is preferred to reduce toxicity. Because of its abuse potential, cocaine is listed as a schedule II controlled substance by the U.S. Drug Enforcement Agency.

LIDOCAINE

Lidocaine (XYLOCAINE, others), an aminoethylamide (Figure 20–1), is the prototypical amide local anesthetic.

Pharmacological Actions. Lidocaine produces faster, more intense, longer-lasting, and more extensive anesthesia than does an equal concentration of procaine. Lidocaine is an alternative choice for individuals sensitive to ester-type local anesthetics.

Absorption, Fate, and Excretion. Lidocaine is absorbed rapidly after parenteral administration and from the GI and respiratory tracts. Although it is effective when used without any vasoconstrictor, epinephrine decreases the rate of absorption, such that the toxicity is decreased and the duration of action usually is prolonged. In addition to preparations for injection, lidocaine is formulated for topical, ophthalmic, mucosal, and transdermal use.

A lidocaine transdermal patch (LIDODERM) is used for relief of pain associated with postherpetic neuralgia. An oral patch (DENTIPATCH) is available for application to accessible mucous membranes of the mouth prior to superficial dental procedures. The combination of lidocaine (2.5%) and prilocaine (2.5%) in an occlusive dressing (EMLA, others) is used as an anesthetic prior to venipuncture, skin graft harvesting, and infiltration of anesthetics into genitalia. Lidocaine in combination with tetracaine (PLIAGLIS) in a formulation that generates a “peel” is approved for topical local analgesia prior to superficial dermatological procedures such as filler injections and laser-based treatments. Lidocaine in combination with tetracaine is marketed in a formulation that generates heat upon exposure to air (SYNERA), which is used prior to venous access and superficial dermatological procedures such as excision, electrodesiccation, and shave biopsy of skin lesions. The mild warming is intended to increase skin temperature by up to 5°C for the purpose of enhancing delivery of local anesthetic into the skin.

Lidocaine is dealkylated in the liver by CYPs to monoethylglycine xylidide and glycine xylidide, which can be metabolized further to monoethylglycine and xylidide. Both monoethylglycine xylidide and glycine xylidide retain local anesthetic activity. In humans, ~75% of the xylidide is excreted in the urine as the further metabolite 4-hydroxy-2, 6-dimethylaniline (Arthur, 1987).

Toxicity. The side effects of lidocaine seen with increasing dose include drowsiness, tinnitus, dysgeusia, dizziness, and twitching. As the dose increases, seizures, coma, and respiratory depression and arrest will occur. Clinically significant cardiovascular depression usually occurs at serum lidocaine levels that produce marked CNS effects. The metabolites monoethylglycine xylidide and glycine xylidide may contribute to some of these side effects.

Clinical Uses. Lidocaine has a wide range of clinical uses as a local anesthetic; it has utility in almost any application where a local anesthetic of intermediate duration is needed. Lidocaine also is used as an antiarrhythmic agent (Chapter 29).

BUPIVACAINE

Pharmacological Actions. Bupivacaine (MARCAINE, SENSORCAINE, others), is a widely used amide local anesthetic; its structure is similar to that of lidocaine except that the amine-containing group is a butyl piperidine (Figure 20–1). Bupivacaine is a potent agent capable of producing prolonged anesthesia. Its long duration of action plus its tendency to provide more sensory than motor block has made it a popular drug for providing prolonged analgesia during labor or the postoperative period. By taking advantage of indwelling catheters and continuous infusions, bupivacaine can be used to provide several days of effective analgesia.

Toxicity. Bupivacaine is more cardiotoxic than equi-effective doses of lidocaine. Clinically, this is manifested by severe ventricular arrhythmias and myocardial depression after inadvertent intravascular administration. Although lidocaine and bupivacaine both rapidly block cardiac Na⁺ channels during systole, bupivacaine dissociates much more slowly than does lidocaine during diastole, so a significant fraction of Na⁺ channels at physiological heart rates remains blocked with bupivacaine at the end of diastole (Clarkson and Hondeghem, 1985). Thus, the block by bupivacaine is cumulative and substantially more than would be predicted by its local anesthetic potency. At least a portion of the cardiac toxicity of bupivacaine may be mediated centrally, as direct injection of small quantities of bupivacaine into the medulla can produce malignant ventricular arrhythmias (Thomas et al., 1986). Bupivacaine-induced cardiac toxicity can be very difficult to treat, and its severity is enhanced by coexisting acidosis, hypercarbia, and hypoxemia.

OTHER SYNTHETIC LOCAL ANESTHETICS

The number of synthetic local anesthetics is so large that it is impractical to consider them all here. Some local anesthetic agents are too toxic to be given by injection. Their use is restricted to topical application to the eye (Chapter 64), the mucous membranes, or the skin (Chapter 65). Many local anesthetics are suitable,

however, for infiltration or injection to produce nerve block; some of these also are useful for topical application. The main categories of local anesthetics are given in the following discussion; agents are listed alphabetically. See Figure 20–1 for their structures.

Local Anesthetics Suitable for Injection

Articaine. Articaine (SEPTOCAINE) is approved in the U.S. for dental and periodontal procedures. Although it is an amide local anesthetic, it also contains an ester, whose hydrolysis terminates its action. Thus, articaine exhibits a rapid onset (1-6 minutes) and duration of action of ~1 hour.

Chloroprocaine. Chloroprocaine (NESACAINE, others) is a chlorinated derivative of procaine. Its major assets are its rapid onset and short duration of action and its reduced acute toxicity due to its rapid metabolism (plasma $t_{1/2}$ ~25 seconds). Enthusiasm for its use has been tempered by reports of prolonged sensory and motor block after epidural or subarachnoid administration of large doses. This toxicity appears to have been a consequence of low pH and the use of sodium metabisulfite as a preservative in earlier formulations. There are no reports of neurotoxicity with newer preparations of chloroprocaine, which contain calcium EDTA as the preservative, although these preparations also are not recommended for intrathecal administration. A higher than expected incidence of muscular back pain following epidural anesthesia with 2-chloroprocaine has also been reported (Stevens et al., 1993). This back pain is thought to be due to tetany in the paraspinal muscles, which may be a consequence of Ca²⁺ binding by the EDTA included as a preservative; the incidence of back pain appears to be related to the volume of drug injected and its use for skin infiltration.

Mepivacaine. Mepivacaine (CARBOCAINE, POLOCAINE, others) is an intermediate-acting amino amide. Its pharmacological properties are similar to those of lidocaine. Mepivacaine, however, is more toxic to the neonate and thus is not used in obstetrical anesthesia. The increased toxicity of mepivacaine in the neonate is related to ion trapping of this agent because of the lower pH of neonatal blood and the pK_a of mepivacaine rather than to its slower metabolism in the neonate. It appears to have a slightly higher therapeutic index in adults than does lidocaine. Its onset of action is similar to that of lidocaine and its duration slightly longer (~20%) than that of lidocaine in the absence of a co-administered vasoconstrictor. Mepivacaine is not effective as a topical anesthetic.

Prilocaine. Prilocaine (CITANEST) is an intermediate-acting amino amide. It has a pharmacological profile similar to that of lidocaine. The primary differences are that it causes little vasodilation and thus can be used without a vasoconstrictor, and its increased volume of distribution reduces its CNS toxicity, making it suitable for intravenous regional blocks (described later). The use of prilocaine is largely limited to dentistry because the drug is unique among the local anesthetics in its propensity to cause methemoglobinemia. This effect is a consequence of the metabolism of the aromatic ring to *o*-toluidine. Development of methemoglobinemia is dependent on the total dose administered, usually appearing after a dose of 8 mg/kg. If necessary, it can be treated by the intravenous administration of methylene blue (1-2 mg/kg). Methemoglobinemia following prilocaine has limited its use in obstetrical anesthesia, because it

complicates evaluation of the newborn. Also, methemoglobinemia is more common in neonates due to decreased resistance of fetal hemoglobin to oxidant stresses and the immaturity of enzymes in the neonate that convert methemoglobin back to the ferrous state.

Ropivacaine. The cardiac toxicity of bupivacaine stimulated interest in developing a less toxic, long-lasting local anesthetic. One result of that search was the development of the amino ethylamide ropivacaine (NAROPIN, others), the *S*-enantiomer of 1-propyl-2',6'-pipercoloxylidide. The *S*-enantiomer was chosen because it has a lower toxicity than the *R*-isomer (McClure, 1996). Ropivacaine is slightly less potent than bupivacaine in producing anesthesia. In several animal models, it appears to be less cardiotoxic than equipotent doses of bupivacaine. In clinical studies, ropivacaine appears to be suitable for both epidural and regional anesthesia, with a duration of action similar to that of bupivacaine. Interestingly, it seems to be even more motor-sparing than bupivacaine.

Procaine. Procaine (NOVOCAIN, others), introduced in 1905, was the first synthetic local anesthetic and is an amino ester. It has been supplanted by newer agents, and its use now is confined to infiltration anesthesia and occasionally for diagnostic nerve blocks. This is because of its low potency, slow onset, and short duration of action. While its toxicity is fairly low, it is hydrolyzed *in vivo* to produce para-aminobenzoic acid, which inhibits the action of sulfonamides. Thus, large doses should not be administered to patients taking sulfonamide drugs.

Tetracaine. Tetracaine (PONTOCAINE), is a long-acting amino ester. It is significantly more potent and has a longer duration of action than procaine. Tetracaine may exhibit increased systemic toxicity because it is more slowly metabolized than the other commonly used ester local anesthetics. Currently, it is widely used in spinal anesthesia when a drug of long duration is needed. Tetracaine also is incorporated into several topical anesthetic preparations. With the introduction of bupivacaine, tetracaine is rarely used in peripheral nerve blocks because of the large doses often necessary, its slow onset, and its potential for toxicity.

Local Anesthetics Used Primarily to Anesthetize Mucous Membranes and Skin

Some anesthetics are either too irritating or too ineffective to be applied to the eye. However, they are useful as topical anesthetic agents on the skin and/or mucous membranes. These preparations are effective in the symptomatic relief of anal and genital pruritus, poison ivy rashes, and numerous other acute and chronic dermatoses. They sometimes are combined with a glucocorticoid or antihistamine and are available in a number of proprietary formulations (see Figure 20–1 for structures).

Dibucaine (NUPERCAINAL, others) is a quinoline derivative. Its toxicity resulted in its removal from the U.S. market as an injectable preparation; however, it retains wide popularity outside the U.S. as a spinal anesthetic. It currently is available as an over-the-counter ointment for use on the skin.

Dyclonine hydrochloride has a rapid onset of action and duration of effect comparable to that of procaine. It is absorbed through the skin and mucous membranes. The compound has been used as 0.5% or 1% solution for topical anesthesia during endoscopy, for oral mucositis pain following radiation or chemotherapy, and for anogenital procedures; however, marketing of these solutions has been

discontinued in the U.S. Dyclonine is an active ingredient in a number of over-the-counter medications including sore throat lozenges (SUCRETS, others), a patch for cold sores (ORAJEL OVERNIGHT COLD SORE PATCH), and a 0.75% solution (SKIN SHIELD LIQUID BANDAGE).

Pramoxine hydrochloride (TRONOTHANE, others) is a surface anesthetic agent that is not a benzoate ester. Its distinct chemical structure may help minimize the danger of cross-sensitivity reactions in patients allergic to other local anesthetics. Pramoxine produces satisfactory surface anesthesia and is reasonably well tolerated on the skin and mucous membranes. It is too irritating to be used on the eye or in the nose, but an otic solution containing chloroxylenol is marketed. Various preparations including creams, lotions, sprays, gel, wipes, and foams, usually containing 1% pramoxine, are available for topical application.

Anesthetics of Low Solubility

Some local anesthetics are poorly soluble in water, and consequently are too slowly absorbed to be toxic. They can be applied directly to wounds and ulcerated surfaces, where they remain localized for long periods of time, producing a sustained anesthetic action. Chemically, they are esters of para-aminobenzoic acid lacking the terminal amino group possessed by the previously described local anesthetics. The most important member of the series is benzocaine (ethyl aminobenzoate; HURRICAIN, others). Benzocaine is structurally similar to procaine, but lacks the terminal diethylamino group (Figure 20–1). It is incorporated into a large number of topical preparations. Benzocaine can cause methemoglobinemia (see the discussion of methemoglobinemia in the “Prilocaine” section); consequently, dosing recommendations must be followed carefully.

Local Anesthetics Largely Restricted to Ophthalmological Use

Anesthesia of the cornea and conjunctiva can be obtained readily by topical application of local anesthetics. However, most of the local anesthetics that have been described are too irritating for ophthalmological use. The first local anesthetic used in ophthalmology, cocaine, has the severe disadvantages of producing mydriasis and corneal sloughing and has fallen out of favor. The two compounds used most frequently today are proparacaine (ALCAINE, OPHTHAINE, others) and tetracaine (Figure 20–1). In addition to being less irritating during administration, proparacaine has the added advantage of bearing little antigenic similarity to the other benzoate local anesthetics. Thus, it sometimes can be used in individuals sensitive to the amino ester local anesthetics.

For use in ophthalmology, these local anesthetics are instilled a single drop at a time. If anesthesia is incomplete, successive drops are applied until satisfactory conditions are obtained. The duration of anesthesia is determined chiefly by the vascularity of the tissue; thus it is longest in normal cornea and shortest in inflamed conjunctiva. In the latter case repeated instillations may be necessary to maintain adequate anesthesia for the duration of the procedure. Long-term administration of topical anesthesia to the eye has been associated with retarded healing, pitting, and sloughing of the corneal epithelium, and predisposition of the eye to inadvertent injury. Thus, these drugs should not be prescribed for self-administration. For drug delivery, pharmacokinetics, and toxicity issues unique to drugs for ophthalmic use, see Chapter 64.

BIOLOGICAL TOXINS: TETRODOTOXIN AND SAXITOXIN

These two biological toxins also block the pore of the Na⁺ channel. Tetrodotoxin is found in the gonads and other visceral tissues of some fish of the order Tetraodontiformes (to which the Japanese *fugu*, or puffer fish, belongs); it also occurs in the skin of some newts of the family Salamandridae and of the Costa Rican frog *Atelopus*. Saxitoxin is elaborated by the dinoflagellates *Gonyaulax catenella* and *G. tamarensis* and retained in the tissues of clams and other shellfish that eat these organisms. Given the right conditions of temperature and light, the *Gonyaulax* may multiply so rapidly as to discolor the ocean, causing the condition known as *red tide*. Shellfish feeding on *Gonyaulax* at this time become extremely toxic to humans and are responsible for periodic outbreaks of paralytic shellfish poisoning (Stommel and Watters, 2004). Although the toxins are chemically different from each other, their mechanisms of action are similar (Ritchie, 1980). Both toxins, in nanomolar concentrations, specifically block the outer mouth of the pore of Na⁺ channels in the membranes of excitable cells. As a result, the action potential is blocked. The receptor site for these toxins is formed by amino acid residues in the P loop of the Na⁺ channel α subunit (Figure 20-2) in all four domains (Catterall, 2000; Terlau et al., 1991). Not all Na⁺ channels are equally sensitive to tetrodotoxin; some Na⁺ channels in cardiac myocytes and dorsal root ganglion neurons are resistant, and a tetrodotoxin-resistant Na⁺ channel is expressed when skeletal muscle is denervated. Tetrodotoxin and saxitoxin are two of the most potent poisons known; the minimal lethal dose of each in the mouse is ~ 8 μ g/kg. Both toxins have caused fatal poisoning in humans due to paralysis of the respiratory muscles; therefore the treatment of severe cases of poisoning requires support of respiration. Blockade of vasomotor nerves, together with a relaxation of vascular smooth muscle, seems to be responsible for the hypotension that is characteristic of tetrodotoxin poisoning. Early gastric lavage and pressor support also are indicated. If the patient survives paralytic shellfish poisoning for 24 hours, the prognosis is good.

CLINICAL USES OF LOCAL ANESTHETICS

Local anesthesia is the loss of sensation in a body part without the loss of consciousness or the impairment of central control of vital functions. It offers two major advantages. First, physiological perturbations associated with general anesthesia are avoided; second, neurophysiological responses to pain and stress can be modified beneficially. As already discussed, local anesthetics can potentially produce deleterious side effects. Proper choice of a local anesthetic and care in its use are the primary determinants in avoiding toxicity. There is a poor relationship between the amount of local anesthetic injected and peak plasma levels in adults. Furthermore, peak plasma levels vary widely depending on the area of injection. They are highest with interpleural or intercostal blocks and lowest with subcutaneous

infiltration. Thus, recommended maximum doses serve only as general guidelines.

This discussion summarizes the pharmacological and physiological consequences of the use of local anesthetics categorized by method of administration. A more comprehensive discussion of their use and administration is presented in textbooks on regional anesthesia (e.g., Cousins et al., 2008).

Topical Anesthesia

Anesthesia of mucous membranes of the nose, mouth, throat, tracheobronchial tree, esophagus, and genitourinary tract can be produced by direct application of aqueous solutions of salts of many local anesthetics or by suspension of the poorly soluble local anesthetics. Tetracaine (2%), lidocaine (2-10%), and cocaine (1-4%) typically are used. Cocaine is used only in the nose, nasopharynx, mouth, throat, and ear, where it uniquely produces vasoconstriction as well as anesthesia. The shrinking of mucous membranes decreases operative bleeding while improving surgical visualization. Comparable vasoconstriction can be achieved with other local anesthetics by the addition of a low concentration of a vasoconstrictor such as phenylephrine (0.005%). Epinephrine, topically applied, has no significant local effect and does not prolong the duration of action of local anesthetics applied to mucous membranes because of poor penetration. *Maximal* safe total dosages for topical anesthesia in a healthy 70-kg adult are 300 mg for lidocaine, 150 mg for cocaine, and 50 mg for tetracaine.

Peak anesthetic effect following topical application of cocaine or lidocaine occurs within 2-5 minutes (3-8 minutes with tetracaine), and anesthesia lasts for 30-45 minutes (30-60 minutes with tetracaine). Anesthesia is entirely superficial; it does not extend to submucosal structures. This technique does not alleviate joint pain or discomfort from subdermal inflammation or injury.

Local anesthetics are absorbed rapidly into the circulation following topical application to mucous membranes or denuded skin. Thus, topical anesthesia always carries the risk of systemic toxic reactions. Systemic toxicity has occurred even following the use of local anesthetics to control discomfort associated with severe diaper rash in infants. Absorption is particularly rapid when local anesthetics are applied to the tracheobronchial tree. Concentrations in blood after instillation of local anesthetics into the airway are nearly the same as those following intravenous injection. Surface anesthetics for the skin and cornea have been described earlier in the chapter.

Use of eutectic mixtures of local anesthetics lidocaine (2.5%)/prilocaine (2.5%) (EMLA) and lidocaine (7%)/tetracaine (7%) (PLIAGIS) bridges the gap between topical and infiltration anesthesia. The efficacy of each of these combinations lies in the fact that the mixture has a melting point less than that of either compound alone, existing at room temperature as an oil that can penetrate intact skin. These creams produce anesthesia to a maximum depth of 5 mm and are applied as a cream on intact skin under an occlusive dressing in advance (~30-60 min) of any procedure. These mixtures are effective for procedures involving skin and superficial subcutaneous structures (e.g., venipuncture and skin graft harvesting). The component local anesthetics will be absorbed into the systemic circulation, potentially producing toxic effects, as described earlier. Guidelines are available to calculate the maximum

amount of cream that can be applied and area of skin covered. These mixtures must not be used on mucous membranes or abraded skin, as rapid absorption across these surfaces may result in systemic toxicity.

Infiltration Anesthesia

Infiltration anesthesia is the injection of local anesthetic directly into tissue without taking into consideration the course of cutaneous nerves. Infiltration anesthesia can be so superficial as to include only the skin. It also can include deeper structures, including intra-abdominal organs, when these too are infiltrated.

The duration of infiltration anesthesia can be approximately doubled by the addition of epinephrine (5 $\mu\text{g}/\text{mL}$) to the injection solution; epinephrine also decreases peak concentrations of local anesthetics in blood. *Epinephrine-containing solutions should not, however, be injected into tissues supplied by end arteries—for example, fingers and toes, ears, the nose, and the penis. The resulting vasoconstriction may cause gangrene.* For the same reason, epinephrine should be avoided in solutions injected intracutaneously. Since epinephrine also is absorbed into the circulation, its use should be avoided in those for whom adrenergic stimulation is undesirable.

The local anesthetics used most frequently for infiltration anesthesia are lidocaine (0.5-1%), procaine (0.5-1%), and bupivacaine (0.125-0.25%). When used without epinephrine, up to 4.5 mg/kg of lidocaine, 7 mg/kg of procaine, or 2 mg/kg of bupivacaine can be employed in adults. When epinephrine is added, these amounts can be increased by one-third.

The advantage of infiltration anesthesia and other regional anesthetic techniques is that it can provide satisfactory anesthesia without disrupting normal bodily functions. The chief disadvantage of infiltration anesthesia is that relatively large amounts of drug must be used to anesthetize relatively small areas. This is no problem with minor surgery. When major surgery is performed, however, the amount of local anesthetic that is required makes systemic toxic reactions likely. The amount of anesthetic required to anesthetize an area can be reduced significantly and the duration of anesthesia increased markedly by specifically blocking the nerves that innervate the area of interest. This can be done at one of several levels: subcutaneously, at major nerves, or at the level of the spinal roots.

Field Block Anesthesia

Field block anesthesia is produced by subcutaneous injection of a solution of local anesthetic in order to anesthetize the region distal to the injection. For example, subcutaneous infiltration of the proximal portion of the volar surface of the forearm results in an extensive area of cutaneous anesthesia that starts 2-3 cm distal to the site of injection. The same principle can be applied with particular benefit to the scalp, the anterior abdominal wall, and the lower extremity.

The drugs, concentrations, and doses recommended are the same as for infiltration anesthesia. The advantage of field block anesthesia is that less drug can be used to provide a greater area of anesthesia than when infiltration anesthesia is used. Knowledge of the relevant neuroanatomy obviously is essential for successful field block anesthesia.

Nerve Block Anesthesia

Injection of a solution of a local anesthetic into or about individual peripheral nerves or nerve plexuses produces even greater areas of

anesthesia than do the techniques already described. Blockade of mixed peripheral nerves and nerve plexuses also usually anesthetizes somatic motor nerves, producing skeletal muscle relaxation, which is essential for some surgical procedures. The areas of sensory and motor block usually start several centimeters distal to the site of injection. Brachial plexus blocks are particularly useful for procedures on the upper extremity and shoulder. Intercostal nerve blocks are effective for anesthesia and relaxation of the anterior abdominal wall. Cervical plexus block is appropriate for surgery of the neck. Sciatic and femoral nerve blocks are useful for surgery distal to the knee. Other useful nerve blocks prior to surgical procedures include blocks of individual nerves at the wrist and at the ankle, blocks of individual nerves such as the median or ulnar at the elbow, and blocks of sensory cranial nerves.

There are four major determinants of the onset of sensory anesthesia following injection near a nerve:

- proximity of the injection to the nerve
- concentration and volume of drug
- degree of ionization of the drug
- time

Local anesthetic is never intentionally injected into the nerve, as this would be painful and could cause nerve damage. Instead, the anesthetic agent is deposited as close to the nerve as possible. Thus the local anesthetic must diffuse from the site of injection into the nerve, where it acts. The rate of diffusion is determined chiefly by the concentration of the drug, its degree of ionization (ionized local anesthetic diffuses more slowly), its hydrophobicity, and the physical characteristics of the tissue surrounding the nerve. Higher concentrations of local anesthetic will provide a more rapid onset of peripheral nerve block. The utility of higher concentrations, however, is limited by systemic toxicity and by direct neural toxicity of concentrated local anesthetic solutions. For a given concentration, local anesthetics with lower $\text{p}K_a$ values tend to have a more rapid onset of action because more drug is uncharged at neutral pH. For example, the onset of action of lidocaine occurs in ~3 minutes; 35% of lidocaine is in the basic form at pH 7.4. In contrast, the onset of action of bupivacaine requires ~15 minutes; only 5-10% of bupivacaine is uncharged at this pH. Increased hydrophobicity might be expected to speed onset by increased penetration into nerve tissue. However, it also will increase binding in tissue lipids. Furthermore, the more hydrophobic local anesthetics also are more potent (and toxic) and thus must be used at lower concentrations, decreasing the concentration gradient for diffusion. Tissue factors also play a role in determining the rate of onset of anesthetic effects. The amount of connective tissue that must be penetrated can be significant in a nerve plexus compared to isolated nerves and can slow or even prevent adequate diffusion of local anesthetic to the nerve fibers.

Duration of nerve block anesthesia depends on the physical characteristics of the local anesthetic used and the presence or absence of vasoconstrictors. Especially important physical characteristics are lipid solubility and protein binding. Local anesthetics can be broadly divided into three categories:

- those with a short (20-45 minutes) duration of action in mixed peripheral nerves, such as procaine
- those with an intermediate (60-120 minutes) duration of action, such as lidocaine and mepivacaine

- those with a long (400-450 minutes) duration of action, such as bupivacaine, ropivacaine, and tetracaine

Block duration of the intermediate-acting local anesthetics such as lidocaine can be prolonged by the addition of epinephrine (5 $\mu\text{g}/\text{mL}$). The degree of block prolongation in peripheral nerves following the addition of epinephrine appears to be related to the intrinsic vasodilatory properties of the local anesthetic and thus is most pronounced with lidocaine.

The types of nerve fibers that are blocked when a local anesthetic is injected about a mixed peripheral nerve depend on the concentration of drug used, nerve-fiber size, internodal distance, and frequency and pattern of nerve-impulse transmission (see above, sections on *Frequency and Voltage-Dependence* and *Differential Sensitivity*). Anatomical factors are similarly important. A mixed peripheral nerve or nerve trunk consists of individual nerves surrounded by an investing epineurium. The vascular supply usually is centrally located. When a local anesthetic is deposited about a peripheral nerve, it diffuses from the outer surface toward the core along a concentration gradient (DeJong, 1994; Winnie et al., 1977). Consequently, nerves in the outer mantle of the mixed nerve are blocked first. These fibers usually are distributed to more proximal anatomical structures than are those situated near the core of the mixed nerve and often are motor. If the volume and concentration of local anesthetic solution deposited about the nerve are adequate, the local anesthetic eventually will diffuse inward in amounts adequate to block even the most centrally located fibers. Lesser amounts of drug will block only nerves in the mantle and the smaller and more sensitive central fibers. Furthermore, since removal of local anesthetics occurs primarily in the core of a mixed nerve or nerve trunk, where the vascular supply is located, the duration of blockade of centrally located nerves is shorter than that of more peripherally situated fibers.

The choice of local anesthetic and the amount and concentration administered are determined by the nerves and the types of fibers to be blocked, the required duration of anesthesia, and the size and health of the patient. For blocks of 2-4 hours, lidocaine (1-1.5%) can be used in the amounts recommended earlier (see “Infiltration Anesthesia”). Mepivacaine (up to 7 mg/kg of a 1-2% solution) provides anesthesia that lasts about as long as that from lidocaine. Bupivacaine (2-3 mg/kg of a 0.25-0.375% solution) can be used when a longer duration of action is required. Addition of 5 $\mu\text{g}/\text{mL}$ epinephrine slows systemic absorption and therefore prolongs duration and lowers the plasma concentration of the intermediate-acting local anesthetics.

Peak plasma concentrations of local anesthetics depend on the amount injected, the physical characteristics of the local anesthetic, whether epinephrine is used, the rate of blood flow to the site of injection, and the surface area exposed to local anesthetic. This is of particular importance in the safe application of nerve block anesthesia, since the potential for systemic reactions is related to peak free serum concentrations. For example, peak concentrations of lidocaine in blood following injection of 400 mg without epinephrine for intercostal nerve blocks average 7 $\mu\text{g}/\text{mL}$; the same amount of lidocaine used for block of the brachial plexus results in peak concentrations in blood of ~ 3 $\mu\text{g}/\text{mL}$ (Covino and Vassallo, 1976). Therefore, the amount of local anesthetic that can be injected must be adjusted according to the anatomical site of the nerve(s) to be blocked to minimize untoward effects. Addition of epinephrine can

decrease peak plasma concentrations by 20-30%. Multiple nerve blocks (e.g., intercostal block) or blocks performed in vascular regions require reduction in the amount of anesthetic that can be given safely, because the surface area for absorption or the rate of absorption is increased.

Intravenous Regional Anesthesia (Bier's Block)

This technique relies on using the vasculature to bring the local anesthetic solution to the nerve trunks and endings. In this technique, an extremity is exsanguinated with an Esmarch (elastic) bandage, and a proximally located tourniquet is inflated to 100-150 mm Hg above the systolic blood pressure. The Esmarch bandage is removed, and the local anesthetic is injected into a previously cannulated vein. Typically, complete anesthesia of the limb ensues within 5-10 minutes. Pain from the tourniquet and the potential for ischemic nerve injury limits tourniquet inflation to 2 hours or less. However, the tourniquet should remain inflated for at least 15-30 minutes to prevent toxic amounts of local anesthetic from entering the circulation following deflation. Lidocaine, 40-50 mL (0.5 mL/kg in children) of a 0.5% solution without epinephrine is the drug of choice for this technique. For intravenous regional anesthesia in adults using a 0.5% solution without epinephrine, the dose administered should not exceed 4 mg/kg. A few clinicians prefer prilocaine (0.5%) over lidocaine because of its higher therapeutic index. The attractiveness of this technique lies in its simplicity. Its primary disadvantages are that it can be used only for a few anatomical regions, sensation (pain) returns quickly after tourniquet deflation, and premature release or failure of the tourniquet can produce toxic levels of local anesthetic (e.g., 50 mL of 0.5% lidocaine contains 250 mg of lidocaine). For the last reason and because its longer durations of action offer no advantage, the more cardiotoxic local anesthetic, bupivacaine, is not recommended for this technique. Intravenous regional anesthesia is used most often for surgery of the forearm and hand, but can be adapted for the foot and distal leg.

Spinal Anesthesia

Spinal anesthesia follows the injection of local anesthetic into the cerebrospinal fluid (CSF) in the lumbar space. For a number of reasons, including the ability to produce anesthesia of a considerable fraction of the body with a dose of local anesthetic that produces negligible plasma levels, spinal anesthesia remains one of the most popular forms of anesthesia. In most adults, the spinal cord terminates above the second lumbar vertebra; between that point and the termination of the thecal sac in the sacrum, the lumbar and sacral roots are bathed in CSF. Thus, in this region there is a relatively large volume of CSF within which to inject drug, thereby minimizing the potential for direct nerve trauma.

A brief discussion of the physiological effects of spinal anesthesia relating to the pharmacology of the local anesthetics used is presented here. See more specialized texts (e.g., Cousins et al., 2008) for additional details.

Physiological Effects of Spinal Anesthesia. Most of the physiological side effects of spinal anesthesia are a consequence of the sympathetic blockade produced by local anesthetic block of the sympathetic fibers in the spinal nerve roots. A thorough understanding of these physiological effects is necessary for the safe and

successful application of spinal anesthesia. Although some of them may be deleterious and require treatment, others can be beneficial for the patient or can improve operating conditions. Most sympathetic fibers leave the spinal cord between T1 and L2 (Chapter 8, Figure 8–1). Although local anesthetic is injected below these levels in the lumbar portion of the dural sac, cephalad spread of the local anesthetic occurs with all but the smallest volumes injected. This cephalad spread is of considerable importance in the practice of spinal anesthesia and potentially is under the control of numerous variables, of which patient position and baricity (density of the drug relative to the density of the CSF) are the most important (Greene, 1983). The degree of sympathetic block is related to the height of sensory anesthesia; often the level of sympathetic blockade is several spinal segments higher, since the preganglionic sympathetic fibers are more sensitive to low concentrations of local anesthetic. The effects of sympathetic blockade involve both the actions (now partially unopposed) of the parasympathetic nervous system and the response of the unblocked portion of the sympathetic nervous system. Thus, as the level of sympathetic block ascends, the actions of the parasympathetic nervous system are increasingly dominant, and the compensatory mechanisms of the unblocked sympathetic nervous system are diminished. As most sympathetic nerve fibers leave the cord at T1 or below, few additional effects of sympathetic blockade are seen with cervical levels of spinal anesthesia. The consequences of sympathetic blockade will vary among patients as a function of age, physical conditioning, and disease state. Interestingly, sympathetic blockade during spinal anesthesia appears to be minimal in healthy children.

Clinically, the most important effects of sympathetic blockade during spinal anesthesia are on the cardiovascular system. At all but the lowest levels of spinal blockade, some vasodilation will occur. Vasodilation is more marked on the venous than on the arterial side of the circulation, resulting in blood pooling in the venous capacitance vessels. This reduction in circulating blood volume is well tolerated at low levels of spinal anesthesia in healthy patients. With an increasing level of block, this effect becomes more marked and venous return becomes gravity-dependent. If venous return decreases too much, cardiac output and organ perfusion decline precipitously. Venous return can be increased by a modest (10–15 degree) head-down tilt or by elevating the legs. At high levels of spinal blockade, the cardiac accelerator fibers, which exit the spinal cord at T1–T4, will be blocked. This is detrimental in patients dependent on elevated sympathetic tone to maintain cardiac output (e.g., during congestive heart failure or hypovolemia), and it also removes one of the compensatory mechanisms available to maintain organ perfusion during vasodilation. Thus, as the level of spinal block ascends, the rate of cardiovascular compromise can accelerate if not carefully observed and treated. Sudden asystole also can occur, presumably because of loss of sympathetic innervation in the continued presence of parasympathetic activity at the sinoatrial node (Caplan et al., 1988). In the usual clinical situation, blood pressure serves as a surrogate marker for cardiac output and organ perfusion. Treatment of hypotension usually is warranted when the blood pressure decreases to ~30% of resting values. Therapy is aimed at maintaining brain and cardiac perfusion and oxygenation. To achieve these goals, administration of oxygen, fluid infusion, manipulation of patient position, and the administration of vasoactive drugs are all options. In practice,

patients typically are administered a bolus (500–1000 mL) of fluid prior to the administration of spinal anesthesia in an attempt to prevent some of the deleterious effects of spinal blockade. Since the usual cause of hypotension is decreased venous return, possibly complicated by decreased heart rate, drugs with preferential vasoconstrictive and chronotropic properties are preferred. For this reason, ephedrine, 5–10 mg intravenously, often is the drug of choice. In addition to the use of ephedrine to treat deleterious effects of sympathetic blockade, direct-acting α_1 adrenergic receptor agonists such as phenylephrine (Chapter 12) can be administered either by bolus or continuous infusion.

A beneficial effect of spinal anesthesia partially mediated by the sympathetic nervous system is on the intestine. Sympathetic fibers originating from T5–L1 inhibit peristalsis; thus, their blockade produces a small, contracted intestine. This, together with a flaccid abdominal musculature, produces excellent operating conditions for some types of bowel surgery. The effects of spinal anesthesia on the respiratory system mostly are mediated by effects on the skeletal musculature. Paralysis of the intercostal muscles will reduce a patient's ability to cough and clear secretions, which may produce dyspnea in patients with bronchitis or emphysema. Respiratory arrest during spinal anesthesia is seldom due to paralysis of the phrenic nerves or to toxic levels of local anesthetic in the CSF of the fourth ventricle; it is much more likely to be due to medullary ischemia secondary to hypotension.

Pharmacology of Spinal Anesthesia. Currently in the U.S., the drugs most commonly used in spinal anesthesia are lidocaine, tetracaine, and bupivacaine. Procaine occasionally is used for diagnostic blocks when a short duration of action is desired. The choice of local anesthetic is primarily determined by the desired duration of anesthesia. General guidelines are to use lidocaine for short procedures, bupivacaine for intermediate to long procedures, and tetracaine for long procedures. As mentioned earlier, the factors contributing to the distribution of local anesthetics in the CSF have received much attention because of their importance in determining the height of block. The most important pharmacological factors include the amount, and possibly the volume, of drug injected and its baricity. The speed of injection of the local anesthesia solution also may affect the height of the block, just as the position of the patient can influence the rate of distribution of the anesthetic agent and the height of blockade achieved (described in the next section). For a given preparation of local anesthetic, administration of increasing amounts leads to a fairly predictable increase in the level of block attained. For example, 100 mg of lidocaine, 20 mg of bupivacaine, or 12 mg of tetracaine usually will result in a T4 sensory block. More complete tables of these relationships can be found in standard anesthesiology texts. Epinephrine often is added to spinal anesthetics to increase the duration or intensity of block. Epinephrine's effect on duration of block is dependent on the technique used to measure duration. A commonly used measure of block duration is the length of time it takes for the block to recede by two dermatomes from the maximum height of the block, while a second is the duration of block at some specified level, typically L1. In most studies, addition of 200 μg of epinephrine to tetracaine solutions prolongs the duration of block by both measures. However, addition of epinephrine to lidocaine or bupivacaine does not affect the first measure of duration, but does prolong the block at lower

levels. In different clinical situations, one or the other measure of anesthesia duration may be more relevant, and this must be kept in mind when deciding whether to add epinephrine to spinal local anesthetics. The mechanism of action of vasoconstrictors in prolonging spinal anesthesia is uncertain. It has been hypothesized that these agents decrease spinal cord blood flow, decreasing clearance of local anesthetic from the CSF, but this has not been convincingly demonstrated. Epinephrine and other α -adrenergic agonists have been shown to decrease nociceptive transmission in the spinal cord, and studies in genetically modified mice suggest that α_{2A} adrenergic receptors play a principal role in this response (Stone et al., 1997). Such actions may contribute to the beneficial effects of epinephrine, clonidine, and dexmedetomidine when these agents are added to spinal local anesthetics.

Drug Baricity and Patient Position. The baricity of the local anesthetic injected will determine the direction of migration within the dural sac. Hyperbaric solutions will tend to settle in the dependent portions of the sac, while hypobaric solutions will tend to migrate in the opposite direction. Isobaric solutions usually will stay in the vicinity where they were injected, diffusing slowly in all directions. Consideration of the patient position during and after the performance of the block and the choice of a local anesthetic of the appropriate baricity is crucial for a successful block during some surgical procedures. Lidocaine and bupivacaine are marketed in both isobaric and hyperbaric preparations, and if desired, can be diluted with sterile, preservative-free water to make them hypobaric.

Complications of Spinal Anesthesia. Persistent neurological deficits following spinal anesthesia are extremely rare. Thorough evaluation of a suspected deficit should be performed in collaboration with a neurologist. Neurological sequelae can be both immediate and late. Possible causes include introduction of foreign substances (such as disinfectants or talc) into the subarachnoid space, infection, hematoma, or direct mechanical trauma. Aside from drainage of an abscess or hematoma, treatment usually is ineffective; thus, avoidance and careful attention to detail while performing spinal anesthesia are necessary.

High concentrations of local anesthetic can cause irreversible block. After administration, local anesthetic solutions are diluted rapidly, quickly reaching nontoxic concentrations. However, there are several reports of transient or longer-lasting neurological deficits following lidocaine spinal anesthesia, particularly with 5% lidocaine (i.e., 180 mmol) in 7.5% glucose (Zaric and Pace, 2009). Spinal anesthesia sometimes is regarded as contraindicated in patients with pre-existing disease of the spinal cord. No experimental evidence exists to support this hypothesis. Nonetheless, it is prudent to avoid spinal anesthesia in patients with progressive diseases of the spinal cord. However, spinal anesthesia may be very useful in patients with fixed, chronic spinal cord injury.

A more common sequela following any lumbar puncture, including spinal anesthesia, is a postural headache with classic features. The incidence of headache decreases with increasing age of the patient and decreasing needle diameter. Headache following lumbar puncture must be thoroughly evaluated to exclude serious complications such as meningitis. Treatment usually is conservative, with bed rest and analgesics. If this approach fails, an epidural blood patch with the injection of autologous blood can be performed; this

procedure usually is successful in alleviating postdural puncture headaches, although a second blood patch may be necessary. If two epidural blood patches are ineffective in relieving the headache, the diagnosis of postdural puncture headache should be reconsidered. Intravenous caffeine (500 mg as the benzoate salt administered over 4 hours) also has been advocated for the treatment of postdural puncture headache; however, the efficacy of caffeine is less than that of a blood patch, and relief usually is transient.

Evaluation of Spinal Anesthesia. Spinal anesthesia is a safe and effective technique, especially during surgery involving the lower abdomen, the lower extremities, and the perineum. It often is combined with intravenous medication to provide sedation and amnesia. The physiological perturbations associated with low spinal anesthesia often have less potential harm than those associated with general anesthesia. The same does not apply for high spinal anesthesia. The sympathetic blockade that accompanies levels of spinal anesthesia adequate for mid- or upper-abdominal surgery, coupled with the difficulty in achieving visceral analgesia, is such that equally satisfactory and safer operating conditions can be realized by combining the spinal anesthetic with a “light” general anesthetic or by the administration of a general anesthetic and a neuromuscular blocking agent.

Epidural Anesthesia

Epidural anesthesia is administered by injecting local anesthetic into the epidural space—the space bounded by the ligamentum flavum posteriorly, the spinal periosteum laterally, and the dura anteriorly. Epidural anesthesia can be performed in the sacral hiatus (caudal anesthesia) or in the lumbar, thoracic, or cervical regions of the spine. Its current popularity arises from the development of catheters that can be placed into the epidural space, allowing either continuous infusions or repeated bolus administration of local anesthetics. The primary site of action of epidurally administered local anesthetics is on the spinal nerve roots. However, epidurally administered local anesthetics also may act on the spinal cord and on the paravertebral nerves.

The selection of drugs available for epidural anesthesia is similar to that for major nerve blocks. As for spinal anesthesia, the choice of drugs to be used during epidural anesthesia is dictated primarily by the duration of anesthesia desired. However, when an epidural catheter is placed, short-acting drugs can be administered repeatedly, providing more control over the duration of block. Bupivacaine, 0.5-0.75%, is used when a long duration of surgical block is desired. Due to enhanced cardiotoxicity in pregnant patients, the 0.75% solution is not approved for obstetrical use. Lower concentrations—0.25%, 0.125%, or 0.0625%—of bupivacaine, often with 2 μ g/mL of fentanyl added, frequently are used to provide analgesia during labor. They also are useful preparations for providing postoperative analgesia in certain clinical situations. Lidocaine 2% is the most frequently used intermediate-acting epidural local anesthetic. Chloroprocaine, 2% or 3%, provides rapid onset and a very short duration of anesthetic action. However, its use in epidural anesthesia has been clouded by controversy regarding its potential ability to cause neurological complications if the drug is accidentally injected into the subarachnoid space (discussed earlier). The duration of action of epidurally administered local anesthetics frequently is prolonged, and systemic toxicity decreased, by addition of epinephrine. Addition of epinephrine also makes inadvertent

intravascular injection easier to detect and modifies the effect of sympathetic blockade during epidural anesthesia.

For each anesthetic agent, a relationship exists between the volume of local anesthetic injected epidurally and the segmental level of anesthesia achieved. For example, in 20- to 40-year-old, healthy, nonpregnant patients, each 1-1.5 mL of 2% lidocaine will give an additional segment of anesthesia. The amount needed decreases with increasing age and also decreases during pregnancy and in children.

The concentration of local anesthetic used determines the type of nerve fibers blocked. The highest concentrations are used when sympathetic, somatic sensory, and somatic motor blockade are required. Intermediate concentrations allow somatic sensory anesthesia without muscle relaxation. Low concentrations will block only preganglionic sympathetic fibers. As an example, with bupivacaine these effects might be achieved with concentrations of 0.5%, 0.25%, and 0.0625%, respectively. The total amounts of drug that can be injected with safety at one time are approximately those mentioned earlier in the chapter under "Nerve Block Anesthesia" and "Infiltration Anesthesia." Performance of epidural anesthesia requires a greater degree of skill than does spinal anesthesia. The technique of epidural anesthesia and the volumes, concentrations, and types of drugs used are described in detail in standard texts on regional anesthesia (e.g., Cousins et al., 2008).

A significant difference between epidural and spinal anesthesia is that the dose of local anesthetic used can produce high concentrations in blood following absorption from the epidural space. Peak concentrations of lidocaine in blood following injection of 400 mg (without epinephrine) into the lumbar epidural space average 3-4 $\mu\text{g/mL}$; peak concentrations of bupivacaine in blood average 1 $\mu\text{g/mL}$ after the lumbar epidural injection of 150 mg. Addition of epinephrine (5 $\mu\text{g/mL}$) decreases peak plasma concentrations by ~25%. Peak blood concentrations are a function of the total dose of drug administered rather than the concentration or volume of solution following epidural injection (Covino and Vassallo, 1976). The risk of inadvertent intravascular injection is increased in epidural anesthesia, as the epidural space contains a rich venous plexus.

Another major difference between epidural and spinal anesthesia is that there is no zone of differential sympathetic blockade with epidural anesthesia; thus, the level of sympathetic block is close to the level of sensory block. Because epidural anesthesia does not result in the zones of differential sympathetic blockade observed during spinal anesthesia, cardiovascular responses to epidural anesthesia might be expected to be less prominent. In practice this is not the case; the potential advantage of epidural anesthesia is offset by the cardiovascular responses to the high concentration of anesthetic in blood that occurs during epidural anesthesia. This is most apparent when, as is often the case, epinephrine is added to the epidural injection. The resulting concentration of epinephrine in blood is sufficient to produce significant β_2 adrenergic receptor-mediated vasodilation. As a consequence, blood pressure decreases, even though cardiac output increases due to the positive inotropic and chronotropic effects of epinephrine (Chapter 12). The result is peripheral hyperperfusion and hypotension. Differences in cardiovascular responses to equal levels of spinal and epidural anesthesia also are observed when a local anesthetic such as

lidocaine is used without epinephrine. This may be a consequence of the direct effects of high concentrations of lidocaine on vascular smooth muscle and the heart. The magnitude of the differences in responses to equal sensory levels of spinal and epidural anesthesia varies, however, with the local anesthetic used for the epidural injection (assuming no epinephrine is used). For example, local anesthetics such as bupivacaine, which are highly lipid soluble, are distributed less into the circulation than are less lipid-soluble agents such as lidocaine.

High concentrations of local anesthetics in blood during epidural anesthesia are especially important when this technique is used to control pain during labor and delivery. Local anesthetics cross the placenta, enter the fetal circulation, and at high concentrations may cause depression of the neonate. The extent to which they do so is determined by dosage, acid-base status, the level of protein binding in both maternal and fetal blood, placental blood flow, and solubility of the agent in fetal tissue. These concerns have been lessened by the trend toward using more dilute solutions of bupivacaine for labor analgesia.

Epidural and Intrathecal Opiate Analgesia. Small quantities of opioid injected intrathecally or epidurally produce segmental analgesia (Yaksh and Rudy, 1976). This observation led to the clinical use of spinal and epidural opioids during surgical procedures and for the relief of postoperative and chronic pain (Cousins and Mather, 1984). As with local anesthesia, analgesia is confined to sensory nerves that enter the spinal cord dorsal horn in the vicinity of the injection. Presynaptic opioid receptors inhibit the release of substance P and other neurotransmitters from primary afferents, while postsynaptic opioid receptors decrease the activity of certain dorsal horn neurons in the spinothalamic tracts (Willcockson et al., 1986; see also Chapters 8 and 18). Since conduction in autonomic, sensory, and motor nerves is not affected by the opioids, blood pressure, motor function, and non-nociceptive sensory perception typically are not influenced by spinal opioids. The volume-evoked micturition reflex is inhibited, as manifested by urinary retention. Other side effects include pruritus, nausea, and vomiting in susceptible individuals. Delayed respiratory depression and sedation, presumably from cephalad spread of opioid within the CSF, occur infrequently with the doses of opioids currently used.

Spinally administered opioids by themselves do not provide satisfactory anesthesia for surgical procedures. Thus, opioids have found the greatest use in the treatment of postoperative and chronic pain. In selected patients, spinal or epidural opioids can provide excellent analgesia following thoracic, abdominal, pelvic, or lower extremity surgery without the side effects associated with high doses of systemically administered opioids. For post-operative analgesia, spinally administered morphine, 0.2-0.5 mg, usually will provide 8-16 hours of analgesia. Placement of an epidural catheter and repeated boluses or an infusion of opioid permits an increased duration of analgesia. Many opioids have been used epidurally. Morphine, 2-6 mg, every 6 hours, commonly is used for bolus injections, while fentanyl, 20-50 $\mu\text{g/hour}$, often combined with bupivacaine, 5-20 mg/hour, is used for infusions. For cancer pain, repeated doses of epidural opioids can provide analgesia of several months' duration. The dose of epidural morphine, e.g., is far less than the

dose of systemically administered morphine that would be required to provide similar analgesia. This reduces the complications that usually accompany the administration of high doses of systemic opioids, particularly sedation and constipation. Unfortunately, as with systemic opioids, tolerance will develop to the analgesic effects of epidural opioids, but this usually can be managed by increasing the dose.

Pharmacotherapy of the Epilepsies

James O. McNamara

The epilepsies are common and frequently devastating disorders, affecting ~2.5 million people in the U.S. alone. More than 40 distinct forms of epilepsy have been identified. Epileptic seizures often cause transient impairment of consciousness, leaving the individual at risk of bodily harm and often interfering with education and employment. Therapy is symptomatic in that available drugs inhibit seizures, but neither effective prophylaxis nor cure is available. Compliance with medication is a major problem because of the need for long-term therapy together with unwanted effects of many drugs.

The mechanisms of action of anti-seizure drugs fall into three major categories.

1. The first mechanism is to limit the sustained, repetitive firing of neurons, an effect mediated by promoting the inactivated state of voltage-activated Na^+ channels.
2. A second mechanism appears to involve enhanced γ -aminobutyric acid (GABA)-mediated synaptic inhibition, an effect mediated either by a presynaptic or postsynaptic action. Drugs effective against the most common forms of epileptic seizures, partial and secondarily generalized tonic-clonic seizures, appear to work by one of these two mechanisms.
3. Drugs effective against absence seizure, a less common form of epileptic seizure, work by a third mechanism, inhibition of voltage-activated Ca^{2+} channels responsible for T-type Ca^{2+} currents.

Although many treatments are available, much effort is being devoted to elucidating the genetic causes and the cellular and molecular mechanisms by which a normal brain becomes epileptic, insights that promise to provide molecular targets for both symptomatic and preventive therapies.

TERMINOLOGY AND EPILEPTIC SEIZURE CLASSIFICATION

The term *seizure* refers to a transient alteration of behavior due to the disordered, synchronous, and rhythmic firing of populations of brain neurons. The term *epilepsy* refers to a disorder of brain function characterized by the periodic and unpredictable occurrence of seizures. Seizures can be “non-epileptic” when evoked in a normal brain by treatments such as electroshock or chemical convulsants, or “epileptic” when occurring without evident provocation. Pharmacological agents in current clinical use inhibit seizures, and thus are referred to as anti-seizure drugs. Whether any of these prevent the development of epilepsy (epileptogenesis) is uncertain.

Seizures are thought to arise from the cerebral cortex, and not from other central nervous system (CNS) structures such as the thalamus, brainstem, or cerebellum. Epileptic seizures have been classified into *partial* seizures, those beginning focally in a cortical site, and *generalized* seizures, those that involve both hemispheres widely from the outset (Commission on Classification and Terminology, 1981). The behavioral manifestations of a seizure are determined by the functions normally served by the cortical site at which the seizure arises. For example, a seizure involving motor cortex is associated with clonic jerking of the body part controlled by this region of cortex. A *simple* partial seizure is associated with preservation of consciousness. A *complex* partial seizure is associated with impairment of consciousness. The majority of complex partial seizures originate from the temporal lobe. Examples of generalized seizures include absence, myoclonic, and tonic-clonic. The type of epileptic seizure is one determinant of the drug selected for

therapy. More detailed information is presented in Table 21–1.

Apart from this epileptic seizure classification, an additional classification specifies epileptic syndromes, which refer to a cluster of symptoms frequently occurring together and include seizure types, etiology, age of onset, and other factors (Commission on Classification and Terminology, 1989). More than 50 distinct epileptic syndromes have been identified and categorized into partial versus generalized epilepsies. The partial epilepsies may consist of any of the partial seizure types (Table 21–1) and account for roughly 60% of all epilepsies. The etiology commonly consists of a lesion in some part of the cortex, such as a tumor, developmental malformation,

or damage due to trauma or stroke. Such lesions often are evident on brain magnetic resonance imaging (MRI). Alternatively, the etiology may be genetic. The generalized epilepsies are characterized most commonly by one or more of the generalized seizure types listed in Table 21–1 and account for ~40% of all epilepsies. The etiology is usually genetic. The most common generalized epilepsy is referred to as juvenile myoclonic epilepsy, accounting for ~10% of all epileptic syndromes. The age of onset is in the early teens, and the condition is characterized by myoclonic, tonic-clonic, and often absence seizures. Like most of the generalized-onset epilepsies, juvenile myoclonic epilepsy is a complex genetic disorder that is probably due to inheritance of multiple susceptibility genes; there is a familial clustering of cases, but the pattern of inheritance is not

Table 21–1

Classification of Epileptic Seizures

SEIZURE TYPE	FEATURES	CONVENTIONAL ANTI-SEIZURE DRUGS	RECENTLY DEVELOPED ANTI-SEIZURE DRUGS
Partial Seizures			
Simple partial	Diverse manifestations determined by the region of cortex activated by the seizure (e.g., if motor cortex representing left thumb, clonic jerking of left thumb results; if somatosensory cortex representing left thumb, paresthesia of left thumb results), lasting approximating 20-60 seconds. <i>Key feature is preservation of consciousness.</i>	Carbamazepine, phenytoin, valproate	Gabapentin, lacosamide, lamotrigine, levetiracetam, rufinamide, tiagabine, topiramate, zonisamide
Complex partial	Impaired consciousness lasting 30 seconds to 2 minutes, often associated with purposeless movements such as lip smacking or hand wringing.		
Partial with secondarily generalized tonic-clonic seizure	Simple or complex partial seizure evolves into a tonic-clonic seizure with loss of consciousness and sustained contractions (tonic) of muscles throughout the body followed by periods of muscle contraction alternating with periods of relaxation (clonic), typically lasting 1-2 minutes		
Generalized Seizures			
Absence seizure	Abrupt onset of impaired consciousness associated with staring and cessation of ongoing activities typically lasting less than 30 seconds.	Ethosuximide, valproate, clonazepam	Lamotrigine
Myoclonic seizure	A brief (perhaps a second), shocklike contraction of muscles that may be restricted to part of one extremity or may be generalized.	Valproate, clonazepam	Levetiracetam
Tonic-clonic seizure	As described earlier in table for partial with secondarily generalized tonic-clonic seizures except that it is not preceded by a partial seizure.	Carbamazepine, phenobarbital, phenytoin, primidone, valproate	Lamotrigine, levetiracetam, topiramate

mendelian. The classification of epileptic syndromes guides clinical assessment and management, and in some instances, selection of anti-seizure drugs.

NATURE AND MECHANISMS OF SEIZURES AND ANTI-SEIZURE DRUGS

Partial Epilepsies

More than a century ago, John Hughlings Jackson, the father of modern concepts of epilepsy, proposed that seizures were caused by “occasional, sudden, excessive, rapid and local discharges of gray matter,” and that a generalized convulsion resulted when normal brain tissue was invaded by the seizure activity initiated in the abnormal focus. This insightful proposal provided a valuable framework for thinking about mechanisms of partial epilepsy. The advent of the electroencephalogram (EEG) in the 1930s permitted the recording of electrical activity from the scalp of humans with epilepsy and demonstrated that the epilepsies are disorders of neuronal excitability.

The pivotal role of synapses in mediating communication among neurons in the mammalian brain suggested that defective synaptic function might lead to a seizure. That is, a reduction of inhibitory synaptic activity or enhancement of excitatory synaptic activity might be expected to trigger a seizure; pharmacological studies of seizures support this notion. The neurotransmitters mediating the bulk of synaptic transmission in the mammalian brain are amino acids, with γ -aminobutyric acid (GABA) and glutamate being the principal inhibitory and excitatory neurotransmitters, respectively (Chapter 14). Pharmacological studies disclosed that *antagonists* of the GABA_A receptor or *agonists* of different glutamate-receptor subtypes (NMDA, AMPA, or kainic acid) (Chapter 14) trigger seizures in experimental animals *in vivo*. Conversely, pharmacological agents that enhance GABA-mediated synaptic inhibition suppress seizures in diverse models. Glutamate-receptor antagonists also inhibit seizures in diverse models, including seizures evoked by electroshock and chemical convulsants such as pentylenetetrazol.

Such studies support the idea that pharmacological regulation of synaptic function can regulate the propensity for seizures and provide a framework for electrophysiological analyses aimed at elucidating the role of both synaptic and nonsynaptic mechanisms in seizures and epilepsy. Progress in techniques has fostered the progressive refinement of the analysis of seizure mechanisms from the EEG to populations of neurons (field potentials) to individual neurons to individual synapses and individual ion channels on individual neurons. Beginning in the mid-1960s, cellular electrophysiological

studies of epilepsy focused on elucidating the mechanisms underlying the depolarization shift (DS), the intracellular correlate of the “interictal spike” (Figure 21–1). The interictal (or between-seizures) spike is a sharp waveform recorded in the EEG of patients with epilepsy; it is asymptomatic in that it is accompanied by no overt change in the patient’s behavior. The location of the interictal spike helps localize the brain region from which seizures originate in a given patient. The DS consists of a large depolarization of the neuronal membrane associated with a burst of action potentials. In most cortical neurons, the DS is generated by a large excitatory synaptic current that can be enhanced by activation of voltage-gated intrinsic membrane currents. Although the mechanisms generating the DS are increasingly understood, it remains unclear whether the interictal spike triggers a seizure, inhibits a seizure, or is an epiphenomenon with respect to seizure occurrence in an epileptic brain. While these questions remain unanswered, the study of the mechanisms of DS generation set the stage for inquiry into the cellular mechanisms of a seizure.

During the 1980s, various *in vitro* models of seizures were developed in isolated brain slice preparations, in which many synaptic connections are preserved. Electrographic events with features similar to those recorded during seizures *in vivo* have been produced in hippocampal slices by multiple methods, including altering ionic constituents of media bathing the brain slices (McNamara, 1994) such as low Ca²⁺, zero Mg²⁺, or elevated K⁺. The accessibility and experimental control provided by these preparations has permitted mechanistic investigations into the induction of seizures. Analyses of multiple *in vitro* models confirmed the importance of synaptic function for initiating a seizure, demonstrating that subtle (e.g., 20%) reductions of inhibitory synaptic function could lead to epileptiform activity and that activation of excitatory synapses could be pivotal in seizure initiation. Other important factors were identified, including the volume of the extracellular space as well as intrinsic properties of a neuron, such as voltage-gated ion channels (e.g., K⁺, Na⁺, and Ca²⁺ channels) (Traynelis and Dingledine, 1988). Identification of these diverse synaptic and nonsynaptic factors controlling seizures *in vitro* provides potential pharmacological targets for regulating seizure susceptibility *in vivo*.

Additional studies have centered on understanding the mechanisms by which a normal brain is transformed into an epileptic brain. Some common forms of partial epilepsy arise months to years after cortical injury sustained as a consequence of stroke, trauma, or other factors. An effective prophylaxis administered to patients at high risk would be highly desirable. The drugs described in this chapter provide symptomatic therapy; that is, the drugs inhibit seizures in patients with epilepsy. No effective anti-epileptogenic agent has been identified.

Understanding the mechanisms of epileptogenesis in cellular and molecular terms should provide a framework for development of novel therapeutic approaches. The availability of animal models provides an opportunity to investigate the underlying mechanisms.

Figure 21-1. Relations among cortical EEG, extracellular, and intracellular recordings in a seizure focus induced by local application of a convulsant agent to mammalian cortex. The extracellular recording was made through a high-pass filter. Note the high-frequency firing of the neuron evident in both extracellular and intracellular recording during the paroxysmal depolarization shift (PDS). (Modified with permission from Ayala GF, Dichter M, Gumnit RJ, et al. Genesis of epileptic interictal spikes. New knowledge of cortical feedback systems suggests a neurophysiological explanation of brief paroxysms. *Brain Res*, 1973, 52:1-17. Copyright © Elsevier.)

One model, termed “kindling,” is induced by periodic administration of brief, low-intensity electrical stimulation of the amygdala or other limbic structures. Initial stimulations evoke a brief electrical seizure recorded on the EEG without behavioral change, but repeated (e.g., 10-20) stimulations result in progressive intensification of seizures, culminating in tonic-clonic seizures. Once established, the enhanced sensitivity to electrical stimulation persists for the life of the animal. Despite the exquisite propensity to intense seizures, spontaneous seizures or a truly epileptic condition do not occur until 100-200 stimulations have been administered. The ease of control of kindling induction (i.e., stimulations administered at the investigator’s convenience), its graded onset, and the ease of quantitating epileptogenesis (number of stimulations required to evoke tonic-clonic seizures) simplify experimental study. In mice, deletion of the gene encoding the receptor tyrosine kinase, TrkB, prevents epileptogenesis in the kindling model (He et al., 2004), which advances TrkB and its downstream signaling pathways as attractive targets for developing small molecule inhibitors for prevention of epilepsy or its progression.

Additional models are produced by induction of continuous seizures for hours (“status epilepticus”), with the inciting agent being a chemoconvulsant, such as kainic acid or pilocarpine, or sustained electrical stimulation. The fleeting episode of status epilepticus is followed weeks later by the onset of spontaneous seizures, an

intriguing parallel to the scenario of complicated febrile seizures in young children preceding the emergence of spontaneous seizures years later. In contrast to the limited or absent neuronal loss characteristic of the kindling model, overt destruction of hippocampal neurons occurs in the status epilepticus models, reflecting aspects of hippocampal sclerosis observed in humans with severe limbic seizures. Indeed, the discovery that complicated febrile seizures precede and presumably are the cause of hippocampal sclerosis in young children (VanLandingham et al., 1998) establishes yet another commonality between these models and the human condition.

Several questions arise with respect to these models. What transpires during the latent period between status epilepticus and emergence of spontaneous seizures that causes the epilepsy? Might an anti-epileptogenic agent that was effective in one of these models be effective in other models?

Important insights into the mechanisms of action of drugs that are effective against partial seizures have emerged in the past two decades (Rogawski and Loscher, 2004). These insights largely have come from electrophysiological studies of relatively simple *in vitro* models, such as neurons isolated from the mammalian CNS and maintained in primary culture. The experimental control and accessibility provided by these

models—together with careful attention to clinically relevant concentrations of the drugs—led to clarification of their mechanisms. Although it is difficult to prove unequivocally that a given drug effect observed *in vitro* is both necessary and sufficient to inhibit a seizure in an animal or humans *in vivo*, there is an excellent likelihood that the putative mechanisms identified do in fact underlie the clinically relevant anti-seizure effects. Table 21–2 summarizes putative mechanisms of action of anti-seizure drugs.

Electrophysiological analyses of individual neurons during a partial seizure demonstrate that the neurons undergo depolarization and fire action potentials at high frequencies (Figure 21–1). This pattern of neuronal firing is characteristic of a seizure and is uncommon during physiological neuronal activity. Thus, selective inhibition of this pattern of firing would be expected to reduce seizures with minimal unwanted effects. Carbamazepine, lamotrigine, phenytoin, and valproic acid inhibit high-frequency firing at concentrations

Table 21–2

Proposed Mechanisms of Action of Anti-Seizure Drugs

MOLECULAR TARGET AND ACTIVITY	DRUG	CONSEQUENCES OF ACTION
Na⁺ channel modulators that: <i>enhance fast inactivation</i>	PHT, CBZ, LTG, FBM, OxCBZ, TPM, VPA	<ul style="list-style-type: none"> • block action potential propagation • stabilize neuronal membranes • ↓ neurotransmitter release, focal firing, and seizure spread

Figure 21-2. Anti-seizure drug-enhanced Na^+ channel inactivation. Some anti-seizure drugs (shown in blue text) prolong the inactivation of the Na^+ channels, thereby reducing the ability of neurons to fire at high frequencies. Note that the inactivated channel itself appears to remain open, but is blocked by the inactivation gate I. A, activation gate.

known to be effective at limiting seizures in humans (Rogawski and Loscher, 2004). Inhibition of the high-frequency firing is thought to be mediated by reducing the ability of Na^+ channels to recover from inactivation (Figure 21-2). That is, depolarization-triggered opening of the Na^+ channels in the axonal membrane of a neuron is required for an action potential; after opening, the channels spontaneously close, a process termed *inactivation*. This inactivation is thought to cause the refractory period, a short time after an action potential during which it is not possible to evoke another action potential. Upon recovery from inactivation, the Na^+ channels are again poised to participate in another action potential. Because firing at a slow rate permits sufficient time for Na^+ channels to recover from inactivation, inactivation has little or no effect on low-frequency firing. However, reducing the rate of recovery of Na^+ channels from inactivation would limit the ability of a neuron to fire at high frequencies, an effect that likely underlies the effects of carbamazepine, lamotrigine, phenytoin, topiramate, valproic acid, and zonisamide against partial seizures.

Insights into mechanisms of seizures suggest that enhancing GABA-mediated synaptic inhibition would reduce neuronal excitability and raise the seizure threshold. Several drugs are thought to inhibit seizures by regulating GABA-mediated synaptic inhibition through an action at distinct sites of the synapse (Rogawski and Loscher, 2004). The principal postsynaptic receptor of synaptically released GABA is termed the GABA_A receptor (Chapters 14 and 17). Activation of the GABA_A receptor inhibits the postsynaptic cell by increasing the inflow of Cl^- ions into the

Figure 21-3. Enhanced GABA synaptic transmission. In the presence of GABA, the GABA_A receptor (structure on left) is opened, allowing an influx of Cl^- , which in turn increases membrane polarization (Chapter 14). Some anti-seizure drugs (shown in larger blue text) act by reducing the metabolism of GABA. Others act at the GABA_A receptor, enhancing Cl^- influx in response to GABA. As outlined in the text, gabapentin acts presynaptically to promote GABA release; its molecular target is currently under investigation. \blacktriangledown GABA molecules, GABA-T, GABA transaminase; GAT-1, GABA transporter.

cell, which tends to hyperpolarize the neuron. Clinically relevant concentrations of both benzodiazepines and barbiturates enhance GABA_A receptor-mediated inhibition through distinct actions on the GABA_A receptor (Figure 21-3), and this enhanced inhibition probably underlies the effectiveness of these compounds against partial and tonic-clonic seizures in humans. At higher concentrations, such as might be used for status epilepticus, these drugs also can inhibit high-frequency firing of action potentials. A second mechanism of enhancing GABA-mediated synaptic inhibition is thought to underlie the anti-seizure mechanism of tiagabine; tiagabine inhibits the GABA transporter, GAT-1, and reduces neuronal and glial uptake of GABA (Rogawski and Loscher, 2004).

Generalized-Onset Epilepsies: Absence Seizures

In contrast to partial seizures, which arise from localized regions of the cerebral cortex, generalized-onset

seizures arise from the reciprocal firing of the thalamus and cerebral cortex (Huguenard and McCormick, 2007). Among the diverse forms of generalized seizures, absence seizures have been studied most intensively. The striking synchrony in appearance of generalized seizure discharges in widespread areas of neocortex led to the idea that a structure in the thalamus and/or brainstem (the “centrencephalon”) synchronized these seizure discharges. Focus on the thalamus in particular emerged from the demonstration that low-frequency stimulation of midline thalamic structures triggered EEG rhythms in the cortex similar to spike-and-wave discharges characteristic of absence seizures. Intra-cerebral electrode recordings from humans subsequently demonstrated the presence of thalamic and neocortical involvement in the spike-and-wave discharge of absence seizures.

Many of the structural and functional properties of the thalamus and neocortex that lead to the generalized spike-and-wave discharges have been elucidated (Huguenard and McCormick, 2007).

The EEG hallmark of an absence seizure is generalized spike-and-wave discharges at a frequency of 3 per second (3 Hz). These bilaterally synchronous spike-and-wave discharges, recorded locally from electrodes in both the thalamus and the neocortex, represent oscillations between the thalamus and neocortex. A comparison of EEG and intracellular recordings reveals that the EEG spikes are associated with the firing of action potentials and the following slow wave with prolonged inhibition. These reverberatory, low-frequency rhythms are made possible by a combination of factors, including reciprocal excitatory synaptic connections between the neocortex and thalamus as well as intrinsic properties of neurons in the thalamus (Huguenard and McCormick, 2007). One intrinsic property of thalamic neurons that is pivotally involved in the generation of the 3-Hz spike-and-wave discharges is a particular type of Ca^{2+} current, the low threshold (“T-type”) current. T-type Ca^{2+} channels are activated at a much more negative membrane potential (hence “low threshold”) than most other voltage-gated Ca^{2+} channels expressed in the brain. T-type currents are much larger in many thalamic neurons compared to neurons outside the thalamus. Indeed, bursts of action potentials in thalamic neurons are mediated by activation of the T-type currents. T-type currents amplify thalamic membrane potential oscillations, with one oscillation being the 3-Hz spike-and-wave discharge of the absence seizure. Importantly, the principal mechanism by which anti-absence-seizure drugs (ethosuximide, valproic acid) are thought to act is by inhibition of the T-type Ca^{2+} channels (Figure 21–4) (Rogawski and Loscher, 2004). Thus, inhibiting voltage-gated ion channels is a common mechanism of action among anti-seizure drugs, with anti-partial-seizure drugs inhibiting voltage-activated Na^+ channels and anti-absence-seizure drugs inhibiting voltage-activated Ca^{2+} channels.

Genetic Approaches to the Epilepsies

Genetic causes contribute to a wide diversity of human epilepsies. Genetic causes are solely responsible for

Figure 21–4. Anti-seizure drug-induced reduction of current through T-type Ca^{2+} channels. Some anti-seizure drugs (shown in blue text) reduce the flow of Ca^{2+} through T-type Ca^{2+} channels thus reducing the pacemaker current that underlies the thalamic rhythm in spikes and waves seen in generalized absence seizures.

rare forms inherited in an autosomal dominant or autosomal recessive manner. Genetic causes also are mainly responsible for more common forms such as juvenile myoclonic epilepsy (JME) or childhood absence epilepsy (CAE), the majority of which are likely due to inheritance of two or more susceptibility genes. Genetic determinants also may contribute some degree of risk to epilepsies caused by injury of the cerebral cortex.

Enormous progress has been made in understanding the genetics of mammalian epilepsy. Mutant genes have been identified for a number of symptomatic epilepsies, in which the epilepsy is a manifestation of the underlying neurodegenerative disease. Because most patients with epilepsy are neurologically normal, elucidating the mutant genes underlying familial epilepsy in otherwise normal individuals is of particular interest; this has led to the identification of 25 distinct genes implicated in distinct idiopathic epilepsy syndromes that account for < 1% of all of the human epilepsies. Interestingly, almost all of the mutant genes encode voltage- or ligand-gated ion channels (Reid et al., 2008). Mutations have been identified in Na^+ , K^+ , Ca^{2+} , and Cl^- channels, in channels gated by GABA and acetylcholine, and most recently, in intracellular Ca^{2+} release channels (RyR2) activated by Ca^{2+} . The genotype-phenotype correlations of these genetic syndromes are complex; the same mutation in one channel can be associated with divergent clinical syndromes ranging from simple febrile seizures to intractable seizures with intellectual decline. Conversely, clinically indistinguishable epilepsy syndromes have been associated with mutation of distinct genes. The implication of genes encoding ion channels in familial epilepsy is particularly interesting because episodic disorders involving other organs also result from mutations of these genes. For example, episodic disorders of the heart (cardiac arrhythmias), skeletal muscle (periodic paralyses), cerebellum (episodic ataxia), vasculature (familial hemiplegic migraine), and other organs all have been linked to mutations in genes encoding components of voltage-gated ion channels (Ptacek and Fu, 2001).

The cellular electrophysiological consequences of these mutations can inform on the mechanisms of seizures and anti-seizure drugs. For example, generalized epilepsy with febrile seizures (GEFS+) is caused by a point mutation in the β subunit of a voltage-gated Na^+ channel (*SCN1B*). As described previously, several anti-seizure drugs act on Na^+ channels to promote their inactivation; the phenotype of the mutated Na^+ channel appears to involve defective inactivation (Wallace et al., 1998).

Spontaneous mutations in *SCN1A* (encoding the α subunit of the major voltage-gated Na^+ channel in neurons) that result in truncations and presumed loss of Na^+ channel function have been identified in a subset of infants with a catastrophic severe myoclonic epilepsy of infancy. An intriguing clue as to how this genotype may lead to an epileptic phenotype has emerged from the study of *SCN1A* knock-out mice (Yu et al., 2006). Heterozygote mice have only one functional allele and provide a mouse model of this epileptic syndrome. Because activation of voltage-gated Na^+ channels depolarizes and activates a neuron, it seemed odd that a loss of function mutation of *SCN1A* would result in increased excitability of networks of neurons and epilepsy. This led to the discovery of impaired firing of inhibitory interneurons, but not excitatory principal neurons, in *SCN1A* heterozygous mice (Yu et al., 2006). These findings suggest that loss of function mutations of *SCN1A* may cause epilepsy as a consequence of reduced firing of inhibitory interneurons. Because interneurons effect inhibition by releasing GABA, this suggests that drugs acting to enhance GABA-mediated inhibition may be effective anticonvulsants in *SCN1A* mutant mice and infants with these mutations. Consistent with this hypothesis, preliminary findings reveal that an experimental anti-seizure drug that increases the duration of GABA_A receptor channel open times (Quilichini et al., 2006) was beneficial in children with severe myoclonic epilepsy of infancy (Chiron, 2007). If confirmed, this would provide the first instance of rational use of anti-seizure drugs in that insight into the cellular mechanism of the epilepsy would guide selection of drugs acting by a given mechanism.

ANTI-SEIZURE DRUGS: GENERAL CONSIDERATIONS

History. The first anti-epileptic drug was bromide, which was used in the late 19th century. Phenobarbital was the first synthetic organic agent recognized as having anti-seizure activity. Its usefulness, however, was limited to generalized tonic-clonic seizures, and to a lesser degree, simple and complex partial seizures. It had no effect on absence seizures. Merritt and Putnam developed the electroshock seizure test in experimental animals to screen chemical agents for anti-seizure effectiveness; in the course of screening a variety of drugs, they discovered that diphenylhydantoin (later renamed phenytoin) suppressed seizures in the absence of sedative effects. The electroshock seizure test is extremely valuable, because drugs that are effective against tonic hind limb extension induced by electroshock generally have proven to be effective against partial and tonic-clonic seizures in humans. Another screening test, seizures induced by the chemoconvulsant pentylenetetrazol, is most useful in identifying drugs that are effective against myoclonic seizures in humans. These screening tests are still used. The chemical structures of most of the

drugs introduced before 1965 were closely related to phenobarbital. These included the hydantoins and the succinimides. Between 1965 and 1990, the chemically distinct structures of the benzodiazepines, an iminostilbene (carbamazepine), and a branched-chain carboxylic acid (valproic acid) were introduced, followed in the 1990s by a phenyltriazine (lamotrigine), a cyclic analog of GABA (gabapentin), a sulfamate-substituted monosaccharide (topiramate), a nipecotic acid derivative (tiagabine), and a pyrrolidine derivative (levetiracetam).

Therapeutic Aspects. The ideal anti-seizure drug would suppress all seizures without causing any unwanted effects. Unfortunately, the drugs used currently not only fail to control seizure activity in some patients, but frequently cause unwanted effects that range in severity from minimal impairment of the CNS to death from aplastic anemia or hepatic failure. In 2009, all manufacturers of anti-seizure drugs were required to update their product labeling to include a warning about an increased risk of suicidal thoughts or actions and to develop information targeted at helping patients understand this risk. The risk applies to all anti-seizure drugs used for any indication. Details are online at the FDA website.

The clinician who treats patients with epilepsy is faced with the task of selecting the appropriate drug or combination of drugs that best controls seizures in an individual patient at an acceptable level of untoward effects. As a general rule, complete control of seizures can be achieved in up to 50% of patients, while another 25% can be improved significantly. The degree of success varies as a function of seizure type, cause, and other factors.

To minimize toxicity, treatment with a single drug is preferred. If seizures are not controlled with the initial agent at adequate plasma concentrations, substitution of a second drug is preferred to the concurrent administration of another agent. However, multiple-drug therapy may be required, especially when two or more types of seizure occur in the same patient.

Measurement of drug concentrations in plasma facilitates optimizing anti-seizure medication, especially when therapy is initiated, after dosage adjustments, in the event of therapeutic failure, when toxic effects appear, or when multiple-drug therapy is instituted. However, clinical effects of some drugs do not correlate well with their concentrations in plasma, and recommended concentrations are only guidelines for therapy. The ultimate therapeutic regimen must be determined by clinical assessment of effect and toxicity.

The individual agents are introduced in the next sections, followed by a discussion of some general principles of the drug therapy of the epilepsies.

HYDANTOINS

Phenytoin

Phenytoin (diphenylhydantoin; DILANTIN, others) is effective against all types of partial and tonic-clonic seizures but not absence seizures. Properties of other hydantoin (ethotoin, PEGANONE) are described in previous editions of this book.

History. Phenytoin was first synthesized in 1908 by Biltz, but its anticonvulsant activity was not discovered until 1938. In contrast to the earlier accidental discovery of the anti-seizure properties of bromide and phenobarbital, phenytoin was the product of a search among non-sedative structural relatives of phenobarbital for agents capable of suppressing electroshock convulsions in laboratory animals. It was introduced for the treatment of epilepsy in the same year. Since this agent is not a sedative in ordinary doses, it established that anti-seizure drugs need not induce drowsiness and encouraged the search for drugs with selective anti-seizure action.

PHENYTOIN

Structure-Activity Relationship. A 5-phenyl or other aromatic substituent appears essential for activity against generalized tonic-clonic seizures. Alkyl substituents in position 5 contribute to sedation, a property absent in phenytoin. The carbon 5 position permits asymmetry, but there appears to be little difference in activity between isomers.

Pharmacological Effects

Central Nervous System. Phenytoin exerts anti-seizure activity without causing general depression of the CNS. In toxic doses, it may produce excitatory signs and at lethal levels a type of decerebrate rigidity.

The most significant effect of phenytoin is its ability to modify the pattern of maximal electroshock seizures. The characteristic tonic phase can be abolished completely, but the residual clonic seizure may be exaggerated and prolonged. This seizure-modifying action is observed with many other anti-seizure drugs that are effective against generalized tonic-clonic seizures. By contrast, phenytoin does not inhibit clonic seizures evoked by pentylenetetrazol.

Mechanism of Action. Phenytoin limits the repetitive firing of action potentials evoked by a sustained depolarization of mouse spinal cord neurons maintained *in vitro* (McLean and Macdonald, 1986a). This effect is mediated by a slowing of the rate of recovery of voltage-activated Na^+ channels from inactivation, an action that is both voltage- (greater effect if membrane is depolarized) and use-dependent. These effects of phenytoin are evident at concentrations in the range of therapeutic drug levels in cerebrospinal fluid (CSF)

in humans, which correlate with the free (or unbound) concentration of phenytoin in the serum. At these concentrations, the effects on Na^+ channels are selective, and no changes of spontaneous activity or responses to iontophoretically applied GABA or glutamate are detected. At concentrations 5- to 10-fold higher, multiple effects of phenytoin are evident, including reduction of spontaneous activity and enhancement of responses to GABA; these effects may underlie some of the unwanted toxicity associated with high levels of phenytoin.

Pharmacokinetic Properties. Phenytoin is available in two types of oral formulations that differ in their pharmacokinetics: rapid-release and extended-release forms. Once-daily dosing is possible only with the extended-release formulations, and due to differences in dissolution and other formulation-dependent factors, the plasma phenytoin level may change when converting from one formulation to another. Confusion also can arise because different formulations can include either phenytoin or phenytoin sodium. Therefore, comparable doses can be approximated by considering “phenytoin equivalents,” but serum level monitoring is also necessary to assure therapeutic safety.

The pharmacokinetic characteristics of phenytoin are influenced markedly by its binding to serum proteins, by the nonlinearity of its elimination kinetics, and by its metabolism by hepatic CYPs (Table 21–3). Phenytoin is extensively bound (~90%) to serum proteins, mainly albumin. Small variations in the percentage of phenytoin that is bound dramatically affect the absolute amount of free (active) drug; increased proportions of free drug are evident in the neonate, in patients with hypoalbuminemia, and in uremic patients. Some agents can compete with phenytoin for binding sites on plasma proteins and increase free phenytoin at the time the new drug is added to the regimen. However, the effect on free phenytoin is only short-lived and usually does not cause clinical complications unless inhibition of phenytoin metabolism also occurs. For example, valproate competes for protein binding sites and inhibits phenytoin metabolism, resulting in marked and sustained increases in free phenytoin. Measurement of free rather than total phenytoin permits direct assessment of this potential problem in patient management.

Phenytoin is one of the few drugs for which the rate of elimination varies as a function of its concentration (i.e., the rate is nonlinear). The plasma $t_{1/2}$ of phenytoin ranges between 6 and 24 hours at plasma concentrations below 10 $\mu\text{g/mL}$ but increases with higher concentrations; as a result, plasma drug concentration increases disproportionately as dosage is

increased, even with small adjustments for levels near the therapeutic range.

The majority (95%) of phenytoin is metabolized in the hepatic endoplasmic reticulum by CYP2C9/10 and to a lesser extent CYP2C19 (Table 21–3). The principal metabolite, a parahydroxyphenyl derivative, is inactive. Because its metabolism is saturable, other drugs that are metabolized by these enzymes can inhibit the metabolism of phenytoin and increase its plasma concentration. Conversely, the degradation rate of other drugs that are substrates for these enzymes can be inhibited by phenytoin; one such drug is warfarin, and addition of phenytoin to a patient receiving warfarin can lead to bleeding disorders (Chapter 30). An alternative mechanism of drug interactions arises from phenytoin's ability to induce diverse CYPs (Chapter 6); co-administration of phenytoin and medications metabolized by these enzymes can lead to an increased degradation of such medications. Of particular note in this regard are oral contraceptives, which are metabolized by CYP3A4; treatment with phenytoin can enhance the metabolism of oral contraceptives and lead to unplanned pregnancy. The potential teratogenic effects of phenytoin underscore the importance of attention to this interaction. Carbamazepine, oxcarbazepine, phenobarbital, and primidone also can induce CYP3A4 and likewise might increase degradation of oral contraceptives.

The low water solubility of phenytoin hindered its intravenous use and led to production of fosphenytoin, a water-soluble prodrug. *Fosphenytoin* (CEREBYX, others) is converted into phenytoin by phosphatases in liver and red blood cells with a $t_{1/2}$ of

8–15 minutes. Fosphenytoin is extensively bound (95–99%) to human plasma proteins, primarily albumin. This binding is saturable and fosphenytoin displaces phenytoin from protein-binding sites. Fosphenytoin is useful for adults with partial or generalized seizures when intravenous or intramuscular administration is indicated.

Toxicity. The toxic effects of phenytoin depend on the route of administration, the duration of exposure, and the dosage.

When fosphenytoin, the water-soluble prodrug, is administered intravenously at an excessive rate in the emergency treatment of status epilepticus, the most notable toxic signs are cardiac arrhythmias with or without hypotension, and/or CNS depression. Although cardiac toxicity occurs more frequently in older patients and in those with known cardiac disease, it also can develop in young, healthy patients. These complications can be minimized by administering fosphenytoin at a rate of < 150 mg of phenytoin sodium equivalents per minute. Acute oral overdose results primarily in signs referable to the cerebellum and vestibular system; high doses have been associated with marked cerebellar atrophy. Toxic effects associated with chronic treatment also are primarily dose-related cerebellar-vestibular effects but also include other CNS effects, behavioral changes, increased frequency of seizures, GI symptoms, gingival hyperplasia, osteomalacia, and megaloblastic anemia. Hirsutism is an annoying untoward effect in young females. Usually, these phenomena can be diminished by proper adjustment of dosage. Serious adverse effects, including those on the skin, bone marrow, and liver, probably are manifestations of

drug allergy. Although rare, they necessitate withdrawal of the drug. Moderate elevation of the plasma concentrations of hepatic transaminases sometimes are observed; since these changes are transient and may result in part from induced synthesis of the enzymes, they do not necessitate withdrawal of the drug.

Gingival hyperplasia occurs in ~20% of all patients during chronic therapy and is probably the most common manifestation of phenytoin toxicity in children and young adolescents. It may be more frequent in those individuals who also develop coarsened facial features. The overgrowth of tissue appears to involve altered collagen metabolism. Toothless portions of the gums are not affected. The condition does not necessarily require withdrawal of medication and can be minimized by good oral hygiene.

A variety of endocrine effects have been reported. Inhibition of release of anti-diuretic hormone (ADH) has been observed in patients with inappropriate ADH secretion. Hyperglycemia and glycosuria appear to be due to inhibition of insulin secretion. Osteomalacia, with hypocalcemia and elevated alkaline phosphatase activity, has been attributed to both altered metabolism of vitamin D and the attendant inhibition of intestinal absorption of Ca^{2+} . Phenytoin also increases the metabolism of vitamin K and reduces the concentration of vitamin K–dependent proteins that are important for normal Ca^{2+} metabolism in bone. This may explain why the osteomalacia is not always ameliorated by the administration of vitamin D.

Hypersensitivity reactions include morbilliform rash in 2–5% of patients and occasionally more serious skin reactions, including Stevens-Johnson syndrome and toxic epidermal necrolysis. Systemic lupus erythematosus and potentially fatal hepatic necrosis have been reported rarely. Hematological reactions include neutropenia and leukopenia. A few cases of red-cell aplasia, agranulocytosis, and mild thrombocytopenia also have been reported. Lymphadenopathy, resembling Hodgkin's disease and malignant lymphoma, is associated with reduced immunoglobulin A (IgA) production. Hypoprothrombinemia and hemorrhage have occurred in the newborns of mothers who received phenytoin during pregnancy; vitamin K is effective treatment or prophylaxis.

Plasma Drug Concentrations. A good correlation usually is observed between the total concentration of phenytoin in plasma and its clinical effect. Thus, control of seizures generally is obtained with total concentrations above 10 $\mu\text{g}/\text{mL}$, while toxic effects such as nystagmus develop at total concentrations around 20 $\mu\text{g}/\text{mL}$. Control of seizures generally is obtained with free phenytoin concentrations of 0.75–1.25 $\mu\text{g}/\text{mL}$.

Drug Interactions. Concurrent administration of any drug metabolized by CYP2C9 or CYP2C10 can increase the plasma concentration of phenytoin by decreasing its rate of metabolism (Table 21–3). Carbamazepine, which may enhance the metabolism of phenytoin, causes a well-documented *decrease* in phenytoin concentration. Conversely, phenytoin reduces the concentration of carbamazepine. Interaction between phenytoin and phenobarbital is variable.

Therapeutic Uses

Epilepsy. Phenytoin is one of the more widely used anti-seizure agents, and it is effective against partial and tonic-clonic but not absence seizures. The use of phenytoin and other agents in the therapy of epilepsies is

discussed further at the end of this chapter. Phenytoin preparations differ significantly in bioavailability and rate of absorption. In general, patients should consistently be treated with the same drug from a single manufacturer. However, if it becomes necessary to temporarily switch between products, care should be taken to select a therapeutically equivalent product and patients should be monitored for loss of seizure control or onset of new toxicities.

Other Uses. Trigeminal and related neuralgias occasionally respond to phenytoin, but carbamazepine may be preferable. The use of phenytoin in the treatment of cardiac arrhythmias is discussed in Chapter 29.

ANTI-SEIZURE BARBITURATES

The pharmacology of the barbiturates as a class is described in Chapter 17; discussion in this chapter is limited to phenobarbital. Use of other long-acting barbiturates (e.g., mephobarbital, MEBARAL) for therapy of the epilepsies is described in previous editions of this book.

Phenobarbital

Phenobarbital (LUMINAL, others) was the first effective organic anti-seizure agent. It has relatively low toxicity, is inexpensive, and is still one of the more effective and widely used drugs for this purpose.

Structure-Activity Relationship. The structural formula of phenobarbital (5-phenyl-5-ethylbarbituric acid) is shown in Chapter 17. The structure-activity relationships of the barbiturates have been studied extensively. Maximal anti-seizure activity is obtained when one substituent at carbon 5 position is a phenyl group. The 5,5-diphenyl derivative has less anti-seizure potency than does phenobarbital, but it is virtually devoid of hypnotic activity. By contrast, 5,5-dibenzyl barbituric acid causes convulsions.

Anti-Seizure Properties. Most barbiturates have anti-seizure properties. However, only some of these agents, such as phenobarbital, exert maximal anti-seizure action at doses below those required for hypnosis, which determines their clinical utility as anti-seizure agents. Phenobarbital is active in most anti-seizure tests in animals but is relatively nonselective. It inhibits tonic hind limb extension in the maximal electroshock model, clonic seizures evoked by pentylenetetrazol, and kindled seizures.

Mechanism of Action. The mechanism by which phenobarbital inhibits seizures likely involves potentiation of synaptic inhibition through an action on the GABA_A receptor. Intracellular recordings of mouse cortical or spinal cord neurons demonstrated that phenobarbital enhances responses to iontophoretically applied GABA.

These effects have been observed at therapeutically relevant concentrations of phenobarbital. Analyses of single channels in outside-out patches isolated from mouse spinal cord neurons demonstrated that phenobarbital increased the GABA_A receptor-mediated current by increasing the duration of bursts of GABA_A receptor-mediated currents without changing the frequency of bursts (Twyman et al., 1989). At levels exceeding therapeutic concentrations, phenobarbital also limits sustained repetitive firing; this may underlie some of the anti-seizure effects of higher concentrations of phenobarbital achieved during therapy of status epilepticus.

Pharmacokinetic Properties. Oral absorption of phenobarbital is complete but somewhat slow; peak concentrations in plasma occur several hours after a single dose. It is 40-60% bound to plasma proteins and bound to a similar extent in tissues, including brain. Up to 25% of a dose is eliminated by pH-dependent renal excretion of the unchanged drug; the remainder is inactivated by hepatic microsomal enzymes, principally CYP2C9, with minor metabolism by CYP2C19 and CYP2E1. Phenobarbital induces uridine diphosphate-glucuronosyltransferase (UGT) enzymes as well as the CYP2C and CYP3A subfamilies. Drugs metabolized by these enzymes can be more rapidly degraded when co-administered with phenobarbital; importantly, oral contraceptives are metabolized by CYP3A4.

Toxicity. Sedation, the most frequent undesired effect of phenobarbital, is apparent to some extent in all patients upon initiation of therapy, but tolerance develops during chronic medication. Nystagmus and ataxia occur at excessive dosage. Phenobarbital can produce irritability and hyperactivity in children, and agitation and confusion in the elderly.

Scarlatiniform or morbilliform rash, possibly with other manifestations of drug allergy, occurs in 1-2% of patients. Exfoliative dermatitis is rare. Hypoprothrombinemia with hemorrhage has been observed in the newborns of mothers who have received phenobarbital during pregnancy; vitamin K is effective for treatment or prophylaxis. As with phenytoin, megaloblastic anemia that responds to folate and osteomalacia that responds to high doses of vitamin D occur during chronic phenobarbital therapy of epilepsy. Other adverse effects of phenobarbital are discussed in Chapter 17.

Plasma Drug Concentrations. During long-term therapy in adults, the plasma concentration of phenobarbital averages 10 µg/mL per daily dose of 1 mg/kg; in children, the value is 5-7 µg/mL per 1 mg/kg. Although a precise relationship between therapeutic results and concentration of drug in plasma does not exist, plasma concentrations of 10-35 µg/mL are usually recommended for control of seizures.

The relationship between plasma concentration of phenobarbital and adverse effects varies with the development of tolerance. Sedation, nystagmus, and ataxia usually are absent at concentrations below 30 µg/mL during long-term therapy, but adverse effects may be apparent for several days at lower concentrations when therapy is initiated or whenever the dosage is increased. Concentrations > 60 µg/mL may be associated with marked intoxication in the non-tolerant individual.

Since significant behavioral toxicity may be present despite the absence of overt signs of toxicity, the tendency to maintain

patients, particularly children, on excessively high doses of phenobarbital should be resisted. The plasma phenobarbital concentration should be increased above 30-40 µg/mL only if the increment is adequately tolerated and only if it contributes significantly to control of seizures.

Drug Interactions. Interactions between phenobarbital and other drugs usually involve induction of the hepatic CYPs by phenobarbital (see Table 21-3 and Chapters 6 and 17). The interaction between phenytoin and phenobarbital is variable. Concentrations of phenobarbital in plasma may be elevated by as much as 40% during concurrent administration of valproic acid.

Therapeutic Uses. Phenobarbital is an effective agent for generalized tonic-clonic and partial seizures. Its efficacy, low toxicity, and low cost make it an important agent for these types of epilepsy. However, its sedative effects and its tendency to disturb behavior in children have reduced its use as a primary agent. It is not effective for absence seizures.

IMINOSTILBENES

Carbamazepine

Carbamazepine (TEGRETOL, CARBATROL, others) was initially approved in the U.S. for use as an anti-seizure agent in 1974. It has been employed since the 1960s for the treatment of trigeminal neuralgia. It is now considered to be a primary drug for the treatment of partial and tonic-clonic seizures.

Chemistry. Carbamazepine is related chemically to the tricyclic antidepressants. It is a derivative of iminostilbene with a carbamyl group at the 5 position; this moiety is essential for potent anti-seizure activity.

Pharmacological Effects. Although the effects of carbamazepine in animals and humans resemble those of phenytoin in many ways, the two drugs exhibit important differences. Carbamazepine has been found to produce therapeutic responses in manic-depressive patients, including some in whom lithium carbonate is not effective. Further, carbamazepine has anti-diuretic effects that are sometimes associated with increased concentrations of anti-diuretic hormone (ADH) in plasma. The mechanisms responsible for these effects of carbamazepine are not clearly understood.

Mechanism of Action. Like phenytoin, carbamazepine limits the repetitive firing of action potentials evoked by a sustained depolarization of mouse spinal cord or cortical neurons maintained *in vitro* (McLean and Macdonald, 1986a). This appears to be mediated by a slowing of the rate of recovery of voltage-activated Na⁺ channels from inactivation. These effects of carbamazepine are evident at

concentrations in the range of therapeutic drug levels in CSF in humans. The effects of carbamazepine are selective at these concentrations, in that there are no effects on spontaneous activity or on responses to iontophoretically applied GABA or glutamate. The carbamazepine metabolite, 10,11-epoxycarbamazepine, also limits sustained repetitive firing at therapeutically relevant concentrations, suggesting that this metabolite may contribute to the anti-seizure efficacy of carbamazepine.

Pharmacokinetic Properties. The pharmacokinetics of carbamazepine are complex. They are influenced by its limited aqueous solubility and by the ability of many anti-seizure drugs, including carbamazepine itself, to increase their conversion to active metabolites by hepatic oxidative enzymes (Table 21–3).

Carbamazepine is absorbed slowly and erratically after oral administration. Peak concentrations in plasma usually are observed 4–8 hours after oral ingestion, but may be delayed by as much as 24 hours, especially following the administration of a large dose. The drug distributes rapidly into all tissues. Approximately 75% of carbamazepine binds to plasma proteins and concentrations in the CSF appear to correspond to the concentration of free drug in plasma.

The predominant pathway of metabolism in humans involves conversion to the 10,11-epoxide. This metabolite is as active as the parent compound in various animals, and its concentrations in plasma and brain may reach 50% of those of carbamazepine, especially during the concurrent administration of phenytoin or phenobarbital. The 10,11-epoxide is metabolized further to inactive compounds, which are excreted in the urine principally as glucuronides. Carbamazepine also is inactivated by conjugation and hydroxylation. Hepatic CYP3A4 is primarily responsible for biotransformation of carbamazepine. Carbamazepine induces CYP2C, CYP3A, and UGT, thus enhancing the metabolism of drugs degraded by these enzymes. Of particular importance in this regard are oral contraceptives, which are also metabolized by CYP3A4.

Toxicity. Acute intoxication with carbamazepine can result in stupor or coma, hyperirritability, convulsions, and respiratory depression. During long-term therapy, the more frequent untoward effects of the drug include drowsiness, vertigo, ataxia, diplopia, and blurred vision. The frequency of seizures may increase, especially with overdosage. Other adverse effects include nausea, vomiting, serious hematological toxicity (aplastic anemia, agranulocytosis), and hypersensitivity reactions (dangerous skin reactions, eosinophilia, lymphadenopathy, splenomegaly). A late complication of therapy with carbamazepine is retention of water, with decreased osmolality and concentration of Na^+ in plasma, especially in elderly patients with cardiac disease.

Some tolerance develops to the neurotoxic effects of carbamazepine, and they can be minimized by gradual increase in dosage

or adjustment of maintenance dosage. Various hepatic or pancreatic abnormalities have been reported during therapy with carbamazepine, most commonly a transient elevation of hepatic transaminases in plasma in 5–10% of patients. A transient, mild leukopenia occurs in ~10% of patients during initiation of therapy and usually resolves within the first 4 months of continued treatment; transient thrombocytopenia also has been noted. In ~2% of patients, a persistent leukopenia may develop that requires withdrawal of the drug. The initial concern that aplastic anemia might be a frequent complication of long-term therapy with carbamazepine has not materialized. In most cases, the administration of multiple drugs or the presence of another underlying disease has made it difficult to establish a causal relationship. The prevalence of aplastic anemia appears to be ~1 in 200,000 patients who are treated with the drug. It is not clear whether monitoring of hematological function can avert the development of irreversible aplastic anemia. Although carbamazepine is carcinogenic in rats, it is not known to be carcinogenic in humans. Possible teratogenic effects are discussed later in the chapter.

Plasma Drug Concentrations. There is no simple relationship between the dose of carbamazepine and concentrations of the drug in plasma. Therapeutic concentrations are reported to be 6–12 $\mu\text{g}/\text{mL}$, although considerable variation occurs. Side effects referable to the CNS are frequent at concentrations above 9 $\mu\text{g}/\text{mL}$.

Drug Interactions. Phenobarbital, phenytoin, and valproate may increase the metabolism of carbamazepine by inducing CYP3A4; carbamazepine may enhance the biotransformation of phenytoin. Concurrent administration of carbamazepine may lower concentrations of valproate, lamotrigine, tiagabine, and topiramate. Carbamazepine reduces both the plasma concentration and therapeutic effect of haloperidol. The metabolism of carbamazepine may be inhibited by propoxyphene, erythromycin, cimetidine, fluoxetine, and isoniazid.

Therapeutic Uses. Carbamazepine is useful in patients with generalized tonic-clonic and both simple and complex partial seizures (Table 21–1). When it is used, renal and hepatic function and hematological parameters should be monitored. The therapeutic use of carbamazepine is discussed further at the end of this chapter.

Carbamazepine is the primary agent for treatment of trigeminal and glossopharyngeal neuralgias. It is also effective for lightning-type (“tabetic”) pain associated with bodily wasting. Most patients with neuralgia benefit initially, but only 70% obtain continuing relief. Adverse effects require discontinuation of medication in 5–20% of patients. The therapeutic range of plasma concentrations for anti-seizure therapy serves as a guideline for its use in neuralgia. Carbamazepine is also used in the treatment of bipolar affective disorders, as discussed further in Chapter 16.

Oxcarbazepine

Oxcarbazepine (TRILEPTAL, others) (10,11-dihydro-10-oxocarbamazepine) is a keto analog of carbamazepine.

596 Oxcarbazepine is a prodrug that is almost immediately converted to its main active metabolite, a 10-monohydroxy derivative, which is inactivated by glucuronide conjugation and eliminated by renal excretion.

Its mechanism of action is similar to that of carbamazepine. Oxcarbazepine is a less potent enzyme inducer than carbamazepine. Substitution of oxcarbazepine for carbamazepine is associated with increased levels of phenytoin and valproic acid, presumably because of reduced induction of hepatic enzymes. Oxcarbazepine does not induce the hepatic enzymes involved in its own degradation. Although oxcarbazepine does not appear to reduce the anticoagulant effect of warfarin, it does induce CYP3A and thus reduces plasma levels of steroid oral contraceptives. It has been approved for monotherapy or adjunct therapy for partial seizures in adults, as monotherapy for partial seizures in children ages 4-16, and as adjunctive therapy in children 2 years of age and older with epilepsy.

SUCCINIMIDES

Ethosuximide

Ethosuximide (ZARONTIN, others) is a primary agent for the treatment of absence seizures.

Structure-Activity Relationship. The structure-activity relationship of the succinimides is in accord with that for other anti-seizure classes. Methsuximide (CELONTIN) has phenyl substituents and is more active against maximal electroshock seizures. It is no longer in common use. Discussion of its properties can be found in previous editions of this book. Ethosuximide, with alkyl substituents, is the most active of the succinimides against seizures induced by pentylenetetrazol and is the most selective for absence seizures.

Pharmacological Effects. The most prominent characteristic of ethosuximide at nontoxic doses is protection against clonic motor seizures induced by pentylenetetrazol. By contrast, at nontoxic doses ethosuximide does not inhibit tonic hind limb extension of electroshock seizures or kindled seizures. This profile correlates with efficacy against absence seizures in humans.

Mechanism of Action. Ethosuximide reduces low threshold Ca^{2+} currents (T-type currents) in thalamic neurons (Coulter et al., 1989). The thalamus plays an important role in generation of 3-Hz spike-and-wave rhythms typical of absence seizures (Huguenard and McCormick, 2007). Neurons in the thalamus exhibit large-amplitude T-type currents that underlie bursts of action potentials and likely play an important role in thalamic oscillatory activity such as 3-Hz spike-and-wave activity. At clinically relevant concentrations, ethosuximide inhibits the T-type current, as is evident in voltage-clamp recordings of acutely isolated, ventrobasal thalamic neurons from rats and guinea pigs. Ethosuximide reduces this current without modifying the voltage dependence of steady-state inactivation or the time course of recovery from inactivation. By contrast, succinimide derivatives with convulsant properties do not inhibit this current. Ethosuximide does not inhibit sustained repetitive firing or enhance GABA responses at clinically relevant concentrations. Inhibition of T-type currents likely is the mechanism by which ethosuximide inhibits absence seizures.

Pharmacokinetic Properties. Absorption of ethosuximide appears to be complete, with peak concentrations in plasma within ~3 hours after a single oral dose. Ethosuximide is not significantly bound to plasma proteins; during long-term therapy, its concentration in the CSF is similar to that in plasma. The apparent volume of distribution averages 0.7 L/kg.

Approximately 25% of the drug is excreted unchanged in the urine. The remainder is metabolized by hepatic microsomal enzymes, but whether CYPs are responsible is unknown. The major metabolite, the hydroxyethyl derivative, accounts for ~40% of administered drug, is inactive, and is excreted as such and as the glucuronide in the urine. The plasma $t_{1/2}$ of ethosuximide averages between 40 and 50 hours in adults and ~30 hours in children.

Toxicity. The most common dose-related side effects are gastrointestinal complaints (nausea, vomiting, and anorexia) and CNS effects (drowsiness, lethargy, euphoria, dizziness, headache, and hiccough). Some tolerance to these effects develops. Parkinson-like symptoms and photophobia also have been reported. Restlessness, agitation, anxiety, aggressiveness, inability to concentrate, and other behavioral effects have occurred primarily in patients with a prior history of psychiatric disturbance.

Urticaria and other skin reactions, including Stevens-Johnson syndrome, as well as systemic lupus erythematosus, eosinophilia, leukopenia, thrombocytopenia, pancytopenia, and aplastic anemia also have been attributed to the drug. The leukopenia may be transient despite continuation of the drug, but several deaths have resulted from bone marrow depression. Renal or hepatic toxicity has not been reported.

Plasma Drug Concentrations. During long-term therapy, the plasma concentration of ethosuximide averages ~2 $\mu\text{g}/\text{mL}$ per daily dose of 1 mg/kg. A plasma concentration of 40-100 $\mu\text{g}/\text{mL}$ usually is required for satisfactory control of absence seizures.

Therapeutic Uses. Ethosuximide is effective against absence seizures but not tonic-clonic seizures.

An initial daily dose of 250 mg in children (3-6 years old) and 500 mg in older children and adults is increased by 250-mg increments at weekly intervals until seizures are adequately controlled or toxicity intervenes. Divided dosage is required occasionally to prevent nausea or drowsiness associated with once-daily dosing. The usual maintenance dose is 20 mg/kg per day. Increased caution is required if the daily dose exceeds 1500 mg in adults or 750-1000 mg in children. The therapeutic use of ethosuximide is discussed further at the end of the chapter.

VALPROIC ACID

The anti-seizure properties of valproic acid (DEPAKENE, others) were discovered serendipitously when it was employed as a vehicle for other compounds that were being screened for anti-seizure activity.

Chemistry. Valproic acid (*n*-dipropylacetic acid) is a simple branched-chain carboxylic acid. Certain other branched-chain carboxylic acids have potencies similar to that of valproic acid in antagonizing pentylenetetrazol-induced convulsions. However, increasing the number of carbon atoms to nine introduces marked sedative properties. Straight-chain carboxylic acids have little or no activity.

Pharmacological Effects. Valproic acid is strikingly different from phenytoin or ethosuximide in that it is effective in inhibiting seizures in a variety of models. Like phenytoin and carbamazepine, valproate inhibits tonic hind limb extension in maximal electroshock seizures and kindled seizures at nontoxic doses. Like ethosuximide, valproic acid at subtoxic doses inhibits clonic motor seizures induced by pentylenetetrazol. Its efficacy in diverse models parallels its efficacy against absence as well as partial and generalized tonic-clonic seizures in humans.

Mechanism of Action. Valproic acid produces effects on isolated neurons similar to those of phenytoin and ethosuximide (Table 21–2). At therapeutically relevant concentrations, valproate inhibits sustained repetitive firing induced by depolarization of mouse cortical or spinal cord neurons (McLean and Macdonald, 1986b). The action is similar to that of both phenytoin and carbamazepine and appears to be mediated by a prolonged recovery of voltage-activated Na⁺ channels from inactivation. Valproic acid does not modify neuronal responses to iontophoretically applied GABA. In neurons isolated from the nodose ganglion, valproate also produces small reductions of T-type Ca²⁺ currents (Kelly et al., 1990) at clinically relevant but slightly higher concentrations than those that limit sustained repetitive firing; this effect on T-type currents is similar to that of ethosuximide in thalamic neurons (Coulter et al., 1989). Together, these actions of limiting sustained repetitive firing and reducing T-type currents may contribute to the effectiveness of valproic acid against partial and tonic-clonic seizures and absence seizures, respectively.

Another potential mechanism that may contribute to valproate's anti-seizure actions involves metabolism of GABA. Although valproate has no effect on responses to GABA, it does increase the amount of GABA that can be recovered from the brain after the drug is administered to animals. *In vitro*, valproate can stimulate the activity of the GABA synthetic enzyme, glutamic acid decarboxylase, and inhibit GABA degradative enzymes, GABA transaminase and succinic semialdehyde dehydrogenase. Thus far it has been difficult to relate the increased GABA levels to the anti-seizure activity of valproate.

Pharmacokinetic Properties. Valproic acid is absorbed rapidly and completely after oral administration. Peak concentration in plasma is observed in 1–4 hours, although this can be delayed for several hours if the drug is administered in enteric-coated tablets or is ingested with meals.

The apparent volume of distribution for valproate is ~0.2 L/kg. Its extent of binding to plasma proteins is usually ~90%, but the

fraction bound is reduced as the total concentration of valproate is increased through the therapeutic range. Although concentrations of valproate in CSF suggest equilibration with free drug in the blood, there is evidence for carrier-mediated transport of valproate both into and out of the CSF.

The vast majority of valproate (95%) undergoes hepatic metabolism, with < 5% excreted unchanged in urine. Its hepatic metabolism occurs mainly by UGT enzymes and β -oxidation. Valproate is a substrate for CYP2C9 and CYP2C19, but metabolism by these enzymes accounts for a relatively minor portion of its elimination. Some of the drug's metabolites, notably 2-propyl-2-pentenoic acid and 2-propyl-4-pentenoic acid, are nearly as potent anti-seizure agents as the parent compound; however, only the former (2-en-valproic acid) accumulates in plasma and brain to a potentially significant extent. The $t_{1/2}$ of valproate is ~15 hours but is reduced in patients taking other anti-epileptic drugs.

Toxicity. The most common side effects are transient GI symptoms, including anorexia, nausea, and vomiting in ~16% of patients. Effects on the CNS include sedation, ataxia, and tremor; these symptoms occur infrequently and usually respond to a decrease in dosage. Rash, alopecia, and stimulation of appetite have been observed occasionally and weight gain has been seen with chronic valproic acid treatment in some patients. Valproic acid has several effects on hepatic function. Elevation of hepatic transaminases in plasma is observed in up to 40% of patients and often occurs asymptotically during the first several months of therapy.

A rare complication is a fulminant hepatitis that is frequently fatal (Dreifuss et al., 1989). Pathological examination reveals a microvesicular steatosis without evidence of inflammation or hypersensitivity reaction. Children below 2 years of age with other medical conditions who were given multiple anti-seizure agents were especially likely to suffer fatal hepatic injury. At the other extreme, there were no deaths reported for patients over the age of 10 years who received only valproate. Acute pancreatitis and hyperammonemia also have been frequently associated with the use of valproic acid. Valproic acid can also produce teratogenic effects such as neural tube defects.

Plasma Drug Concentrations. Valproate plasma concentrations associated with therapeutic effects are ~30–100 μ g/mL. However, there is a poor correlation between the plasma concentration and efficacy. There appears to be a threshold at ~30–50 μ g/mL; this is the concentration at which binding sites on plasma albumin begin to become saturated.

Drug Interactions. Valproate primarily inhibits the metabolism of drugs that are substrates for CYP2C9, including phenytoin and phenobarbital. Valproate also inhibits UGT and thus inhibits the metabolism of lamotrigine and lorazepam. A high proportion of valproate is bound to albumin, and the high molar concentrations of valproate in the clinical setting result in valproate's displacing phenytoin and other drugs from albumin. With respect to phenytoin in particular, valproate's inhibition of the drug's metabolism is exacerbated by

displacement of phenytoin from albumin. The concurrent administration of valproate and clonazepam has been associated with the development of absence status epilepticus; however, this complication appears to be rare.

Therapeutic Uses. Valproate is a broad-spectrum anti-seizure drug effective in the treatment of absence, myoclonic, partial, and tonic-clonic seizures. The initial daily dose usually is 15 mg/kg, increased at weekly intervals by 5-10 mg/kg per day to a maximum daily dose of 60 mg/kg. Divided doses should be given when the total daily dose exceeds 250 mg. The therapeutic uses of valproate in epilepsy are discussed further at the end of this chapter.

BENZODIAZEPINES

The benzodiazepines are used primarily as sedative-anti-anxiety drugs; their pharmacology is described in Chapters 14 and 17. Discussion here is limited to their use in the therapy of the epilepsies. A large number of benzodiazepines have broad anti-seizure properties, but only clonazepam (KLONOPIN, others) and clorazepate (TRANXENE, others) have been approved in the U.S. for the long-term treatment of certain types of seizures. Midazolam was designated an orphan drug in 2006 for intermittent treatment of bouts of increased seizure activity in refractory patients with epilepsy who are on stable regimens of anti-seizure drugs. Diazepam (VALIUM, DIASTAT; others) and lorazepam (ATIVAN, others) have well-defined roles in the management of status epilepticus. The structures of the benzodiazepines are shown in Chapter 17.

Anti-Seizure Properties. In animal models, inhibition of pentylenetetrazol-induced seizures by the benzodiazepines is much more prominent than is their modification of the maximal electroshock seizure pattern. Clonazepam is unusually potent in antagonizing the effects of pentylenetetrazol, but it is almost without action on seizures induced by maximal electroshock. Benzodiazepines, including clonazepam, suppress the spread of kindled seizures and generalized convulsions produced by stimulation of the amygdala, but do not abolish the abnormal discharge at the site of stimulation.

Mechanism of Action. The anti-seizure actions of the benzodiazepines, as well as other effects that occur at nonsedating doses, result in large part from their ability to enhance GABA-mediated synaptic inhibition. Molecular cloning and study of recombinant receptors have demonstrated that the benzodiazepine receptor is an integral part of the GABA_A receptor (Chapter 17). At therapeutically relevant concentrations, benzodiazepines act at subsets of GABA_A receptors and increase the frequency, but not duration, of openings at GABA-activated Cl⁻ channels (Twyman et al., 1989). At higher concentrations, diazepam and many other benzodiazepines can reduce sustained high-frequency firing of neurons, similar to the

effects of phenytoin, carbamazepine, and valproate. Although these concentrations correspond to concentrations achieved in patients during treatment of status epilepticus with diazepam, they are considerably higher than those associated with anti-seizure or anxiolytic effects in ambulatory patients.

Pharmacokinetic Properties. Benzodiazepines are well absorbed after oral administration, and concentrations in plasma are usually maximal within 1-4 hours. After intravenous administration, they are redistributed in a manner typical of that for highly lipid-soluble agents. Central effects develop promptly, but wane rapidly as the drugs move to other tissues. Diazepam is redistributed especially rapidly, with a $t_{1/2}$ of redistribution of ~1 hour. The extent of binding of benzodiazepines to plasma proteins correlates with lipid solubility, ranging from ~99% for diazepam to ~85% for clonazepam (Appendix II).

The major metabolite of diazepam, N-desmethyl-diazepam, is somewhat less active than the parent drug and may behave as a partial agonist. This metabolite also is produced by the rapid decarboxylation of clorazepate following its ingestion. Both diazepam and N-desmethyl-diazepam are slowly hydroxylated to other active metabolites, such as oxazepam. The $t_{1/2}$ of diazepam in plasma is between 1 and 2 days, while that of N-desmethyl-diazepam is ~60 hours. Clonazepam is metabolized principally by reduction of the nitro group to produce inactive 7-amino derivatives. Less than 1% of the drug is recovered unchanged in the urine. The $t_{1/2}$ of clonazepam in plasma is ~23 hours. Lorazepam is metabolized chiefly by conjugation with glucuronic acid; its $t_{1/2}$ in plasma is ~14 hours.

Toxicity. The principal side effects of long-term oral therapy with clonazepam are drowsiness and lethargy. These occur in ~50% of patients initially, but tolerance often develops with continued administration. Muscular incoordination and ataxia are less frequent. Although these symptoms usually can be kept to tolerable levels by reducing the dosage or the rate at which it is increased, they sometimes force drug discontinuation.

Other side effects include hypotonia, dysarthria, and dizziness. Behavioral disturbances, especially in children, can be very troublesome; these include aggression, hyperactivity, irritability, and difficulty in concentration. Both anorexia and hyperphagia have been reported. Increased salivary and bronchial secretions may cause difficulties in children. Seizures are sometimes exacerbated, and status epilepticus may be precipitated if the drug is discontinued abruptly. Other aspects of the toxicity of the benzodiazepines are discussed in Chapter 17. Cardiovascular and respiratory depression may occur after the intravenous administration of diazepam, clonazepam, or lorazepam, particularly if other anti-seizure agents or central depressants have been administered previously.

Plasma Drug Concentrations. Because tolerance affects the relationship between drug concentration and drug anti-seizure effect, plasma concentrations of benzodiazepines are of limited value.

Therapeutic Uses. Clonazepam is useful in the therapy of absence seizures as well as myoclonic seizures in children. However, tolerance to its anti-seizure effects usually develops after 1-6 months of administration, after which some patients will no longer respond to

clonazepam at any dosage. The initial dose of clonazepam for adults should not exceed 1.5 mg per day and for children 0.01-0.03 mg/kg per day. The dose-dependent side effects are reduced if two or three divided doses are given each day. The dose may be increased every 3 days in amounts of 0.25-0.5 mg per day in children and 0.5-1 mg per day in adults. The maximal recommended dose is 20 mg per day for adults and 0.2 mg/kg per day for children. Clonazepam intranasal spray is designated as an orphan drug for recurrent acute repetitive seizures.

While diazepam is an effective agent for treatment of status epilepticus, its short duration of action is a disadvantage, leading to the more frequent use of lorazepam. Although diazepam is not useful as an oral agent for the treatment of seizure disorders, clorazepate is effective in combination with certain other drugs in the treatment of partial seizures. The maximal initial dose of clorazepate is 22.5 mg per day in three portions for adults and children > 12 years and 15 mg per day in two divided doses in children 9-12 years of age. Clorazepate is not recommended for children under the age of 9.

OTHER ANTI-SEIZURE DRUGS

Gabapentin and Pregabalin

Gabapentin (NEURONTIN, others) and pregabalin (LYRICA) are anti-seizure drugs that consist of a GABA molecule covalently bound to a lipophilic cyclohexane ring or isobutane, respectively. Gabapentin was designed to be a centrally active GABA agonist, with its high lipid solubility aimed at facilitating its transfer across the blood-brain barrier. The structures of gabapentin and pregabalin are:

Pharmacological Effects and Mechanisms of Action. Gabapentin inhibits tonic hind limb extension in the electroshock seizure model. Interestingly, gabapentin also inhibits clonic seizures induced by pentylenetetrazol. Its efficacy in both these tests parallels that of valproic acid and distinguishes it from phenytoin and carbamazepine. Despite their design as GABA agonists, neither gabapentin nor pregabalin mimics GABA when iontophoretically applied to neurons in primary culture. These compounds bind with high affinity to a protein in cortical membranes with an amino acid sequence identical to that of the Ca^{2+} channel subunit $\alpha 2\delta$ -1 (Gee et al., 1996). It has been speculated that the anticonvulsant effects of gabapentin are mediated by $\alpha 2\delta$ -1 protein, but whether and how the binding of gabapentin to the $\alpha 2\delta$ -1 regulates neuronal excitability remains unclear. Pregabalin binding is reduced but not eliminated in mice carrying a mutation in the $\alpha 2\delta$ -1 protein (Field et al., 2006). Analgesic efficacy of pregabalin is eliminated in these mice; whether the anticonvulsant effects of pregabalin are also eliminated was not reported. It is unclear whether the anticonvulsant and analgesic effects of gabapentin and pregabalin are mediated by affecting Ca^{2+} currents and, if so, how.

Pharmacokinetics. Gabapentin and pregabalin are absorbed after oral administration and are not metabolized in humans. These compounds are not bound to plasma proteins and are excreted unchanged, mainly in the urine. Their half-lives, when used as monotherapy, approximate 6 hours. These compounds have no known interactions with other anti-seizure drugs.

Therapeutic Uses. Gabapentin and pregabalin are effective for partial seizures, with and without secondary generalization, when used in addition to other anti-seizure drugs.

Double-blind placebo-controlled trials of adults with refractory partial seizures demonstrated that addition of gabapentin or pregabalin to other anti-seizure drugs is superior to placebo (Sivenius et al., 1991; French et al., 2003). A double-blind study of gabapentin (900 or 1800 mg/day) monotherapy disclosed that gabapentin was equivalent to carbamazepine (600 mg/day) for newly diagnosed partial or generalized epilepsy (Chadwick et al., 1998). Gabapentin also is being used for the treatment of migraine, chronic pain, and bipolar disorder.

Gabapentin usually is effective in doses of 900-1800 mg daily in three doses, although 3600 mg may be required in some patients to achieve reasonable seizure control. Therapy usually is begun with a low dose (300 mg once on the first day), which is increased in daily increments of 300 mg until an effective dose is reached.

Toxicity. Overall, gabapentin is well tolerated with the most common adverse effects of somnolence, dizziness, ataxia, and fatigue. These effects usually are mild to moderate in severity but resolve within 2 weeks of onset during continued treatment. Gabapentin and pregabalin are listed in pregnancy category C.

Lamotrigine

Lamotrigine (LAMICTAL, others) is a phenyltriazine derivative initially developed as an antifolate agent based on the incorrect idea that reducing folate would effectively combat seizures. Structure-activity studies indicate that its effectiveness as an anti-seizure drug is unrelated to its antifolate properties (Macdonald and Greenfield, 1997).

Pharmacological Effects and Mechanisms of Action. Lamotrigine suppresses tonic hind limb extension in the maximal electroshock model and partial and secondarily generalized seizures in the kindling model, but does not inhibit clonic motor seizures induced by pentylenetetrazol. Lamotrigine blocks sustained repetitive firing of mouse spinal cord neurons and delays the recovery from inactivation of recombinant Na^{+} channels, mechanisms similar to those of phenytoin and carbamazepine (Xie et al., 1995). This may well

explain lamotrigine's actions on partial and secondarily generalized seizures. However, as mentioned in the subsequent "Therapeutic Use" section, lamotrigine is effective against a broader spectrum of seizures than phenytoin and carbamazepine, suggesting that lamotrigine may have actions in addition to regulating recovery from inactivation of Na⁺ channels. The mechanisms underlying its broad spectrum of actions are incompletely understood. One possibility involves lamotrigine's inhibition of glutamate release in rat cortical slices treated with veratridine, a Na⁺ channel activator, raising the possibility that lamotrigine inhibits synaptic release of glutamate by acting at Na⁺ channels themselves.

Pharmacokinetics. Lamotrigine is completely absorbed from the gastrointestinal tract and is metabolized primarily by glucuronidation. The plasma $t_{1/2}$ of a single dose is 24-30 hours. Administration of phenytoin, carbamazepine, or phenobarbital reduces the $t_{1/2}$ and plasma concentrations of lamotrigine. Conversely, addition of valproate markedly increases plasma concentrations of lamotrigine, likely by inhibiting glucuronidation. Addition of lamotrigine to valproic acid produces a reduction of valproate concentrations by ~25% over a few weeks. Concurrent use of lamotrigine and carbamazepine is associated with increases of the 10,11-epoxide of carbamazepine and clinical toxicity in some patients.

Therapeutic Use. Lamotrigine is useful for monotherapy and add-on therapy of partial and secondarily generalized tonic-clonic seizures in adults and Lennox-Gastaut syndrome in both children and adults. Lennox-Gastaut syndrome is a disorder of childhood characterized by multiple seizure types, mental retardation, and refractoriness to anti-seizure medication.

Lamotrigine monotherapy in newly diagnosed partial or generalized tonic-clonic seizures is equivalent to carbamazepine or phenytoin, monotherapy (Brodie et al., 1995; Steiner et al., 1999). A double-blind, placebo-controlled trial of addition of lamotrigine to existing anti-seizure drugs further demonstrated effectiveness of lamotrigine against tonic-clonic seizures and drop attacks in children with the Lennox-Gastaut syndrome (Motte et al., 1997). Lamotrigine was also found to be superior to placebo in a double-blind study of children with newly diagnosed absence epilepsy (Frank et al., 1999).

Patients who are already taking a hepatic enzyme-inducing anti-seizure drug (such as carbamazepine, phenytoin, phenobarbital, or primidone, but not valproate) should be given lamotrigine initially at 50 mg/day for 2 weeks. The dose is increased to 50 mg twice per day for 2 weeks and then increased in increments of 100 mg/day each week up to a maintenance dose of 300-500 mg/day divided into two doses. For patients taking valproate in addition to an enzyme-inducing anti-seizure drug, the initial dose should be 25 mg every other day for 2 weeks, followed by an increase to 25 mg/day for 2 weeks; the dose then can be increased by 25-50 mg/day every 1-2 weeks up to a maintenance dose of 100-150 mg/day divided into two doses.

Toxicity. The most common adverse effects are dizziness, ataxia, blurred or double vision, nausea, vomiting, and rash when lamotrigine was added to another anti-seizure drug. A few cases of Stevens-Johnson syndrome and disseminated intravascular coagulation have been reported. The incidence of serious rash in pediatric patients (~0.8%) is higher than in the adult population (0.3%).

Levetiracetam

Levetiracetam (KEPPRA, others) is a pyrrolidine, the racemically pure *S*-enantiomer of α -ethyl-2-oxo-1-pyrrolidineacetamide and is FDA-approved for adjunctive therapy for myoclonic, partial-onset, and primary generalized tonic-clonic seizures in adults and children as young as 4 years old.

Pharmacological Effects and Mechanism of Action. Levetiracetam exhibits a novel pharmacological profile insofar as it inhibits partial and secondarily generalized tonic-clonic seizures in the kindling model, yet is ineffective against maximum electroshock- and pentylenetetrazol-induced seizures, findings consistent with clinical effectiveness against partial and secondarily generalized tonic-clonic seizures. The mechanism by which levetiracetam exerts these anti-seizure effects is unknown. No evidence for an action on voltage-gated Na⁺ channels or either GABA- or glutamate-mediated synaptic transmission has emerged. The correlation between binding affinity of levetiracetam analogs and their potency toward audiogenic seizures suggests that a synaptic vesicle protein, SV2A, mediates the anticonvulsant effects of levetiracetam (Rogawski and Bazil, 2008). Uncertainty as to the function of SV2A limits insights into how binding of levetiracetam to SV2A might affect cellular function or neuronal excitability.

Pharmacokinetics. Levetiracetam is rapidly and almost completely absorbed after oral administration and is not bound to plasma proteins. Ninety-five percent of the drug and its inactive metabolite are excreted in the urine, 65% of which is unchanged drug; 24% of the drug is metabolized by hydrolysis of the acetamide group. It neither induces nor is a high-affinity substrate for CYP isoforms or glucuronidation enzymes and thus is devoid of known interactions with other anti-seizure drugs, oral contraceptives, or anticoagulants.

Therapeutic Use. Double-blind, placebo-controlled trials of adults with either refractory partial seizures or uncontrolled generalized tonic-clonic seizures associated with idiopathic generalized epilepsy revealed that addition of levetiracetam to other anti-seizure medications was superior to placebo. Levetiracetam also has efficacy as adjunctive therapy for refractory generalized myoclonic seizures (Andermann et al., 2005). Insufficient evidence is available about its use as monotherapy for partial or generalized epilepsy.

Toxicity. Levetiracetam is well tolerated. The most frequently reported adverse effects are somnolence, asthenia, and dizziness.

Tiagabine

Tiagabine (GABITRIL) is a derivative of nipecotic acid and approved by the FDA as adjunct therapy for partial seizures in adults.

Pharmacological Effects and Mechanism of Action. Tiagabine inhibits the GABA transporter, GAT-1, and thereby reduces GABA uptake into neurons and glia. In CA1 neurons of the hippocampus, tiagabine increases the duration of inhibitory synaptic currents, findings consistent with prolonging the effect of GABA at inhibitory synapses through reducing its reuptake by GAT-1. Tiagabine inhibits maximum electroshock seizures and both limbic and secondarily generalized tonic-clonic seizures in the kindling model, results suggestive of clinical efficacy against partial and tonic-clonic seizures. Paradoxically, tiagabine has been associated with the occurrence of seizures in patients without epilepsy and off-label use of the drug is discouraged.

Pharmacokinetics. Tiagabine is rapidly absorbed after oral administration, extensively bound to serum or plasma proteins, and metabolized mainly in the liver, predominantly by CYP3A. Its $t_{1/2}$ of ~8 hours is shortened by 2-3 hours when co-administered with hepatic enzyme-inducing drugs such as phenobarbital, phenytoin, or carbamazepine.

Therapeutic Use. Double-blind, placebo-controlled trials have established tiagabine's efficacy as add-on therapy of refractory partial seizures with or without secondary generalization. Its efficacy as monotherapy for newly diagnosed or refractory partial and generalized epilepsy has not been established.

Toxicity. The principal adverse effects include dizziness, somnolence, and tremor; they appear to be mild to moderate in severity and appear shortly after initiation of therapy. Tiagabine and other drugs that enhance effects of synaptically released GABA can facilitate spike-and-wave discharges in animal models of absence seizures. Case reports suggest that tiagabine treatment of patients with a history of spike-and-wave discharges causes exacerbations of their EEG abnormalities. Thus, tiagabine may be contraindicated in patients with generalized absence epilepsy.

Topiramate

Topiramate (TOPAMAX, others) is a sulfamate-substituted monosaccharide that is FDA-approved as initial monotherapy (in patients at least 10 years old) and as adjunctive therapy (for patients as young as 2 years of age) for partial-onset or primary generalized tonic-clonic seizures, for Lennox-Gastaut syndrome in patients 2 years of age and older, and for migraine headache prophylaxis in adults.

Pharmacological Effects and Mechanisms of Action. Topiramate reduces voltage-gated Na^+ currents in cerebellar granule cells and may act on the inactivated state of the channel similar to phenytoin. In addition, topiramate activates a hyperpolarizing K^+ current, enhances postsynaptic GABA_A -receptor currents, and limits activation of the AMPA-kainate-subtype(s) of glutamate receptor. Topiramate is a weak carbonic anhydrase inhibitor. Topiramate inhibits maximal electroshock and pentylenetetrazol-induced seizures as well as partial and secondarily generalized tonic-clonic seizures in the kindling model, findings predictive of a broad spectrum of anti-seizure actions clinically.

Pharmacokinetics. Topiramate is rapidly absorbed after oral administration, exhibits little (10-20%) binding to plasma proteins, and is mainly excreted unchanged in the urine. The remainder undergoes metabolism by hydroxylation, hydrolysis, and glucuronidation with no single metabolite accounting for > 5% of an oral dose. Its $t_{1/2}$ is ~1 day. Reduced estradiol plasma concentrations occur with concurrent topiramate, suggesting the need for higher doses of oral contraceptives when coadministered with topiramate.

Therapeutic Use. A double-blind study revealed topiramate to be equivalent to valproate and carbamazepine in children and adults with newly diagnosed partial and primary generalized epilepsy (Privitera et al., 2003). Additional studies disclosed topiramate to be effective as monotherapy for refractory partial epilepsy (Sachdeo et al., 1997) and refractory generalized tonic-clonic seizures (Biton et al., 1999). Topiramate also was found to be significantly more effective than placebo against both drop attacks and tonic-clonic seizures in patients with Lennox-Gastaut syndrome (Sachdeo et al., 1999).

Toxicity. Topiramate is well tolerated. The most common adverse effects are somnolence, fatigue, weight loss, and nervousness. It can precipitate renal calculi, which is most likely due to inhibition of carbonic anhydrase. Topiramate has been associated with cognitive impairment and patients may complain about a change in the taste of carbonated beverages.

Felbamate

Felbamate (FELBATOL) is a dicarbamate that was approved by the FDA for partial seizures in 1993. An association between felbamate and aplastic anemia in at least 10 cases resulted in a recommendation by the FDA and the manufacturer for the immediate withdrawal of most patients from treatment with this drug. Postmarketing experience revealed an association between felbamate exposure and liver failure.

602 Pharmacological Effects and Mechanisms of Action. Felbamate is effective in both the maximal electroshock and pentylenetetrazol seizure models. Clinically relevant concentrations of felbamate inhibit NMDA-evoked responses and potentiate GABA-evoked responses in whole-cell, voltage-clamp recordings of cultured rat hippocampal neurons (Rho et al., 1994). This dual action on excitatory and inhibitory transmitter responses may contribute to the wide spectrum of action of the drug in seizure models.

Therapeutic Use. An active control, randomized, double-blind protocol demonstrated the efficacy of felbamate in patients with poorly controlled partial and secondarily generalized seizures (Sachdeo et al., 1992). Felbamate also reduced seizures in patients with Lennox-Gastaut syndrome (Felbamate Study Group in Lennox-Gastaut Syndrome, 1993). The clinical efficacy of this compound, which inhibits responses to NMDA and potentiates those to GABA, underscores the potential value of additional anti-seizure agents with similar mechanisms of action.

Zonisamide

Zonisamide (ZONEGRAN, others) is a sulfonamide derivative that is FDA approved as adjunctive therapy of partial seizures in adults.

Pharmacological Effects and Mechanism of Action. Zonisamide inhibits the T-type Ca²⁺ currents. In addition, zonisamide inhibits the sustained, repetitive firing of spinal cord neurons, presumably by prolonging the inactivated state of voltage-gated Na⁺ channels in a manner similar to actions of phenytoin and carbamazepine.

Zonisamide inhibits tonic hind limb extension evoked by maximal electroshock and inhibits both partial and secondarily generalized seizures in the kindling model, results predictive of clinical effectiveness against partial and secondarily generalized tonic-clonic seizures. Zonisamide does not inhibit minimal clonic seizures induced by pentylenetetrazol, suggesting that the drug will not be effective clinically against myoclonic seizures.

Pharmacokinetics. Zonisamide is almost completely absorbed after oral administration, has a long $t_{1/2}$ (~63 hours), and is ~40% bound to plasma protein. Approximately 85% of an oral dose is excreted in the urine, principally as unmetabolized zonisamide and a glucuronide of sulfamoylacetyl phenol, which is a product of metabolism by CYP3A4. Phenobarbital, phenytoin, and carbamazepine decrease the plasma concentration/dose ratio of zonisamide, whereas lamotrigine increases this ratio. Conversely, zonisamide has little effect on the plasma concentrations of other anti-seizure drugs.

Therapeutic Use. Double-blind, placebo-controlled studies of patients with refractory partial seizures demonstrated that addition of zonisamide to other drugs was superior to placebo. There is insufficient evidence for its efficacy as monotherapy for newly diagnosed or refractory epilepsy.

Toxicity. Overall, zonisamide is well tolerated. The most common adverse effects include somnolence, ataxia, anorexia, nervousness,

and fatigue. Approximately 1% of individuals develop renal calculi during treatment with zonisamide, which may relate to its ability to inhibit carbonic anhydrase. Post-marketing experience indicates that zonisamide can cause metabolic acidosis in some patients. Patients with predisposing conditions (e.g., renal disease, severe respiratory disorders, diarrhea, surgery, ketogenic diet) may be at greater risk. The risk of zonisamide-induced metabolic acidosis also appears to be more frequent and severe in younger patients. Measurement of serum bicarbonate prior to initiating therapy and periodically thereafter, even in the absence of symptoms, is recommended.

Lacosamide

Lacosamide (VIMPAT) is a functionalized amino acid that was approved by the FDA in 2008 as adjunctive therapy for partial-onset seizures in patients 17 years of age and older. An injectable formulation is available for short term use when oral administration is not feasible.

Pharmacological Effects and Mechanism of Action. Lacosamide enhances slow inactivation of voltage-gated Na⁺ channels and limits sustained repetitive firing, the neuronal firing pattern characteristic of partial seizures. Lacosamide also binds collapsin response mediator protein 2 (crmp-2), a phosphoprotein involved in neuronal differentiation and axon outgrowth. Its anti-seizure mechanism of action is more likely mediated by its enhancing slow inactivation of Na⁺ channels.

Therapeutic Use. Double-blind, placebo-controlled studies of adults with refractory partial seizures demonstrated that addition of lacosamide to other drugs was superior to placebo.

Rufinamide

Rufinamide (BANZEL) is a triazole derivative structurally unrelated to other marketed anti-epileptic drugs. It was approved by the FDA in 2008 for adjunctive treatment of seizures associated with Lennox-Gastaut syndrome in children 4 years and older and adults.

Pharmacological Effects and Mechanism of Action. Rufinamide enhances slow inactivation of voltage gated Na⁺ channels and limits sustained repetitive firing, the firing pattern characteristic of partial seizures. Whether this is the mechanism by which rufinamide suppresses seizures is presently unclear.

Therapeutic Use. A double-blind, placebo-controlled study of children with Lennox-Gastaut syndrome demonstrated that rufinamide reduced tonic-atonic seizure frequency to a greater extent than placebo.

Vigabatrin

Vigabatrin (SABRIL) was approved by the FDA in 2009 as adjunctive therapy of refractory partial complex seizures in adults. In addition, vigabatrin is designated as an orphan drug for treatment of infantile spasms (described in the subsequent “Therapeutic Use” section). Due to progressive and permanent bilateral vision loss, vigabatrin must be reserved for patients who have failed several alternative therapies; its availability is restricted under the conditions of the SHARE special distribution program.

Pharmacological Effects and Mechanism of Action. Vigabatrin is a structural analog of GABA that irreversibly inhibits the major degradative enzyme for GABA, GABA-transaminase, thereby leading to increased concentrations of GABA in the brain. Its mechanism of action is thought to involve enhancement of GABA-mediated inhibition.

Therapeutic Use. A 2-week, randomized, single masked clinical trial of vigabatrin for infantile spasms in children < 2 years old revealed time- and dose-dependent increases in responders, evident as freedom from spasms for 7 consecutive days. The subset of children in whom infantile spasms were caused by tuberous sclerosis was particularly responsive to vigabatrin.

Acetazolamide

Acetazolamide, the prototype for the carbonic anhydrase inhibitors, is discussed in Chapter 25. Its anti-seizure actions have been discussed in previous editions of this textbook. Although it is sometimes effective against absence seizures, its usefulness is limited by the rapid development of tolerance. Adverse effects are minimal when it is used in moderate dosage for limited periods.

GENERAL PRINCIPLES AND CHOICE OF DRUGS FOR THE THERAPY OF THE EPILEPSIES

Early diagnosis and treatment of seizure disorders with a single appropriate agent offers the best prospect of achieving prolonged seizure-free periods with the lowest risk of toxicity. An attempt should be made to determine the cause of the epilepsy with the hope of discovering a

correctable lesion, either structural or metabolic. The drugs commonly used for distinct seizure types are listed in Table 21–1. The efficacy combined with the unwanted effects of a given drug determine which particular drug is optimal for a given patient.

The first decision to make is whether and when to initiate treatment (French and Pedley, 2008). For example, it may not be necessary to initiate anti-seizure therapy after an isolated tonic-clonic seizure in a healthy young adult who lacks a family history of epilepsy and who has a normal neurological exam, a normal EEG, and a normal brain MRI scan. The odds of seizure recurrence in the next year (15%) are similar to the risk of a drug reaction sufficiently severe to warrant discontinuation of medication (Bazil and Pedley, 1998). On the other hand, a similar seizure occurring in an individual with a positive family history of epilepsy, an abnormal neurological exam, an abnormal EEG, and an abnormal MRI carries a risk of recurrence approximating 60%, odds that favor initiation of therapy.

Unless extenuating circumstances such as status epilepticus exist, only monotherapy should be initiated. Initial dosing should target steady-state plasma drug concentrations within at least the lower portion of the range associated with clinical efficacy. At the same time the initial dose should be as low as possible to minimize dose-related adverse effects. Dosage is increased at appropriate intervals as required for control of seizures or as limited by toxicity. Such adjustment should be assisted by monitoring of drug concentrations in plasma. Compliance with a properly selected, single drug in maximal tolerated dosage results in complete control of seizures in ~50% of patients. If a seizure occurs despite optimal drug levels, the physician should assess the presence of potential precipitating factors such as sleep deprivation, a concurrent febrile illness, or drugs (e.g., large amounts of caffeine or over-the-counter medications that can lower the seizure threshold).

If compliance has been confirmed yet seizures persist, another drug should be substituted. Unless serious adverse effects of the drug dictate otherwise, dosage always should be reduced gradually to minimize risk of seizure recurrence. In the case of partial seizures in adults, the diversity of available drugs permits selection of a second drug that acts by a different mechanism (see Table 21–2). Among previously untreated patients, 47% became seizure free with the first drug and an additional 14% became seizure free with a second or third drug (Kwan and Brodie, 2000).

If therapy with a second single drug also is inadequate, combination therapy is warranted. This decision

should not be taken lightly, because most patients obtain optimal seizure control with fewest unwanted effects when taking a single drug. Nonetheless, some patients will not be controlled adequately without the simultaneous use of two or more anti-seizure agents. No properly controlled studies have systematically compared one particular drug combination with another. The chances of complete control with this approach are not high; Kwan and Brodie (2000), found that epilepsy was controlled by treatment with two drugs in only 3% of patients. It seems wise to select two drugs that act by distinct mechanisms (e.g., one that promotes Na⁺ channel inactivation and another that enhances GABA-mediated synaptic inhibition). Side effects of each drug and the potential drug interactions also should be considered. As specified in Table 21–3, many of these drugs induce expression of CYPs and thereby impact the metabolism of themselves and/or other drugs (Table 21–3).

Essential to optimal management of epilepsy is the filling out of a seizure chart by the patient or a relative. Frequent visits to the physician may be necessary early in the period of treatment, since hematological and other possible side effects may require a change in medication. Long-term follow-up with neurological examinations and possibly EEG and neuroimaging studies is appropriate. Most crucial for successful management is patient adherence to the drug regimen; noncompliance is the most frequent cause for failure of therapy with anti-seizure drugs.

Measurement of plasma drug concentration at appropriate intervals greatly facilitates the initial adjustment of dosage to minimize dose-related adverse effects without sacrificing seizure control. Periodic monitoring during maintenance therapy can also detect non-compliance. Knowledge of plasma drug concentrations can be especially helpful during multiple-drug therapy. If toxicity occurs, monitoring helps to identify the particular drug(s) responsible and can guide adjustment of dosage.

Duration of Therapy

Once initiated, anti-seizure drugs are typically continued for at least 2 years. Tapering and discontinuing therapy should be considered, if the patient is seizure free after 2 years.

Factors associated with high risk for recurrent seizures following discontinuation of therapy include EEG abnormalities, known structural lesions, abnormalities on neurological exam, and history of frequent seizures or medically refractory seizures prior to control. Conversely, factors associated with low risk for recurrent seizures include idiopathic epilepsy, normal EEG, onset in childhood, and seizures easily controlled with a single drug. The risk of

recurrent seizures ranges from 12-66% (French and Pedley, 2008). Typically 80% of recurrences will occur within 4 months of discontinuing therapy. The clinician and patient must weigh the risk of recurrent seizure and the associated potential deleterious consequences (e.g., loss of driving privileges) against the various implications of continuing medication including cost, unwanted effects, implications of diagnosis of epilepsy, etc. Medications should be tapered slowly over a period of several months.

Simple and Complex Partial and Secondly Generalized Tonic-Clonic Seizures

The efficacy and toxicity of carbamazepine, phenobarbital, and phenytoin for treatment of partial and secondarily generalized tonic-clonic seizures in adults have been examined in a double-blind prospective study (Mattson et al., 1985). Carbamazepine and phenytoin were the most effective agents. The choice between carbamazepine and phenytoin required assessment of toxic effects of each drug. Decreased libido and impotence were associated with all three drugs (carbamazepine 13%, phenobarbital 16%, and phenytoin 11%). In direct comparison with valproate, carbamazepine provided superior control of complex partial seizures (Mattson et al., 1992). With respect to adverse effects, carbamazepine was more commonly associated with skin rash, but valproate was more commonly associated with tremor and weight gain. Overall, the data demonstrated that carbamazepine and phenytoin are preferable for treatment of partial seizures, but phenobarbital and valproic acid are also efficacious.

Control of secondarily generalized tonic-clonic seizures did not differ significantly with carbamazepine, phenobarbital, or phenytoin (Mattson et al., 1985). Valproate was as effective as carbamazepine for control of secondarily generalized tonic-clonic seizures (Mattson et al., 1992). Since secondarily generalized tonic-clonic seizures usually coexist with partial seizures, these data indicate that among drugs introduced before 1990, carbamazepine and phenytoin are the first-line drugs for these conditions.

One key issue confronting the treating physician is choosing the optimal drug for initiating treatment in new onset epilepsy. At first glance, this issue may appear unimportant because ~50% of newly diagnosed patients become seizure free with the first drug, whether old or new drugs are used (Kwan and Brodie, 2000). However, responsive patients typically receive the initial drug for several years, underscoring the importance of proper drug selection. Among the drugs available before 1990, phenytoin, carbamazepine, and phenobarbital induce hepatic CYPs, thereby complicating use of multiple anti-seizure drugs as well as impacting metabolism of oral contraceptives, warfarin, and many other drugs. These drugs also enhance metabolism of endogenous compounds including gonadal steroids and vitamin D, potentially impacting reproductive function and bone density. By contrast, most of the newer drugs have little if any effect on the CYPs. Factors arguing against use of recently introduced drugs include higher costs and less clinical experience with the compounds.

Ideally, a prospective study would systematically compare newly introduced anti-seizure drugs with drugs available before 1990 in a study design adjusting dose as needed and observing responses for extended periods of time (e.g., 2 years or more), in much the same manner as that used when comparing the older anti-seizure drugs with one another as described earlier (Mattson et al., 1985).

Unfortunately, such a study has not been performed. Many of the studies referenced in description of newer drugs did compare a new with an older anti-seizure drug, but study design did not permit declaring a clearly superior drug; moreover, differences in study design and patient populations preclude comparing a new drug with multiple older drugs or with other new drugs. The use of recently introduced anti-seizure drugs for newly diagnosed epilepsy was analyzed by subcommittees of the American Academy of Neurology and the American Epilepsy Society (French et al., 2004a; French et al., 2004b); the authors concluded that available evidence supported the use of gabapentin, lamotrigine, and topiramate for newly diagnosed partial or mixed seizure disorders. None of these drugs, however, has been approved by the FDA for either of these indications. Insufficient evidence was available on the remaining newly introduced drugs to permit meaningful assessment of their effectiveness for this indication.

Absence Seizures

Ethosuximide and valproate are considered equally effective in the treatment of absence seizures (Mikati and Browne, 1988). Between 50% and 75% of newly diagnosed patients are free of seizures following therapy with either drug. If tonic-clonic seizures are present or emerge during therapy, valproate is the agent of first choice. French and others concluded that available evidence indicates that lamotrigine is also effective for newly diagnosed absence epilepsy despite the fact that lamotrigine is not approved for this indication by the FDA.

Myoclonic Seizures

Valproic acid is the drug of choice for myoclonic seizures in the syndrome of juvenile myoclonic epilepsy, in which myoclonic seizures often coexist with tonic-clonic and absence seizures. Levetiracetam also has demonstrated efficacy as adjunctive therapy for refractory generalized myoclonic seizures.

Febrile Convulsions

Two to four percent of children experience a convulsion associated with a febrile illness. From 25-33% of these children will have another febrile convulsion. Only 2-3% become epileptic in later years, a 6-fold increase in risk compared with the general population. Several factors are associated with an increased risk of developing epilepsy: preexisting neurological disorder or developmental delay, a family history of epilepsy, or a complicated febrile seizure (i.e., the febrile seizure lasted > 15 minutes, was one-sided, or was followed by a second seizure in the same day). If all of these risk factors are present, the risk of developing epilepsy is ~10%.

The increased risk of developing epilepsy or other neurological sequelae led many physicians to prescribe anti-seizure drugs prophylactically after a febrile seizure. Uncertainties regarding the efficacy of prophylaxis for reducing epilepsy combined with substantial side effects of phenobarbital prophylaxis (Farwell et al., 1990) argue against the use of chronic therapy for prophylactic purposes (Freeman, 1992). For children at high risk of developing recurrent febrile seizures and epilepsy, rectally administered diazepam at the time of fever may prevent recurrent seizures and avoid side effects of chronic therapy.

Seizures in Infants and Young Children

Infantile spasms with *hypsarrhythmia* (abnormal inter-ictal high amplitude slow waves and multifocal asynchronous spikes on EEG)

are refractory to the usual anti-seizure agents. Corticotropin or the glucocorticoids are commonly used and repository corticotropin (H.P. ACTHAR GEL) was designated as an orphan drug for this purpose in 2003. A randomized study found vigabatrin (γ -vinyl GABA; SABRIL) to be efficacious in comparison to placebo (Appleton et al., 1999). Constriction of visual fields has been reported in a high percentage of patients treated with vigabatrin (Miller et al., 1999). The potential for progressive and permanent vision loss has resulted in vigabatrin being labeled with a black-box warning and marketed under a restrictive distribution program. The drug received orphan drug status for the treatment of infantile spasms in the U.S. in 2000 (and was FDA-approved in 2009 as adjunctive therapy for adults with refractory complex partial seizures). Ganaxolone also has been designated as an orphan drug since 1994 for the treatment of infantile spasms and completed a phase II clinical trial for uncontrolled partial-onset seizures in adults in 2009.

The Lennox-Gastaut syndrome is a severe form of epilepsy which usually begins in childhood and is characterized by cognitive impairments and multiple types of seizures including tonic-clonic, tonic, atonic, myoclonic, and atypical absence seizures. Addition of lamotrigine to other anti-seizure drugs resulted in improved seizure control in comparison to placebo in a double-blind trial (Motte et al., 1997), demonstrating lamotrigine to be an effective and well-tolerated drug for this treatment-resistant form of epilepsy. Felbamate also was found to be effective for seizures in this syndrome, but the occasional occurrence of aplastic anemia and hepatic failure have limited its use (French et al., 1999). Topiramate has also been demonstrated to be effective for Lennox-Gastaut syndrome (Sachdeo et al., 1999).

Status Epilepticus and Other Convulsive Emergencies

Status epilepticus is a neurological emergency. Mortality for adults approximates 20% (Lowenstein and Alldredge, 1998). The goal of treatment is rapid termination of behavioral and electrical seizure activity; the longer the episode of status epilepticus is untreated, the more difficult it is to control and the greater the risk of permanent brain damage. Critical to the management is a clear plan, prompt treatment with effective drugs in adequate doses, and attention to hypoventilation and hypotension. Since hypoventilation may result from high doses of drugs used for treatment, it may be necessary to assist respiration temporarily. Drugs should be administered by the intravenous route only. Because of slow and unreliable absorption, the intramuscular route has no place in treatment of status epilepticus. To assess the optimal initial drug regimen, a double-blind, multicenter trial compared four intravenous treatments: diazepam followed by phenytoin; lorazepam; phenobarbital; and phenytoin alone (Treiman et al., 1998). The treatments had similar efficacies, with success rates ranging from 44-65%. Lorazepam alone was significantly better than phenytoin alone. No significant differences were found with respect to recurrences or adverse reactions.

Anti-Seizure Therapy and Pregnancy

Use of anti-seizure drugs has diverse implications of great importance for the health of women. Issues include interactions with oral contraceptives, potential teratogenic effects, and effects on vitamin K metabolism in pregnant women (Pack, 2006). Guidelines for the care

The effectiveness of oral contraceptives appears to be reduced by concomitant use of anti-seizure drugs. The failure rate of oral contraceptives is 3.1/100 years in women receiving anti-seizure drugs compared to a rate of 0.7/100 years in non-epileptic women. One attractive explanation of the increased failure rate is the increased rate of oral contraceptive metabolism caused by anti-seizure drugs that induce hepatic enzymes (Table 21–2); particular caution is needed with anti-seizure drugs that induce CYP3A4.

Teratogenicity. Epidemiological evidence suggests that anti-seizure drugs have teratogenic effects (Pack, 2006). These teratogenic effects add to the deleterious consequences of oral contraceptive failure. Infants of epileptic mothers are at 2-fold greater risk of major congenital malformations than offspring of non-epileptic mothers (4–8% compared to 2–4%). These malformations include congenital heart defects, neural tube defects, cleft lip, cleft palate, and others. Inferring causality from the associations found in large epidemiological studies with many uncontrolled variables can be hazardous, but a causal role for anti-seizure drugs is suggested by association of congenital defects with higher concentrations of a drug or with polytherapy compared to monotherapy. Phenytoin, carbamazepine, valproate, lamotrigine, and phenobarbital all have been associated with teratogenic effects. Newer anti-seizure drugs have teratogenic effects in animals but whether such effects occur in humans is yet uncertain. One consideration for a woman with epilepsy who wishes to become pregnant is a trial free of anti-seizure drug; monotherapy with careful attention to drug levels is another alternative. Polytherapy with toxic levels should be avoided. Folate supplementation (0.4 mg/day) has been recommended by the U.S. Public Health Service for all women of childbearing age to reduce the likelihood of neural tube defects, and this is appropriate for epileptic women as well.

Anti-seizure drugs that induce CYPs have been associated with vitamin K deficiency in the newborn, which can result in a coagulopathy and intracerebral hemorrhage. Treatment with vitamin K₁, 10 mg/day during the last month of gestation, has been recommended for prophylaxis.

chapter

Treatment of Central Nervous System Degenerative Disorders

David G. Standaert
and Erik D. Roberson

Neurodegenerative disorders are characterized by progressive and irreversible loss of neurons from specific regions of the brain. Prototypical neurodegenerative disorders include Parkinson disease (PD) and Huntington's disease (HD), where loss of neurons from structures of the basal ganglia results in abnormalities in the control of movement; Alzheimer's disease (AD), where the loss of hippocampal and cortical neurons leads to impairment of memory and cognitive ability; and amyotrophic lateral sclerosis (ALS), where muscular weakness results from the degeneration of spinal, bulbar, and cortical motor neurons.

As a group, these disorders are relatively common and represent a substantial medical and societal problem. They are primarily disorders of later life, developing in individuals who are neurologically normal, although childhood-onset forms of each of the disorders are recognized. PD is observed in more than 1% of individuals over the age of 65 (Tanner, 1992), whereas AD affects as many as 10% of the same population (Evans et al., 1989). HD, which is a genetically determined autosomal dominant disorder, is less frequent in the population as a whole but affects, on average, 50% of each generation in families carrying the gene. ALS also is relatively rare but often leads rapidly to disability and death (Kurtzke, 1982).

Currently available therapies for neurodegenerative disorders alleviate the disease symptoms but do not alter the underlying neurodegenerative process. Symptomatic treatment for PD, where the neurochemical deficit produced by the disease is well defined, is, in general, relatively successful, and a number of effective agents are available. The available symptomatic treatments for AD, HD, and ALS are much more limited in

effectiveness. On the horizon are pharmacological treatments aimed at preventing or retarding progression of neurodegeneration. A wide range of such disease-modifying approaches hold the promise to transform the approach to both the diagnosis and the treatment of neurodegenerative disorders.

SELECTIVE VULNERABILITY AND NEUROPROTECTIVE STRATEGIES

Selective Vulnerability. A striking feature of neurodegenerative disorders is the exquisite specificity of the disease processes for particular types of neurons. For example, in PD there is extensive destruction of the dopaminergic neurons of the substantia nigra, whereas neurons in the cortex and many other areas of the brain are unaffected. In contrast, neural injury in AD is most severe in the hippocampus and neocortex, and even within the cortex, the loss of neurons is not uniform but varies dramatically in different functional regions (Arnold et al., 1991). Even more striking is the observation that in HD the mutant gene responsible for the disorder is expressed throughout the brain and in many other organs, yet the pathological changes are most prominent in the neostriatum (Landwehrmeyer et al., 1995). In ALS, there is loss of spinal motor neurons and the cortical neurons that provide their descending input (Tandan and Bradley, 1985). The diversity of these patterns of neural degeneration suggests that the process of neural injury results from the interaction of genetic and environmental influences with the intrinsic physiological characteristics of the affected populations of neurons. The intrinsic factors may include susceptibility to

610 excitotoxic injury, regional variation in capacity for oxidative metabolism, and the production of toxic free radicals as by-products of cellular metabolism. New neuroprotective agents may target the factors that convey selective vulnerability.

Genetics and Environment. Each of the major neurodegenerative disorders may be familial in nature. HD is exclusively familial; it is transmitted by autosomal dominant inheritance, and the molecular mechanism of the genetic defect has been defined. Nevertheless, environmental factors importantly influence the age of onset and rate of progression of HD symptoms. PD, AD, and ALS are mostly sporadic without clear pattern of inheritance. But for each there are well-recognized genetic forms. For example, there are both dominant (*α-synuclein*, *LRRK2*) and recessive (*parkin*, *DJ-1*, *PINK1*) gene mutations that may give rise to PD (Farrer, 2006). In AD, mutations in the genes coding for the amyloid precursor protein (APP) and proteins known as the presenilins (involved in APP processing) lead to inherited forms of the disease (Selkoe and Podlisny, 2002). Mutations in the gene coding for copper-zinc superoxide dismutase (*SOD1*) account for about 2% of the cases of adult-onset ALS (Boillée et al., 2006). Several other less common mutations have also been described.

In addition to these monogenic forms of neurodegenerative disease, there are also genetic risk factors that influence the probability of disease onset and modify the phenotype. For example, the apolipoprotein E (apo E) genotype constitutes an important risk factor for AD. Three distinct isoforms of this protein exist. Although all isoforms carry out their primary role in lipid metabolism equally well, individuals who are homozygous for the apoE4 allele (“4/4”) have a much higher lifetime risk of AD than do those homozygous for the apoE2 allele (“2/2”). The mechanism by which the apoE4 protein increases the risk of AD is not exactly known. ApoE4 probably has multiple effects, some of which are mediated through altering β -amyloid (A β) aggregation or processing, and some of which that are A β -independent (Mahley et al., 2006).

Environmental factors including infectious agents, environmental toxins, and acquired brain injury have been proposed in the etiology of neurodegenerative disorders. The role of infection is best documented in the cases of PD that developed following the epidemic of encephalitis lethargica (Von Economo’s encephalitis) in the early part of the 20th century. Most contemporary cases of PD are not preceded by encephalitis, and there is no convincing evidence for an infectious contribution to HD, AD, or ALS. Traumatic brain injury has been suggested as a trigger for neurodegenerative disorders, and in the case of AD there is some evidence to support this view (Cummins et al., 1998). At least one toxin, *N*-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), can induce a condition closely resembling PD (Langston et al., 1983). More recently, evidence has linked pesticide exposure with PD (Costello et al., 2009).

Exposure of soldiers to neurotoxic chemicals has been implicated in ALS (as part of “Gulf War syndrome”) (Golomb, 2008). While these examples illustrate the potential of environmental factors to influence neurodegenerative disease, it is clear that the causes identified so far are too few to account for more than a small minority of the cases. Further progress in understanding the causes of neurodegenerative disorders will require a deeper understanding of the interactions between genetic predisposition and environmental factors, an area that is just beginning to be explored.

Common Cellular Mechanisms of Neurodegeneration. Despite their varied phenotypes, the neurodegenerative disorders share some common features. For example, misfolded and aggregated proteins are found in every major neurodegenerative disorder: alpha-synuclein, in PD; amyloid- β (A β) and tau in AD; huntingtin in HD; and SOD and TDP-43 in ALS. The accumulation of misfolded proteins may result from either genetic mutations producing abnormal structure, or from impaired cellular clearance. Age-related decline in the ability to clear misfolded proteins may be an important predisposing factor, and strategies to augment the clearance of misfolded proteins are being studied as potential therapies.

The term *excitotoxicity* describes the neural injury that results from the presence of excess glutamate in the brain. Glutamate is used as a neurotransmitter by many different neural systems and is believed to mediate most excitatory synaptic transmission in the mammalian brain (see Table 14–3). Although glutamate is required for normal brain function, the presence of excessive amounts of glutamate can lead to excitotoxic cell death (see Figure 14–13). The destructive effects of glutamate are mediated by glutamate receptors, particularly those of the *N*-methyl-D-aspartate (NMDA) type. Excitotoxic injury contributes to the neuronal death that occurs in acute processes such as stroke and head trauma (Choi and Rothman, 1990). The role of excitotoxicity is less certain in the chronic neurodegenerative disorders; nevertheless, regional and cellular differences in susceptibility to excitotoxic injury, conveyed, e.g., by differences in types of glutamate receptors, may contribute to selective vulnerability. This has led to the development of glutamate antagonists as neuroprotective therapies, with two such agents (memantine and riluzole, described later) currently in clinical use.

Aging is associated with a progressive impairment in the capacity of neurons for oxidative metabolism, perhaps in part because of a progressive accumulation of mutations in the mitochondrial genome. A consequence of impaired oxidative capacities is the production of reactive compounds such as hydrogen peroxide and oxygen radicals. Unchecked, these reactive species can lead to DNA damage, peroxidation of membrane lipids, and neuronal death. This has led to pursuit of drugs that can enhance cellular metabolism

(such as the mitochondrial cofactor coenzyme Q₁₀) and anti-oxidant strategies as treatments to prevent or retard degenerative diseases (Beal, 2005).

Parkinson Disease (PD)

Clinical Overview. Parkinsonism is a clinical syndrome consisting of four cardinal features:

- bradykinesia (slowness and poverty of movement)
- muscular rigidity
- resting tremor (which usually abates during voluntary movement)
- an impairment of postural balance leading to disturbances of gait and falling

The most common form of parkinsonism is idiopathic PD, first described by James Parkinson in 1817 as *paralysis agitans*, or the “shaking palsy.” The pathological hallmark of PD is the loss of the pigmented, dopaminergic neurons of the substantia nigra pars compacta, with the appearance of intracellular inclusions known as *Lewy bodies*. Progressive loss of dopamine (DA) containing neurons is a feature of normal aging; however, most people do not lose the 70-80% of dopaminergic neurons required to cause symptomatic PD. Without treatment, PD progresses over 5-10 years to a rigid, akinetic state in which patients are incapable of caring for themselves. Death frequently results from complications of immobility, including aspiration pneumonia or pulmonary embolism. The availability of effective pharmacological treatment has radically altered the prognosis of PD; in most cases, good functional mobility can be maintained for many years. Life expectancy of adequately treated patients is increased substantially, but overall mortality remains higher than that of the general population. In addition, while DA neuron loss is the most prominent feature of the disease, the disorder affects a wide range of other brain structures, including the brainstem, hippocampus, and cerebral cortex (Braak and Del Tredici, 2008). This pathology is likely responsible for the “non-motor” features of PD, which include sleep disorders, depression, and memory impairment. As treatments for the motor features have improved, these non-motor aspects have become important sources of disability for patients (Langston, 2006).

It is important to recognize that several disorders other than idiopathic PD also may produce parkinsonism, including some relatively rare neurodegenerative disorders, stroke, and intoxication with DA-receptor antagonists. Drugs that may cause parkinsonism include antipsychotics such as haloperidol and thiorazine

(Chapter 16) and anti-emetics such as prochlorperazine and metoclopramide (Chapter 46). Although a complete discussion of the clinical diagnosis of parkinsonism exceeds the scope of this chapter, the distinction between idiopathic PD and other causes of parkinsonism is important because parkinsonism arising from other causes usually is refractory to all forms of treatment.

Pathophysiology. The dopaminergic deficit in PD arises from a loss of the neurons in the substantia nigra pars compacta that provide innervation to the striatum (caudate and putamen). The current understanding of the pathophysiology of PD is based on the finding that the striatal DA content is reduced in excess of 80%. This paralleled the loss of neurons from the substantia nigra, suggesting that replacement of DA could restore function (Cotzias et al., 1969; Hornykiewicz, 1973). These fundamental observations led to an extensive investigative effort to understand the metabolism and actions of DA and to learn how a deficit in DA gives rise to the clinical features of PD. We now have a model of the function of the basal ganglia that, while incomplete, is still useful.

Dopamine Synthesis, Metabolism, and Receptors. DA, a catecholamine, is synthesized in the terminals of dopaminergic neurons from tyrosine and stored, released, and metabolized by processes described in Chapter 13 and summarized in Figure 22–1. The actions of DA in the brain are mediated by a family of DA-receptor proteins. Two types of DA receptors were identified in the mammalian brain using pharmacological techniques: D₁ receptors, which stimulate the synthesis of the intracellular second messenger cyclic AMP; and D₂ receptors, which inhibit cyclic AMP synthesis as well as suppress Ca²⁺ currents and activate receptor-operated K⁺ currents. More recently, genetic studies revealed at least five distinct DA receptors (D₁-D₅) (Chapter 13). All the DA receptors are G protein-coupled receptors (GPCRs) (Chapter 3). The D₁ and D₅ proteins have a long intracellular carboxy-terminal tail and are members of the class defined pharmacologically as D₁; they stimulate the formation of cyclic AMP and phosphatidylinositol hydrolysis. The D₂, D₃, and D₄ receptors share a large third intracellular loop and are of the D₂ class. They decrease cyclic AMP formation and modulate K⁺ and Ca²⁺ currents. Each of the five DA receptor proteins has a distinct anatomical pattern of expression in the brain. The D₁ and D₂ proteins are abundant in the striatum and are the most important receptor sites with regard to the causes and treatment of PD. The D₄ and D₅ proteins are largely extrastriatal, whereas D₃ expression is low in the caudate and putamen but more abundant in the nucleus accumbens and olfactory tubercle.

Neural Mechanism of Parkinsonism. Considerable effort has been devoted to understanding how the loss of dopaminergic input to the neurons of the neostriatum gives rise to the clinical features of PD (for review, see Albin et al., 1989; Mink and Thach, 1993; and Wichmann and DeLong, 1993). The basal ganglia can be viewed as a modulatory side loop that regulates the flow of information from the cerebral cortex to the motor neurons of the spinal cord (Figure 22–2). The neostriatum is the principal input structure of the basal ganglia and receives excitatory glutamatergic input from many areas of the cortex. Most neurons within the striatum are projection neurons that innervate other basal ganglia structures. A small but important

Figure 22–1. Dopaminergic nerve terminal. Dopamine (DA) is synthesized from tyrosine in the nerve terminal by the sequential actions of tyrosine hydroxylase (TH) and aromatic amino acid decarboxylase (AADC). DA is sequestered by VMAT2 in storage granules and released by exocytosis. Synaptic DA activates presynaptic autoreceptors and postsynaptic D1 and D2 receptors. Synaptic DA may be taken up into the neuron via the DA and NE transporters (DAT, NET), or removed by postsynaptic uptake via OCT3 transporters. Cytosolic DA is subject to degradation by monoamine oxidase (MAO) and aldehyde dehydrogenase (ALDH) in the neuron, and by catechol-O-methyl transferase (COMT) and MAO/ALDH in non-neuronal cells; the final metabolic product is homovanillic acid (HVA). See structures in Figure 22-4. PH, phenylalanine hydroxylase.

subgroup of striatal neurons consists of interneurons that connect neurons within the striatum but do not project beyond its borders. Acetylcholine (ACh) and neuropeptides are used as transmitters by these striatal interneurons.

The outflow of the striatum proceeds along two distinct routes, termed the *direct* and *indirect pathways*. The direct pathway is formed by neurons in the striatum that project directly to the output stages of the basal ganglia, the substantia nigra pars reticulata (SNpr) and the globus pallidus interna (GPi); these, in turn, relay to the ventroanterior and ventrolateral thalamus, which provides excitatory input to the cortex. The neurotransmitter of both links of the direct pathway is γ -aminobutyric acid (GABA), which is inhibitory, so that the net effect

of stimulation of the direct pathway at the level of the striatum is to increase the excitatory outflow from the thalamus to the cortex. The indirect pathway is composed of striatal neurons that project to the globus pallidus externa (GPe). This structure, in turn, innervates the subthalamic nucleus (STN), which provides outflow to the SNpr and GPi output stage. As in the direct pathway, the first two links—the projections from striatum to GPe and GPe to STN—use the inhibitory transmitter GABA; however, the final link—the projection from STN to SNpr and GPi—is an excitatory glutamatergic pathway. Thus, the net effect of stimulating the indirect pathway at the level of the striatum is to reduce the excitatory outflow from the thalamus to the cerebral cortex.

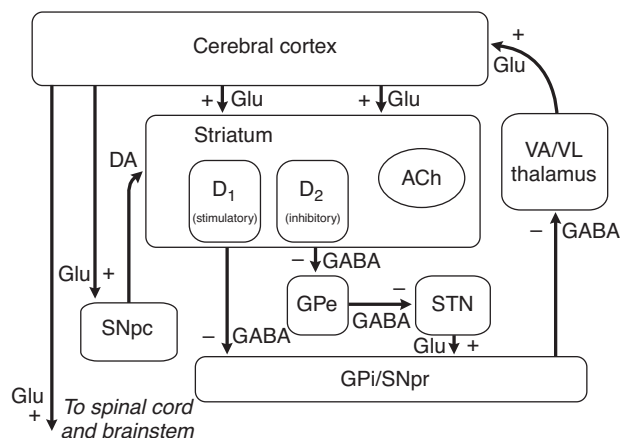

Figure 22–2. Schematic wiring diagram of the basal ganglia. The striatum is the principal input structure of the basal ganglia and receives excitatory glutamatergic input from many areas of cerebral cortex. The striatum contains projection neurons expressing predominantly D₁ or D₂ dopamine receptors, as well as interneurons that use ACh as a neurotransmitter. Outflow from the striatum proceeds along two routes. The direct pathway, from the striatum to the substantia nigra pars reticulata (SNpr) and globus pallidus interna (GPI), uses the inhibitory transmitter GABA. The indirect pathway, from the striatum through the globus pallidus externa (GPe) and the subthalamic nucleus (STN) to the SNpr and GPI, consists of two inhibitory GABAergic links and one excitatory glutamatergic projection (Glu). The substantia nigra pars compacta (SNpc) provides dopaminergic innervation to the striatal neurons, giving rise to both the direct and indirect pathways, and regulates the relative activity of these two paths. The SNpr and GPI are the output structures of the basal ganglia and provide feedback to the cerebral cortex through the ventroanterior and ventrolateral nuclei of the thalamus (VA/VL).

The key feature of this model of basal ganglia function, which accounts for the symptoms observed in PD as a result of loss of dopaminergic neurons, is the differential effect of DA on the direct and indirect pathways (Figure 22–3). The dopaminergic neurons of the substantia nigra pars compacta (SNpc) innervate all parts of the striatum; however, the target striatal neurons express distinct types of DA receptors. The striatal neurons giving rise to the direct pathway express primarily the *excitatory* D₁ dopamine receptor protein, whereas the striatal neurons forming the indirect pathway express primarily the *inhibitory* D₂ type. Thus, DA released in the striatum tends to increase the activity of the direct pathway and reduce the activity of the indirect pathway, whereas the depletion that occurs in PD has the opposite effect. The net effect of the reduced dopaminergic input in PD is to increase markedly the inhibitory outflow from the SNpr and GPI to the thalamus and reduce excitation of the motor cortex.

There are several limitations of this model of basal ganglia function (Parent and Cicchetti, 1998): The anatomical connections are considerably more complex than envisioned originally. In addition, many of the pathways involved use not just one, but several

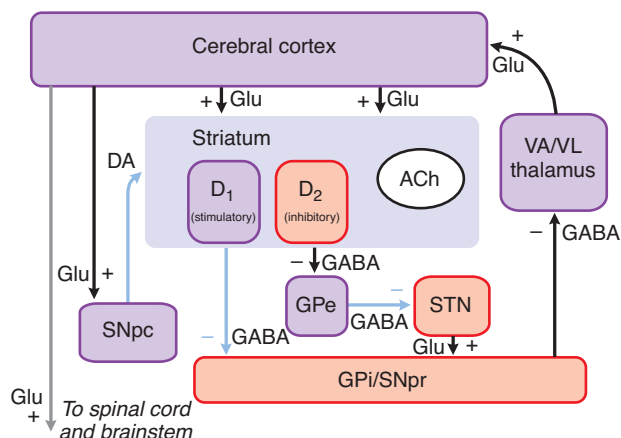

Figure 22–3. The basal ganglia in Parkinson disease. The primary defect is destruction of the dopaminergic neurons of the SNpc. The striatal neurons that form the direct pathway from the striatum to the SNpr and GPI express primarily the *excitatory* D₁ DA receptor, whereas the striatal neurons that project to the GPe and form the indirect pathway express the *inhibitory* D₂ dopamine receptor. Thus, loss of the dopaminergic input to the striatum has a differential effect on the two outflow pathways; the direct pathway to the SNpr and GPI is less active (*structures in purple*), whereas the activity in the indirect pathway is increased (*structures in red*). The net effect is that neurons in the SNpr and GPI become more active. This leads to increased inhibition of the VA/VL thalamus and reduced excitatory input to the cortex. Light blue lines indicate primary pathways with reduced activity. (See legend to Figure 22–2 for definitions of anatomical abbreviations.)

neurotransmitters. For example, the neuropeptides substance P and dynorphin are found predominantly in striatal neurons making up the direct pathway, whereas most of the indirect pathway neurons express enkephalin. These transmitters are expected to have slow modulatory effects on signaling, in contrast to the rapid effects of glutamate and GABA, but the functional significance of these modulatory effects remains unclear. Nevertheless, the model is useful and has important implications for the rational design and use of pharmacological agents in PD. First, it suggests that to restore the balance of the system through stimulation of DA receptors, the complementary effect of actions at both D₁ and D₂ receptors, as well as the possibility of adverse effects that may be mediated by D₃, D₄, or D₅ receptors, must be considered. Second, it explains why replacement of DA is not the only approach to the treatment of PD. Drugs that inhibit cholinergic receptors have long been used for treatment of parkinsonism. Although their mechanisms of action are not completely understood, their effect is likely mediated at the level of the striatal projection neurons, which normally receive cholinergic input from striatal cholinergic interneurons. Only few clinically useful drugs for parkinsonism are presently available based on actions through GABA and glutamate receptors, even though both have crucial roles in the circuitry of the basal ganglia. However, they represent a promising avenue for drug development (Hallet and Standaert, 2004).

Treatment of Parkinson Disease

Commonly used medications for the treatment of PD are summarized in Table 22–1.

Levodopa. Levodopa (L-DOPA, LARODOPA, L-3,4-dihydroxyphenylalanine), the metabolic precursor of DA, is

the single most effective agent in the treatment of PD. Levodopa is itself largely inert; both its therapeutic and adverse effects result from the decarboxylation of levodopa to DA. When administered orally, levodopa is absorbed rapidly from the small bowel by the transport system for aromatic amino acids. Concentrations of the

Table 22–1

Commonly Used Medications for the Treatment of Parkinson Disease

AGENT	TYPICAL INITIAL DOSE	DAILY DOSE RANGE	COMMENTS
Levodopa Formulations			
Carbidopa/levodopa	25 mg carbidopa + 100 mg levodopa (“25/100” tablet), 2-3x daily	200-1200 mg levodopa	
Carbidopa/levodopa sustained-release	50 mg carbidopa + 200 mg levodopa (“50/200 sustained-release” tablet) 2x daily	200-1200 mg levodopa	Bioavailability 75% of immediate-release form
Carbidopa-levodopa orally disintegrating tablets (PARCOPA)	25 mg carbidopa + 100 mg levodopa (“25/100” tablet), 2-3x daily	200-1200 mg levodopa	
COMT Inhibitors			
Entacapone	200 mg with each dose of levodopa/carbidopa	600-2000 mg	
Tolcapone	100 mg with carbidopa/levodopa	100-300 mg	May be hepatotoxic. Use only in patients not responding satisfactorily to other treatments. Requires monitoring of liver function
Carbidopa/levodopa/entacapone	12.5 mg carbidopa + 50 mg levodopa + 200 mg entacapone (STALEVO 50), 3x daily	150-1200 mg levodopa	
DA Agonists			
Apomorphine	2 mg subcutaneous	6-18 mg subcutaneous	Trimethobenzamide is used to reduce nausea when initiating therapy
Bromocriptine	1.25 mg	2.5-15 mg daily	Ergot; long-term use is associated with cardiac valve fibrosis
Pramipexole	0.125 mg 3x daily	1.5-4.5 mg	
Ropinirole	0.25 mg 3x daily	1.5-24 mg	
Ropinirole sustained-release	2 mg per day	2-24 mg	
MAO Inhibitors			
Rasagiline	1 mg daily	0.5-1 mg	
Selegiline	5 mg 2x daily	2.5-10 mg	
Other Medications			
Trihexyphenidyl HCl	1 mg 2x daily	2-15 mg	
Amantadine	100 mg 2x daily	100-200 mg	

drug in plasma usually peak between 0.5 and 2 hours after an oral dose. The $t_{1/2}$ in plasma is short (1–3 hours). The rate and extent of absorption of levodopa depends on the rate of gastric emptying, the pH of gastric juice, and the length of time the drug is exposed to the degradative enzymes of the gastric and intestinal mucosa. Competition for absorption sites in the small bowel from dietary amino acids also may have a marked effect on the absorption of levodopa; administration of levodopa with high-protein meals delays absorption and reduces peak plasma concentrations. Entry of the drug into the CNS across the blood-brain barrier also is mediated by a membrane transporter for aromatic amino acids, and competition between dietary protein and levodopa may occur at this level. In the brain, levodopa is converted to DA by decarboxylation primarily within the presynaptic terminals of dopaminergic neurons in the striatum. The DA produced is responsible for the therapeutic effectiveness of the drug in PD; after release, it is either transported back into dopaminergic terminals by the presynaptic uptake mechanism or metabolized by the actions of MAO and catechol-*O*-methyltransferase (COMT) (Figure 22–4).

In clinical practice, levodopa is almost always administered in combination with a peripherally acting inhibitor of aromatic L-amino acid decarboxylase, such

as carbidopa or benserazide (available outside the U.S.), drugs that do not penetrate well into the CNS. If levodopa is administered alone, the drug is largely decarboxylated by enzymes in the intestinal mucosa and other peripheral sites so that relatively little unchanged drug reaches the cerebral circulation and probably <1% penetrates the CNS. In addition, DA release into the circulation by peripheral conversion of levodopa produces undesirable effects, particularly nausea. Inhibition of peripheral decarboxylase markedly increases the fraction of administered levodopa that remains unmetabolized and available to cross the blood-brain barrier (Figure 22–5) and reduces the incidence of GI side effects.

In most individuals, a daily dose of 75 mg carbidopa is sufficient to prevent the development of nausea. For this reason, the most commonly prescribed form of carbidopa/levodopa (SINEMET, ATAMET, others) is the 25/100 form, containing 25 mg carbidopa and 100 mg levodopa. With this formulation, dosage schedules of three or more tablets daily provide acceptable inhibition of decarboxylase in most individuals. Occasionally, individuals will require larger doses of carbidopa to minimize gastrointestinal side effects, and administration of supplemental carbidopa (LODOSYN) may be beneficial. Carbidopa/levodopa is also available in an orally disintegrating tablet (PARCOPA). This may be useful in patients with swallowing difficulty, although it is important to note that levodopa is not absorbed through the oral mucosa, and must still be delivered to the small intestine for absorption. Thus, the time to onset of action of PARCOPA is not appreciably different from that of standard oral formulations.

Figure 22–4. Metabolism of levodopa (*L*-DOPA). ALDH, aldehyde dehydrogenase; COMT, catechol-*O*-methyltransferase; DBH, dopamine β -hydroxylase; AADC, aromatic L-amino acid decarboxylase; MAO, monoamine oxidase.

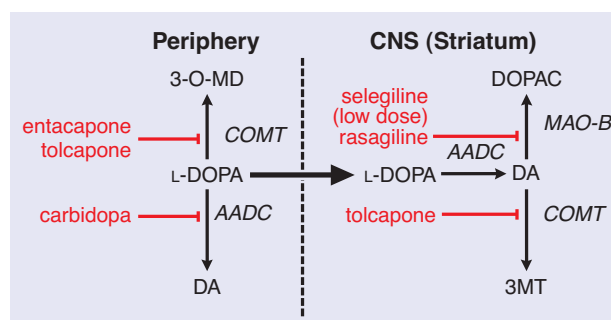

Figure 22–5. Pharmacological preservation of *L*-DOPA and striatal dopamine. The principal site of action of inhibitors of catechol-*O*-methyltransferase (COMT) (such as tolcapone and entacapone) is in the peripheral circulation. They block the *O*-methylation of levodopa (*L*-DOPA) and increase the fraction of the drug available for delivery to the brain. Tolcapone also has effects in the CNS. Inhibitors of MAO-B, such as low-dose selegiline and rasagiline, will act within the CNS to reduce oxidative deamination of DA, thereby enhancing vesicular stores. AADC, aromatic L-amino acid decarboxylase; DA, dopamine; DOPAC, 3,4-dihydroxyphenylacetic acid; MAO, monoamine oxidase; 3MT, 3-methoxytyramine; 3-O-MD, 3-*O*-methyl DOPA

Levodopa therapy can have a dramatic effect on all the signs and symptoms of PD. Early in the course of the disease, the degree of improvement in tremor, rigidity, and bradykinesia may be nearly complete. In early PD, the duration of the beneficial effects of levodopa may exceed the plasma lifetime of the drug, suggesting that the nigrostriatal DA system retains some capacity to store and release DA. A principal limitation of the long-term use of levodopa therapy is that with time this apparent “buffering” capacity is lost, and the patient’s motor state may fluctuate dramatically with each dose of levodopa, a condition described as *motor complications* of levodopa. A common problem is the development of the “wearing off” phenomenon: each dose of levodopa effectively improves mobility for a period of time, perhaps 1-2 hours, but rigidity and akinesia return rapidly at the end of the dosing interval. Increasing the dose and frequency of administration can improve this situation, but this often is limited by the development of dyskinesias, excessive and abnormal involuntary movements. Dyskinesias are observed most often when the plasma levodopa concentration is high, although in some individuals dyskinesias or dystonia may be triggered when the level is rising or falling. These movements can be as uncomfortable and disabling as the rigidity and akinesia of PD. In the later stages of PD, patients may fluctuate rapidly between being “off,” having no beneficial effects from their medications, and being “on” but with disabling dyskinesias, a situation called the *on/off phenomenon*.

Recent evidence has indicated that induction of motor complications may be the result of an active process of adaptation to variations in brain and plasma levodopa levels. This process of adaptation is apparently complex, involving not only alterations in the function of DA receptors but also downstream changes in the postsynaptic striatal neurons, including modification of NMDA glutamate receptors (Hallett and Standaert, 2004). When levodopa levels are maintained constant by intravenous infusion, dyskinesias and fluctuations are greatly reduced, and the clinical improvement is maintained for up to several days after returning to oral levodopa dosing (Mouradian et al., 1990). A sustained-release formulation consisting of carbidopa/levodopa in an erodable wax matrix (SINEMET CR) has been marketed in an attempt to produce more stable plasma levodopa levels than can be obtained with oral administration of standard carbidopa/levodopa formulations. This formulation is helpful in some cases, but absorption of the sustained-release formulation is not entirely predictable. Other approaches to more continuous delivery of levodopa, including gel and transdermal formulations, are under study.

An important unanswered question regarding the use of levodopa in PD is whether this medication alters the course of the underlying disease or merely modifies the symptoms. A recent randomized

trial has provided evidence that levodopa does not have an adverse effect on the course of the underlying disease, but has also confirmed that high doses of levodopa are associated with early onset of dyskinesias (Fahn et al., 2004). Most practitioners have adopted a pragmatic approach, using levodopa only when the symptoms of PD cause functional impairment and other treatments are inadequate or not well tolerated.

In addition to motor complications and nausea, several other adverse effects may be observed with levodopa treatment. A frequent and troubling adverse effect is the induction of hallucinations and confusion, especially in elderly patients or in patients with preexisting cognitive dysfunction. This adverse effect often limits the ability to treat parkinsonian symptoms adequately. Conventional antipsychotic agents, such as the phenothiazines, are effective against levodopa-induced psychosis but may cause marked worsening of parkinsonism, probably through actions at the D₂ DA receptor. An alternative approach has been to use “atypical” antipsychotic agents (Chapter 16). However, not all of these are equally useful in this setting, and some of the “atypical” agents may nevertheless worsen PD symptoms. The two drugs which appear to be most effective and best tolerated in patients with advanced PD are clozapine and quetiapine (Friedman and Factor, 2000).

Peripheral decarboxylation of levodopa and release of DA into the circulation may activate vascular DA receptors and produce orthostatic hypotension. Administration of levodopa with nonspecific inhibitors of MAO, such as phenelzine and tranylcypromine, markedly accentuates the actions of levodopa and may precipitate life-threatening hypertensive crisis and hyperpyrexia; nonspecific MAO inhibitors always should be discontinued at least 14 days before levodopa is administered (note that this prohibition does not include the MAO-B subtype-specific inhibitors selegiline and rasagiline (AZILECT), which, as discussed later, are often administered safely in combination with levodopa). Abrupt withdrawal of levodopa or other dopaminergic medications may precipitate the *neuroleptic malignant syndrome* of confusion, rigidity, and hyperthermia, a potentially lethal adverse effect.

Dopamine-Receptor Agonists. An alternative to levodopa is the use of drugs that are direct agonists of striatal DA receptors, an approach that offers several potential advantages. Since enzymatic conversion of these drugs is not required for activity, they do not depend on the functional capacities of the nigrostriatal neurons. The DA receptor agonists in clinical use have durations of action substantially longer than that of levodopa; they are often used in the management of dose-related fluctuations in motor state, and may be helpful in preventing motor complications. Finally, it has been suggested that DA receptor agonists may have the potential to modify the course of PD by reducing endogenous release of DA as well as the need for exogenous levodopa, thereby reducing free radical formation.

Two orally administered DA receptor agonists are commonly used for treatment of PD: ropinirole (REQUIP) and pramipexole (MIRAPEX).

ROPINIROLE

PRAMIPEXOLE

These agents are better tolerated and have largely replaced the older agents (e.g., bromocriptine, pergolide), which have to be titrated more slowly. Pergolide was withdrawn from the U.S. market in 2007 because of cardiac valve fibrosis. Ropinirole and pramipexole have selective activity at D_2 class sites (specifically at the D_2 and D_3 receptor) and little or no activity at D_1 class sites. Both are well absorbed orally and have similar therapeutic actions. Like levodopa, they can relieve the clinical symptoms of PD. The duration of action of the DA agonists (8–24 hours) often is longer than that of levodopa (6–8 hours), and they are particularly effective in the treatment of patients who have developed on/off phenomena. Ropinirole is also available in a once-daily sustained release formulation (REQUIP XL), which is more convenient and may reduce adverse effects related to intermittent dosing. Both pramipexole and ropinirole may produce hallucinosis or confusion, similar to that observed with levodopa, and may cause nausea and orthostatic hypotension. They should be initiated at low dose and titrated slowly to minimize these effects. The DA agonists, as well as levodopa itself, are also associated with fatigue and somnolence. The somnolence in some cases may be quite severe, and several instances of sudden attacks of irresistible sleepiness leading to motor vehicle accidents have been reported (Frucht et al., 1999). Although an uncommon complication, it is prudent to advise patients of this possibility and to switch to another agent when somnolence is an issue.

Apomorphine. Apomorphine (APOKYN) is a dopaminergic agonist that can be administered by subcutaneous injection. It has high affinity for D_4 receptors; moderate affinity for D_2 , D_3 , D_5 , and adrenergic α_{1D} , α_{2B} , and α_{2C} receptors; and low affinity for D_1 receptors. Apomorphine has been used in Europe for many years and is FDA-approved as a “rescue therapy” for the acute intermittent treatment of “off” episodes in

patients with a fluctuating response to dopaminergic therapy.

Apomorphine has the same side effects as discussed earlier for the oral DA agonists. In addition, apomorphine is highly emetogenic and requires pre- and post-treatment anti-emetic therapy. Oral trimethobenzamide (TIGAN), at a dose of 300 mg three times daily, should be started 3 days prior to the initial dose of apomorphine and continued at least during the first 2 months of therapy. Profound hypotension and loss of consciousness have occurred when apomorphine was administered with ondansetron; hence, the concomitant use of apomorphine with antiemetic drugs of the 5-HT₃ antagonist class is contraindicated. Other potentially serious side effects of apomorphine include QT prolongation, injection-site reactions, and the development of a pattern of abuse characterized by increasingly frequent dosing leading to hallucinations, dyskinesia, and abnormal behavior. Because of these potential adverse effects, use of apomorphine is appropriate only when other measures, such as oral DA agonists or COMT inhibitors, have failed to control the “off” episodes. Apomorphine therapy should be initiated with a 2-mg test dose in a setting where the patient can be monitored carefully. If tolerated, it can be titrated slowly up to a maximum dosage of 6 mg. For effective control of symptoms, patients may require three or more injections daily.

Catechol-O-Methyltransferase (COMT) Inhibitors.

Drugs for the treatment of PD include inhibitors of the enzyme COMT, which, together with MAO, metabolizes levodopa and DA. COMT transfers a methyl group from the donor *S*-adenosyl-L-methionine, producing the pharmacologically inactive compounds 3-*O*-methyl DOPA (from levodopa) and 3-methoxytyramine (from DA; Figure 22–5). When levodopa is administered orally, nearly 99% of the drug is metabolized and does not reach the brain. Most is converted by aromatic L-amino acid decarboxylase (AADC) to DA, which causes nausea and hypotension. Addition of an AADC inhibitor such as carbidopa reduces the formation of DA but increases the fraction of levodopa that is methylated by COMT. The principal therapeutic action of the COMT inhibitors is to block this peripheral conversion of levodopa to 3-*O*-methyl DOPA, increasing both the plasma $t_{1/2}$ of levodopa as well as the fraction of each dose that reaches the CNS.

Two COMT inhibitors presently are available for this use in the United States, tolcapone (TASMAR) and entacapone (COMTAN). In double-blind clinical trials, both agents significantly reduced the “wearing off” symptoms in patients treated with levodopa/carbidopa (Parkinson Study Group, 1997). The two drugs differ only in their pharmacokinetic properties and adverse effects: tolcapone has a relatively long duration of action, allowing for administration two to three times a day, and appears to act by both central and peripheral inhibition of COMT. Entacapone has a short duration of action (2 hours) and usually is administered simultaneously with each dose

of levodopa/carbidopa. The action of entacapone is attributable principally to peripheral inhibition of COMT. The common adverse effects of these agents are similar to those of levodopa/carbidopa alone and include nausea, orthostatic hypotension, vivid dreams, confusion, and hallucinations. An important adverse effect associated with tolcapone is hepatotoxicity. Up to 2% of the patients treated have increased serum alanine aminotransferase and aspartate transaminase; and at least three fatal cases of fulminant hepatic failure in patients taking tolcapone have been observed, leading to addition of a black box warning to the label. At present, tolcapone should be used only in patients who have not responded to other therapies and with appropriate monitoring for hepatic injury. Entacapone has not been associated with hepatotoxicity and requires no special monitoring. Entacapone also is available in fixed-dose combinations with levodopa/carbidopa (STALEVO).

Selective MAO-B Inhibitors. Two isoenzymes of MAO oxidize monoamines. While both isoenzymes (MAO-A and MAO-B) are present in the periphery and inactivate monoamines of intestinal origin, the isoenzyme MAO-B is the predominant form in the striatum and is responsible for most of the oxidative metabolism of DA in the brain. Two selective MAO-B inhibitors are used for the treatment of PD: selegiline (ELDEPRYL, EMSAM, ZELAPAR) and rasagiline (AZILECT). When used at recommended doses, these agents selectively inactivate MAO-B through irreversible inhibition of the enzyme (Elmer and Bertoni, 2008). Both agents exert modest beneficial effects on the symptoms of PD. The basis of this efficacy is presumed to be the inhibition of breakdown of DA in the striatum. Unlike nonspecific inhibitors of MAO (such as phenelzine, tranylcypromine, and isocarboxazid), selective MAO-B inhibitors do not substantially inhibit the peripheral metabolism of catecholamines and can be taken safely with levodopa. These agents also do not exhibit the “cheese effect,” the potentially lethal potentiation of catecholamine action observed when patients on nonspecific MAO inhibitors ingest indirectly acting sympathomimetic amines such as the tyramine found in certain cheeses and wine.

Selegiline has been used for many years as a symptomatic treatment for PD and is generally well tolerated in younger patients with early or mild PD. In patients with more advanced PD or underlying cognitive impairment, selegiline may accentuate the adverse motor and cognitive effects of levodopa therapy. Metabolites of selegiline include amphetamine and methamphetamine, which may cause anxiety, insomnia, and other adverse symptoms. Recently, selegiline has become available in an orally disintegrating tablet (ZELEPAR) as well as a transdermal patch (EMSAM). Both of these delivery routes are intended to reduce hepatic first-pass metabolism and limit the formation of the amphetamine metabolites.

Unlike selegiline, rasagiline does not give rise to undesirable amphetamine metabolites. In randomized controlled clinical trials, rasagiline monotherapy was effective in early PD. Adjunctive

therapy significantly reduced levodopa-related “wearing off” symptoms in advanced PD.

A consequence of the inhibition of MAO-B in the brain is a reduction in the overall catabolism of DA, which may reduce the formation of potentially toxic free radicals. This observation has led to studies which have examined the question of whether MAO-B inhibition can alter the rate of neurodegeneration in PD. The potential protective role of selegiline in idiopathic PD was evaluated in several multicenter randomized trials; although there was some evidence supporting a neuroprotective effect, the outcomes were obscured by the difficulty of distinguishing long-term neuroprotective effects from short-term symptomatic effects (Parkinson Study Group, 1993; Yacoubian and Standaert, 2008). A more recent study, using a different design, has produced more convincing data suggesting a neuroprotective effect of rasagiline (Olanow, 2008).

Although selective MAO-B inhibitors are generally well tolerated, drug interactions can be troublesome. Similar to the nonspecific MAO inhibitors, selegiline can lead to the development of stupor, rigidity, agitation, and hyperthermia when administered with the analgesic meperidine. Although the mechanics, of this interaction is uncertain, selegiline or rasagiline should not be given in combination with meperidine. Adverse effects have been reported from coadministration of MAO-B inhibitors with tricyclic antidepressants or with serotonin-reuptake inhibitors. However, interactions with antidepressants are uncommon, and many patients do take these combinations of medications without apparent adverse interaction; nonetheless, concomitant administration of selegiline or rasagiline with serotonergic drugs should be done with caution, especially in patients on high doses of serotonin-reuptake inhibitors.

Muscarinic Receptor Antagonists. Antagonists of muscarinic acetylcholine receptors were used widely for the treatment of PD before the discovery of levodopa. The biological basis for the therapeutic actions of anticholinergics is not completely understood. They may act within the neostriatum through the receptors that normally mediate the response to intrinsic cholinergic innervation of this structure, which arises primarily from cholinergic striatal interneurons. Several muscarinic cholinergic receptors have been cloned (Chapters 9 and 14); like the DA receptors, these are GPCRs. Five subtypes of muscarinic receptors exist. All five subtypes are probably present in the striatum, although each one has a distinct distribution (Hersch et al., 1994). Anticholinergic drugs currently used in the treatment of PD include trihexyphenidyl (2-4 mg three times per day), benzotropine mesylate (1-4 mg two times per day), and diphenhydramine hydrochloride (25-50 mg three or four times per day). Diphenhydramine also is a histamine H₁ antagonist (Chapter 32).

All of these drugs have relatively modest antiparkinsonian activity and are only used in the treatment of early PD or as an adjunct to dopaminergic therapy. Adverse effects result from their anticholinergic properties. Most troublesome are sedation and mental

confusion. Other side effects are constipation, urinary retention, and blurred vision through cycloplegia. All anticholinergic drugs must be used with caution in patients with narrow-angle glaucoma (Chapter 65).

Amantadine. Amantadine (SYMMETREL), an antiviral agent used for the prophylaxis and treatment of influenza A (Chapter 58), has antiparkinsonian activity. Amantadine appears to alter DA release in the striatum, has anticholinergic properties, and blocks NMDA glutamate receptors. However, it is not well understood which of amantadine's pharmacological effects are responsible for its antiparkinsonian actions. In any case, the effects of amantadine in PD are modest. It is used as initial therapy of mild PD. It also may be helpful as an adjunct in patients on levodopa with dose-related fluctuations and dyskinesias. The antidyskinetic properties of amantadine have been attributed to actions at NMDA receptors (Hallett and Standaert, 2004), although the closely related NMDA receptor antagonist memantine (discussed later) does not seem to have this effect.

Amantadine is usually administered at a dose of 100 mg twice a day and is well tolerated. Dizziness, lethargy, anticholinergic effects, and sleep disturbance, as well as nausea and vomiting, have been observed occasionally, but even when present, these effects are mild and reversible.

Neuroprotective Treatments for Parkinson Disease. It would be desirable to identify a treatment that modifies the progressive degeneration that underlies PD rather than simply controlling the symptoms. Current research strategies are based on the disease mechanisms described earlier (e.g., energy metabolism, oxidative stress, environmental triggers, and excitotoxicity) and on discoveries related to the genetics of PD (Yacoubian and Standaert, 2008). Several studies have examined the potential neuroprotective effects of existing medications. In a randomized controlled trial, levodopa did not worsen the disease state. Some benefits persisted for several weeks after treatment was stopped, but whether this was truly a "neuroprotective" effect remains uncertain (Fahn et al., 2004).

Two trials have attempted to examine the effect of pramipexole or ropinirole on neurodegeneration in PD (Parkinson Study Group, 2002; Whone et al., 2003). Both trials observed that in patients treated with either one of these agonists, there was a reduced rate of loss of markers of dopaminergic neurotransmission measured by brain imaging compared with a similar group of patients treated with levodopa. These intriguing data should be viewed cautiously, particularly because there is considerable uncertainty about the relationship of the imaging results techniques used and the true rate of neurodegeneration (Albin and Frey, 2003).

Inhibition of MAO-B in the brain reduces the overall catabolism of DA, which may decrease the formation of potentially toxic free radicals and consequently the rate of neurodegeneration in PD. The protective role of selegiline in idiopathic PD was evaluated in several multicenter randomized trials. Unfortunately, distinguishing long-term neuroprotective effects from short-term symptomatic

effects was difficult in the earlier studies (Parkinson Study Group, 1993; Yacoubian and Standaert, 2008). A different study design showed more convincingly a neuroprotective effect of rasagiline (2008).

Another strategy under study is the use of compounds that augment cellular energy metabolism such coenzyme Q10, a cofactor required for the mitochondrial electron-transport chain. A small study has demonstrated that this drug is well tolerated in PD and has suggested that coenzyme Q10 may slow the course of the disease (Shults et al., 2002). A much larger study is in progress. Therapies directly targeting the molecules which are implicated in the pathogenesis of PD are still in a nascent stage, and may require unconventional delivery strategies such as gene therapy (Lewis and Standaert, 2008).

Clinical Summary. Pharmacological treatment of PD should be tailored to the individual patient. Drug therapy is not obligatory in early PD; many patients can be managed for a time with exercise and lifestyle interventions. For patients with mild symptoms, MAO-B inhibitors, amantadine, or (in younger patients) anticholinergics are reasonable choices. In most patients, treatment with a dopaminergic drug, either levodopa or a DA agonist, is eventually required. Large controlled clinical trials provide convincing evidence for a reduced rate of motor fluctuation in patients in which DA agonists are used as initial treatment. This benefit was, however, accompanied by an increased rate of adverse effects, especially somnolence and hallucinations (Parkinson Study Group, 2000; Rascol et al., 2000). Practitioners prefer DA agonist as initial therapy in younger patients in order to reduce the occurrence of motor complications. In older patients or those with substantial comorbidity, levodopa/carbidopa is generally better tolerated.

ALZHEIMER'S DISEASE (AD)

Clinical Overview. The brain region most vulnerable to neuronal dysfunction and cell loss in AD is the medial temporal lobe, including entorhinal cortex and hippocampus. Typical early AD symptoms are due to dysfunction of these structures resulting in anterograde episodic memory loss: repeated questions, misplaced items, missed appointments, and forgotten details of daily life. A typical patient presents with memory dysfunction that is noticeable by the patient and/or family members, but not severe enough to impair daily function. Because current diagnostic criteria for AD require the presence of dementia (i.e., cognitive impairments sufficient to reduce function), these patients are generally given a diagnosis of mild cognitive impairment (MCI). Patients with MCI progress at a rate of about 10% per

year to AD (Petersen et al., 2005), although not all MCI patients will develop AD. The decline in both cognitive and functional capacity follows a course of gradual but relentless progression in AD, spreading to involve other cognitive domains including visuospatial and executive function. The later stages of the disease are characterized by increasing dependence and progression toward the akinetic-mute state that typifies end-stage neurologic disease. Death, most often from a complication of immobility such as pneumonia or pulmonary embolism, usually ensues within 6-12 years of onset.

At present, the diagnosis of AD is based on the clinical assessment of the patient. Structural neuroimaging and appropriate laboratory tests are used to exclude other disorders that may mimic AD. In the near future, laboratory measures to specifically identify AD, including analysis of biomarkers such as CSF or serum factors, genetic testing, and molecular or functional neuroimaging, are likely to be incorporated into AD diagnostic criteria to enhance the sensitivity of diagnosis, especially at early stages of the disease (Dubois et al., 2007). A direct antemortem confirmatory test currently does not exist.

Genetics. Mutations in three genes have been identified as causes of autosomal dominant, early-onset AD: *APP*, which encodes amyloid- β precursor protein, and *PSEN1* and *PSEN2*, encoding presenilin 1 and 2. All three genes are involved in the production of amyloid- β peptides ($A\beta$). $A\beta$ is generated by sequential proteolytic cleavage of APP by two enzymes, β -secretase and γ -secretase; the presenilins

form the catalytic core of γ -secretase. The genetic evidence, combined with the fact that $A\beta$ accumulates in the brain in the form of soluble oligomers and amyloid plaques, and is toxic when applied to neurons, forms the basis for the amyloid hypothesis of AD pathogenesis (Tanzi and Bertram, 2005).

Autosomal-dominant cases of AD are quite rare, but there is also a significant genetic component to the more common, sporadic, late-onset cases of AD. Many genes have been identified as having alleles that increase AD risk (Bertram et al., 2007). By far the most important of these is *APOE*, which encodes the lipid carrier protein apolipoprotein E (apoE) (Raber et al., 2004). Individuals inheriting the $\epsilon 4$ allele of *APOE* have a more than 3-fold higher risk of developing AD. While they make up less than one-fourth of the population, they account for more than half of all AD cases. Several clinical trials have shown a different response rate between apoE4-carriers and noncarriers, suggesting an important potential pharmacogenetic influence of apoE genotype on the choice of therapy. However, at this point genetic testing for apoE status is not a routine part of the clinical evaluation for AD.

Pathophysiology. The pathological hallmarks of AD are amyloid plaques, which are extracellular accumulations of $A\beta$, and intracellular neurofibrillary tangles composed of the microtubule-associated protein tau (Figure 22-6). While the development of amyloid plaques is an early and invariant feature of AD, tangle burden accrues over time in a manner that correlates more closely with the development of cognitive impairment. The current consensus is that $A\beta$ accumulation is an upstream event that triggers tau pathology, resulting in impaired neuronal function and cell loss. In autosomal dominant AD, $A\beta$ accumulates due to mutations that cause its overproduction. The cause of high cerebral $A\beta$ levels in late-onset sporadic AD is unclear but is likely caused by impaired clearance rather than overproduction.

Figure 22-6. Molecular and cellular processes presumed to participate in AD pathogenesis. (From Roberson ED, Mucke L. 100 years and counting: Prospects for defeating Alzheimer's disease. *Science*, 2006, 314:781-784. Reprinted with permission from AAAS.)

Aggregation of A β is an important event in AD pathogenesis. While plaques consist of highly ordered fibrils of A β , it appears that soluble A β oligomers, perhaps as small as dimers, are more highly pathogenic. Tau also aggregates to form the paired helical filaments that make up neurofibrillary tangles. Post-translational modifications of tau including phosphorylation, proteolysis, and other changes cause loss of tau's normal functions and increase its propensity to aggregate. Mechanisms by which A β and tau induce neuronal dysfunction and death may include direct impairment of synaptic transmission and plasticity, excitotoxicity, oxidative stress, and neuroinflammation. The factors underlying the selective vulnerability of particular cortical neurons to the pathological effects of AD are not known.

Neurochemistry. The most striking neurochemical disturbance in AD is a deficiency of acetylcholine. The anatomical basis of the cholinergic deficit is atrophy and degeneration of subcortical cholinergic neurons, particularly those in the basal forebrain (nucleus basalis of Meynert) that provide cholinergic innervation to the cerebral cortex. The selective deficiency of ACh in AD, as well as the observation that central cholinergic antagonists such as atropine can induce a confusional state that bears some resemblance to the dementia of AD, has given rise to the “cholinergic hypothesis,” which proposes that a deficiency of ACh is critical in the genesis of the AD symptoms (Perry, 1986). Although viewing AD as a “cholinergic deficiency syndrome” akin to the “dopaminergic deficiency syndrome” of PD provides a useful framework, it is important to note that the deficit in AD is far more complex. AD involves multiple neurotransmitter systems, including glutamate, 5-HT, and neuropeptides, and there is destruction of not only cholinergic neurons but also the cortical and hippocampal targets that receive cholinergic input.

Treatment of Alzheimer's Disease

At present, no disease-modifying therapy for AD is available. While aggressive attempts to develop drugs

targeting A β , tau, apoE, and other molecules involved in AD pathogenesis are underway (Roberson and Mucke, 2006), current treatment is aimed at alleviating symptoms.

Treatment of Cognitive Symptoms. Augmentation of the cholinergic transmission is currently the mainstay of AD treatment. Three drugs, donepezil, rivastigmine, and galantamine, are widely used for this purpose; a fourth, tacrine, was the first drug approved to treat AD but is rarely used now because it has much more extensive side effects compared to the newer agents (Table 22–2). All four agents are reversible antagonists of cholinesterases, enzymes that act to limit cholinergic neurotransmission by catalyzing the cleavage of acetylcholine in the synaptic cleft into choline and acetate (Chapter 10). Cholinesterase inhibitors are the usual first-line therapy for symptomatic treatment of cognitive impairments in mild or moderate AD. These agents have a beneficial, albeit quite modest, effect on cognition in clinical AD studies (Birks, 2006). They are also widely used to treat other neurodegenerative diseases with cholinergic deficits, including dementia with Lewy bodies (Bhasin et al., 2007) and vascular dementia (Kavirajan and Schneider, 2007). In addition, they are sometimes used in MCI, where they may also have symptomatic benefit but do not slow the conversion to AD (Raschetti et al., 2007). The drugs are usually well tolerated, with the most common side effects being GI distress, muscle cramping, and abnormal dreams. Because of their cholinergic and

Table 22–2

Cholinesterase Inhibitors Used for the Treatment of Alzheimer's Disease

	DONEPEZIL	RIVASTIGMINE	GALANTAMINE	TACRINE ^a
Brand name	ARICEPT	EXELON, generic	RAZADYNE, generic	COGNEX
Enzymes inhibited ^b	AChE	AChE, BuChE	AChE	AChE, BuChE
Mechanism	Noncompetitive	Noncompetitive	Competitive	Noncompetitive
Typical maintenance dose ^c	10 mg once daily	9.5 mg/24h (transdermal) 3-6 mg twice daily (oral)	8-12 mg twice daily (immediate-release) 16-24 mg/day (extended-release)	20 mg, four times daily
FDA-approved indications	Mild–severe AD	Mild–moderate AD, Mild–moderate PDD ^d	Mild–moderate AD	Mild–moderate AD
Metabolism ^e	CYP2D6, CYP3A4	Esterases	CYP2D6, CYP3A4	CYP1A2

^aTacrine was the first cholinesterase inhibitor approved for the treatment of AD, but is now rarely used because of hepatotoxicity and adverse effects.

^bAChE (acetylcholinesterase) is the major cholinesterase in the brain; BuChE (butyrylcholinesterase) is a serum and hepatic cholinesterase that is upregulated in AD brain. ^cTypical starting doses are one-half of the maintenance dose and are given for the first month of therapy. ^dPDD, Parkinson disease dementia. ^eDrugs metabolized by CYP2D6 and CYP3A4 are subject to increased serum levels when co-administered with drugs known to inhibit these enzymes, such as ketoconazole and paroxetine. Similarly, tacrine levels are increased by co-administration with the CYP1A2 inhibitors theophylline, cimetidine, and fluvoxamine.

622 potentially vagotonic properties, they should be used with caution in patients with bradycardia or syncope.

Memantine (NAMENDA) is used either as an adjunct or an alternative to cholinesterase inhibitors in AD, and is also commonly used to treat other neurodegenerative dementias. Memantine is a noncompetitive antagonist of the NMDA-type glutamate receptor. It interacts with the Mg^{2+} binding site of the channel to prevent excessive activation while sparing normal function (Lipton, 2007). Memantine significantly reduces the rate of clinical deterioration in patients with moderate to severe AD (Raina et al., 2008). Whether this is due to a true disease-modifying effect, possibly reduced excitotoxicity, or to a symptomatic effect of the drug is unclear. Adverse effects of memantine include headache or dizziness, but are usually mild and reversible. The drug is excreted by the kidneys, and dosage should be reduced in patients with severe renal impairment.

Treatment of Behavioral Symptoms. In addition to cognitive decline, behavioral and psychiatric symptoms in dementia (BPSD) are common, particularly in middle stages of the disease. These symptoms, including irritability and agitation, paranoia and delusional thinking, wandering, anxiety, and depression, are a major source of caregiver distress and often precipitate nursing home placement. Treatment can be difficult, and non-pharmacological approaches should generally be first-line (Beier, 2007; Sink et al., 2005).

A variety of pharmacological options are also available. In addition to their effects on cognitive measures, both cholinesterase inhibitors and memantine reduce some BPSD (Maidment et al., 2008; Trinh et al., 2003). However, their effects are modest, and they do not treat some of the most troublesome symptoms, such as agitation (Howard et al., 2007). Furthermore, because most AD patients are already treated with these drugs, other options are often needed when behavioral symptoms emerge.

Atypical antipsychotics, such as risperidone, olanzapine, and quetiapine (Chapter 16), are the most efficacious therapy for agitation and psychosis in AD. Risperidone and olanzapine are effective, but their use is often limited by adverse effects, including parkinsonism, sedation, and falls (Schneider et al., 2006). In addition, the use of atypical antipsychotics in elderly patients with dementia-related psychosis has been associated with a higher risk of stroke and overall mortality (Douglas and Smeeth, 2008; Schneider et al., 2005), leading the FDA to order inclusion of a boxed warning in the prescribing information for all

drugs in this class. Unfortunately, there are few effective alternatives.

Mood stabilizers (Chapter 16) have been the focus of several trials for BPSD. Carbamazepine has shown some benefit in small trials but carries numerous risks in the elderly, especially the potential for drug-drug interactions. There is little evidence of benefit from valproic acid. Lithium is of considerable interest given its ability to inhibit glycogen synthase kinase, which is implicated in AD pathogenesis, but clinical trial results are limited and concerns persist about the narrow therapeutic window in elderly patients. Benzodiazepines (Chapter 17) can be used for occasional control of acute agitation, but are not recommended for long-term management because of their adverse effects on cognition and other risks in the elderly population. The typical antipsychotic haloperidol (Chapter 16) may be useful for aggression, but sedation and extrapyramidal symptoms limit its use to control of acute episodes.

Antidepressants (Chapter 15) can be useful for BPSD, particularly when depression or anxiety contribute. Because of the adverse anticholinergic effects of tricyclic agents, serotonergic antidepressants are favored. These agents are generally well tolerated. Trazodone has modest benefits, but for the most part, selective serotonin reuptake inhibitors (SSRIs) are the preferred class of drugs.

Clinical Summary. The typical AD patient presenting in early stages of disease should probably be treated with a cholinesterase inhibitor. Patients and families should be counseled that a realistic goal of therapy is to induce a temporary reprieve from progression, or at least a reduction in the rate of decline, rather than long-term recovery of cognition. As the disease progresses, memantine can be added to the regimen. Behavioral symptoms are often treated with a serotonergic antidepressant or, if they are severe enough to warrant the risk of higher mortality, an atypical antipsychotic. Eliminating drugs likely to aggravate cognitive impairments, particularly anticholinergics, benzodiazepines, and other sedative/hypnotics, from the patient's regimen is another important aspect of AD pharmacotherapy.

HUNTINGTON'S DISEASE (HD)

Clinical Features. HD is a dominantly inherited disorder characterized by the gradual onset of motor incoordination and cognitive decline in midlife. Symptoms develop insidiously, either as a movement disorder manifest by brief, jerk-like movements of the extremities, trunk, face, and neck (chorea) or as personality changes or both. Fine-motor incoordination and impairment of rapid eye movements are early features. Occasionally, especially when the onset of symptoms occurs before age 20, choreic movements are less prominent; instead, bradykinesia and dystonia predominate. As the disorder

progresses, the involuntary movements become more severe, dysarthria and dysphagia develop, and balance is impaired. The cognitive disorder manifests first as slowness of mental processing and difficulty in organizing complex tasks. Memory is impaired, but affected persons rarely lose their memory of family, friends, and the immediate situation. Such persons often become irritable, anxious, and depressed. Less frequently, paranoia and delusional states are manifest. The outcome of HD is invariably fatal; over a course of 15–30 years, the affected person becomes totally disabled and unable to communicate, requiring full-time care; death ensues from the complications of immobility (Shoulson, 1992).

Pathology and Pathophysiology. HD is characterized by prominent neuronal loss in the striatum (caudate/putamen) of the brain (Vonsattel et al., 1985). Atrophy of these structures proceeds in an orderly fashion, first affecting the tail of the caudate nucleus and then proceeding anteriorly from mediodorsal to ventrolateral. Other areas of the brain also are affected, although much less severely; morphometric analyses indicate that there are fewer neurons in cerebral cortex, hypothalamus, and thalamus. Even within the striatum, the neuronal degeneration of HD is selective. Interneurons and afferent terminals are largely spared, whereas the striatal projection neurons (the medium spiny neurons) are severely affected. This leads to large decreases in striatal GABA concentrations, whereas SST and DA concentrations are relatively preserved (Ferrante et al., 1987).

Selective vulnerability also appears to underlie the most conspicuous clinical feature of HD, the development of chorea. In most adult-onset cases, the medium spiny neurons that project to the GPi and SNpr (the indirect pathway) appear to be affected earlier than those projecting to the GPe (the direct pathway; Figure 22–5) (Albin et al., 1992). The disproportionate impairment of the indirect pathway increases excitatory drive to the neocortex, producing involuntary choreiform movements (Figure 22–7). In some individuals, rigidity rather than chorea is the predominant clinical feature; this is especially common in juvenile-onset cases. Here, the striatal neurons giving rise to both the direct and indirect pathways are impaired to a comparable degree.

Genetics. HD is an autosomal dominant disorder with nearly complete penetrance. The average age of onset is between 35 and 45 years, but the range varies from as early as age 2 to as late as the middle 80s. Although the disease is inherited equally from mother and father, more than 80% of those developing symptoms before age 20 inherit the defect from the father. This is an example of *anticipation*, or the tendency for the age of onset of a disease to decline with each succeeding generation, which also is observed in other neurodegenerative diseases with similar genetic mechanisms. Known homozygotes for HD show clinical characteristics identical to the typical HD heterozygote, indicating that the unaffected chromosome does not attenuate the disease symptomatology. Until the discovery of the genetic defect responsible for HD, *de novo* mutations causing HD were thought to be unusual; but it is now clear that the disease can arise from unaffected parents, especially when one carries an “intermediate allele,” as described in the next paragraph.

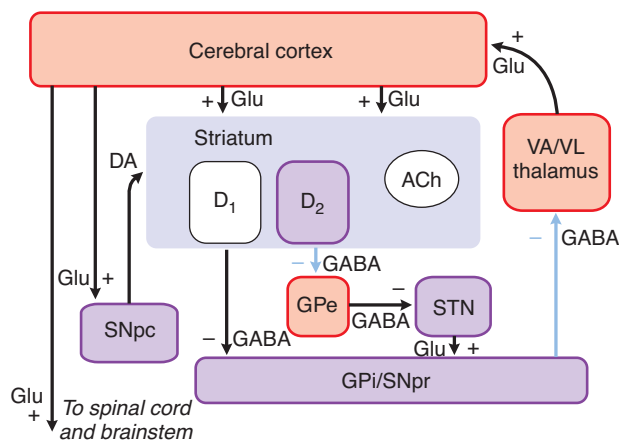

Figure 22–7. The basal ganglia in Huntington's disease. HD is characterized by loss of neurons from the striatum. The neurons that project from the striatum to the GPe and form the indirect pathway are affected earlier in the course of the disease than those which project to the GPi. This leads to a loss of inhibition of the GPe. The increased activity in this structure, in turn, inhibits the STN, SNpr, and GPi, resulting in a loss of inhibition to the VA/VL thalamus and increased thalamocortical excitatory drive. Structures in purple have reduced activity in HD, whereas structures in red have increased activity. Light blue lines indicate primary pathways of reduced activity. (See legend to Figure 22–2 for definitions of anatomical abbreviations.)

The discovery of the genetic mutation responsible for HD was the product of an arduous 10-year, multi-investigator collaborative effort. In 1993, a region near the end of the short arm of chromosome 4 was found to contain a polymorphic (CAG)_n trinucleotide repeat that was significantly expanded in all individuals with HD (Huntington's Disease Collaborative Research Group, 1993). The expansion of this trinucleotide repeat is the genetic alteration responsible for HD. The CAG repeat is unstable, and may expand during the DNA synthesis associated with meiosis. This is particularly common during spermatogenesis, and accounts for the phenomenon of anticipation. The range of CAG repeat length in normal individuals is between 9 and 34 triplets, with a median repeat length on normal chromosomes of 19. The repeat length in HD varies from 40 to over 100. Repeat lengths of 35–39 represent intermediate alleles; some of these individuals develop HD late in life, whereas others are not affected. Repeat length is correlated inversely with age of onset. The younger the age of onset, the higher the probability of a large repeat number. This correlation is most powerful in individuals with onset before age 30; with onset above age 30, the correlation is weaker. Thus, repeat length cannot serve as an adequate predictor of age of onset in most individuals. Several other neurodegenerative diseases also arise through expansion of a CAG repeat, including hereditary spinocerebellar ataxias and Kennedy's disease, a rare inherited disorder of motor neurons.

Selective Vulnerability. The mechanism by which the expanded trinucleotide repeat leads to the clinical and pathological features of HD is unknown. The HD mutation lies within a large gene (10 kilobases)

designated *IT15*. It encodes a protein of approximately 348,000 DA. The trinucleotide repeat, which encodes the amino acid glutamine, occurs at the 5'5' end of *IT15* and is followed directly by a second, shorter repeat of (CCG)_n that encodes proline. The protein, named huntingtin, does not resemble any other known protein, and the normal function of the protein has not been identified. Mice with a genetic knockout of huntingtin die early in embryonic life, so it must have an essential cellular function. It is thought that the mutation results in a gain of function—that is, the mutant protein acquires a new function or property not found in the normal protein. The nature of the function gained remains uncertain, although some evidence points to effects on cellular energy metabolism and gene transcription (Imarisio, 2008).

Treatment of Huntington's Disease

Symptomatic Treatment. Treatment for symptomatic HD emphasizes the selective use of medications (Shoulson, 1992). None of the currently available medications slows the progression of the disease. HD patients are frequently very sensitive to side effects of medications. Treatment is needed for patients who are depressed, irritable, paranoid, excessively anxious, or psychotic. Depression can be treated effectively with standard antidepressant drugs with the caveat that drugs with substantial anticholinergic profiles can exacerbate chorea. Fluoxetine (Chapter 15) is effective treatment for both the depression and the irritability manifest in symptomatic HD. Carbamazepine (Chapter 21) also has been found to be effective for depression. Paranoia, delusional states, and psychosis are treated with antipsychotic drugs, but usually at lower doses than those used in primary psychiatric disorders (Chapter 16). These agents also reduce cognitive function and impair mobility and thus should be used in the lowest doses possible and should be discontinued when the psychiatric symptoms resolve. In individuals with predominantly rigid HD, clozapine, quetiapine (Chapter 16), or carbamazepine may be more effective for treatment of paranoia and psychosis.

The movement disorder of HD *per se* only rarely justifies pharmacological therapy. For those with large-amplitude chorea causing frequent falls and injury, tetrabenazine (XENAZINENITOMAN) has recently become available in the U.S. for the treatment of chorea associated with HD. Tetrabenazine, and the related drug reserpine, are inhibitors of the vesicular monoamine transporter 2 (VMAT2), and cause presynaptic depletion of catecholamines. Tetrabenazine is a reversible inhibitor; inhibition by reserpine is irreversible and may lead to long-lasting effects. Both drugs may cause hypotension and depression with suicidality; the shorter duration of effect of tetrabenazine greatly simplifies the clinical management. Antipsychotic agents also can be used, but these often do not improve overall function because they decrease fine motor coordination and increase rigidity. Many HD patients exhibit worsening of involuntary movements as a result of anxiety or stress. In these situations, judicious

use of sedative or anxiolytic benzodiazepines can be very helpful. In juvenile-onset cases where rigidity rather than chorea predominates, DA agonists have had variable success in the improvement of rigidity. These individuals also occasionally develop myoclonus and seizures that can be responsive to clonazepam, valproic acid, and other anticonvulsants (Chapter 21).

Clinical Summary. HD is an autosomal dominant disorder caused by mutations in the *IT15* gene that encodes huntingtin. The gene defect leads to progressive motor and cognitive symptoms. At present there is no effective treatment for the primary disorder, although antidepressant and antipsychotic medications may be useful to control specific symptoms and catecholamine depleting agents may be useful to control the motor features of the disease.

AMYOTROPHIC LATERAL SCLEROSIS (ALS)

Clinical Features and Pathology. ALS (or Lou Gehrig's disease) is a disorder of the motor neurons of the ventral horn of the spinal cord (lower motor neurons) and the cortical neurons that provide their afferent input (upper motor neurons). The disorder is characterized by rapidly progressive weakness, muscle atrophy and fasciculations, spasticity, dysarthria, dysphagia, and respiratory compromise. Sensory, autonomic, and oculomotor function is generally spared. While it was previously thought that higher cortical function was also unaffected, many ALS patients exhibit behavioral changes and cognitive dysfunction, and there is clinical, genetic, and neuropathological overlap between ALS and frontotemporal dementia spectrum disorders (Strong et al., 2009). ALS usually is progressive and fatal. Most patients die of respiratory compromise and pneumonia after 2-3 years, although some individuals have a more indolent course and survive for many years. The pathology of ALS corresponds closely to the clinical features: There is prominent loss of the spinal and brainstem motor neurons that project to striated muscles (although the oculomotor neurons are spared), as well as loss of the large pyramidal motor neurons in layer V of motor cortex, which are the origin of the descending corticospinal tracts.

Etiology. About 10% of ALS cases are familial (FALS), usually with an autosomal dominant pattern of inheritance. Most of the mutations responsible have not been identified, but an important subset of FALS patients are families with a mutation in the gene for the enzyme SOD1 (Rosen et al., 1993). Mutations in this protein account for about 20% of cases of FALS. Most of the mutations are

alterations of single amino acids, but more than 30 different alleles have been found in different kindreds. Transgenic mice expressing mutant human *SOD1* develop a progressive degeneration of motor neurons that closely mimics the human disease, providing an important animal model for research and pharmaceutical trials. Interestingly, many of the mutations of *SOD1* that can cause disease do not reduce the capacity of the enzyme to perform its primary function, the catabolism of superoxide radicals. Thus, as may be the case in HD, mutations in *SOD1* may confer a toxic “gain of function,” the precise nature of which is unclear.

More recently, mutations in the *TARDBP* gene encoding TAR DNA-binding protein (TDP-43) and in the *FUS/TLS* gene have been identified as causes of FALS (Lagier-Tourenne and Cleveland, 2009). Both TDP-43 and FUS/TLS bind DNA and RNA, and regulate transcription and alternative splicing.

More than 90% of ALS cases are sporadic. Of these, a few are caused by *de novo* mutations in *SOD1*, *TDP-43*, *FUS/TLS*, or other genes, but for the majority of sporadic cases the etiology remains unclear. Possible pathogenic mechanisms underlying sporadic ALS include autoimmunity, excitotoxicity, free radical toxicity, and viral infection (Rothstein, 2009), although none is well supported by available data. There is evidence that glutamate reuptake may be abnormal in the disease, leading to accumulation of glutamate and excitotoxic injury (Rothstein et al., 1992). The only currently approved therapy for ALS, riluzole, is based on these observations (Brooks, 2009).

Treatment of ALS

Riluzole. Riluzole (2-amino-6-[trifluoromethoxy] benzothiazole; RILUTEK) is an agent with complex actions in the nervous system (Doble, 1996; Zarate and Manji, 2008).

Riluzole is absorbed orally and is highly protein bound. It undergoes extensive metabolism in the liver by both CYP-mediated hydroxylation and glucuronidation. Its $t_{1/2}$ is about 12 hours. *In vitro* studies have shown that riluzole has both presynaptic and postsynaptic effects. It inhibits glutamate release, but it also blocks postsynaptic NMDA- and kainate-type glutamate receptors and inhibits voltage-dependent Na^+ channels. Some of the effects of riluzole *in vitro* are blocked by pertussis toxin, implicating the drug's interaction with an as yet-undefined G protein-coupled receptor (GPCR). In clinical trials riluzole has modest but genuine effects on the survival of patients with ALS.

Meta-analyses of the available trials indicate that riluzole extends survival by 2-3 months (Miller et al., 2007). The recommended dose is 50 mg twice daily, taken 1 hour before or 2 hours after a meal. Riluzole usually is well tolerated, although nausea or

diarrhea may occur. Rarely, riluzole may produce hepatic injury with elevations of serum transaminases, and periodic monitoring of these is recommended. Although the magnitude of the effect of riluzole on ALS is small, it represents a significant therapeutic milestone in the treatment of a disease refractory to all previous treatments.

Symptomatic Therapy of ALS: Spasticity. Spasticity is an important component of the clinical features of ALS and the feature most amenable to present forms of treatment. Spasticity often leads to considerable pain and discomfort and further reduces mobility, which already is compromised by weakness. *Spasticity* is defined as an increase in muscle tone characterized by an initial resistance to passive displacement of a limb at a joint, followed by a sudden relaxation (the so-called clasp-knife phenomenon). Spasticity results from loss of descending inputs to the spinal motor neurons, and the character of the spasticity depends on which nervous system pathways are affected (Sheean, 2008). Whole repertoires of movement can be generated directly at the spinal cord level; it is beyond the scope of this chapter to describe these in detail. The monosynaptic tendon-stretch reflex is the simplest of the spinal mechanisms contributing to spasticity. Primary Ia afferents from muscle spindles, activated when the muscle is stretched rapidly, synapse directly on motor neurons going to the stretched muscle, causing it to contract and resist the movement. A collateral of the primary Ia afferent synapses on a “Ia-coupled interneuron” that inhibits the motor neurons innervating the antagonist of the stretched muscle, allowing contraction of the muscle to be unopposed. Upper motor neurons from the cerebral cortex (the pyramidal neurons) suppress spinal reflexes and the lower motor neurons indirectly by activating the spinal cord inhibitory interneuron pools (Figure 22–8).

The pyramidal neurons use glutamate as a neurotransmitter. When the pyramidal influences are removed, the reflexes are released from inhibition and become more active, leading to hyperreflexia. Other descending pathways from the brainstem, including the rubro-, reticulo-, and vestibulospinal pathways and the descending catecholamine pathways, also influence spinal reflex activity. When just the pyramidal pathway is affected, extensor tone in the legs and flexor tone in the arms are increased. When the vestibulospinal and catecholamine pathways are impaired, increased flexion of all extremities is observed, and light cutaneous stimulation can lead to disabling whole-body spasms. In ALS, pyramidal pathways are impaired with relative preservation of the other descending pathways, resulting in hyperactive deep-tendon reflexes, impaired fine motor coordination, increased extensor tone in the legs, and increased flexor tone in the arms. The gag reflex often is overactive as well.

The best agent for the symptomatic treatment of spasticity in ALS is baclofen (LIORESAL), a GABA_B receptor agonist. Initial doses

Figure 22–8. Monosynaptic muscle stretch reflex with descending control via inhibitory interneurons. Primary Ia afferents (green) from muscle spindles, activated when the muscle is stretched rapidly, synapse directly on motor neurons (blue) going to the stretched muscle, causing it to contract and resist the movement. Pyramidal upper motor neurons (aqua) from the cerebral cortex suppress spinal reflexes and the lower motor neurons indirectly by activating the spinal cord inhibitory interneuron pools (red). When the pyramidal influences are removed, the reflexes are released from inhibition and become more active, leading to hyperreflexia and spasticity. Baclofen acts to restore the lost inhibition by stimulating postsynaptic GABA receptors. Tizanidine acts presynaptically to stimulate GABA release from spinal cord inhibitory interneuron.

of 5–10 mg/day are recommended, which can be increased to as much as 200 mg/day if necessary. If weakness occurs, the dose should be lowered. Alternatively, baclofen can be delivered directly into the space around the spinal cord using a surgically implanted pump and an intrathecal catheter. This approach minimizes the adverse effects of the drug, especially sedation, but it carries the risk of potentially life-threatening CNS depression. Moreover, abrupt withdrawal of intrathecal baclofen can cause rebound spasticity, rhabdomyolysis, multi-organ failure, and even death. Intrathecal baclofen should be used only by physicians trained in delivering chronic intrathecal therapy.

Tizanidine (ZANAFLEX) is an agonist of α_2 adrenergic receptors in the CNS. It reduces muscle spasticity and is assumed to act by increasing presynaptic inhibition of motor neurons. Tizanidine is primarily used in the treatment of spasticity in multiple sclerosis or after stroke, but it also may be effective in patients with ALS. Treatment should be initiated at a low dose of 2–4 mg at bedtime and titrated upward gradually. Drowsiness, asthenia, and dizziness may limit the dose that can be administered. Benzodiazepines (Chapter 17) such as clonazepam (KLONIPIN) are effective antispasticity agents, but they may contribute to respiratory depression in patients with advanced ALS. Dantrolene (DANTRIUM) also is approved in the U.S. for the treatment of muscle spasm. In contrast to the other agents discussed, dantrolene acts directly on skeletal muscle fibers, impairing Ca^{2+} release from the sarcoplasmic reticulum. Because it can exacerbate muscular weakness, it is not used in ALS but is effective in treating spasticity associated with stroke or spinal cord injury and in treating malignant hyperthermia (Chapter 8). Dantrolene may cause hepatotoxicity, so it is important to monitor liver associated enzymes before and during therapy with the drug.

Clinical Summary. ALS is a progressive degenerative disease of spinal motor neurons leading to weakness and eventually paralysis. It is the most rapidly progressive of the common neurodegenerative disorders and often is fatal within 2–3 years of onset. The only therapy established to alter the course of ALS is the drug riluzole, which acts through inhibition of glutamate release as well as other mechanisms. The effect of this treatment is modest, prolonging survival by a few months.

23 chapter

Ethanol and Methanol

Marc A. Schuckit

The two-carbon alcohol ethanol ($\text{CH}_3\text{CH}_2\text{OH}$), or beverage alcohol, is one of the most versatile drugs known to man, with multiple direct effects on a diverse range of neurochemical systems. Produced in nature, rewarding in its effects, and easy to manufacture, it has been taken by humans since the beginning of recorded history, is consumed by a large majority of people in the Western world, and is likely to contribute to more morbidity, mortality, and public health costs than all of the illicit drugs combined. Yet most pharmacologists, pharmacists, and healthcare providers receive only minimal education about ethanol and the mechanisms through which it contributes to such diverse pathology.

This chapter presents an overview of the effects of ethanol on various physiological systems, then focuses on the mechanisms of ethanol's effects in the central nervous system (CNS) as the basis for understanding the rewards, disease processes, and treatments for ethanol-related conditions. First, it is worthwhile to recount the history of the human use of alcoholic beverages.

Human Consumption of Ethanol: A Brief History. The use of alcoholic beverages has been documented since at least 10,000 BC (Hanson, 1995). By about 3000 BC, the Greeks, Romans, and inhabitants of Babylon continued to incorporate ethanol into religious festivals, while also using these beverages for pleasure, to facilitate socialization, as a source of nutrition, and as part of medicinal practices. The role of ethanol in society continued through biblical times, with beverage alcohol incorporated into most religions, and occupying a central role in daily life. Over the last 2000 years, alcoholic beverages have been identified in most cultures, including pre-Columbian America in ~200 AD, and the Islamic world in the 700s.

Whiskey was invented in ~1400 in Ireland and rapidly increased in popularity; champagne was developed in France in 1670. In 1690, the English government enacted a law encouraging the consumption of distilled spirits, and the production of gin subsequently increased from about 0.5 million gallons in 1685 to 5 million by 1727 and 18 million gallons by the early 1800s.

The dangers of heavy consumption of beverage alcohol have been recognized by almost all cultures, with most stressing the

importance of moderation. Despite these warnings, problems with ethanol are as ancient as the pattern of use of this beverage itself, and were noted early on in India, Greece, and Rome. The increase in use of ethanol in the 1800s, along with industrialization and need for a more dependable work force, contributed to the development of more widespread organized efforts to discourage drunkenness. The subsequent temperance movements set the stage for the prohibition against drinking instituted in the U.S. in 1920. In 1933, the long tradition of the use of alcohol, as well as the large minority of the population who favored the availability of alcoholic beverages, resulted in the repeal of the constitutional amendment enacting prohibition.

Beverage alcohol has widespread use in today's society, with an average age of first use of ~15 years in most Western countries. Almost two-thirds of women and as many as 80% of men in these countries have consumed alcoholic beverages, with one-half to two-thirds reporting alcohol consumption within the past year (Faden, 2006). The highest quantities and frequencies of drinking are usually observed in the late teens to early 20s, and in the U.S., the average adult consumes alcoholic beverages containing the equivalent of 2.2 gallons (8.3 L) of absolute alcohol per year. Among drinkers, as many as half have had a temporary alcohol-related problem such as missing school or work, alcohol-related amnesia (blackouts), or operating a motor vehicle after consuming alcohol. More severe repetitive problems with alcohol (known as abuse and dependence) have a lifetime risk in men of almost 20% and in women of 10-15% (Hasin et al., 2007). The annual costs associated with heavy drinking and associated problems have been estimated to be \$185 billion in the U.S. in recent years, and this drug contributes to 100,000 deaths per year in the U.S. alone, including as many as 20,000 alcohol-related fatal car accidents annually (Harwood et al., 1999; Rehm et al., 2007). Thus, the delivery of optimal medical care in modern times is greatly affected by the use of beverage alcohol, with this drug adversely affecting many body systems, interacting with medications and other drugs, and responsible for a great deal of the healthcare dollar.

Ethanol Consumption. Compared with other drugs, surprisingly large amounts of alcohol are required for physiological effects, resulting in its consumption more as a food than a drug. The alcohol content of beverages typically ranges from 4-6% (volume/volume) for beer, 10-15% for wine, and 40% and higher for distilled spirits

(the “proof” of an alcoholic beverage is twice its percentage of alcohol; e.g., 40% alcohol is 80 proof). A glass of beer or wine, a mixed drink, or a shot of spirits contains about 14 g alcohol, or about 0.3 mol ethanol. Consumption of 1–2 mol over a few hours is not uncommon. Thus, alcohol is consumed in gram quantities, whereas most other drugs are taken in milligram or microgram doses.

Since the ratio of ethanol in end-expiratory alveolar air and ethanol in the blood is relatively consistent, blood ethanol levels (BELs) in humans can be estimated readily by the measurement of alcohol levels in expired air; the partition coefficient for ethanol between blood and alveolar air is approximately 2000:1. Because of the causal relationship between excessive alcohol consumption and vehicular accidents, there has been a near-universal adoption of laws attempting to limit the operation of vehicles while under the influence of alcohol. Legally allowed BELs typically are set at or below 80 mg% (80 mg ethanol per 100 mL blood; 0.08% w/v), which is equivalent to a concentration of 17 mM ethanol in blood. A 12-oz bottle of beer, a 5-oz glass of wine, and a 1.5-oz “shot” of 40% liquor each contains approximately 14 g ethanol, and the consumption of one of these beverages by a 70-kg person would produce a BEL of approximately 30 mg%. However, it is important to note that this is approximate because the BEL is determined by a number of factors, including the rate of drinking, sex, body weight and water percentage, and the rates of metabolism and stomach emptying (see “Acute Ethanol Intoxication” later in the chapter).

PHARMACOLOGICAL PROPERTIES

Absorption, Distribution, and Metabolism

Ethanol. After oral administration, ethanol is absorbed rapidly into the bloodstream from the stomach and small intestine and distributes into total-body water (0.5–0.7 L/kg). Peak blood levels occur about 30 minutes after ingestion of ethanol when the stomach is empty. Because absorption occurs more rapidly from the small intestine than from the stomach, delays in gastric emptying (owing, e.g., to the presence of food) slow ethanol absorption. Because of first-pass metabolism by gastric and liver alcohol dehydrogenase (ADH), oral ingestion of ethanol leads to lower BELs than would be obtained if the same quantity were administered intravenously. Gastric metabolism of ethanol is lower in women than in men, which may contribute to the greater susceptibility of women to ethanol (Lieber,

2000; Schukit, 2006a). *Aspirin* increases ethanol bioavailability by inhibiting gastric ADH.

Ethanol is metabolized largely by sequential hepatic oxidation, first to acetaldehyde by ADH and then to acetic acid by aldehyde dehydrogenase (ALDH) (Figure 23–1). Each metabolic step requires NAD⁺; thus oxidation of 1 mol ethanol (46 g) to 1 mol acetic acid requires 2 mol NAD⁺ (approximately 1.3 kg). This greatly exceeds the supply of NAD⁺ in the liver; indeed, NAD⁺ availability limits ethanol metabolism to about 8 g or 10 mL (approximately 170 mmol) per hour in a 70-kg adult, or approximately 120 mg/kg per hour. Thus, hepatic ethanol metabolism functionally saturates at relatively low blood levels compared with the high BELs achieved, and ethanol metabolism is a zero-order process (constant amount per unit time). Small amounts of ethanol are excreted in urine, sweat, and breath, but metabolism to acetate accounts for 90–98% of ingested ethanol, mostly owing to hepatic metabolism by ADH and ADLH.

A hepatic cytochrome P450, CYP2E1, also can contribute (Figure 23–1), especially at higher ethanol concentrations and under conditions such as alcoholism, where its activity may be induced. Catalase also can produce acetaldehyde from ethanol, but hepatic H₂O₂ availability usually is too low to support significant flux of ethanol through this pathway. Although CYP2E1 usually is not a major factor in ethanol metabolism, it can be an important site of interactions of ethanol with other drugs. CYP2E1 is induced by chronic consumption of ethanol, increasing the clearance of its substrates and the activation of certain toxins such as CCl₄. There can be decreased clearance of the same drugs, however, after acute consumption of ethanol because ethanol competes with them for oxidation by the enzyme system (e.g., phenytoin and warfarin).

The large increase in the hepatic NADH:NAD⁺ ratio during ethanol oxidation has profound consequences in addition to limiting the rate of ethanol metabolism. Enzymes requiring NAD⁺ are inhibited; thus lactate accumulates, activity of the tricarboxylic acid cycle is reduced, and acetyl coenzyme A (acetyl CoA) accumulates (and it is produced in quantity from ethanol-derived acetic acid; Figure 23–1). The combination of increased NADH and elevated acetyl CoA supports fatty acid synthesis and the storage and accumulation of triacylglycerides. Ketone bodies accrue, exacerbating lactic acidosis. Ethanol metabolism by the CYP2E1 pathway produces elevated NADP⁺, limiting the availability of NADPH for the regeneration of reduced glutathione (GSH), thereby enhancing oxidative stress.

Figure 23–1. Metabolism of ethanol and methanol.

The mechanisms underlying hepatic disease resulting from heavy ethanol use probably reflect a complex combination of these metabolic factors, CYP2E1 induction (and enhanced activation of toxins and production of H_2O_2 and oxygen radicals), and possibly enhanced release of endotoxin as a consequence of ethanol's effect on gram-negative flora in the GI tract. Effects of heavy ethanol ingestion on various organs are summarized in the following discussion; damage to tissues very likely reflects the poor nutritional status of alcoholics (malabsorption and lack of vitamins A and D and thiamine), suppression of immune function by ethanol, and a variety of other generalized effects.

Methanol. One carbon alcohol, methanol (CH_3OH), is also known as methyl and wood alcohol. It is an important industrial reagent and solvent found in products such as paint removers, shellac, and antifreeze (Lushine et al., 2003); methanol is added to industrial-use ethanol to mark it unsafe for human consumption.

Methanol is rapidly absorbed via the oral route, inhalation, and through the skin, with the latter two routes most relevant to industrial settings. Methanol also is metabolized by ADH and ALDH, with damaging consequences (described later in the chapter). Competition between methanol and ethanol for ADH forms the basis of the use of ethanol in methanol poisoning. Several drugs inhibit alcohol metabolism, including fomepizole (4-methylpyrazole) an ADH inhibitor useful in ethylene glycol poisoning, and *disulfiram*, an ALDH inhibitor used in treating alcoholism (described later in the chapter). Ethanol also can competitively inhibit the metabolism of other substrates of ADH and CYP2E1, such as methanol and ethylene glycol, and therefore is an effective antidote.

Feelings of intoxication from methanol, while similar in many ways to those with ethanol, are less intense, and often delayed by 8 or more hours from ingestion, progressing even more slowly if

methanol is taken along with ethanol. As little as 15 mL of methanol can produce toxicity, including blindness, with doses in excess of 70 mL capable of producing death. Methanol poisoning consists of headache, GI distress, and pain (partially related to pancreatic injury), difficulty breathing, restlessness, and blurred vision associated with hyperemic optic disks. Severe metabolic acidosis can develop due to the accumulation of formic acid, and the respiratory depression can be severe, especially in the context of coma. The visual disturbances associated with methanol intoxication are a prominent part of the picture, and occur as a consequence of injury to ganglion cells of the retina by the metabolite, formic acid, with subsequent inflammation, atrophy, and potential bilateral blindness. The clinical picture can also include necrosis of the pancreas.

Genetic Variation in Ethanol Metabolism. The enzymes involved in ethanol metabolism (Figure 23–1) are mainly ADH and ALDH, and secondarily, catalase and CYP2E1. Several of these enzymes have genetic variants that alter alcohol metabolism and susceptibility to its effects.

The genetics of the ADH isoforms are important for understanding risk factors for severe repetitive ethanol problems. The three relevant forms are ADH1A, 1B, and 1C (genes on chromosome 4q22). These class I ADHs have $K_m < 34$ mmol (0.15 g/dL) and are responsible for 70% of the ethanol metabolizing capacity at BECs of 22 mM (i.e., ~0.10 g/dL) (Edenberg et al., 2006). These ADH forms are the rate-limiting step in ethanol metabolism, reducing the blood ethanol concentrations by ~4–5 mM (0.015–0.020 g/dL) per hour, the approximate levels of alcohol resulting from the consumption of one standard drink.

The ADH1A gene has no polymorphisms known to significantly affect the rate of alcohol metabolism. The ADH1B gene has a polymorphism, ADH1B*2, with arginine 47 replaced by histidine to produce a variant form of ADH with a 40-fold higher V_{max} than ADH1B. This polymorphism is seen in 30–45% of Chinese, Japanese, and Koreans, less than 10% of most Europeans, but in 50–90% of Russians and Jews (Edenberg et al., 2006). The potential faster metabolism of ethanol may result in a transient slightly higher blood level of acetaldehyde and is reported to be associated with a lower risk for heavy drinking and ethanol-related problems. A second polymorphism for ADH1B, ADH1B*3 (arginine 269 replaced by cysteine), has a 30-fold higher V_{max} . ADH1B*3 is seen in about 30% of Africans and also is associated with lower risk of heavy drinking and ethanol problems.

A third ADH gene found in the chromosome 4q22 cluster, ADH1C, exhibits two polymorphisms in high linkage disequilibrium, the $\gamma 1$ and $\gamma 2$ forms. The V_{max} of $\gamma 1$ is twice that of $\gamma 2$, and this ADH1C*1 allele is hypothesized to be associated with a slightly faster metabolism of ethanol and/or a higher level of acetaldehyde. The independent effects of ADH1C*1 and ADH1B*2 alleles are difficult to determine. The ADH cluster on chromosome 4 also contains class II ADHs with $K_m = 34$ mM (~0.15 g/dL). The class II forms contribute about 30% of the ethanol metabolizing capacity noted above. There are polymorphisms hypothesized to be associated with the alcoholism risk, but less information is known about these forms (Luo et al., 2007).

Other systems also contribute to the metabolism of ethanol to acetaldehyde including via catalase (Kuo et al., 2008). In addition, at higher BELs, the microsomal ethanol metabolizing system (MEOS) is important, especially CYP2E1, but also CYPs1A2 and

3A4. Variations of the CYP2E1 gene located on chromosome 10 have been hypothesized to relate to the level of sensitivity or reaction to the ethanol observed in the brain.

Acetaldehyde is produced from the breakdown of ethanol at the rate of approximately one standard drink per hour. As shown in Figure 23–1, the acetaldehyde is then rapidly broken down through the actions of ALDH2, primarily in the mitochondria of liver cells. The actions of ALDH2, a phase 2 enzyme (Chapter 6), are important because low levels of acetaldehyde may be perceived as rewarding and stimulating, while high blood levels of this substance produce severe adverse reactions that can include vomiting, diarrhea, and unstable blood pressure (Husemoen et al., 2008). There is a mutation in the ALDH2 gene (12q24), ALDH2*2 (resulting from a substitution of glycine 487 with lysine). Homozygotes with a nonfunctional ALDH2*2 occur in 5–10% of Japanese, Chinese, and Korean individuals, for whom severe adverse reactions occur after consumption of one drink or less. Consequently, their risk for severe repetitive heavy drinking is close to zero. This reaction operates through the same mechanism that occurs with drinking after taking the ALDH2 inhibitor, disulfiram. Heterozygotes for this polymorphism (ALDH2*2, 2*1) make up 30–40% of Asian individuals who, after consuming ethanol experience a facial flush and an enhanced sensitivity to beverage alcohol, but who do not necessarily report an overall adverse response to the drug (Wall and Ehlers, 1995). The heterozygotes tend to drink lower quantities of ethanol than the general population, although repeated intake may relate to an enhanced risk for adverse ethanol-related organ damage (including esophageal cancer and, perhaps, pancreatitis), possibly associated with higher acetaldehyde levels. While additional ALDH mutations occur, less is known about potential associations between these polymorphisms and the risk from alcohol.

EFFECTS OF ETHANOL ON PHYSIOLOGICAL SYSTEMS

William Shakespeare described the acute pharmacological effects of imbibing ethanol in the Porter scene (act 2, scene 3) of *Macbeth*. The Porter, awakened from an alcohol-induced sleep by Macduff, explains three effects of alcohol and then wrestles with a fourth effect that combines the contradictory aspects of soaring overconfidence with physical impairment:

Porter: . . . and drink, sir, is a great provoker of three things.

Macduff: What three things does drink especially provoke?

Porter: Marry, sir, nose-painting [*cutaneous vasodilation*], sleep [*CNS depression*], and urine [*a consequence of the inhibition of antidiuretic hormone (vasopressin) secretion, exacerbated by volume loading*]. Lechery, sir, it provokes and unprovokes: it provokes the desire but it takes away the performance. Therefore much drink may be said to be an equivocator with lechery: it makes him and it mars him; it sets him on and it takes him off; it persuades him and disheartens him, makes him stand to and not stand to [*the imagination desires what the corpus cavernosum cannot deliver*]; in conclusion, equivocates him in a sleep, and, giving him the lie, leaves him.

More recent research has added details to Shakespeare's enumeration—see the bracketed additions to the Porter's words in the preceding paragraph and the section on organ systems later in the chapter—but the most noticeable consequences of the recreational use of ethanol still are well summarized by the gregarious and garrulous Porter, whose delighted and devilish demeanor demonstrates a frequently observed influence of modest concentrations of ethanol on the CNS. The sections that follow detail ethanol's effects on physiological systems.

Central Nervous System

Although the public often views alcoholic drinks as stimulating, ethanol primarily is a CNS depressant. Ingestion of moderate amounts of ethanol, like that of other depressants such as barbiturates and benzodiazepines, can have anti-anxiety actions and produce behavioral disinhibition at a wide range of dosages. Individual signs of intoxication vary from expansive and vivacious affect to uncontrolled mood swings and emotional outbursts that may have violent components. With more severe intoxication, CNS function generally is impaired, and a condition of general anesthesia ultimately prevails. However, there is little margin between the anesthetic actions and lethal effects (usually owing to respiratory depression).

About 10% of alcohol drinkers progress to levels of consumption that are physically and socially detrimental. Chronic abuse is accompanied by tolerance, dependence, and craving for the drug (*see* Tolerance, Dependence, and Chronic Ethanol Use, and Chapter 24). Alcoholism is characterized by compulsive use despite clearly deleterious social and medical consequences. Alcoholism is a progressive illness, and brain damage from chronic alcohol abuse contributes to the deficits in cognitive functioning and judgment seen in alcoholics. Alcoholism is a leading cause of dementia in the U.S. (Oslin et al., 1998). Chronic alcohol abuse results in shrinkage of the brain owing to loss of both white and gray matter (Krill and Halliday, 1999). The frontal lobes are particularly sensitive to damage by alcohol, and the extent of damage is determined by the amount and duration of alcohol consumption, with older alcoholics being more vulnerable than younger ones (Pfefferbaum et al., 1998). It is important to note that ethanol itself is neurotoxic, and although malnutrition or vitamin deficiencies probably play roles in complications of alcoholism such as Wernicke's encephalopathy and Korsakoff's psychosis, most of the alcohol-induced brain damage in Western countries is due to alcohol itself. In addition to loss of brain tissue, alcohol abuse also reduces brain metabolism (as determined by positron-emission tomography), and this hypometabolic state rebounds to a level of increased metabolism during detoxification. The magnitude of decrease in metabolic state is determined by the number of years of alcohol use and the age of the patients (Volkow et al., 1994).

Table 23–1

Impact of Ethanol on Key Neurochemical Systems

NEUROTRANSMITTER SYSTEM	EFFECTS
GABA _A	GABA release, ↑ receptor density
NMDA	Inhibition of postsynaptic NMDA receptors; with chronic use, up-regulation
DA	↑ Synaptic DA, ↑ effects on ventral tegmentum/nucleus accumbens reward
ACTH	↑ CNS and blood levels of ACTH
Opioid	Release of β endorphins, activation of μ receptors
5-HT	↑ in 5-HT synaptic space
Cannabinoid	↑ CB1 activity → changes in DA, GABA, glutamate activity

Actions of Ethanol on Neurochemical Pathways and Signaling.

Ethanol affects almost all brain systems. The changes across neurochemical pathways occur simultaneously and the alterations often interact. An additional complication in describing CNS effects is the rapid adaptation to ethanol observed in the brain, with the result that the acute effects of the first dose of ethanol are often the opposite of the neurochemical consequences from repeated administration and those observed during falling blood ethanol levels and withdrawal syndromes (Schuckit, 2006b).

Alcohol perturbs the balance between excitatory and inhibitory influences in the brain, resulting in anxiolysis, ataxia, and sedation. This is accomplished by either enhancing inhibitory or antagonizing excitatory neurotransmission. Ethanol likely produces its effects by simultaneously altering the functioning of a number of proteins that can affect neuronal excitability (Table 23–1). A key issue has been to identify proteins that determine neuronal excitability and are sensitive to ethanol at the concentrations (5–20 mM) that produce behavioral effects. Many of the prominent effects are on ligand-gated and voltage-gated ion channels and GPCR systems.

Ion Channels. The primary mediators of inhibitory neurotransmission in the brain are the ligand-gated γ -aminobutyric acid A (GABA_A) receptors, whose function is markedly enhanced by a number of classes of sedative, hypnotic, and anesthetic agents, including barbiturates, benzodiazepines, and volatile anesthetics (Chapter 14). Substantial data implicate the GABA_A receptor as an important target for the *in vivo* actions of ethanol. Stimulation of this multi-subunit, ligand-gated Cl[−] channel system contributes to feelings of sleepiness, muscle relaxation, and the acute anticonvulsant properties associated with all GABA-boosting drugs (Krystal et al.,

2006). Acutely, ethanol results in GABA release; chronic heavy use alters the pattern of expression of genes impacting on GABA_A subunits. Intoxication with ethanol can be viewed as a GABA-rich state, and withdrawal phenomena are related in part to GABA_A activity deficiencies. Several GABA_A receptor gene polymorphisms correlate with a predisposition toward heavy drinking and alcohol use disorders (Dick et al., 2006a,b).

The nicotinic ACh receptor is also sensitive to the effects of ethanol. Drinking acutely increases ACh in the ventral tegmental area, with a subsequent increase in DA in the nucleus accumbens (Joslyn et al., 2008). Varenicline, a partial agonist at the $\alpha_4\beta_2$ subtype of the nicotinic ACh receptor (Chapter 11), decreases ethanol-seeking behavior and ethanol consumption in a rodent model, similar to its actions to effects on nicotine dependence (Steensland et al., 2007). Effects of ethanol on these receptors may be particularly important because there is an association between nicotine exposure (smoking) and alcohol consumption in humans. Furthermore, several studies indicate that nicotine increases alcohol consumption in animal models (Smith et al., 1999).

Excitatory ionotropic glutamate receptors are divided into the N-methyl-D-aspartate (NMDA) and non-NMDA receptor classes, with the latter consisting of kainate- and AMPA-receptor subtypes (see Chapter 14). Ethanol inhibits the function of the NMDA- and kainate-receptor subtypes; AMPA receptors are largely resistant to alcohol (Carta et al., 2003). As with the GABA_A receptors, phosphorylation of the glutamate receptor can modulate sensitivity to ethanol.

A number of other types of channels are sensitive to alcohol at concentrations routinely achieved *in vivo*. Ethanol enhances the activity of large conductance, Ca²⁺-activated K⁺ channels in neurohypophyseal terminals (Dopico et al., 1999), perhaps contributing to the reduced release of oxytocin and vasopressin after ethanol consumption. Ethanol inhibits N- and P/Q-type Ca²⁺ channels in a manner that can be antagonized by channel phosphorylation by PKA (Solem et al., 1997). BK (Maxi-K, slo1) channels also are a target for alcohol action (Davies et al., 2003). G protein-gated inwardly rectifying K⁺ channels (GIRK or Kir channels) can be activated by the $\beta\gamma$ subunits of the G_i/G_o family, by PIP₂, and, via a different mechanism, by alcohols. Small alcohols bind to a hydrophobic binding pocket on GIRKs, leading to channel activation via stabilization of the open conformation (Aryal et al., 2009).

Other Neurotransmitter Systems. Dopamine-related systems have central importance regarding the feelings of reward and craving associated with all intoxicating substances (Koob and Kreek, 2007). Of special importance are alterations in DA activity in the ventral tegmental and related areas, especially the nucleus accumbens, which are likely to play a major role in feelings of euphoria and reward. Acute alcohol results in an increase in synaptic DA; repeated administration is associated with changes in both D₂ and D₄ receptors that may be important in the perpetuation of alcohol use as well as in relapse (Voronin et al., 2008).

The impact of ethanol on dopaminergic pathways is closely linked to changes in stress-related systems. These changes are hypothesized to relate to reinforcement from beverage alcohol and other drugs of abuse, as well as withdrawal symptoms and negative moods related to problems with regulation of the DA-rich brain reward systems. Dopaminergic activity in the nucleus accumbens is affected by multiple types of opioid receptors, and

acute ethanol causes the release of β endorphins (Job et al., 2007). These actions subsequently activate μ opioid receptors in the ventral tegmentum and nucleus accumbens, with associated release of DA. Thus, many of the effects of alcohol on reward systems, and changes in how the CNS reacts to ethanol (including sensitization), may relate to alterations in opioid systems (Pastor and Aragon, 2006).

The acute administration of ethanol is associated with a significant increase in 5-HT in the synaptic space; continued use of ethanol produces an up-regulation of 5-HT receptors. Lower levels of 5-HT in the synapse, perhaps related to a more rapid reuptake by the 5-HT transporter, is associated with higher levels of alcohol intake and, potentially, lower levels of intensity of reaction to beverage alcohol (Barr et al., 2005). Changes in DA systems are likely to relate to alterations in 5-HT as well.

Cannabinoid receptors, especially CB₁ encoded by the gene CNR1, are also affected by ethanol (Hutchinson et al., 2008; Perra et al., 2008). CB₁ is a GPCR that is densely represented in the ventral tegmentum, nucleus accumbens, and prefrontal cortex. Activation of CB₁ occurs with acute ethanol administration and affects the release of DA, GABA, and glutamate, and reward circuits of the brain. Antagonists of CB₁ receptors, such as rimonabant, may block the effect of ethanol on dopaminergic systems.

Protein Kinases and Signaling Enzymes. Knockout mice lacking the γ isoform of PKC display reduced effects of ethanol measured behaviorally and a loss of enhancement by ethanol of GABA's effects measured *in vitro* (Harris et al., 1995). Intracellular signal-transduction cascades, such as MAPK, tyrosine kinases, and neurotrophic factor receptors, also are thought to be affected by ethanol (Valenzuela and Harris, 1997). Translocation of PKC and PKA between subcellular compartments also is sensitive to alcohol (Constantinescu et al., 1999).

Ethanol enhances the activities of several isoforms of adenylyl cyclase, with AC7 being the most sensitive (Tabakoff and Hoffman, 1998). This promotes increased production of cyclic AMP and thus increased activity of PKA. Ethanol's actions appear to be mediated by activation of G_s and promotion of the interaction between G_s and adenylyl cyclase.

Ethanol Consumption and CNS Function. There are a series of relatively common and temporary effects of ethanol with relatively high prevalence rates reflecting changes in the GABA system that are generally caused by CNS depressants. Large doses of ethanol can interfere with encoding of memories, producing anterograde amnesia, commonly referred to as *alcoholic blackouts*; affected individuals are unable to recall all or part of experiences during the period of heavy intake. At even 2-3 drinks, ethanol consumption can produce disturbances in sleep architecture, with frequent awakenings and restless sleep; high doses are associated with vivid and disturbing dreams late as a consequence of earlier suppression of night rapid eye movement dream state at higher blood ethanol levels. Perhaps reflecting the effect of ethanol on respirations as well as the muscle-relaxant effects of this drug, heavier drinking can be associated with sleep apnea, especially in older alcohol-dependent subjects (Sakurai et al., 2007). The transient CNS effects of heavy ethanol consumption that produce a hangover—the “next morning” syndrome of headache, thirst, nausea, and cognitive impairment—contribute to much time lost from work and school, and may reflect mechanisms

similar to mild alcohol withdrawal, dehydration, and/or mild acidosis (Stephens et al., 2008).

Chronic heavy drinking reportedly increases the probability of developing a more permanent cognitive deficit often referred to as *alcoholic dementia*. However, the signs of cognitive deficits and brain atrophy observed soon after a heavy drinking period often reverse over the subsequent several weeks to months following abstinence (Bartsch et al., 2007). The thiamine depletion that can accompany heavy ethanol consumption contributes to Wernicke-Korsakoff syndromes; however, the ataxia and ophthalmoparesis of Wernicke's, and the severe anterograde and retrograde amnesias of Korsakoff's, are seen in <<1% of chronic alcohol-dependent individuals. Additional severe neurological syndromes associated with chronic heavy use of alcohol include cerebellar degeneration with associated atrophy of the cerebellar vermis (seen in ~1% of alcoholics), and a peripheral neuropathy (observed in ~10% of alcoholics) (Alexander-Kaufman et al., 2007; Peters et al., 2006). The specific mechanisms associated with damage to the cerebellum and peripheral nerves have not been definitively identified.

Heavy doses of ethanol over multiple days or weeks are also associated with several temporary but disturbing "alcohol-induced" psychiatric syndromes (Schuckit, 2006a). As many as 40% of alcohol-dependent humans develop severe alcohol-related depressive symptoms that can include temporary suicidal thoughts and behaviors. Similarly, a range of anxiety conditions, including those characterized by panic attacks and generalized anxiety, are likely in a large minority of alcohol-dependent individuals during the withdrawal syndrome. Perhaps 3% of alcohol-dependent men and women report experiencing temporary auditory hallucinations and paranoid delusions that resemble schizophrenia beginning during periods of heavy intoxication; all of these psychiatric syndromes are likely to markedly improve within several days to a month of abstinence, with residual mild symptoms continuing to diminish thereafter. While no definitive data on the mechanisms for these alcohol-induced psychiatric conditions are available, it is logical to assume that alcohol-related changes in CNS pathways (NE and 5-HT levels, the balance between GABA_A and NMDA receptor activity, dopaminergic activity) may operate here in a manner similar to those seen in depression, anxiety, and schizophrenic disorders.

Cardiovascular System

Ethanol intake greater than three standard drinks per day elevates the risk for heart attacks and bleeding-related strokes (Hvidtfeldt et al., 2008). Indeed, vascular-related diseases are among the leading causes of early death in alcohol-dependent individuals. The risk includes a 6-fold increased risk for coronary artery disease, a heightened risk for cardiac arrhythmias, and an elevated rate of congestive heart failure. The causes are complex and observations are complicated by certain positive effects of small amounts of ethanol.

Serum Lipoproteins and Cardiovascular Effects. In most countries, the risk of mortality due to coronary heart disease (CHD) is correlated with a high dietary intake of saturated fat and elevated serum cholesterol

levels. France is an exception to this rule, with relatively low mortality from CHD despite the consumption of high quantities of saturated fats (the "French paradox"). Epidemiological studies suggest that widespread wine consumption (20-30 g ethanol per day) is one of the factors conferring a cardioprotective effect, with 1-3 drinks per day resulting in a 10-40% decreased risk of coronary heart disease compared with abstainers. In contrast, daily consumption of greater amounts of alcohol leads to an increased incidence of non-coronary causes of cardiovascular failure, such as arrhythmias, cardiomyopathy, and hemorrhagic stroke, offsetting the beneficial effects of alcohol on coronary arteries; that is, alcohol has a J-shaped dose-mortality curve. Reduced risks for CHD are seen at intakes as low as one-half drink per day (Libby et al., 2007). Young women and others at low risk for heart disease derive little benefit from light to moderate alcohol intake, whereas those of both sexes who are at high risk and who may have had a myocardial infarction clearly benefit. Data based on a number of prospective, cohort, cross-cultural, and case-control studies in diverse populations consistently reveal lower rates of angina pectoris, myocardial infarction, and peripheral artery disease in those consuming light (1-20 g/day) to moderate (21-40 g/day) amounts of alcohol.

One possible mechanism by which alcohol could reduce the risk of CHD is through its effects on blood lipids. Changes in plasma lipoprotein levels, particularly increases in high-density lipoprotein (HDL; Chapter 31), have been associated with the protective effects of ethanol. HDL binds cholesterol and returns it to the liver for elimination or reprocessing, decreasing tissue cholesterol levels. Ethanol-induced increases in HDL-cholesterol thus could antagonize cholesterol accumulation in arterial walls, lessening the risk of infarction. Approximately half the risk reduction associated with ethanol consumption is explained by changes in total HDL levels (Langer et al., 1992). HDL is found as two subfractions, named HDL₂ and HDL₃. Increased levels of HDL₂ (and possibly also HDL₃) are associated with reduced risk of myocardial infarction. Levels of both subfractions are increased following alcohol consumption and decrease when alcohol consumption ceases. Apolipoproteins A-I and A-II are constituents of HDL. Increased levels of both apolipoproteins A-I and A-II are associated with individuals who are daily heavy drinkers. In contrast, there are reports of decreased serum apolipoprotein(a) levels following acute alcohol consumption. Elevated apolipoprotein(a) levels have been associated with an increased risk for the development of atherosclerosis.

All forms of alcoholic beverages confer cardio-protection. A variety of alcoholic beverages increase HDL levels while decreasing the risk of myocardial infarction. The flavonoids found in red wine (and purple grape juice) may have an additional antiatherogenic role by protecting low-density lipoprotein (LDL) from oxidative damage. Oxidized LDL has been implicated in several steps of

atherogenesis (Chapter 31). Another way in which alcohol consumption conceivably could play a cardioprotective role is by altering factors involved in blood clotting. Alcohol consumption elevates the levels of tissue plasminogen activator, a clot-dissolving enzyme (Chapter 30), decreasing the likelihood of clot formation. Decreased fibrinogen concentrations seen following ethanol consumption also could be cardioprotective (Rimm et al., 1999), and epidemiological studies have linked the moderate consumption of ethanol to an inhibition of platelet activation (Rubin, 1999).

Should abstainers from alcohol be advised to consume ethanol in moderate amounts? The answer is *no*. There have been no randomized clinical trials to test the efficacy of daily alcohol use in reducing rates of coronary heart disease and mortality, and it is inappropriate for physicians to advocate alcohol ingestion solely to prevent heart disease. Many abstainers avoid alcohol because of a family history of alcoholism or for other health reasons, and it is imprudent to suggest that they begin drinking. Other lifestyle changes or medical treatments should be encouraged if patients are at risk for the development of CHD.

Hypertension. Heavy alcohol use can raise diastolic and systolic blood pressure. Studies indicate a positive, non-linear association between alcohol use and hypertension that is unrelated to age, education, smoking status, or the use of oral contraceptives. Consumption above 30 g alcohol per day (more than 2 standard drinks) is associated with a 1.5-2.3 mm Hg rise in diastolic and systolic blood pressure.

The prevalence of hypertension attributable to excess alcohol consumption is not known, but studies suggest a range of 5-11%. The prevalence probably is higher for men than for women because of higher alcohol consumption by men. A reduction in or cessation of alcohol use in heavy drinkers may reduce the need for antihypertensive medication or reduce the blood pressure to the normal range. A safe amount of alcohol consumption for hypertensive patients who are light drinkers (1-2 drinks per occasion and less than 14 drinks per week) has not been determined. Factors to consider are a personal history of ischemic heart disease, a history of binge drinking, or a family history of alcoholism or of cerebrovascular accident. Hypertensive patients with any of these risk factors should abstain from alcohol use.

Cardiac Arrhythmias. Alcohol has a number of pharmacological effects on cardiac conduction, including prolongation of the QT interval, prolongation of ventricular repolarization, and sympathetic stimulation. Atrial arrhythmias associated with chronic alcohol use include supraventricular tachycardia, atrial fibrillation, and atrial flutter. Some 15-20% of idiopathic cases of atrial fibrillation may be induced by chronic ethanol use (Libby et al., 2007). Ventricular tachycardia may be

responsible for the increased risk of unexplained sudden death that has been observed in persons who are alcohol-dependent (Kupari and Koskinen, 1998). During continued alcohol use, treatment of these arrhythmias may be more resistant to cardioversion, digoxin, or Ca²⁺ channel blocking agents. Patients with recurrent or refractory atrial arrhythmias should be questioned carefully about alcohol use.

Cardiomyopathy. Ethanol is known to have dose-related toxic effects on both skeletal and cardiac muscle. Numerous studies have shown that alcohol can depress cardiac contractility and lead to cardiomyopathy. Echocardiography demonstrates global hypokinesis. Approximately half of all patients with idiopathic cardiomyopathy are alcohol-dependent. Although the clinical signs and symptoms of idiopathic and alcohol-induced cardiomyopathy are similar, alcohol-induced cardiomyopathy has a better prognosis if patients are able to stop drinking. Women are at greater risk of alcohol-induced cardiomyopathy than are men (Urbano-Marquez et al., 1995). Since 40-50% of persons with alcohol-induced cardiomyopathy who continue to drink die within 3-5 years, abstinence remains the primary treatment.

Stroke. Clinical studies indicate an increased incidence of hemorrhagic and ischemic stroke in persons who drink more than 40-60 g alcohol per day (Hansagi et al., 1995). Many cases of stroke follow prolonged binge drinking, especially when stroke occurs in younger patients. Proposed etiological factors include:

- alcohol-induced cardiac arrhythmias and associated thrombus formation
- high blood pressure from chronic alcohol consumption and subsequent cerebral artery degeneration
- acute increases in systolic blood pressure and alterations in cerebral artery tone
- head trauma

The effects on hemostasis, fibrinolysis, and blood clotting are variable and could prevent or precipitate acute stroke (Numminen et al., 1996). The effects of alcohol on the formation of intracranial aneurysms are controversial, but the statistical association disappears when one controls for tobacco use and gender (Qureshi et al., 1998).

Skeletal Muscle

Alcohol has a number of effects on skeletal muscle. Chronic, heavy, daily alcohol consumption is associated with decreased muscle strength, even when adjusted for

other factors such as age, nicotine use, and chronic illness. Heavy doses of alcohol also can cause irreversible damage to muscle, reflected by a marked increase in the activity of creatine kinase in plasma.

Muscle biopsies from heavy drinkers also reveal decreased glycogen stores and reduced pyruvate kinase activity (Vernet et al., 1995). Approximately 50% of chronic heavy drinkers have evidence of type II fiber atrophy. These changes correlate with reductions in muscle protein synthesis and serum carnosinase activities (Wassif et al., 1993). Most patients with chronic alcoholism show electromyographical changes, and many show evidence of a skeletal myopathy similar to alcoholic cardiomyopathy.

Body Temperature

Ingestion of ethanol causes a feeling of warmth because alcohol enhances cutaneous and gastric blood flow. Increased sweating also may occur. Heat, therefore, is lost more rapidly, and the internal body temperature falls. After consumption of large amounts of ethanol, the central temperature-regulating mechanism becomes depressed, and the fall in body temperature may become pronounced. The action of alcohol in lowering body temperature is greater and more dangerous when the ambient environmental temperature is low. Studies of deaths from hypothermia suggest that alcohol is a major risk factor in these events. Patients with ischemic limbs secondary to peripheral vascular disease are particularly susceptible to cold damage.

Diuresis

Alcohol inhibits the release of vasopressin (antidiuretic hormone) from the posterior pituitary gland, resulting in enhanced diuresis. The volume loading that accompanies imbibing complements the diuresis that occurs as a result of reduced vasopressin secretion.

Alcoholics have less urine output than do control subjects in response to a challenge dose with ethanol, suggesting that tolerance develops to the diuretic effects of ethanol (Collins et al., 1992). Alcoholics withdrawing from alcohol exhibit increased vasopressin release and a consequent retention of water, as well as dilutional hyponatremia.

Gastrointestinal System

Esophagus. Alcohol frequently is either the primary etiologic factor or one of multiple causal factors associated with esophageal dysfunction. Ethanol also is associated with the development of esophageal reflux, Barrett's esophagus, traumatic rupture of the esophagus, Mallory-Weiss tears, and esophageal cancer.

When compared with nonalcoholic nonsmokers, alcohol-dependent patients who smoke have a 10-fold increased risk of developing cancer of the esophagus. There is little change in esophageal function at low blood alcohol concentrations, but at higher blood alcohol concentrations, a decrease in peristalsis and decreased lower esophageal sphincter pressure occur. Patients with chronic reflux esophagitis may respond to proton pump inhibitors and abstinence from alcohol.

Stomach. Heavy alcohol use can disrupt the gastric mucosal barrier and cause acute and chronic gastritis. Ethanol appears to stimulate gastric secretions by exciting sensory nerves in the buccal and gastric mucosa and promoting the release of gastrin and histamine. Beverages containing more than 40% alcohol also have a direct toxic effect on gastric mucosa. While these effects are seen most often in chronic heavy drinkers, they can occur after moderate and short-term alcohol use. The diagnosis may not be clear because many patients have normal endoscopic examinations and upper gastrointestinal radiographs. Clinical symptoms include acute epigastric pain that is relieved with antacids or histamine H₂ receptor blockers.

Alcohol is not thought to play a role in the pathogenesis of peptic ulcer disease. Unlike acute and chronic gastritis, peptic ulcer disease is not more common in alcoholics. Nevertheless, alcohol exacerbates the clinical course and severity of ulcer symptoms. It appears to act synergistically with *Helicobacter pylori* to delay healing (Lieber, 1997). Acute bleeding from the gastric mucosa, while uncommon, can be a life-threatening emergency. Upper GI bleeding is associated more commonly with esophageal varices, traumatic rupture of the esophagus, and clotting abnormalities.

Intestines. Many alcoholics have chronic diarrhea as a result of malabsorption in the small intestine (Addolorato et al., 1997). The major symptom is frequent loose stools. The rectal fissures and *pruritus ani* that frequently are associated with heavy drinking probably are related to chronic diarrhea. The diarrhea is caused by structural and functional changes in the small intestine (Papa et al., 1998); the intestinal mucosa has flattened villi, and digestive enzyme levels often are decreased. These changes frequently are reversible after a period of abstinence. Treatment is based on replacing essential vitamins and electrolytes, slowing transit time with an agent such as loperamide, and abstaining from all alcoholic beverages. Patients with severe magnesium deficiencies (serum Mg²⁺ < 1 mEq/L) or symptomatic patients (a positive Chvostek's sign or asterixis) should receive 1 g MgSO₄ intravenously or intramuscularly every 4 hours until the serum [Mg²⁺] > 1 mEq/L.

Pancreas. Heavy alcohol use is the most common cause of both acute and chronic pancreatitis in the U.S. While

pancreatitis has been known to occur after a single episode of heavy alcohol use, prolonged heavy drinking is common in most cases. Acute alcoholic pancreatitis is characterized by the abrupt onset of abdominal pain, nausea, vomiting, and increased levels of serum or urine pancreatic enzymes. Computed tomography is being used increasingly for diagnostic testing. While most attacks are not fatal, hemorrhagic pancreatitis can develop and lead to shock, renal failure, respiratory failure, and death. Management usually involves intravenous fluid replacement—often with nasogastric suction—and opioid pain medication. The etiology of acute pancreatitis probably is related to a direct toxic metabolic effect of alcohol on pancreatic acinar cells.

Two-thirds of patients with recurrent alcoholic pancreatitis will develop chronic pancreatitis. Chronic pancreatitis is treated by replacing the endocrine and exocrine deficiencies that result from pancreatic insufficiency. The development of hyperglycemia often requires insulin for control of blood-sugar levels (Chapter 43). Pancreatic enzyme capsules containing lipase, amylase, and proteases may be necessary to treat malabsorption (Chapter 46).

Liver. Ethanol produces a constellation of dose-related deleterious effects in the liver (Fickert and Zatloukal, 2000). The primary effects are fatty infiltration of the liver, hepatitis, and cirrhosis. Because of its intrinsic toxicity, alcohol can injure the liver in the absence of dietary deficiencies (Lieber, 2000). The accumulation of fat in the liver is an early event and can occur in normal individuals after the ingestion of relatively small amounts of ethanol. This accumulation results from inhibition of both the tricarboxylic acid cycle and the oxidation of fat, in part owing to the generation of excess NADH produced by the actions of ADH and ALDH (Figure 23–1).

Fibrosis, resulting from tissue necrosis and chronic inflammation, is the underlying cause of alcoholic cirrhosis. Normal liver tissue is replaced by fibrous tissue. Alcohol can affect stellate cells in the liver directly; chronic alcohol use is associated with transformation of stellate cells into collagen-producing, myofibroblast-like cells, resulting in deposition of collagen around terminal hepatic venules (Lieber, 2000). The histological hallmark of alcoholic cirrhosis is the formation of Mallory bodies, which are thought to be related to an altered intermediate cytoskeleton (Denk et al., 2000).

A number of molecular mechanisms for alcoholic cirrhosis have been proposed. In nonhuman primate models, alcohol alters phospholipid peroxidation. Ethanol decreases phosphatidylcholine levels in hepatic mitochondria, a change associated with decreased oxidase activity and O₂ consumption. Cytokines, such as transforming growth factor β and tumor necrosis factor α , can increase rates of

fibrinogenesis and fibrosis in the liver. Acetaldehyde is thought to have a number of adverse effects, including depletion of glutathione (Lieber, 2000), depletion of vitamins and trace metals, and decreased transport and secretion of proteins owing to inhibition of tubulin polymerization. Acetaminophen-induced hepatic toxicity (Chapters 4, 6, and 34) has been associated with alcoholic cirrhosis as a result of alcohol-induced increases in microsomal production of toxic acetaminophen metabolites (Whitcomb and Block, 1994). Liver failure secondary to cirrhosis and resulting in impaired clearance of toxins such as ammonia also may contribute to alcohol-induced hepatic encephalopathy. Ethanol also appears to increase intracellular free hydroxy-ethyl radical formation.

Vitamins and Minerals

The almost complete lack of protein, vitamins, and most other nutrients in alcoholic beverages predisposes those who consume large quantities of alcohol to nutritional deficiencies. Alcoholics often present with these deficiencies owing to decreased intake, decreased absorption, or impaired utilization of nutrients. The peripheral neuropathy, Korsakoff's psychosis, and Wernicke's encephalopathy seen in alcoholics probably are caused by deficiencies of the B complex of vitamins (particularly thiamine), although direct toxicity produced by alcohol itself has not been ruled out (Harper, 1998). Chronic alcohol abuse decreases the dietary intake of retinoids and carotenoids and enhances the metabolism of retinol by the induction of degradative enzymes (Lieber, 2000). Retinol and ethanol compete for metabolism by ADH; vitamin A supplementation therefore should be monitored carefully in alcoholics when they are consuming alcohol to avoid retinol-induced hepatotoxicity. The chronic consumption of alcohol inflicts an oxidative stress on the liver owing to the generation of free radicals, contributing to ethanol-induced liver injury. The antioxidant effects of α -tocopherol (vitamin E) may ameliorate some of this ethanol-induced toxicity in the liver. Plasma levels of α -tocopherol often are reduced in myopathic alcoholics compared with alcoholic patients without myopathy.

Chronic alcohol consumption has been implicated in osteoporosis (Chapter 44). The reasons for this decreased bone mass remain unclear, although impaired osteoblastic activity has been implicated. Acute administration of ethanol produces an initial reduction in serum parathyroid hormone (PTH) and Ca²⁺ levels, followed by a rebound increase in PTH that does not restore Ca²⁺ levels to normal. Alcohol-induced osteopenia improves with abstinence (Alvisa-Negrin J, et al., 2009). Since vitamin D requires hydroxylation in the liver for activation, alcohol-induced liver damage can indirectly affect the role of vitamin D in the intestinal and renal absorption of Ca²⁺.

Sexual Function

Despite the widespread belief that alcohol can enhance sexual activities, the opposite effect is generally noted. Many drugs of abuse, including alcohol, have disinhibiting effects that may lead initially to increased libido.

Both acute and chronic alcohol use can lead to impotence in men. Increased blood alcohol concentrations lead to decreased sexual arousal, increased ejaculatory latency, and decreased orgasmic pleasure. The incidence of impotence may be as high as 50% in

patients with chronic alcoholism. Additionally, many chronic alcoholics develop testicular atrophy and decreased fertility. The mechanism involved in this is complex and likely involves altered hypothalamic function and a direct toxic effect of alcohol on Leydig cells. Gynecomastia is associated with alcoholic liver disease and is related to increased cellular response to estrogen and to accelerated metabolism of testosterone.

Sexual function in alcohol-dependent women is less clearly understood. Many female alcoholics complain of decreased libido, decreased vaginal lubrication, and menstrual cycle abnormalities. Their ovaries often are small and without follicular development. Some data suggest that fertility rates are lower for alcoholic women. The presence of comorbid disorders such as anorexia nervosa or bulimia can aggravate the problem. The prognosis for patients who abstain is favorable in the absence of significant hepatic or gonadal failure (O'Farrell et al., 1997).

Hematological and Immunological Effects

Chronic alcohol use is associated with a number of anemias. Microcytic anemia can occur because of chronic blood loss and iron deficiency. Macrocytic anemias and increases in mean corpuscular volume are common and may occur in the absence of vitamin deficiencies. Normochromic anemias also can occur owing to effects of chronic illness on hematopoiesis. In the presence of severe liver disease, morphological changes can include the development of burr cells, schistocytes, and ringed sideroblasts. Alcohol-induced sideroblastic anemia may respond to vitamin B₆ replacement (Wartenberg, 1998). Alcohol use also is associated with reversible thrombocytopenia, although platelet counts under 20,000/mm³ are rare. Bleeding is uncommon unless there is an alteration in vitamin K₁-dependent clotting factors (Chapter 30); proposed mechanisms have focused on platelet trapping in the spleen and marrow.

Alcohol also affects granulocytes and lymphocytes (Schirmer et al., 2000). Effects include leukopenia, alteration of lymphocyte subsets, decreased T-cell mitogenesis, and changes in immunoglobulin production. These disorders may play a role in alcohol-related liver disease. In some patients, depressed leukocyte migration into inflamed areas may account in part for the poor resistance of alcoholics to some types of infection (e.g., *Klebsiella pneumoniae*, listeriosis, and tuberculosis). Alcohol consumption also may alter the distribution and function of lymphoid cells by disrupting cytokine regulation, in particular that involving interleukin 2 (IL-2). Alcohol appears to play a role in the development of infection with the human immunodeficiency virus-1 (HIV). *In vitro* studies with human lymphocytes suggest that alcohol can suppress CD4 T-lymphocyte function and concanavalin A-stimulated IL-2 production and enhance *in vitro* replication of HIV. Moreover, persons who abuse alcohol have higher rates of high-risk sexual behavior.

ACUTE ETHANOL INTOXICATION

Signs of intoxication typical of CNS depression are seen in most people following 2-3 drinks, with the most prominent effect seen at the times of peak BEL, ~30-60 minutes following consumption on an empty stomach. These symptoms include an initial feeling of stimulation (perhaps due to inhibition of CNS inhibitory systems), giddiness, muscle relaxation, and impaired judgment. Higher blood levels (~80 mg/dL or ~17 mM) are associated with slurred speech, incoordination, unsteady gait, and potential impairments of attention; levels between 80 and 200 mg/dL (~17-43 mM) are associated with more intense mood lability, and greater cognitive deficits, potentially accompanied by aggressiveness, and anterograde amnesia (an alcoholic blackout) (Schuckit, 2009c). Blood ethanol levels >200 mg/dL can produce nystagmus and unwanted falling asleep; levels of 300 mg/dL (~65 mM) and higher can produce failing vital signs, coma, and death. All of these symptoms are likely to be exacerbated and occur at a lower BEC when ethanol is taken along with other CNS depressants (e.g., diazepam or similar benzodiazepines), or with any drug or medication for which sleepiness and incoordination are likely.

An increased reaction time, diminished fine motor control, impulsivity, and impaired judgment become evident when the concentration of ethanol in the blood is 20-30 mg/dL. More than 50% of persons are grossly intoxicated by a concentration of 150 mg/dL. In fatal cases, the average concentration is about 400 mg/dL, although alcohol-tolerant individuals often can withstand comparable blood alcohol levels. The definition of intoxication varies by state and country. In the U.S., most states set the ethanol level defined as intoxication at 80 mg/dL. There is increasing evidence that lowering the limit to 50-80 mg/dL can reduce motor vehicle injuries and fatalities significantly. While alcohol can be measured in saliva, urine, sweat, and blood, measurement of levels in exhaled air remains the primary method of assessing the level of intoxication.

Many factors, such as body weight and composition and the rate of absorption from the GI tract, determine the concentration of ethanol in the blood after ingestion of a given amount of ethanol. On average, the ingestion of 3 standard drinks (42 g ethanol) on an empty stomach results in a maximum blood concentration of 67-92 mg/dL in men. After a mixed meal, the maximal blood concentration from three drinks is 30-53 mg/dL in men. Concentrations of alcohol in blood will be higher in women than in men consuming the same amount of alcohol because, on average, women are smaller than men, have less body water per unit of weight into which ethanol can distribute, and have less gastric ADH activity than men. For individuals with normal hepatic function, ethanol is metabolized at a rate of one standard drink every 60-90 minutes.

The characteristic signs and symptoms of alcohol intoxication are well known. Nevertheless, an erroneous diagnosis of drunkenness

may occur with patients who appear inebriated but who have not ingested ethanol. Diabetic coma, e.g., may be mistaken for severe alcoholic intoxication. Drug intoxication, cardiovascular accidents, and skull fractures also may be confused with alcohol intoxication. The odor of the breath of a person who has consumed ethanol is due not to ethanol vapor but to impurities in alcoholic beverages. Breath odor in a case of suspected intoxication can be misleading because there can be other causes of breath odor similar to that after alcohol consumption. Blood alcohol levels are necessary to confirm the presence or absence of alcohol intoxication (Schuckit, 2006b).

The treatment of acute alcohol intoxication is based on the severity of respiratory and CNS depression. Acute alcohol intoxication can be a medical emergency, and a number of young people die every year from this disorder. Patients who are comatose and who exhibit evidence of respiratory depression should be intubated to protect the airway and to provide ventilatory assistance (see Chapter 4). The stomach may be lavaged, but care must be taken to prevent pulmonary aspiration of the return flow. Since ethanol is freely miscible with water, ethanol can be removed from blood by hemodialysis (Schuckit, 2006b).

Acute alcohol intoxication is not always associated with coma, and careful observation is the primary treatment. Usual care involves observing the patient in the emergency room for 4–6 hours while the patient metabolizes the ingested ethanol. Blood alcohol levels will be reduced by ~15 mg/dL per hour. During this period, some individuals may display extremely violent behavior. Sedatives and antipsychotic agents have been employed to quiet such patients. Great care must be taken, however, when using sedatives to treat patients who have ingested an excessive amount of another CNS depressant, such as ethanol, because of synergistic effects.

CLINICAL USES OF ETHANOL

Dehydrated alcohol may be injected in close proximity to nerves or sympathetic ganglia to relieve the long-lasting pain related to trigeminal neuralgia, inoperable carcinoma, and other conditions. Epidural, subarachnoid, and lumbar paravertebral injections of ethanol also have been employed for inoperable pain. For example, lumbar paravertebral injections of ethanol may destroy sympathetic ganglia and thereby produce vasodilation, relieve pain, and promote healing of lesions in patients with vascular disease of the lower extremities.

Systemically administered ethanol is confined to the treatment of poisoning by methyl alcohol and ethylene glycol. The ingestion results in formation of methanol's metabolites, formaldehyde and formic acid (Figure 23–1). Formic acid causes nerve damage; its effects on the retina and optic nerve can cause blindness. Treatment consists of sodium bicarbonate to combat acidosis, hemodialysis, and the administration of ethanol, which slows formate production by competing with methanol for metabolism by alcohol dehydrogenase.

The use of alcohol to treat patients in alcohol withdrawal or obstetrical patients with premature contractions is no longer recommended (Chapter 24).

TOLERANCE, DEPENDENCE, AND CHRONIC ETHANOL USE

Tolerance is defined as a reduced behavioral or physiological response to the same dose of ethanol (Chapter 24).

There is a marked acute tolerance that is detectable soon after administration of ethanol. Acute tolerance can be demonstrated by measuring behavioral impairment at the same BELs on the ascending limb of the absorption phase of the BEL–time curve (minutes after ingestion of alcohol) and on the descending limb of the curve as BELs are lowered by metabolism (one or more hours after ingestion). Behavioral impairment and subjective feelings of intoxication are much greater at a given BEL on the ascending than on the descending limb. There also is a chronic tolerance that develops in the long-term heavy drinker. In contrast to acute tolerance, chronic tolerance often has a metabolic component owing to induction of alcohol-metabolizing enzymes.

Physical dependence is demonstrated by the elicitation of a withdrawal syndrome when alcohol consumption is terminated. The symptoms and severity are determined by the amount and duration of alcohol consumption and include sleep disruption, autonomic nervous system (sympathetic) activation, tremors, and in severe cases, seizures. In addition, two or more days after withdrawal, some individuals experience *delirium tremens*, characterized by hallucinations, delirium, fever, and tachycardia. Delirium tremens can be fatal. Another aspect of dependence is craving and drug-seeking behavior, often termed *psychological dependence*.

Ethanol tolerance and physical dependence are studied readily in animal models. Strains of mice with genetic differences in tolerance and dependence have been characterized, and a search for the relevant genes and ethanol-sensitive microRNAs is under way (Miranda et al., 2010). Neurobiological mechanisms of tolerance and dependence are not understood completely, but chronic alcohol consumption results in changes in synaptic and intracellular signaling likely owing to changes in gene expression. Most of the systems that are acutely affected by ethanol also are affected by chronic exposure, resulting in an adaptive or maladaptive response that can cause tolerance and dependence (see Table 23–1). In particular, chronic actions of ethanol likely require changes in signaling by glutamate and GABA receptors and down-stream signaling pathways. The increase in NMDA-receptor function after chronic alcohol ingestion could contribute to the CNS hyperexcitability and neurotoxicity seen during ethanol withdrawal. Arginine vasopressin, acting on V_1 receptors, maintains tolerance to ethanol in laboratory animals even after chronic ethanol administration has ceased (Hoffman et al., 1990).

The neurobiological basis of the switch from controlled, volitional alcohol use to compulsive and uncontrolled addiction remains obscure. Impairment of the dopaminergic reward system and the resulting increase in alcohol consumption in an attempt to regain activation of the system is a possibility. In addition, the prefrontal cortex is particularly sensitive to damage from alcohol abuse and influences decision making and emotion, processes clearly compromised in the alcoholic (Pfefferbaum et al., 1998). Thus, impairment of executive function in cortical regions by chronic alcohol consumption

may be responsible for some of the lack of judgment and control that is expressed as obsessive alcohol consumption. The loss of brain volume and impairment of function seen in the chronic alcoholic is at least partially reversible by abstinence but will worsen with continued drinking. Early diagnosis and treatment of alcoholism are important in limiting the brain damage that promotes the progression to severe addiction.

Etiology of Alcohol Use Disorders and the Role of Genes

A wide range of social, cultural, interpersonal, and biological factors combine to contribute to the risk for heavier drinking and alcohol use disorders (Schuckit, 2009b). The initial decision to consume alcohol is predominantly a response to the environment and culture in which one lives. Environmental and cultural factors that contribute to alcohol use include stress, expectations regarding the effects alcohol is likely to produce, drinking patterns within one's culture and peer group, availability of alcohol, and attitudes toward drunkenness. These nonbiological forces contribute to perhaps 70-80% of the initial decision to drink and at least 40% of the transition from drinking to alcohol-related problems and alcohol use disorders. Correspondingly, ~60% of the susceptibility to alcohol use disorders results from heritable factors (Table 23–2).

The search for the genes and alleles responsible for alcoholism is complicated by the polygenetic nature of the disease and the general difficulty in defining multiple genes responsible for complex diseases. As noted earlier in the chapter, polymorphisms in the enzymes of ethanol metabolism seem to explain why some populations (mainly Asian) are protected from alcoholism. This has been attributed to genetic differences in alcohol- and aldehyde-metabolizing enzymes. Specifically, genetic variants of ADH that exhibit high activity and

variants of ALDH that exhibit low activity protect against heavy drinking, probably because alcohol consumption by individuals who have these variants results in accumulation of acetaldehyde, which produces a variety of unpleasant effects (Li, 2000).

In contrast to these protective genetic variants, there are few consistent data about genes responsible for increased risk for alcoholism. A genetic mechanism associated with an enhanced risk for both alcohol and other drug use disorders operates through the intermediate characteristic (or phenotype) of impulsivity and disinhibition (King et al., 2004). The identified polymorphisms include two variations of the GABA_A receptors (Dick et al., 2006a,b), a variation in ADH4 hypothesized to be related to personality characteristics (Edenberg et al., 2006), and a muscarinic cholinergic receptor gene, CHRM2 (Jones et al., 2006).

Another phenotype related to an enhanced risk for alcohol use disorders (but not other drug use disorders) is associated with a low level of response (perhaps reflecting low sensitivity) to ethanol (Schuckit, 2009b). The need for higher amounts of ethanol to achieve the desired effects may contribute to the decision to drink more per occasion, which in turn leads to altered expectations of the effects of beverage alcohol, an enhanced probability of selecting heavier-drinking peers, as well as problematic approaches to dealing with stress (Schuckit et al., 2008). To date, genetic contributions to the level of response have been tentatively identified for two GABA_A subunits (Dick et al., 2006a,b), a polymorphism in the promoter region of the 5-HT transporter that is associated with lower levels of 5-HT in the synaptic space (Barr et al., 2005), a polymorphism of the K⁺ channel-related KCNMA1 (Schuckit et al., 2005), and a variant nicotinic Ach receptor that is also related to an increased risk for heavy smoking and related consequences (Joslyn et al., 2008). Antisocial alcoholism has been linked with polymorphisms of several 5-HT receptors (Ducci et al., 2009). Polymorphisms in dopaminergic and opioid systems and in genes that correlate with a predisposition to bipolar disorder, schizophrenia, and several anxiety disorders may also contribute to a general vulnerability to a range of substance abuse disorders.

TERATOGENIC EFFECTS: FETAL ALCOHOL SYNDROME

Children born to alcoholic mothers display a common pattern of distinct dysmorphology known as *fetal alcohol syndrome* (FAS) (Jones and Smith, 1973; Lemoine et al., 1968). The diagnosis of FAS typically is based on the observance of a triad of abnormalities in the newborn, including:

- a cluster of craniofacial abnormalities
- CNS dysfunction
- pre- and/or postnatal stunting of growth

Hearing, language, and speech disorders also may become evident as the child ages (Church and Kaltenebach, 1997). Children who do not meet all the criteria for a diagnosis of FAS still may show physical and mental deficits consistent with a partial phenotype,

Table 23–2

Genes for Intermediate Phenotypes Affecting Risk for Alcohol Use Disorder

PHENOTYPE	GENES
Facial flush after drinking	ALDH2 ADH1B, ADH1C
Impulsivity and disinhibition	GABRA2 ADH4 CHRM2 DRD2, DRD4
Low level of response to ethanol	GABRA1, GABRA6 5HTT promoter KCNMA1 CHRN cluster

termed *fetal alcohol effects* (FAEs) or *alcohol-related neurodevelopmental disorders*. FAS is seen in offspring born to ~5% of heavy-drinking females. The incidence of FAS is believed to be in the range of 0.5-1 per 1000 live births in the general U.S. population, with rates as high as 2-3 per 1000 in African-American and Native-American populations. A lower socioeconomic status of the mother rather than racial background *per se* appears to be primarily responsible for the higher incidence of FAS observed in those groups (Abel, 1995). The incidence of FAEs is likely higher than that of FAS, making alcohol consumption during pregnancy a major public health problem.

Craniofacial abnormalities commonly observed in the diagnosis of FAS consist of a pattern of microcephaly, a long and smooth philtrum, shortened palpebral fissures, a flat midface, and epicanthal folds. Magnetic resonance imaging studies demonstrate decreased volumes in the basal ganglia, corpus callosum, cerebrum, and cerebellum (Mattson et al., 1992). The severity of alcohol effects can vary greatly and depends on the drinking patterns and amount of alcohol consumed by the mother. Maternal drinking in the first trimester has been associated with craniofacial abnormalities; facial dysmorphism also is seen in mice exposed to ethanol at the equivalent time in gestation.

CNS dysfunction following *in utero* exposure to alcohol manifests in the form of hyperactivity, attention deficits, mental retardation, and learning disabilities. FAS is the most common cause of preventable mental retardation in the Western world (Abel and Sokol, 1987), with afflicted children consistently scoring lower than their peers on a variety of IQ tests. It now is clear that FAS represents the severe end of a spectrum of alcohol effects. A number of studies have documented intellectual deficits, including mental retardation, in children not displaying the craniofacial deformities or retarded growth seen in FAS. Although cognitive improvements are seen with time, decreased IQ scores of FAS children tend to persist as they mature, indicating that the deleterious prenatal effects of alcohol are irreversible. Although a correlation exists between the amount of alcohol consumed by the mother and infant scores on mental and motor performance tests, there is considerable variation in performance on such tests among children of mothers consuming similar quantities of alcohol. The peak BEL reached may be a critical factor in determining the severity of deficits seen in the offspring. Although the evidence is not conclusive, there is a suggestion that even moderate alcohol consumption (two drinks per day) in the second trimester of pregnancy is correlated with impaired academic performance of offspring at age 6 (Goldschmidt et al., 1996). Maternal age also may be a factor. Pregnant women over age 30 who drink alcohol create greater risks to their children than do younger women who consume similar amounts of alcohol (Jacobson et al., 1996).

Children exposed prenatally to alcohol most frequently present with attentional deficits and hyperactivity, even in the absence of intellectual deficits or craniofacial abnormalities. Furthermore, attentional problems have been observed in the absence of hyperactivity, suggesting that the two phenomena are not necessarily related. Fetal alcohol exposure also has been identified as a risk factor for alcohol

abuse by adolescents (Baer et al., 1998). Apart from the risk of FAS or FAEs to the child, the intake of high amounts of alcohol by a pregnant woman, particularly during the first trimester, greatly increases the chances of spontaneous abortion.

Studies with laboratory animals have demonstrated many of the consequences of *in utero* exposure to ethanol observed in humans, including hyperactivity, motor dysfunction, and learning deficits. In animals, *in utero* exposure to ethanol alters the expression patterns of a wide variety of proteins, changes neuronal migration patterns, and results in brain region-specific and cell type-specific alterations in neuronal numbers. Indeed, specific periods of vulnerability may exist for particular neuronal populations in the brain. Genetics also may play a role in determining vulnerability to ethanol: There are differences among strains of rats in susceptibility to the prenatal effects of ethanol. Finally, multidrug abuse, such as the concomitant administration of cocaine with ethanol, enhances fetal damage and mortality.

PHARMACOTHERAPY OF ALCOHOLISM

The core of care is a process of interventions and sessions that help enhance changes in how the person views their problem, along with efforts to help them alter the problematic behaviors (Schuckit, 2009). With cognitive-behavioral approaches serving as the core of treatment, and a 20% or greater rate of spontaneous remission in alcohol use disorders, the role of medications can be difficult to evaluate. Thus, only those pharmacological approaches that have been shown to be superior to placebo through double-blind control trials are worth considering in clinical practice.

Currently, three drugs are approved in the U.S. for treatment of alcoholism: disulfiram (ANTABUSE), naltrexone (REVIA), and acamprosate (Table 23-3). Disulfiram has a long history of use but has fallen into disfavor because of its side effects and problems with patient adherence to therapy. Naltrexone and acamprosate were introduced more recently. The goal of these medications is to assist the patient in maintaining abstinence.

Naltrexone

Naltrexone is chemically related to the highly selective opioid-receptor antagonist naloxone (NARCAN) but has higher oral bioavailability and a longer duration of action. Neither drug has appreciable opioid-receptor agonist effects. These drugs were used initially in the treatment of opioid overdose and dependence because of their ability to antagonize all the actions of opioids (Chapters 18 and 24). There is evidence that naltrexone blocks activation by alcohol of dopaminergic pathways in the brain that are thought to be critical to reward.

Naltrexone helps to maintain abstinence by reducing the urge to drink and increasing control when a “slip” occurs. It is not a

Table 23-3

Oral Medications for Treating Alcohol Abuse

MEDICATION	USUAL DOSE	MECHANISM/EFFECT
Disulfiram	250 mg/day (range 125-500 mg/day)	Inhibits ALDH with resulting \uparrow acetaldehyde after drinking. Abstinence is reinforced to avoid the resulting adverse reaction.
Naltrexone	50 mg/day	μ opioid receptor antagonist; felt to \downarrow drinking through \downarrow feelings of reward with alcohol and/or \downarrow craving.
Acamprostate	666 mg three times daily	Weak antagonist of NMDA receptors, activator of GABA _A receptors; may \downarrow mild protracted abstinence syndromes with \downarrow feelings of a "need" for alcohol.

"cure" for alcoholism and does not prevent relapse in all patients. Naltrexone works best when used in conjunction with some form of psychosocial therapy, such as cognitive behavioral therapy (Anton et al., 1999). It typically is administered after detoxification and given at a dose of 50 mg/day for several months. Adherence to the regimen is important to ensure the therapeutic value of naltrexone and has proven to be a problem for some patients. The most common side effect of naltrexone is nausea, which is more common in women than in men and subsides if the patients abstain from alcohol. When given in excessive doses, naltrexone can cause liver damage. It is contraindicated in patients with liver failure or acute hepatitis and should be used only after careful consideration in patients with active liver disease.

Nalmefene (REVEX) is another opioid antagonist that appears promising in preliminary clinical tests (Mason et al., 1999). It has a number of advantages over naltrexone, including greater oral bioavailability, longer duration of action, and lack of dose-dependent liver toxicity.

Acamprostate

Acamprostate (*N*-acetylhomotaurine; CAMPRAL) is an analogue of GABA.

A number of double-blind, placebo-controlled studies have demonstrated that acamprostate (1.3-2 g/day) decreases drinking frequency and reduces relapse drinking in abstinent alcoholics and appears to have efficacy similar to that of naltrexone. Studies in laboratory animals have shown that acamprostate decreases alcohol intake without affecting food or water consumption. Acamprostate generally is well tolerated by patients, with diarrhea being the main side effect (Garbutt et al., 1999). No abuse liability has been noted. The drug undergoes minimal metabolism in the liver, is excreted primarily by the kidneys, and has an elimination $t_{1/2}$ of 18 hours after

oral administration. Concomitant use of disulfiram appears to increase the effectiveness of acamprostate, without any adverse drug interactions being noted (Besson et al., 1998).

Disulfiram

Disulfiram (tetraethylthiuram disulfide; ANTABUSE) was ingested in the course of an investigation of its potential anthelmintic efficacy by two Danish physicians, who became ill at a cocktail party and were quick to realize that the compound had altered their responses to alcohol. They initiated a series of pharmacological and clinical studies that provided the basis for the use of disulfiram as an adjunct in the treatment of chronic alcoholism. Similar responses to alcohol ingestion are produced by various congeners of disulfiram, namely, cyanamide, the fungus *Coprinus atramentarius*, the hypoglycemic sulfonylureas, metronidazole, and certain cephalosporins.

Disulfiram, given alone, is a relatively nontoxic substance, but it inhibits ALDH activity and causes the blood acetaldehyde concentration to rise to 5-10 times above the level achieved when ethanol is given to an individual not pretreated with disulfiram. Acetaldehyde, produced as a result of the oxidation of ethanol by ADH, ordinarily does not accumulate in the body because it is further oxidized almost as soon as it is formed. Following the administration of disulfiram, both cytosolic and mitochondrial forms of ALDH are irreversibly inactivated to varying degrees, and the concentration of acetaldehyde rises. It is unlikely that disulfiram itself is responsible for the enzyme inactivation *in vivo*; several active

metabolites of the drug, especially diethylthiomethylcarbamate, behave as suicide-substrate inhibitors of ALDH *in vitro*. These metabolites reach significant concentrations in plasma following the administration of disulfiram (Johansson, 1992).

The ingestion of alcohol by individuals previously treated with disulfiram gives rise to marked signs and symptoms of acetaldehyde poisoning. Within 5-10 minutes, the face feels hot and soon afterward becomes flushed and scarlet in appearance. As the vasodilation spreads over the whole body, intense throbbing is felt in the head and neck, and a pulsating headache may develop. Respiratory difficulties, nausea, copious vomiting, sweating, thirst, chest pain, considerable hypotension, orthostatic syncope, marked uneasiness, weakness, vertigo, blurred vision, and confusion are observed. The facial flush is replaced by pallor, and the blood pressure may fall to shock levels.

Alarming reactions may result from the ingestion of even small amounts of alcohol in persons being treated with disulfiram. The use of disulfiram as a therapeutic agent thus is not without danger, and it should be attempted only under careful medical and nursing supervision. Patients must be warned that as long as they are taking disulfiram, the ingestion of alcohol in any form will make them sick and may endanger their lives. Patients must learn to avoid disguised forms of alcohol, as in sauces, fermented vinegar, cough syrups, and even after-shave lotions and back rubs.

The drug never should be administered until the patient has abstained from alcohol for at least 12 hours. In the initial phase of treatment, a maximal daily dose of 500 mg is given for 1-2 weeks. Maintenance dosage then ranges from 125-500 mg daily depending on tolerance to side effects. Unless sedation is prominent, the daily dose should be taken in the morning, the time when the resolve not to drink may be strongest. Sensitization to alcohol may last as long as 14 days after the last ingestion of disulfiram because of the slow rate of restoration of ALDH (Johansson, 1992).

Disulfiram and/or its metabolites can inhibit many enzymes with crucial sulfhydryl groups, and it thus has a wide spectrum of biological effects. It inhibits hepatic CYPs and thereby interferes with the metabolism of phenytoin, chlorthalidone, barbiturates, warfarin, and other drugs.

Disulfiram by itself usually is innocuous, but it may cause acne-form eruptions, urticaria, lassitude, tremor, restlessness, headache, dizziness, a garlic-like or metallic taste, and mild GI disturbances. Peripheral neuropathies, psychosis, and ketosis also have been reported.

Other Agents

Ondansetron, a 5-HT₃-receptor antagonist and antiemetic drug (Chapters 13 and 46), reduces alcohol consumption in laboratory animals and currently is being tested in humans. Preliminary findings suggest that ondansetron is effective in the treatment of early-onset alcoholics, who respond poorly to psychosocial treatment alone, although the drug does not appear to work well in other types of alcoholics. Ondansetron administration lowers the amount of alcohol consumed, particularly by drinkers who consume fewer than 10 drinks per day (Sellers et al., 1994). It also decreases the subjective effects of ethanol on 6 of 10 scales measured, including the desire to drink (Johnson et al., 1993), while at the same time not having any effect on the pharmacokinetics of ethanol.

Topiramate, a drug used for treating seizure disorders (Chapter 21), appears useful for treating alcohol dependence. Compared with the placebo group, patients taking topiramate

achieved more abstinent days and a lower craving for alcohol (Johnson et al., 2003). The mechanism of action of topiramate is not well understood but is distinct from that of other drugs used for the treatment of dependence (e.g., opioid antagonists), suggesting that it may provide a new and unique approach to pharmacotherapy of alcoholism.

Drug Addiction

Charles P. O'Brien

The terminology used in discussing drug dependence, abuse, and addiction has long been confusing. Confusion stems from the fact that repeated use of certain prescribed medications can produce neuroplastic changes resulting in two distinctly abnormal states. The first is *dependence*, sometimes called “physical” dependence, produced when there is progressive pharmacological adaptation to the drug resulting in tolerance. In the tolerant state, repeating the same dose of drug produces a smaller effect. If the drug is abruptly stopped, a withdrawal syndrome ensues in which the adaptive responses are now unopposed by the drug. Thus, withdrawal symptoms are opposite to the original drug effects. The appearance of withdrawal symptoms is the cardinal sign of “physical” dependence. As thus defined, dependence can occur with the use of opioids, β blockers, antidepressants, benzodiazepines, and stimulants, even when these agents are used as prescribed for therapeutic purposes. The state of “physical” dependence is a normal response, easily treatable by tapering the drug dose, and is not in itself a sign of addiction.

The second abnormal state that can be produced by repeated drug use occurs in only a minority of those who initiate drug use. It leads progressively to compulsive, out-of-control drug use. Unfortunately, in 1987 the American Psychiatric Association (APA) chose to use the word “dependence” when defining the state of uncontrolled drug use more commonly known as *addiction*. The word “addiction” was at that time considered pejorative and thus to be avoided. The result, over the last two decades, is that confusion has developed between dependence as a normal response and dependence as addiction. The newest version of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-V) due to be released in 2012 will correct this confusion.

This distinction between dependence and addiction is important because patients with pain sometimes

are deprived of adequate opioid medication simply because they have shown evidence of tolerance or they exhibit withdrawal symptoms if the analgesic medication is stopped or reduced abruptly.

Modern neuroscience has greatly increased our understanding of the phenomenology of addiction. Using animal models as well as human brain imaging studies and clinical observations, addiction can be defined fundamentally as a form of maladaptive memory. It begins with the administration of substances (e.g., cocaine) or behaviors (e.g., the thrill of gambling) that directly and intensely activate brain reward circuits. Activation of these circuits motivates normal behavior and most humans simply enjoy the experience without being compelled to repeat it. For some (~16% of those who try cocaine) the experience produces strong conditioned associations to environmental cues that signal the availability of the drug or the behavior. Thus, reflexive activation of reward circuits becomes involuntary and with a very rapid onset. The cues acquire strong salience that overwhelms other behaviors. The individual becomes drawn into compulsive repetition of the experience focusing on the immediate pleasure despite negative long-term consequences and neglect of important social responsibilities. Of course, underlying this behavior are poorly understood changes in neural circuits (Kalivas and O'Brien, 2008).

The framers of DSM-V are strongly motivated to devise a classification well-grounded in neuroscientific evidence. Unfortunately, complex psychiatric disorders still have no proven genetic basis nor are there reliable biomarkers of these disorders. Thus, the plan is to make DSM-V a flexible document that can be further revised as reliable, replicated data are developed.

Origins of Substance Dependence

The chronic, relapsing nature of addiction fulfills criteria for a chronic disease (McLellan et al., 2000), but because of the voluntary component at initiation, the disease concept is controversial. Most of those who initiate drug use do not progress to become addicts. Many variables operate simultaneously to influence the likelihood that a beginning drug user will lose control and develop

650 an addiction. These variables can be organized into three categories: agent (drug), host (user), and environment (Table 24–1).

Agent (Drug) Variables. Drugs vary in their capacity to produce immediate good feelings in the user. Drugs that reliably produce intensely pleasant feelings (euphoria) are more likely to be taken repeatedly. *Reinforcement* refers to the capacity of drugs to produce effects that make the user wish to take them again. The more strongly reinforcing a drug is, the greater is the likelihood that the drug will be abused.

Table 24–1

Multiple Simultaneous Variables Affecting Onset and Continuation of Drug Abuse and Addiction

Agent (drug)

Availability
Cost
Purity/potency
Mode of administration
 Chewing (absorption *via* oral mucous membranes)
 Gastrointestinal
 Intranasal
 Subcutaneous and intramuscular
 Intravenous
 Inhalation
Speed of onset and termination of effects (pharmacokinetics: combination of agent and host)

Host (user)

Heredity
 Innate tolerance
 Speed of developing acquired tolerance
 Likelihood of experiencing intoxication as pleasure
Metabolism of the drug (nicotine and alcohol data already available)
Psychiatric symptoms
Prior experiences/expectations
Propensity for risk-taking behavior

Environment

Social setting
Community attitudes
 Peer influence, role models
Availability of other reinforcers (sources of pleasure or recreation)
Employment or educational opportunities
Conditioned stimuli: environmental cues become associated with drugs after repeated use in the same environment

Reinforcing properties of a drug can be measured reliably in animals. Generally, animals such as rats or monkeys equipped with intravenous catheters connected to lever-regulated pumps will work to obtain injections of the same drugs in roughly the same order of potency that humans will. Thus, medications can be screened for their potential for abuse in humans by the use of animal models. Other drugs such as ethanol can be self-administered by the oral route by experimental animals. Animals can also model relapse to drug-taking in humans. For example, rats learn to drink alcohol in preference to water. If alcohol availability is removed, the animals go through withdrawal. They will restart (“relapse” to) alcohol drinking if presented with cues previously associated with alcohol availability or if given mild stress (foot shock).

Reinforcing properties of drugs are associated with their capacity to increase neuronal activity in critical brain areas (Chapter 14). Cocaine, amphetamine, ethanol, opiates, cannabinoids, and nicotine all reliably increase extracellular fluid dopamine (DA) levels in the ventral striatum, specifically the nucleus accumbens region. In experimental animals, usually rats, brain microdialysis permits sampling of extracellular fluid while the animals are freely moving or receiving drugs. Smaller increases in DA in the nucleus accumbens also are observed when the rat is presented with sweet foods or a sexual partner. In contrast, drugs that block DA receptors generally produce bad feelings, i.e., dysphoric effects. Neither animals nor humans will take such drugs spontaneously. Despite strong correlative findings, a causal relationship between DA and euphoria/dysphoria has not been established, and other findings emphasize additional roles of serotonin (5-HT), glutamate, norepinephrine (NE), endogenous opioids, and γ -aminobutyric acid (GABA) in mediating the reinforcing effects of drugs.

The abuse liability of a drug is enhanced by rapidity of onset because effects that occur soon after administration are more likely to initiate the chain of events that leads to loss of control over drug-taking. The pharmacokinetic variables that influence the time it takes a drug to reach critical receptor sites in the brain are explained in more detail in Chapter 2. The history of cocaine use illustrates the changes in abuse liability of the same compound, depending on the form and the route of administration.

When coca leaves are chewed, cocaine is absorbed slowly through the buccal mucosa. This method produces low cocaine blood levels and correspondingly low levels in the brain. The mild stimulant effects produced by the chewing of coca leaves have a gradual onset, and this practice has produced few, if any, behavior problems despite use over thousands of years by natives of the Andes mountains. Beginning in the late 19th century, scientists isolated cocaine hydrochloride from coca leaves and refined the technology for extraction of pure cocaine. Cocaine could be taken in higher doses by oral ingestion (GI absorption) or by absorption through the nasal

mucosa, producing higher cocaine levels in the blood and a more rapid onset of stimulation. Subsequently, it was found that a solution of cocaine hydrochloride could be administered intravenously, giving a more rapid onset of stimulatory effects. Each newly available cocaine preparation that provided greater speed of onset and an increment in blood level was paralleled by a greater likelihood of addiction. In the 1980s, the availability of cocaine to the American public was increased further with the invention of crack cocaine. Crack, sold illegally and at a low price (\$1-3 per dose), is alkaloidal cocaine (free base), which can be readily vaporized by heating. Simply inhaling the vapors produces blood levels comparable to those resulting from intravenous cocaine owing to the large surface area for absorption into the pulmonary circulation following inhalation. The cocaine-containing blood then enters the left side of the heart and reaches the cerebral circulation without dilution by the systemic circulation. Thus, inhalation of crack cocaine is much more addictive than chewing, drinking, or sniffing cocaine. Inhalation, with rapid attainment of effective drug levels in the brain, also is the preferred route for users of nicotine and cannabis.

Although the drug variables are important, they do not fully explain the development of addiction. Most people who experiment with drugs of high addictive potential (addiction liability) do not intensify their drug use and lose control. The risk for developing addiction among those who try nicotine is about twice that for those who try cocaine (Table 24–2). This does not imply that the pharmacological addiction liability of

nicotine is twice that of cocaine. Rather, there are other variables listed in the categories of host factors and environmental conditions that influence the development of addiction.

Host (User) Variables. In general, effects of drugs vary among individuals. Even blood levels can show wide variation when the same dose of a drug on a milligram-per-kilogram basis is given to different people. Polymorphism of genes that encode enzymes involved in absorption, metabolism, and excretion and in receptor-mediated responses may contribute to the different degrees of reinforcement or euphoria observed among individuals (Chapters 6 and 7).

Children of alcoholics show an increased likelihood of developing alcoholism, even when adopted at birth and raised by non-alcoholic parents. The studies of genetic influences in this disorder show only an *increased risk* for developing alcoholism, not a 100% determinism, consistent with a polygenic disorder that has multiple determinants. Even identical twins, who share the same genetic endowment, do not have 100% concordance when one twin is alcoholic. However, the concordance rate for identical twins is much higher than that for fraternal twins. The abuse of alcohol and other drugs tends to have some familial characteristics, suggesting that common mechanisms may be involved.

Innate tolerance to alcohol as measured by level of response to alcohol administered under experimental conditions may represent a biological trait that contributes to the development of alcoholism (Chapter 23). While innate tolerance increases vulnerability to alcoholism, impaired metabolism may *protect* against it. See Chapter 23 for a discussion of the genetic variation common in Asian populations that results in facial flushing and reduced alcohol intake or no alcohol intake in those homozygous for the gene variant. Similarly, individuals who inherit a gene associated with slow nicotine metabolism may experience unpleasant effects when beginning to smoke and reportedly have a lower probability of becoming nicotine dependent.

Psychiatric disorders constitute another category of host variables. Drugs may produce immediate, subjective effects that relieve preexisting symptoms. People with anxiety, depression, insomnia, or even subtle symptoms such as shyness may find, on experimentation or by accident, that certain drugs give them relief. However, the apparent beneficial effects are transient, and repeated use of the drug may lead to tolerance and eventually compulsive, uncontrolled drug use. While psychiatric symptoms are seen commonly in drug abusers presenting for treatment, most of these symptoms begin *after* the person starts abusing drugs. Thus, drugs of abuse appear to produce more psychiatric symptoms than they relieve.

Environmental Variables. Initiating and continuing illegal drug use appear to be influenced significantly by societal norms and peer pressure. Taking drugs may be seen initially as a form of rebellion against authority. In some communities, drug users and drug dealers are role models who seem to be successful and respected; thus, young people emulate them. There also may be a

Table 24–2

Dependence among Users 1990–1992

AGENT	EVER USED* %	ADDICTION %	RISK OF ADDICTION %
Tobacco	75.6	24.1	31.9
Alcohol	91.5	14.1	15.4
Illicit drugs	51.0	7.5	14.7
<i>Cannabis</i>	46.3	4.2	9.1
<i>Cocaine</i>	16.2	2.7	16.7
<i>Stimulants</i>	15.3	1.7	11.2
<i>Anxiolytics</i>	12.7	1.2	9.2
<i>Analgesics</i>	9.7	0.7	7.5
<i>Psychedelics</i>	10.6	0.5	4.9
<i>Heroin</i>	1.5	0.4	23.1
<i>Inhalants</i>	6.8	0.3	3.7

*The ever-used and addiction percentages are those of the general population. The risk of addiction is specific to the drug indicated and refers to the percentage who met criteria for addiction among those who reported having used the agent at least once (i.e., each value in column 4 was obtained by expressing the number in column 3 as a percentage of the number in column 2, subject to errors of rounding).
Source: Anthony et al., 1994.

652 paucity of other options for pleasure, diversion, or income. These factors are particularly important in communities where educational levels are low and job opportunities scarce.

Pharmacological Phenomena

Tolerance. While abuse and addiction are complex conditions combining the many variables outlined earlier, there are a number of relevant pharmacological phenomena that occur independent of social and psychological dimensions. First are the changes in the way the body responds to a drug with repeated use. *Tolerance*, the most common response to repetitive use of the same drug, can be defined as the reduction in response to the drug after repeated administrations. Figure 24–1 shows an idealized dose-response curve for an administered drug. As the dose of the drug increases, the observed effect of the drug increases. With repeated use of the drug, however, the curve shifts to the right (tolerance). Thus, a higher dose is required to produce the same effect that was once obtained at a lower dose. Diazepam, e.g., typically produces sedation at doses of 5–10 mg in a first-time user, but those who repeatedly use it to produce a kind of “high” may become tolerant to doses of several hundreds of milligrams; some abusers have had documented tolerance to >1000 mg/day. As outlined in Table 24–3, there are many forms of tolerance likely arising through multiple mechanisms.

Tolerance to some drug effects develops much more rapidly than to other effects of the same drug. For example, tolerance develops rapidly to the euphoria produced by opioids such as heroin, and

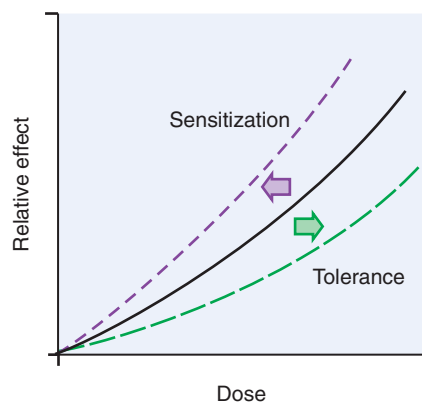

Figure 24–1. Shifts in a dose-response curve with tolerance and sensitization. With tolerance, there is a shift of the curve to the right such that doses higher than initial doses are required to achieve the same effects. With sensitization, there is a leftward shift of the curve such that for a given dose, there is a greater effect than seen after the initial dose.

Table 24–3

Types of Tolerance

Innate (pre-existing sensitivity or insensitivity)
Acquired
Pharmacokinetic (dispositional or metabolic)
Pharmacodynamic
Learned tolerance
Behavioral
Conditioned
Acute tolerance
Reverse tolerance (sensitization)
Cross-tolerance

addicts tend to increase their dose in order to re-experience that elusive “high.” In contrast, tolerance to the gastrointestinal effects of opioids develops more slowly. The discrepancy between tolerance to euphorogenic effects (rapid) and tolerance to effects on vital functions (slow), such as respiration and blood pressure, can lead to potentially fatal overdoses in sedative abusers trying to re-experience the euphoria they recall from earlier use.

Innate tolerance refers to genetically determined lack of sensitivity to a drug that is observed the first time that the drug is administered. Innate tolerance was discussed earlier as a host variable that influences the development of addiction. See Chapter 23 for discussion of the inheritance of level of response to ethanol.

Acquired tolerance can be divided into three major types: pharmacokinetic, pharmacodynamic, and learned tolerance, and includes acute, reverse, and cross-tolerance (Table 24–3).

Pharmacokinetic or *dispositional tolerance* refers to changes in the distribution or metabolism of a drug after repeated administrations such that a given dose produces a lower blood concentration than the same dose did on initial exposure. The most common mechanism is an increase in the rate of metabolism of the drug. For example, barbiturates stimulate the production of higher levels of hepatic CYPs, causing more rapid removal and breakdown of barbiturates from the circulation. Since the same enzymes metabolize many other drugs, they too are metabolized more quickly. This results in a decrease in their plasma levels as well and a reduction in their therapeutic effects.

Pharmacodynamic tolerance refers to adaptive changes that have taken place within systems affected by the drug so that response to a given concentration of the drug is reduced. Examples include drug-induced changes in receptor density or efficiency of receptor coupling to signal-transduction pathways (Chapters 3 and 14).

Learned tolerance refers to a reduction in the effects of a drug owing to compensatory mechanisms that are acquired by past experiences. One type of learned tolerance is called *behavioral tolerance*. This simply describes the skills that can be developed through repeated experiences with attempting to function despite a state of mild to moderate intoxication. A common example is learning to walk a straight line despite the motor impairment produced by alcohol intoxication. This probably involves both acquisition of motor skills and the learned awareness of one’s deficit, causing the person to walk more carefully. At higher levels of intoxication, behavioral tolerance is overcome, and the deficits are obvious.

Conditioned tolerance (situation-specific tolerance) develops when environmental cues such as sights, smells, or situations consistently are paired with the administration of a drug. When a drug affects homeostatic balance by producing sedation and changes in blood pressure, pulse rate, gut activity, and so on, there is usually a reflexive counteraction or adaptation in the direction of maintaining the status quo. If a drug always is taken in the presence of specific environmental cues (e.g., smell of drug preparation and sight of syringe), these cues begin to predict the effects of the drug, and the adaptations begin to occur even before the drug reaches its sites of action. If the drug always is preceded by the same cues, the adaptive response to the drug will be learned, and this will prevent the full manifestation of the drug's effects (tolerance). This mechanism of conditioned tolerance production follows classical (pavlovian) principles of learning and results in drug tolerance under circumstances where the drug is "expected." When the drug is received under novel or "unexpected" circumstances, conditioned tolerance does not occur, and drug effects are enhanced.

The term *acute tolerance* refers to rapid tolerance developing with repeated use on a single occasion, such as in a "binge." For example, cocaine often is used in a binge, with repeated doses over one to several hours, sometimes longer, producing a decrease in response to subsequent doses of cocaine during the binge. This is the opposite of *sensitization*, observed with an intermittent dosing schedule, described in the next section.

Sensitization. With stimulants such as cocaine or amphetamine, *reverse tolerance*, or *sensitization*, can occur. This refers to an increase in response with repetition of the same dose of the drug. Sensitization results in a shift to the left of the dose-response curve (Figure 24-1). For example, with repeated daily administration to rats of a dose of cocaine that produces increased motor activity, the effect increases over several days, even though the dose remains constant. A conditioned response also can be a part of sensitization to cocaine. Simply putting a rat into a cage where cocaine is expected or giving a placebo injection after several days of receiving cocaine under the same circumstances produces an increase in motor activity as though cocaine actually were given, i.e., a conditioned response. Sensitization, in contrast to acute tolerance during a binge, requires a longer interval between doses, usually ~1 day.

Sensitization has been studied in rats equipped with microdialysis cannulas for monitoring extracellular DA (Kalivas and Duffy, 1990) (Figure 24-2). The initial response to 10 mg/kg of cocaine administered intraperitoneally is an increase in measured DA levels. After seven daily injections, the DA increase is significantly greater than on the first day, and the behavioral response also is greater. Figure 24-2 also provides an example of a conditioned response (learned drug effect): injection of saline produced both an increase in DA levels and an increase in behavioral activity when administered 3 days after cocaine injections had stopped. Little research on sensitization has been conducted in human subjects, but the results suggest that the phenomenon can occur. It has been postulated that stimulant psychosis results from a sensitized response after long intermittent periods of use.

Cross-tolerance occurs when repeated use of a drug in a given category confers tolerance not only to that drug but also to other drugs in the same structural and mechanistic category. Understanding cross-tolerance is important in the medical management of persons dependent on any drug. *Detoxification* is a form of treatment for drug

Figure 24-2. Cocaine-induced changes in CNS dopamine release. Dopamine was measured in the extracellular fluid of the nucleus accumbens of rats after daily injections of cocaine (10 mg/kg, i.p.). The first injection of cocaine produced a modest increase and the last, after 7 days, produced a much greater increase in dopamine release. The first saline injection produced no effect on dopamine levels, whereas the second, given 3 days after 7 days of cocaine injections, produced a significant rise in dopamine, presumably due to conditioning. (Adapted from Kalivas and Duffy, 1990.)

dependence that involves giving gradually decreasing doses of the drug to prevent withdrawal symptoms, thereby weaning the patient from the drug of dependence (see "Detoxification" later in the chapter). Detoxification can be accomplished with any medication in the same category as the initial drug of dependence. For example, users of heroin also are tolerant to other opioids. Thus, the detoxification of heroin-dependent patients can be accomplished with any medication that activates opioid receptors.

Physical Dependence

Physical dependence is a state that develops as a result of the adaptation (tolerance) produced by a resetting of homeostatic mechanisms in response to repeated drug use. Drugs can affect numerous systems that previously were in equilibrium; these systems find a new balance in the presence of inhibition or stimulation by a specific drug. A person in this adapted or physically dependent state requires continued administration of the drug to maintain normal function. If administration of the drug is stopped abruptly, there is another imbalance, and the affected systems again must go through a process of readjusting to a new equilibrium without the drug.

Withdrawal Syndrome. The appearance of a withdrawal syndrome when administration of the drug is terminated is the only actual evidence of physical dependence.

654 Withdrawal signs and symptoms occur when drug administration in a physically dependent person is terminated abruptly. Withdrawal symptoms have at least two origins:

- Removal of the drug of dependence
- CNS hyper-arousal owing to readaptation to the absence of the drug of dependence

Pharmacokinetic variables are of considerable importance in the amplitude and duration of the withdrawal syndrome. Withdrawal symptoms are characteristic for a given category of drugs and tend to be opposite to the original effects produced by the drug before tolerance developed. Thus, abrupt termination of a drug (such as an opioid agonist) that produces miotic (constricted) pupils and slow heart rate will produce a withdrawal syndrome including dilated pupils and tachycardia. Tolerance, physical dependence, and withdrawal are all biological phenomena. They are the natural consequences of drug use and can be produced in experimental animals and in any human being who takes certain medications repeatedly. These symptoms in themselves do not imply that the individual is involved in misuse or addictive behavior. This form of dependence should not be confused with addiction (compulsive drug-taking). *Patients who take medicine for appropriate medical indications and in correct dosages still may show tolerance, physical dependence, and withdrawal symptoms if the drug is stopped abruptly rather than gradually.* For example, a hypertensive patient receiving a β adrenergic receptor blocker such as metoprolol may have a good therapeutic response, but if the drug is stopped abruptly, the patient may experience a withdrawal syndrome consisting of rebound increased blood pressure temporarily higher than that prior to beginning the medication. This response is thought to be due to adaptive synthesis of β receptors that, in sudden the absence of antagonist, facilitate an excessive β adrenergic response in cardiac cells.

Medical addict is a term used to describe a patient in treatment for a medical disorder who has become “addicted” to the available prescribed drugs; the patient begins taking them in excessive doses, out of control. An example would be a patient with chronic pain, anxiety, or insomnia who begins using the prescribed medication more often than directed by the physician. If the physician restricts the prescriptions, the patient may begin seeing several doctors without the knowledge of the primary physician. Such patients also may visit emergency rooms for the purpose of obtaining additional medication. This scenario is very uncommon, considering the large number of patients who receive medications capable of producing tolerance and physical dependence. *Fear of producing such medical addicts results in needless*

suffering among patients with pain, because physicians needlessly limit appropriate medications. Tolerance and physical dependence are inevitable consequences of chronic treatment with opioids and certain other drugs, but tolerance and physical dependence by themselves do not imply “addiction.”

CLINICAL ISSUES

The treatment of physical dependence will be discussed with reference to the specific drug of abuse and dependence problems characteristic to each category: CNS depressants, including alcohol and other sedatives; nicotine and tobacco; opioids; psychostimulants, such as amphetamine and cocaine; cannabinoids; psychedelic drugs; and inhalants (volatile solvents, nitrous oxide, and ethyl ether). Abuse of combinations of drugs across these categories is common. Alcohol is so widely available that it is combined with practically all other categories. Some combinations reportedly are taken because of their interactive effects. An example is the combination of heroin and cocaine (“speedball”), which will be described with the opioid category. Alcohol and cocaine is another very common combination. When confronted with a patient exhibiting signs of overdose or withdrawal, the physician must be aware of these possible combinations because each drug may require specific treatment.

CNS Depressants

Ethanol. Experimentation with ethanol is almost universal, and a high proportion of users find the experience pleasant. More than 90% of American adults report experience with ethanol (commonly called “alcohol”), and ~70% report some level of current use. The lifetime prevalence of alcohol use disorders (alcoholism) in men is almost 20% and in women is 10-15% (Hasin et al., 2007). This drug is discussed more fully in Chapter 23. Ethanol is classified as a depressant because it indeed produces sedation and sleep. However, the initial effects of alcohol, particularly at lower doses, often are perceived as stimulation owing to a suppression of inhibitory systems. Those who perceive only sedation from alcohol generally choose not to drink when evaluated in a test procedure (de Wit et al., 1989).

Alcohol impairs recent memory and, in high doses, produces the phenomenon of “blackouts”: the drinker has no memory of his or her behavior while intoxicated. The effects of alcohol on memory are unclear, but evidence suggests that reports from patients about their reasons for drinking and their behavior during a binge are not reliable. Alcohol-dependent persons often say that they drink to relieve anxiety or depression. When allowed to drink under observation, however, alcoholics typically become more dysphoric as drinking continues

(Mendelson and Mello, 1979), thus not supporting the idea that alcoholics drink to relieve tension.

Tolerance, Physical Dependence, and Withdrawal. Mild intoxication by alcohol is familiar to almost everyone, but the symptoms vary among individuals. Some simply experience motor incoordination and sleepiness. Others initially become stimulated and garrulous. As the blood level increases, the sedating effects increase, with eventual coma and death occurring at high alcohol levels. The initial sensitivity (innate tolerance) to alcohol varies greatly among individuals and is related to family history of alcoholism (Wilhelmsen et al., 2003). Experience with alcohol can produce greater tolerance (acquired tolerance) such that extremely high blood levels (300-400 mg/dL) can be found in alcoholics who do not appear grossly sedated. In these cases, the lethal dose does not increase proportionately to the sedating dose, and thus the margin of safety (therapeutic index) is decreased.

Heavy consumers of alcohol not only acquire tolerance but also inevitably develop a state of physical dependence. This often leads to drinking in the morning to restore blood alcohol levels diminished during the night. Eventually, they may awaken during the night and take a drink to avoid the restlessness produced by falling alcohol levels. The alcohol-withdrawal syndrome (Table 24-4) generally depends on the size of the average daily dose and usually is “treated” by resumption of alcohol ingestion. Withdrawal symptoms are experienced frequently but usually are not severe or life-threatening until they occur in conjunction with other problems, such as infection, trauma, malnutrition, or electrolyte imbalance. In the setting of such complications, the syndrome of delirium tremens becomes likely.

Alcohol addiction produces cross-tolerance to other sedatives such as benzodiazepines. This tolerance is operative in abstinent alcoholics, but while the alcoholic is drinking, the sedating effects of alcohol add to those of other sedatives, making the combination more dangerous. This is particularly true for benzodiazepines, which

are relatively safe in overdose when given alone but potentially are lethal in combination with alcohol.

The chronic use of alcohol and other sedatives is associated with the development of depression (McLellan et al., 1979), and the risk of suicide among alcoholics is one of the highest of any diagnostic category. Cognitive deficits have been reported in alcoholics tested while sober. These deficits usually improve after weeks to months of abstinence. More severe recent memory impairment is associated with specific brain damage caused by nutritional deficiencies common in alcoholics (e.g., thiamine deficiency).

Alcohol is toxic to many organ systems. As a result, the medical complications of alcohol abuse and dependence include liver disease, cardiovascular disease, endocrine and GI effects, and malnutrition, in addition to the CNS dysfunctions outlined earlier. Ethanol readily crosses the placental barrier, producing the fetal alcohol syndrome, a major cause of mental retardation (Chapter 23).

Pharmacological Interventions.

Detoxification. A patient who presents in a medical setting with an alcohol-withdrawal syndrome should be considered to have a potentially lethal condition. Although most mild cases of alcohol withdrawal never come to medical attention, severe cases require general evaluation; attention to hydration and electrolytes; vitamins, especially high-dose thiamine; and a sedating medication that has cross-tolerance with alcohol. To block or diminish the symptoms described in Table 24-4, a short-acting benzodiazepine such as oxazepam can be used at a dose of 15-30 mg every 6-8 hours according to the stage and severity of withdrawal; some authorities recommend a long-acting benzodiazepine unless there is demonstrated liver impairment. Anticonvulsants such as carbamazepine have been shown to be effective in alcohol withdrawal, although they appear not to relieve subjective symptoms as well as benzodiazepines. After medical evaluation, uncomplicated alcohol withdrawal can be treated effectively on an outpatient basis. When there are medical problems, a history of seizures, or simultaneous dependence on other drugs, hospitalization is required.

Pharmacotherapy. Detoxification is only the first step of treatment. Complete abstinence is the objective of long-term treatment, and this is accomplished mainly by behavioral approaches. Medications that aid in the prevention of relapse are under development. Disulfiram (ANTABUSE; Chapter 23) has been useful in some programs that focus behavioral efforts on ingestion of the medication. Disulfiram blocks aldehyde dehydrogenase, the second step in ethanol metabolism, resulting in the accumulation of acetaldehyde, which produces an unpleasant flushing reaction when alcohol is ingested. Knowledge of this unpleasant reaction helps the patient to resist taking a drink. Although quite effective pharmacologically, disulfiram has not been found to be effective in controlled clinical trials because so many patients failed to ingest the medication.

Naltrexone (REVIA; Chapter 23), an opioid receptor antagonist that blocks the reinforcing properties of alcohol, is FDA-approved as an adjunct in the treatment of alcoholism. Chronic administration of naltrexone resulted in a decreased rate of relapse to alcohol drinking in the majority of published double-blind clinical trials (Pettinati et al., 2006). It works best in combination with behavioral treatment programs that encourage adherence to medication and abstinence from alcohol. A depot preparation with a duration of 30 days (VIVITROL) was approved by the FDA in 2006; it greatly improves medication adherence, the major problem with the use of medications in alcoholism.

Table 24-4

Alcohol Withdrawal Syndrome

Alcohol craving
Tremor, irritability
Nausea
Sleep disturbance
Tachycardia
Hypertension
Sweating
Perceptual distortion
Seizures (6-48 hours after last drink)
Visual (and occasionally auditory or tactile) hallucinations (12-48 hours after last drink)
Delirium tremens (48-96 hours after last drink; rare in uncomplicated withdrawal)
Severe agitation
Confusion
Fever, profuse sweating
Tachycardia
Nausea, diarrhea
Dilated pupils

A significant development in identifying a potential endophenotype of alcoholism has grown out of the clinical experience with naltrexone. Animal studies have demonstrated that alcohol causes the release of endogenous opioids in brain reward systems and the disinhibition or activation of DA neurons, a condition common to all drugs of abuse. Blocking opioid receptors prevents this dopaminergic effect and results in less stimulation or reward from alcohol (Ray and Hutchison, 2007). A functional allele of the gene for the μ opioid receptor that naltrexone blocks has been associated with alcohol stimulation and with good response to naltrexone treatment among alcoholics (Anton et al., 2006).

Acamprosate (CAMPRAL), another FDA-approved medication for alcoholism (Mason, 2003), is a competitive inhibitor of the *N*-methyl-D-aspartate (NMDA)-type glutamate receptor. The drug appears to normalize the dysregulated neurotransmission associated with chronic ethanol intake and thereby to attenuate one of the mechanisms that lead to relapse (Chapter 23).

Benzodiazepines. Benzodiazepines are among the most commonly prescribed medications worldwide; they are used mainly for the treatment of anxiety disorders and insomnia (Chapters 15 and 17). Considering their widespread use, intentional abuse of prescription benzodiazepines is relatively uncommon. When a benzodiazepine is taken for up to several weeks, there is little tolerance and no difficulty in stopping the medication when the condition no longer warrants its use. After several months, the proportion of patients who become tolerant increases, and reducing the dose or stopping the medication produces withdrawal symptoms (Table 24–5).

It can be difficult to distinguish withdrawal symptoms from the reappearance of the anxiety symptoms for which the benzodiazepine was prescribed initially. Some patients may increase their dose over time because tolerance definitely develops to the sedative effects. Many patients and their physicians, however, contend that anti-anxiety benefits continue to occur long after tolerance to the sedating effects. Moreover, these patients continue to take the medication for years according to medical directions without increasing their dose and are able to function very effectively as long as they

take the benzodiazepine. The degree to which tolerance develops to the anxiolytic effects of benzodiazepines is a subject of controversy. There is, however, good evidence that significant tolerance does not develop to all benzodiazepine actions because some effects of acute doses on memory persist in patients who have taken benzodiazepines for years. According to a task force that reviewed the issues and published guidelines on the proper medical use of benzodiazepines (American Psychiatric Association, 1990), intermittent use only when symptoms occur retards the development of tolerance and therefore is preferable to daily use. Patients with a history of alcohol or other drug-abuse problems have an increased risk for the development of benzodiazepine abuse and should rarely, if ever, be treated with benzodiazepines on a chronic basis.

While relatively few patients who receive benzodiazepines for medical indications abuse their medication, there are individuals who specifically seek benzodiazepines for their ability to produce a “high.” Among these abusers, there are differences in drug popularity; benzodiazepines that have a rapid onset, such as diazepam and alprazolam, tend to be the most desirable. The drugs may be obtained by simulating a medical condition and deceiving physicians or simply through illicit channels. Unsupervised use can lead to self-administration of large doses and therefore tolerance to the benzodiazepine’s sedating effects. For example, while 5–20 mg/day of diazepam is a typical dose for a patient receiving prescribed medication, abusers may take over 1000 mg/day and not appear grossly sedated.

Abusers may combine benzodiazepines with other drugs to increase the effect. For example, it is part of the “street lore” that taking diazepam 30 minutes after an oral dose of methadone will produce an augmented high not obtainable with either drug alone.

While there is some illicit use of benzodiazepines as a primary drug of abuse, most of the unsupervised use seems to be by abusers of other drugs who are attempting to self-medicate the side effects or withdrawal effects of their primary drug of abuse. Thus, cocaine addicts often take diazepam to relieve the irritability and agitation produced by cocaine binges, and opioid addicts find that diazepam and other benzodiazepines relieve some of the anxiety symptoms of opioid withdrawal when they are unable to obtain their preferred drug.

Pharmacological Interventions. If patients receiving long-term benzodiazepine treatment by prescription wish to stop their medication, the process may take months of gradual dose reduction. Withdrawal symptoms (Table 24–5) may occur during this outpatient detoxification, but in most cases the symptoms are mild. If anxiety symptoms return, a non-benzodiazepine such as buspirone may be prescribed, but this agent usually is less effective than benzodiazepines for treatment of anxiety in these patients. Some authorities recommend transferring the patient to a long $t_{1/2}$ benzodiazepine during detoxification; others recommend the anticonvulsants carbamazepine and phenobarbital. Controlled studies comparing different treatment regimens are lacking. Since patients who have been on low doses of benzodiazepines for years usually have no adverse effects, the physician and patient should decide jointly whether detoxification and possible transfer to a new anxiolytic are worth the effort.

The specific benzodiazepine receptor antagonist flumazenil has been found useful in the treatment of overdose and in reversing the effects of long-acting benzodiazepines used in anesthesia. It has been used experimentally in the treatment of persistent withdrawal symptoms after cessation of long-term benzodiazepine treatment.

Table 24–5

Benzodiazepine Withdrawal Symptoms

Following moderate dose usage

- Anxiety, agitation
- Increased sensitivity to light and sound
- Paresthesias, strange sensations
- Muscle cramps
- Myoclonic jerks
- Sleep disturbance
- Dizziness

Following high-dose usage

- Seizures
- Delirium

Deliberate abusers of high doses of benzodiazepines usually require inpatient detoxification. Frequently, benzodiazepine abuse is part of a combined dependence involving alcohol, opioids, and cocaine. Detoxification can be a complex clinical pharmacological problem requiring knowledge of the pharmacokinetics of each drug. The patient's history may be unreliable not simply because of lying but also because the patient frequently does not *know* the true identity or dose of drugs purchased on the street. Medication for detoxification should not be prescribed by the "cookbook" approach but by careful titration and patient observation. The withdrawal syndrome from diazepam, e.g., may not become evident until the patient develops a seizure in the second week of hospitalization. One approach to complex detoxification is to focus on the CNS-depressant drug and temporarily hold the opioid component constant with a low dose of methadone. Opioid detoxification can begin later. A long-acting benzodiazepine such as diazepam or clorazepate (TRANXENE, others) or a long-acting barbiturate such as phenobarbital can be used to block the sedative withdrawal symptoms. The phenobarbital dose should be determined by a series of test doses and subsequent observations to determine the level of tolerance. Most complex detoxifications can be accomplished using this phenobarbital loading-dose strategy (Robinson et al., 1981).

After detoxification, the prevention of relapse requires a long-term outpatient rehabilitation program similar to the treatment of alcoholism. No specific medications have been found to be useful in the rehabilitation of sedative abusers; but, of course, specific psychiatric disorders such as depression or schizophrenia, if present, require appropriate medications.

Barbiturates and Older Sedatives. The use of barbiturates and older non-benzodiazepine sedating medications (e.g., meprobamate, glutethimide, chloral hydrate) has declined greatly in recent years owing to the increased safety and to the efficacy of the benzodiazepines and the newer agents zolpidem, eszopiclone, zaleplon, and ramelteon (Chapters 15 and 17). Abuse problems with barbiturates resemble those seen with benzodiazepines in many ways. Treatment of abuse and addiction should be handled similarly to interventions for the abuse of alcohol and benzodiazepines. Because drugs in this category frequently are prescribed as hypnotics for patients complaining of insomnia, physicians should be aware of the problems that can develop when the hypnotic agent is withdrawn. Insomnia rarely should be treated with medication as a primary disorder except when produced by short-term stressful situations. Insomnia often is a symptom of an underlying chronic problem, such as depression or respiratory dysfunction, or may be due simply to a change in sleep requirements with age. Prescription of sedative medications, however, can change the physiology of sleep with subsequent tolerance to these medication effects. When the sedative is stopped, there is a rebound effect with worsened insomnia. This medication-induced insomnia requires detoxification by gradual dose reduction.

Nicotine

The basic pharmacology of nicotine and agents for smoking cessation are discussed in Chapter 11. Because nicotine provides the reinforcement for cigarette smoking, the most common cause of preventable death and disease in the U.S., it is arguably the most dangerous dependence-producing drug. The dependence produced by nicotine can be extremely durable, as exemplified by the high failure rate among smokers who try to quit. Although >80% of smokers express a desire to quit, only 35% try to stop each year, and fewer than 5% are successful in unaided attempts to quit (American Psychiatric Association, 2000).

Cigarette (nicotine) addiction is influenced by multiple variables. Nicotine itself produces reinforcement; users compare nicotine to stimulants such as cocaine or amphetamine, although its effects are of lower magnitude. While there are many casual users of alcohol and cocaine, few individuals who smoke cigarettes smoke a small enough quantity (≤ 5 cigarettes per day) to avoid dependence. Nicotine is absorbed readily through the skin, mucous membranes, and lungs. The pulmonary route produces discernible CNS effects in as little as 7 seconds. Thus, each puff produces some discrete reinforcement. With 10 puffs per cigarette, the one-pack-per-day smoker reinforces the habit 200 times daily. The timing, setting, situation, and preparation all become associated repetitively with the effects of nicotine.

Nicotine has both stimulant and depressant actions. The smoker feels alert, yet there is some muscle relaxation. Nicotine activates the nucleus accumbens reward system in the brain; increased extracellular DA has been found in this region after nicotine injections in rats. Nicotine affects other systems as well, including the release of endogenous opioids and glucocorticoids.

There is evidence for tolerance to the subjective effects of nicotine. Smokers typically report that the first cigarette of the day after a night of abstinence gives the "best" feeling. Smokers who return to cigarettes after a period of abstinence may experience nausea if they return immediately to their previous dose. Persons naive to the effects of nicotine will experience nausea at low nicotine blood levels, and smokers will experience nausea if nicotine levels are raised above their accustomed levels.

Negative reinforcement refers to the benefits obtained from the termination of an unpleasant state. In dependent smokers, the urge to smoke correlates with a low blood nicotine level, as though smoking were a means to achieve a certain nicotine level and thus avoid withdrawal symptoms. Some smokers even awaken during the night to have a cigarette, which ameliorates the effect of low nicotine blood levels that could disrupt sleep. If the nicotine level is maintained artificially by a slow intravenous infusion, the number of cigarettes smoked and in the number of puffs decrease. Thus, smokers may be smoking to achieve the reward of nicotine effects, to avoid the pain of nicotine withdrawal, or most likely a combination of the two. Nicotine withdrawal symptoms are listed in Table 24-6.

Table 24–6

Nicotine Withdrawal Symptoms

Irritability, impatience, hostility
 Anxiety
 Dysphoric or depressed mood
 Difficulty concentrating
 Restlessness
 Decreased heart rate
 Increased appetite or weight gain

Depressed mood (dysthymic disorder, affective disorder) is associated with nicotine dependence, but it is not known whether depression predisposes one to begin smoking or depression develops during the course of nicotine dependence. Depression increases significantly during smoking withdrawal, and this is cited as one reason for relapse.

Pharmacological Interventions. The nicotine withdrawal syndrome can be alleviated by nicotine-replacement therapy, available with a prescription (e.g., NICOTROL inhaler and nasal spray) or without (e.g., NICORETTE gum and others; COMMIT lozenges and others; and NICODERM CQ transdermal patch and others). Figure 24–3 shows the blood nicotine concentrations achieved by different methods of nicotine delivery. Because nicotine gum and a nicotine patch do not achieve the peak levels seen with cigarettes, they do not produce the same magnitude of subjective effects as smoking. These methods do, however, suppress the symptoms of nicotine withdrawal. Thus, smokers should be able to transfer their dependence to the alternative delivery system and gradually reduce the daily nicotine dose with minimal symptoms. Although this results in more smokers achieving abstinence, most resume smoking over the ensuing weeks or months. Comparisons with placebo treatment show large benefits of nicotine replacement at 6 weeks, but the effect diminishes with time. The nicotine patch produces a steady blood level (Figure 24–3) and seems to have better patient compliance than that observed with nicotine gum. Verified abstinence rates at 12 months are reported to be in the range of 20%. The necessary goal of complete abstinence contributes to the poor success rate; when ex-smokers “slip” and begin smoking a little, they usually relapse quickly to their prior level of dependence.

The search for better medications to treat nicotine addiction has become an important goal of the pharmaceutical industry, and other types of medication have been tested in clinical trials. A sustained-release preparation of the antidepressant bupropion (ZYBAN; Chapter 15), improves abstinence rates among smokers and remains a useful option. The cannabinoid CB₁ receptor inverse agonist rimonabant improves abstinence rates and reduces the weight gain seen frequently in ex-smokers. Unfortunately, the CB₁ inverse agonist mechanism led to a high frequency of depressive and neurologic symptoms, ending its development in the U.S. Varenicline, a partial agonist at the $\alpha_4\beta_2$ subtype of the nicotinic acetylcholine receptor, improves abstinence rates but has also been linked to risk of developing suicidal ideation. Varenicline partially stimulates nicotinic receptors, thereby reducing craving and preventing most withdrawal symptoms. It has high receptor affinity, thus blocking access to nicotine, so if the treated smoker relapses, there is little reward and

Figure 24–3. Nicotine concentrations in blood resulting from five different nicotine delivery systems. Shaded areas (upper panel) indicate the periods of exposure to nicotine. Arrows (lower panel) indicate when the nicotine patch was put on and taken off. (From Benowitz et al., 1988, and Srivastava et al, 1991, with permission. Benowitz et al, 1988 Copyright © Macmillan Publishers Ltd. Srivastava et al, 1991 Copyright © Springer Science and Business Media.)

abstinence is more likely to be maintained. In one recent clinical trial, the abstinence rate for varenicline at 1 year was 36.7% versus 7.9% for placebo (Williams et al., 2007).

Opioids

Opioid drugs are used primarily for the treatment of pain (Chapter 18). Some of the CNS mechanisms that reduce the perception of pain also produce a state of well-being or euphoria. Thus, opioid drugs also are taken outside medical channels for the purpose of obtaining the effects on mood. This potential for abuse has generated much research on separating the mechanism of analgesia from that of euphoria in the hope of eventually developing a potent analgesic that does not activate the brain reward

systems. Although this research has led to advances in understanding the physiology of pain, the standard medications for severe pain remain the derivatives of the opium poppy (opiates) and synthetic drugs that activate the same receptors (opioids). Drugs modeled after the endogenous opioid peptides may one day provide more specific options for the treatment of pain, but none of these currently is available for clinical use. Analgesic medications that do not act at opioid receptors, such as the nonsteroidal anti-inflammatory drugs (NSAIDs), have an important role in mild to moderate types of pain, but for severe pain, the opioid drugs are most effective. Progress in pain control stems from a greater understanding of the mechanism of tolerance to μ opiate receptor-mediated analgesia, which involves NMDA receptors (Trujillo and Akil, 1991). Experimentally, by combining morphine with dextromethorphan, an NMDA-receptor antagonist, tolerance is impaired and analgesia is enhanced without an increase in the dose of opioid.

The subjective effects of opioid drugs are useful in the management of acute pain. This is particularly true in high-anxiety situations, such as the crushing chest pain of myocardial infarction, when the relaxing, anxiolytic effects complement the analgesia. Normal volunteers with no pain given opioids in the laboratory may report the effects as unpleasant because of side effects such as nausea, vomiting, and sedation. Patients with pain usually do not develop abuse or addiction problems. Of course, patients receiving opioids over time develop tolerance routinely, and if the medication is stopped abruptly, they will show the signs of an opioid-withdrawal syndrome, the evidence for physical dependence.

Opioids should never be withheld from patients with cancer out of fear of producing addiction. If chronic opioid medication is indicated, it is preferable to prescribe an orally active, slow-onset opioid with a long duration of action. These qualities reduce the likelihood of producing euphoria at onset and withdrawal symptoms as the medication wears off. In selected patients, methadone is an excellent choice for the management of chronic severe pain. Controlled-release oral morphine (MS CONTIN, others) and controlled-release oxycodone (OXYCONTIN, others) are other possibilities. Rapid-onset, short-duration opioids are excellent for acute short-term use, such as during the postoperative period. As tolerance and physical dependence develop, however, the patient may experience the early symptoms of withdrawal between doses, and during withdrawal, the threshold for pain decreases. Thus, for chronic administration, long-acting opioids are preferred. While methadone is long acting because of its metabolism to active metabolites, the long-acting version of oxycodone has been formulated to release slowly, thereby changing a short-acting opioid into a long-acting one. Unfortunately, this mechanism can be subverted by breaking the tablet and making the full dose of oxycodone immediately available. This has led to diversion of oxycodone to illicit traffic because high-dose oxycodone produces euphoria that is sought by opiate abusers. The diversion of prescription opioids such as oxycodone and hydrocodone to illegal markets has become an important source of opiate abuse in the U.S.

The risk for addiction is highest in patients complaining of pain with no clear physical explanation or in patients with evidence of a chronic, non-life-threatening disorder. Examples are chronic headaches, backaches, abdominal pain, or peripheral neuropathy. Even in these cases, an opioid may be considered as a brief emergency treatment, but long-term treatment with opioids should be used only after other alternatives have been exhausted. In the relatively rare patient who develops abuse, the transition from legitimate use to abuse often begins when the patient returns to his physician earlier than scheduled, asking for a new prescription, or visits emergency rooms of multiple hospitals, complaining of acute pain and asking for an opioid injection.

Heroin is the most frequently abused opiate. There is no legal supply of heroin for clinical use in the U.S. Despite claims that heroin has unique analgesic properties for the treatment of severe pain, double-blind trials have found it to be no more effective than hydromorphone. However, heroin is widely available on the illicit market, and its price dropped sharply in the 1990s, continuing to the present, with purity increased 10-fold.

Previously, street heroin in the U.S. was highly diluted: Each 100-mg bag of powder had only ~4 mg heroin (range: 0-8 mg), and the rest was filler such as quinine. In the mid-1990s, street heroin reached 45-75% purity in many large cities, with some samples testing as high as 90%. This increase in purity has led to increased levels of physical dependence among heroin addicts. Users who interrupt regular dosing develop more severe withdrawal symptoms. Whereas heroin previously required intravenous injection, the more potent supplies can be smoked or administered nasally (snorted), making the initiation of heroin use accessible to people who would not insert a needle into their veins. There is no accurate way to count the number of heroin addicts, but based on extrapolation from overdose deaths, number of applicants for treatment, and number of heroin addicts arrested, the estimates range from 800,000 to 1 million in the U.S.; based on a stratified national sample of adults, ~1 in 4 individuals who report any use of heroin become addicted (Anthony et al., 1994). Recent law enforcement actions may presage the emergence of a domestic supply of heroin precursor (raw opium) harvested from *Papaver somniferum* grown in the Pacific Northwest of the U.S. (Baer, 2009).

Tolerance, Dependence, and Withdrawal. Injection of a heroin solution produces a variety of sensations described as warmth, taste, or high and intense pleasure (“rush”) often compared with sexual orgasm. There are some differences among the opioids in their acute effects, with morphine producing more of a histamine-releasing effect and meperidine producing more excitation or confusion. Even experienced opioid addicts, however, cannot distinguish between heroin and hydromorphone in double-blind tests.

Thus, the popularity of heroin may be due to its availability on the illicit market and its rapid onset. After intravenous injection, the effects begin in less than a minute. Heroin has high lipid solubility,

crosses the blood-brain barrier quickly, and is deacetylated to the active metabolites 6-monoacetyl morphine and morphine. After the intense euphoria, which lasts from 45 seconds to several minutes, there is a period of sedation and tranquility (“on the nod”) lasting up to an hour. The effects of heroin wear off in 3-5 hours, depending on the dose. Experienced users may inject two to four times per day. Thus, the heroin addict is constantly oscillating between being “high” and feeling the sickness of early withdrawal (Figure 24-4). This produces many problems in the homeostatic systems regulated at least in part by endogenous opioids. For example, the hypothalamic-pituitary-gonadal axis and the hypothalamic-pituitary-adrenal axis are abnormal in heroin addicts. Women on heroin have irregular menses, and men have a variety of sexual performance problems. Mood also is affected. Heroin addicts are relatively docile and compliant after taking heroin, but during withdrawal, they become irritable and aggressive.

Based on patient reports, tolerance develops early to the euphoria-producing effects of opioids. There also is tolerance to the respiratory depressant, analgesic, sedative, and emetic properties. Heroin users tend to increase their daily dose, depending on their financial resources and the availability of the drug. If a supply is available, the dose can be increased progressively 100 times. Even in highly tolerant individuals, the possibility of overdose remains if tolerance is exceeded. Overdose is likely to occur when potency of the street sample is unexpectedly high or when the heroin is mixed with a far more potent opioid, such as fentanyl (SUBLIMAZE, others).

Addiction to heroin or other short-acting opioids produces behavioral disruptions and usually becomes incompatible with a productive life. There is a significant risk for opioid abuse and dependence among physicians and other health care workers who have access to potent opioids, tempting them toward unsupervised

experimentation. Physicians often begin by assuming that they can manage their own dose, and they may rationalize their behavior based on the beneficial effects of the drug. Over time, however, the typical unsupervised opioid user loses control, and behavioral changes are observed by family and co-workers. Apart from the behavioral changes and the risk of overdose, especially with very potent opioids, chronic use of opioids is relatively nontoxic.

Opioids frequently are used in combinations with other drugs. A common combination is heroin and cocaine (“speedball”). Users report an improved euphoria because of the combination, and there is evidence of an interaction, because cocaine reduces the signs of opiate withdrawal, and heroin may reduce the irritability seen in chronic cocaine users.

The mortality rate for street heroin users is very high. Early death comes from involvement in crime to support the habit; from the uncertain dose, purity, and even identity of what is purchased on the street; and from serious infections associated with nonsterile drugs and sharing of injection paraphernalia. Heroin users commonly acquire bacterial infections producing skin abscesses; endocarditis; pulmonary infections, especially tuberculosis; and viral infections producing hepatitis C and acquired immune deficiency syndrome (AIDS).

As with other addictions, the first stage of treatment addresses physical dependence and consists of detoxification (Kosten and O’Conner, 2003). The opioid-withdrawal syndrome (Table 24-7) is very unpleasant but not life-threatening. It begins within 6-12 hours after the last dose of a short-acting opioid and as long as 72-84 hours after a very long-acting opioid medication. Heroin addicts go through early stages of this syndrome frequently when heroin is scarce or expensive. Some therapeutic communities as a matter of policy elect not to treat withdrawal so that the addict can experience the suffering while being given group support. The duration and intensity of the syndrome are related to the clearance of the individual drug. Heroin withdrawal is brief (5-10 days) and intense. Methadone withdrawal is slower in onset and lasts longer. Protracted withdrawal also is likely to be longer with methadone. (See more detailed discussions of protracted withdrawal under “Long-Term Management” later in the chapter.)

Figure 24-4. Differences in responses to heroin and methadone. A person who injects heroin (↑) several times per day oscillates between being sick and being high. In contrast, the typical methadone patient (purple line) remains in the “normal” range (indicated in blue) with little fluctuation after dosing once per day. The ordinate values represent the subject’s mental and physical state, not plasma levels of the drug.

Table 24-7

Characteristics of Opioid Withdrawal

SYMPTOMS	SIGNS
<i>Regular withdrawal</i>	
Craving for opioids	Pupillary dilation
Restlessness, irritability	Sweating
Increased sensitivity to pain	Piloerection (“gooseflesh”)
Nausea, cramps	Tachycardia
Muscle aches	Vomiting, diarrhea
Dysphoric mood	Increased blood pressure
Insomnia, anxiety	Yawning
	Fever
<i>Protracted withdrawal</i>	
Anxiety	Cyclic changes in weight,
Insomnia	pupil size, respiratory
Drug craving	center sensitivity

Pharmacological Interventions. Opioid withdrawal signs and symptoms can be treated by three different approaches. The first and most commonly used approach depends on cross-tolerance and consists of transfer to a prescription opioid medication and then gradual dose reduction. The same principles of detoxification apply as for other types of physical dependence. It is convenient to change the patient from a short-acting opioid such as heroin to a long-acting one such as methadone. Detoxification and subsequent maintenance of opiate dependence with methadone is specifically limited to accredited opioid treatment programs (OTPs) and is regulated by Federal Opioid Treatment Standards. The initial dose of methadone is typically 20-30 mg. This is a test dose to determine the level needed to reduce observed withdrawal symptoms. The first day's total dose then can be calculated depending on the response and then reduced by 20% per day during the course of detoxification.

A second approach to detoxification involves the use of oral clonidine (CATAPRES, others), a medication approved only for the treatment of hypertension. Clonidine is an α_2 adrenergic agonist that decreases adrenergic neurotransmission from the locus ceruleus. Many of the autonomic symptoms of opioid withdrawal such as nausea, vomiting, cramps, sweating, tachycardia, and hypertension result from the loss of opioid suppression of the locus ceruleus system during the abstinence syndrome. Clonidine, acting upon distinct receptors but by cellular mechanisms that mimic opioid effects, can alleviate many of the symptoms of opioid withdrawal, but not the generalized aches and opioid craving. When using clonidine to treat withdrawal, the dose must be titrated according to the stage and severity of withdrawal, beginning with 0.2 mg orally; postural hypotension is commonly a side effect. A similar drug, lofexidine (currently in clinical trials in the U.S.), has greater selectivity for α_{2A} adrenergic receptors and is associated with less of the hypotension that limits the usefulness of clonidine in this setting.

A third method of treating opioid withdrawal involves activation of the endogenous opioid system without medication. The techniques proposed include acupuncture and several methods of CNS activation using transcutaneous electrical stimulation. While attractive theoretically, this has not yet been found to be practical. Rapid antagonist-precipitated opioid detoxification under general anesthesia has received considerable publicity because it promises detoxification in several hours while the patient is unconscious and not experiencing withdrawal discomfort. A mixture of medications has been used, but morbidity and mortality as reported in the lay press are unacceptable, with no demonstrated advantage in long-term outcome (Collins et al., 2005).

Long-Term Management. If patients are simply discharged from the hospital after withdrawal from opioids, there is a high probability of a quick return to compulsive opioid use. Addiction is a chronic disorder that requires long-term treatment. Numerous factors influence relapse. One factor is that the withdrawal syndrome does not end in 5-7 days. There are subtle signs and symptoms often called the *protracted withdrawal syndrome* (Table 24-7) that persist for up to 6 months. Physiological measures tend to oscillate as though a new set point were being established; during this phase, outpatient drug-free treatment has a low probability of success, even when the patient has received intensive prior treatment while protected from relapse in a residential program.

The most successful treatment for heroin addiction consists of stabilization on methadone in accordance with state and federal regulations. Patients who relapse repeatedly during drug-free treatment can be transferred directly to methadone without requiring detoxification. The dose of methadone must be sufficient to prevent withdrawal symptoms for at least 24 hours. The introduction of buprenorphine, a partial agonist at μ opioid receptors (Chapter 18), represents a major change in the treatment of opiate addiction. This drug produces minimal withdrawal symptoms when discontinued and has a low potential for overdose, a long duration of action, and the ability to block heroin effects. Treatment can take place in a qualified physician's private office rather than in a special center, as required for methadone. When taken sublingually, buprenorphine (SUBUTEX) is active, but it also has the potential to be dissolved and injected (abused). A buprenorphine-naloxone combination (SUBOXONE) is also available. When taken orally (sublingually), the naloxone moiety is not effective, but if the patient abuses the medication by injecting, the naloxone will block or diminish the subjective high that could be produced by buprenorphine alone.

Agonist or Partial-Agonist Maintenance. Patients receiving methadone or buprenorphine will not experience the ups and downs produced by heroin (Figure 24-4). Drug craving diminishes and may disappear. Neuroendocrine rhythms eventually are restored (Kreek et al., 2002). Because of cross-tolerance (from methadone to heroin), patients who inject street heroin report a reduced effect from usual heroin doses. This cross-tolerance effect is dose-related, so higher methadone maintenance doses result in less illicit opioid use, as determined by random urine testing. Buprenorphine, as a partial agonist, has a ceiling effect at ~16 mg of the sublingual tablet equaling no more than 60 mg methadone. If the patient has a higher level of physical dependence, a full agonist (methadone) must be used. Patients become tolerant to the sedating effects of methadone and can attend school or function in a job. Opioids also have a persistent, mild, stimulating effect noticeable after tolerance to the sedating effect, such that reaction time is quicker and vigilance is increased while on a stable dose of methadone.

Antagonist Treatment. Another pharmacological option is opioid antagonist treatment. Naltrexone (REVIA, others; Chapter 18) is an antagonist with a high affinity for the μ opioid receptor (MOR); it will competitively block the effects of heroin or other MOR agonists. Naltrexone has almost no agonist effects of its own and will not satisfy craving or relieve protracted withdrawal symptoms. For these reasons, naltrexone treatment does not appeal to the average heroin addict, but it can be used after detoxification for patients with high motivation to remain opioid-free. Physicians, nurses, and pharmacists who have frequent access to opioid drugs make excellent candidates for this treatment approach. A depot formulation of naltrexone that provides 30 days of medication after a single injection (VIVITROL) has been approved for the treatment of alcoholism. This formulation eliminates the necessity of daily pill-taking and prevent relapse when the recently detoxified patient leaves a protected environment.

Cocaine and Other Psychostimulants

Cocaine. More than 23 million Americans have used cocaine at some time. Although chronic use and use by

high school students has declined, the number of frequent users (at least weekly) has remained steady since 1991 at ~600,000. Not all users become addicts, and the variables that influence this risk are discussed at the beginning of this chapter. A key factor is the widespread availability of relatively inexpensive cocaine in the alkaloidal form (free base, “crack”) suitable for smoking and in the hydrochloride powder form suitable for nasal or intravenous use. Drug abuse in men occurs about twice as frequently as in women. However, free basing is particularly common in young women of child-bearing age, who may use cocaine in this manner as commonly as do men.

The reinforcing effects of cocaine and cocaine analogs correlate best with their effectiveness in blocking the transporter that recovers DA from the synapse. This leads to increased DA concentrations at critical brain sites (Ritz et al., 1987). However, cocaine also blocks both NE and 5-HT reuptake, and chronic use of cocaine leads to reductions in the neurotransmitter metabolites 3-methoxy-4 hydroxyphenylethylglycol (MOPEG or MHPG) and 5-hydroxyindoleacetic acid (5-HIAA).

The general pharmacology and medicinal use of cocaine as a local anesthetic are discussed in Chapter 20. Cocaine produces a dose-dependent increase in heart rate and blood pressure accompanied by increased arousal, improved performance on tasks of vigilance and alertness, and a sense of self-confidence and well-being. Higher doses produce euphoria, which has a brief duration and often is followed by a desire for more drug. Repeated doses may lead to involuntary motor activity, stereotyped behavior, and paranoia. Irritability and increased risk of violence are found among heavy chronic users. The $t_{1/2}$ of cocaine in plasma is ~50 minutes, but inhalant (crack) users typically desire more cocaine after 10-30 minutes. Intranasal and intravenous uses also result in a high of shorter duration than would be predicted by plasma cocaine levels, suggesting that a declining plasma concentration is associated with termination of the high and resumption of cocaine seeking. This theory is supported by positron-emission tomographic imaging studies using ^{11}C -labeled cocaine, which show that the time course of subjective euphoria parallels the accumulation and decline of the drug in the corpus striatum (Volkow et al., 2003).

The major route for cocaine metabolism involves hydrolysis of each of its two ester groups. Benzoyllecgonine, produced on loss of the methyl group, represents the major urinary metabolite and can be found in the urine for 2-5 days after a binge. As a result, the benzoyllecgonine test is a valid method for detecting cocaine use; the metabolite remains detectable in the urine of heavy users for up to 10 days. Cocaine frequently is used in combination with other drugs, as discussed previously. Ethanol is frequently abused with cocaine, as it reduces the irritability induced by cocaine. Dual addiction to alcohol and cocaine is common. When cocaine and alcohol are taken concurrently, cocaine may be transesterified to cocaethylene, which is equipotent to cocaine in blocking DA reuptake (Hearn et al., 1991).

Addiction is the most common complication of cocaine abuse. Intranasal users can continue intermittent use for years. Others become compulsive users despite elaborate methods to maintain control. In general, stimulants tend to be abused much more irregularly than

opioids, nicotine, and alcohol. Binge use is very common, and a binge may last hours to days, terminating only when supplies of the drug are exhausted.

Toxicity. Other risks of cocaine, beyond the potential for addiction, include cardiac arrhythmias, myocardial ischemia, myocarditis, aortic dissection, cerebral vasoconstriction, and seizures. Death from trauma also is associated with cocaine use. Cocaine may induce premature labor and abruptio placentae (Chasnoff et al., 1989). The developmental abnormalities reported in infants born to cocaine users may be the result of cocaine effects as well as multiple other factors (the infant’s prematurity, multiple-drug and alcohol exposure, and inadequate pre- and postnatal care).

Cocaine has been reported to produce a prolonged and intense orgasm if taken prior to intercourse, and users often indulge in compulsive and promiscuous sexual activity. However, chronic cocaine use reduces sexual drive. Chronic use is also associated with psychiatric disorders, including anxiety, depression, and psychosis, and while some of these disorders undoubtedly existed prior to addiction, many are likely attributable to the drug (McLellan et al., 1979).

Tolerance, Dependence, and Withdrawal. Sensitization, a consistent finding in animal studies of cocaine and other stimulants, is produced by intermittent use and typically is manifested as behavioral hyperactivity. In human cocaine users, the euphoric effect typically is not subject to sensitization. On the contrary, most experienced users become desensitized and, over time, require more cocaine to obtain euphoria, i.e., tolerance develops. In the laboratory, tolerance is rapidly induced by repeated administration of the same dose in one session (tachyphylaxis). Sensitization may involve conditioning (Figure 24–2). Cocaine users often report a strong response on seeing cocaine before it is administered, consisting of physiological arousal and increased drug craving with concomitant activation of brain limbic structures (Childress et al., 1999). Sensitization in humans has been linked to paranoid, psychotic manifestations of cocaine use (Satel et al., 1991). Since cocaine typically is used intermittently, even heavy users go through frequent periods of withdrawal or “crash.” The symptoms of withdrawal seen in users admitted to hospitals are listed in Table 24–8. Careful studies of cocaine users during withdrawal show gradual diminution of these symptoms over 1-3 weeks (Weddington et al., 1990). Residual depression, often seen after cocaine withdrawal, should be treated with antidepressant agents if it persists (Chapter 15).

Pharmacological Interventions. Since cocaine withdrawal is generally mild, treatment of withdrawal symptoms usually is not required. The major problem in treatment is not detoxification but helping the patient to resist the urge to resume compulsive cocaine use. Rehabilitation programs involving individual and group psychotherapy based on the principles of Alcoholics Anonymous, and behavioral treatments based

Table 24–8

Cocaine Withdrawal Symptoms and Signs

Dysphoria, depression
Sleepiness, fatigue
Cocaine craving
Bradycardia

on reinforcing cocaine-free urine tests, result in significant improvement in the majority of cocaine users (Alterman et al., 1994; Higgins et al., 1994). Nonetheless, there is great interest in finding a medication that can aid in the rehabilitation of cocaine addicts.

Numerous medications have been tried in placebo-controlled clinical trials with cocaine addicts, but no medication has yet consistently improved upon the results of behavior therapy alone. Animal models suggest that enhancing GABAergic inhibition can reduce reinstatement of cocaine self-administration, and a controlled clinical trial of topiramate (TOPAMAX) showed a significant reduction in cocaine use. Topiramate also reduced the relapse rate in alcoholics, prompting current studies in patients dually dependent on cocaine and alcohol. Baclofen (LIORESAL, others), a GABA_B agonist, was found in a single-site trial to reduce relapse in cocaine addicts, but was not effective in a multisite trial. A different approach was taken using modafinil (PROVIGIL), a medication that increases alertness and is approved for the treatment of narcolepsy. This medication was found to reduce the euphoria produced by cocaine and to relieve cocaine withdrawal symptoms. Modafinil is currently being tested in clinical trials of cocaine, methamphetamine, alcohol, and other substance abuse disorders. A novel approach to cocaine addiction employs a vaccine that produces cocaine-binding antibodies. Preliminary studies showed some success in reducing cocaine use. Larger trials are in progress. For now, behavioral therapy remains the treatment of choice, with medication indicated for specific co-existing disorders such as depression.

Amphetamine and Related Agents. Subjective effects similar to those of cocaine are produced by amphetamine, dextroamphetamine, methamphetamine, phenmetrazine, methylphenidate, and diethylpropion. Amphetamines increase synaptic DA, NE, and 5-HT primarily by stimulating pre-synaptic release rather than by blockade of reuptake, as is the case with cocaine. Intravenous or smoked methamphetamine produces an abuse/dependence syndrome similar to that of cocaine, although clinical deterioration may progress more rapidly. In animal studies, methamphetamine in doses comparable with those used by human abusers produces neurotoxic effects, as reflected by histologic changes in dopaminergic and serotonergic neurons.

Methamphetamine can be synthesized from ephedrine in small, clandestine laboratories. Methamphetamine addiction has become a major public health problem, particularly in the western half of the U.S. Behavioral and medical treatments for methamphetamine addiction are similar to those used for cocaine. Until recently, ephedrine was a widely available nonprescription stimulant (a “wake-up” pill). Oral stimulants, such as those prescribed in a weight-reduction program, have short-term efficacy because of tolerance development. Only a small proportion of patients introduced to these appetite suppressants subsequently exhibits dose escalation or drug-seeking from various physicians; such patients may meet diagnostic criteria for abuse or addiction.

Caffeine. Caffeine, a mild stimulant, is the most widely used psychoactive drug in the world. It is present in

soft drinks, coffee, tea, cocoa, chocolate, and numerous prescription and over-the-counter drugs. It mildly increases NE and DA release and enhances neural activity in numerous brain areas. Caffeine is absorbed from the digestive tract and is distributed rapidly throughout all tissues and easily crosses the placental barrier. Many of caffeine’s effects are believed to occur by means of competitive antagonism at adenosine receptors; as a methylxanthine, caffeine also inhibits cyclic nucleotide phosphodiesterases. Adenosine is a neuromodulator that influences a number of functions in the CNS, as is cyclic AMP (Chapter 14). The mild sedating effects that occur when adenosine activates particular adenosine-receptor subtypes can be antagonized by caffeine.

Tolerance occurs rapidly to the stimulating effects of caffeine. Thus, a mild withdrawal syndrome has been produced in controlled studies by abruptly discontinuing the intake of as little as one to two cups of coffee per day. Caffeine withdrawal consists of feelings of fatigue and sedation. With higher doses, headaches and nausea have been reported during withdrawal; vomiting is rare (Silverman et al., 1992). Although a withdrawal syndrome can be demonstrated, few caffeine users report loss of control of caffeine intake or significant difficulty in reducing or stopping caffeine, if desired (Dews et al., 1999). Thus, caffeine is not listed in the category of addicting stimulants (American Psychiatric Association, 2000).

Cannabinoids (Marijuana)

The cannabis plant has been cultivated for centuries both for the production of hemp fiber and for its presumed medicinal and psychoactive properties. The smoke from burning cannabis contains many chemicals, including 61 different cannabinoids that have been identified. One of these, Δ -9-tetrahydrocannabinol (Δ -9-THC), produces most of the characteristic pharmacological effects of smoked marijuana.

Marijuana is the most commonly used illegal drug in the U.S. Surveys over the period 2006-2009 report that ~32% of highschool seniors have tied marijuana, down from a high of 51% in 1974, but up from 22% in 1992 (Johnston et al., 2010).

Cannabinoid receptors CB₁ (mainly CNS) and CB₂ (peripheral) have been identified and cloned. An arachidonic acid derivative, anandamide, has been proposed as an endogenous ligand for CB receptors. While the physiological function of these receptors and their endogenous ligands are incompletely understood, they are likely to have important functions because they are dispersed widely with high densities in the cerebral cortex, hippocampus, striatum, and cerebellum (Iversen, 2003). Specific CB₁ antagonists have been

developed and tested in controlled clinical trials. One of these, rimonabant, was found to reduce relapse in cigarette smokers and to produce weight loss in obese patients; however, its development has been abandoned because of depressive and neurologic side effects.

The pharmacological effects of Δ -9-THC vary with the dose, route of administration, experience of the user, vulnerability to psychoactive effects, and setting of use. Intoxication with marijuana produces changes in mood, perception, and motivation, but the effect most frequently sought is the “high” and “mellowing out.” This effect is described as different from the high produced by a stimulant or opiate. Effects vary with dose, but typically last ~2 hours. During the high, cognitive functions, perception, reaction time, learning, and memory are impaired. Coordination and tracking behavior may be impaired for several hours beyond the perception of the high, with obvious implications for the operation of a motor vehicle and performance in the workplace or at school.

Marijuana also produces complex behavioral changes such as giddiness and increased hunger. There are unsubstantiated claims of increased pleasure from sex and increased insight during a marijuana high. Unpleasant reactions such as panic or hallucinations and even acute psychosis may occur; several surveys indicate that 50-60% of marijuana users have reported at least one anxiety experience. These reactions are seen commonly with higher doses and with oral ingestion rather than smoked marijuana, because smoking permits the titration of dose according to the effects. While there is no convincing evidence that marijuana can produce a lasting schizophrenia-like syndrome, association studies suggest a correlation of early marijuana use with an increased risk of later developing schizophrenia. Numerous clinical reports suggest that marijuana use may precipitate a recurrence of psychosis in people with a history of schizophrenia.

One of the most controversial of the reputed effects of marijuana is the production of an “amotivational syndrome.” This syndrome is not an official diagnosis, but it has been used to describe young people who drop out of social activities and show little interest in school, work, or other goal-directed activity. When heavy marijuana use accompanies these symptoms, the drug often is cited as the cause, even though there are no data that demonstrate a causal relationship between marijuana smoking and these behavioral characteristics. There is no evidence that marijuana damages brain cells or produces any permanent functional changes, although there are animal data indicating impairment of maze learning that persists for weeks after the last dose. These findings are consistent with clinical reports of gradual improvement in mental state after cessation of chronic high-dose marijuana use.

Marijuana has medicinal effects, including antiemetic properties that relieve side effects of anticancer chemotherapy. It also has muscle-relaxing effects, anti-convulsant properties, and the capacity to reduce the elevated intraocular pressure of glaucoma. These medical benefits come at the cost of the psychoactive effects that often impair normal activities. Thus, there is no clear advantage of marijuana over conventional treatments for any of these indications (Joy et al., 1999). An oral capsule containing Δ -9-THC (dronabinol; MARINOL, others) is approved for anorexia associated

with weight loss in patients with HIV infection and for cancer chemotherapy-induced nausea and vomiting. With the cloning of cannabinoid receptors, the discovery of endogenous ligands, and the synthesis of specific agonists and antagonists, it is likely that new orally effective medications will be developed without the undesirable properties of smoked marijuana and without the deleterious effects of inhaling smoke particles and the chemical products of high-temperature combustion.

Tolerance, Dependence, and Withdrawal. Tolerance to most of the effects of marijuana can develop rapidly after only a few doses, but also disappears rapidly (Martin et al., 2004). Tolerance to large doses persists in experimental animals for long periods after cessation of drug use. Withdrawal symptoms and signs typically are not seen in clinical populations. In fact, few patients ever seek treatment for marijuana addiction. Human subjects develop a withdrawal syndrome when they receive regular oral doses of the agent (Table 24–9). This syndrome, however, is only seen clinically in persons who use marijuana on a daily basis and then suddenly stop.

Pharmacological Interventions. Marijuana abuse and addiction have no specific treatments. Heavy users may suffer from accompanying depression and thus may respond to antidepressant medication, but this should be decided on an individual basis considering the severity of the affective symptoms after the marijuana effects have dissipated. The residual drug effects may continue for several weeks. The CB₁ receptor antagonist rimonabant has been reported to block the acute effects of smoked marijuana, but development of this drug has been halted due to safety concerns (discussed under “Pharmacological Interventions” in the nicotine section earlier in the chapter).

Psychedelic Agents

Perceptual distortions that include hallucinations, illusions, and disorders of thinking such as paranoia can be produced by toxic doses of many drugs. These phenomena also may follow withdrawal from toxic sedatives such as alcohol. There are, however, certain drugs that have as their primary effect the production of disturbances of perception, thought, or mood at low doses with minimal effects on memory and orientation. These are commonly called *hallucinogenic drugs*, but their

Table 24–9

Marijuana Withdrawal Syndrome

Restlessness
Irritability
Mild agitation
Insomnia
Sleep EEG disturbance
Nausea, cramping

use does not always result in frank hallucinations. In the late 1990s, the use of “club drugs” at all-night dance parties became popular. Such drugs include methylenedioxymethamphetamine (MDMA, “ecstasy”), lysergic acid diethylamide (LSD), phencyclidine (PCP), and ketamine (KETALAR). They often are used in association with illegal sedatives such as flunitrazepam (ROHYPNOL) or γ -hydroxybutyrate (GHB). The latter drug has the reputation of being particularly effective in preventing memory storage, and has been implicated in “date rapes.”

While psychedelic effects can be produced by a variety of different drugs, there are two main categories of psychedelic compounds, indoleamines and phenethylamines. The indoleamine hallucinogens include LSD, N,N-dimethyltryptamine (DMT), and psilocybin. The phenethylamines include mescaline, dimethoxymethylamphetamine (DOM), methylenedioxyamphetamine (MDA), and MDMA. Both groups have a relatively high affinity for 5-HT₂ receptors (Chapter 13), but they differ in their affinity for other subtypes of 5-HT receptors. There is a good correlation between the relative affinity of these compounds for 5-HT₂ receptors and their potency as hallucinogens in humans (Titeler et al., 1988). The 5-HT₂ receptor is further implicated in the mechanism of hallucinations by the observation that antagonists of that receptor, such as ritanserin, are effective in blocking the behavioral and electrophysiological effects of hallucinogenic drugs in animal models. However, LSD interacts with many receptor subtypes at nanomolar concentrations, and it is not possible to attribute the psychedelic effects to any single 5-HT receptor subtype (Peroutka, 1994).

LSD. LSD is the most potent hallucinogenic drug and produces significant psychedelic effects with a total dose of as little as 25-50 μ g. This drug is > 3000 times more potent than mescaline. LSD is sold on the illicit market in a variety of forms. A popular contemporary system involves postage stamp-sized papers impregnated with varying doses of LSD (50-300 μ g or more). While most street samples sold as LSD actually contain LSD, samples of mushrooms and other botanicals sold as sources of psilocybin and other psychedelics have a low probability of containing the advertised hallucinogen.

The effects of hallucinogenic drugs are variable, even in the same individual on different occasions. LSD is absorbed rapidly after oral administration, with effects beginning at 40-60 minutes, peaking at 2-4 hours, and gradually returning to baseline over 6-8 hours. At a dose of 100 μ g, LSD produces perceptual distortions and sometimes hallucinations; mood changes, including elation, paranoia, or depression; intense arousal; and sometimes a feeling of panic. Signs of LSD ingestion include pupillary dilation, increased blood pressure and pulse, flushing, salivation, lacrimation, and hyperreflexia. Visual effects are prominent. Colors seem more intense, and shapes may appear altered. The subject may focus attention on unusual items such as the pattern of hairs on the back of the hand.

A “bad trip” usually consists of severe anxiety, although at times it is marked by intense depression and suicidal thoughts. Visual disturbances usually are prominent. The bad trip from LSD may be difficult to distinguish from reactions to anticholinergic drugs and phencyclidine. There are no documented toxic fatalities from LSD use, but fatal accidents and suicides have occurred during or shortly after intoxication. Prolonged psychotic reactions lasting 2 days or more may occur after the ingestion of a hallucinogen. Schizophrenic episodes may be precipitated in susceptible individuals, and there is some evidence that chronic use of these drugs is associated with the development of persistent psychotic disorders (McLellan et al., 1979).

Claims about the potential of psychedelic drugs for enhancing psychotherapy and for treating addictions and other mental disorders have not been supported by controlled treatment outcome studies. Consequently, there is no current indication for these drugs as medications.

Tolerance, Physical Dependence, and Withdrawal. Frequent, repeated use of psychedelic drugs is unusual, and thus tolerance is not commonly seen. Tolerance does develop to the behavioral effects of LSD after three or four daily doses, but no withdrawal syndrome has been observed. Cross-tolerance among LSD, mescaline, and psilocybin has been demonstrated in animal models.

Pharmacological Intervention. Because of the unpredictability of psychedelic drug effects, any use carries some risk. Dependence and addiction do not occur, but users may require medical attention because of “bad trips.” Severe agitation may respond to diazepam (20 mg orally). “Talking down” by reassurance also is effective and is the management of first choice. Antipsychotic medications (Chapter 16) may intensify the experience and thus are not indicated.

A particularly troubling after-effect of the use of LSD and similar drugs is the occasional occurrence of episodic visual disturbances. These originally were called “flashbacks” and resembled the experiences of prior LSD trips. Flashbacks belong to an official diagnostic category called the *hallucinogen persisting perception disorder* (HPPD; American Psychiatric Association, 1994). The symptoms include false fleeting perceptions in the peripheral fields, flashes of color, geometric pseudohallucinations, and positive afterimages (Abraham and Aldridge, 1993). The visual disorder appears stable in half the cases and represents an apparently permanent alteration of the visual system. Precipitants include stress, fatigue, emergence into a dark environment, marijuana, antipsychotic agents, and anxiety states.

MDMA (“Ecstasy”) and MDA. MDMA and MDA are phenylethylamines that have stimulant as well as psychedelic effects. MDMA became popular during the 1980s on college campuses because of testimonials that it enhances insight and self-knowledge. It was recommended by some psychotherapists as an aid to the process of therapy, although no controlled data exist to support this contention. Acute effects are dose-dependent and include feelings of energy, altered sense of time, and pleasant sensory experiences with enhanced perception. Negative effects include tachycardia, dry mouth, jaw clenching, and muscle aches. At higher doses, visual hallucinations, agitation, hyperthermia, and panic attacks have been reported. A typical oral dose is one or two 100-mg tablets and lasts 3-6 hours, although dosage and potency of street samples are variable (~100 mg per tablet).

MDA and MDMA produce degeneration of serotonergic nerve cells and axons in rats. While nerve degeneration has not been

demonstrated in humans, the cerebrospinal fluid of chronic MDMA users has low levels of serotonin metabolites (Ricaurte et al., 2000). Thus, there is possible neurotoxicity with no evidence that the claimed benefits of MDMA actually occur.

Phencyclidine (PCP). PCP deserves special mention because of its widespread availability and because its pharmacological effects are different from those of the psychedelics such as LSD. PCP was developed originally as an anesthetic in the 1950s and later was abandoned because of a high frequency of postoperative delirium with hallucinations. It was classified as a dissociative anesthetic because, in the anesthetized state, the patient remains conscious with staring gaze, flat facies, and rigid muscles. PCP became a drug of abuse in the 1970s, first in an oral form and then in a smoked version enabling a better regulation of the dose. The effects of PCP have been observed in normal volunteers under controlled conditions. As little as 50 µg/kg produces emotional withdrawal, concrete thinking, and bizarre responses to projective testing. Catatonic posturing also is produced and resembles that of schizophrenia. Abusers taking higher doses may appear to be reacting to hallucinations and may exhibit hostile or assaultive behavior. Anesthetic effects increase with dosage; stupor or coma may occur with muscular rigidity, rhabdomyolysis, and hyperthermia. Intoxicated patients in the emergency room may progress from aggressive behavior to coma, with elevated blood pressure and enlarged nonreactive pupils.

PCP binds with high affinity to sites located in the cortex and limbic structures, resulting in blocking of *N*-methyl-D-aspartate (NMDA)-type glutamate receptors (Chapter 14). LSD and other psychedelics do not bind to NMDA receptors. There is evidence that NMDA receptors are involved in ischemic neuronal death caused by high levels of excitatory amino acids; as a result, there is interest in PCP analogs that block NMDA receptors but with fewer psychoactive effects. Both PCP and ketamine (“Special K”), another “club drug,” produce similar effects by altering the distribution of the neurotransmitter glutamate.

Tolerance, Dependence, and Withdrawal. PCP is reinforcing in monkeys, as evidenced by self-administration patterns that produce continuous intoxication. Humans tend to use PCP intermittently, but a small fraction may use it daily. Tolerance to the behavioral effects of PCP develops in animals, but this has not been studied systematically in humans. Signs of a PCP withdrawal syndrome have been observed in monkeys after interruption of daily access to the drug, and include somnolence, tremor, seizures, diarrhea, piloerection, bruxism, and vocalizations.

Pharmacological Intervention. Overdose must be treated by life support because there is no antagonist of PCP effects and no proven way to enhance excretion, although acidification of the urine has been proposed. PCP coma may last 7-10 days. The agitated or psychotic state produced by PCP can be treated with diazepam. Prolonged psychotic behavior requires antipsychotic medication. Because of the anticholinergic activity of PCP, antipsychotic agents with significant anticholinergic effects such as chlorpromazine should be avoided.

Inhalants

Abused inhalants consist of many different categories of chemicals that are volatile at room temperature and produce abrupt changes in mental state when inhaled.

Examples include toluene (from model airplane glue), kerosene, gasoline, carbon tetrachloride, amyl nitrite, and nitrous oxide. There are characteristic patterns of response for each substance. Solvents such as toluene typically are used by children. The material usually is placed in a plastic bag and the vapors inhaled. After several minutes of inhalation, dizziness and intoxication occur. Aerosol sprays containing fluorocarbon propellants are another source of solvent intoxication. Prolonged exposure or daily use may result in damage to several organ systems. Clinical problems include cardiac arrhythmias, bone marrow depression, cerebral degeneration, and damage to liver, kidney, and peripheral nerves. Death occasionally has been attributed to inhalant abuse, probably from cardiac arrhythmias, especially accompanying exercise or upper airway obstruction.

Amyl nitrite produces dilation of smooth muscle, has been used in the past for the treatment of angina, and continues to be available by prescription as a component of cyanide antidote kits and for certain diagnostic procedures. It is a yellow, volatile, flammable liquid with a fruity odor. In recent years, amyl nitrite and butyl nitrite have been used to relax smooth muscle and enhance orgasm, particularly by male homosexuals. These agents are commercially available as room deodorizers and can produce a feeling of “rush,” flushing, and dizziness. Adverse effects include palpitations, postural hypotension, and headache progressing to loss of consciousness.

Anesthetic gases such as nitrous oxide and halothane sometimes are used as intoxicants by medical personnel. Nitrous oxide also is abused by food-service employees because it is supplied for use as a propellant in disposable aluminum mini tanks for whipping cream canisters. Nitrous oxide produces euphoria and analgesia and then loss of consciousness. Compulsive use and chronic toxicity are reported rarely, but there are obvious risks of overdose (coma) and chronic use (neuropathy) associated with the abuse of this anesthetic.

CLINICAL SUMMARY

The management of drug abuse and addiction must be individualized according to the drugs involved and the associated psychosocial problems of the individual patient. An understanding of the pharmacology of the drug or combination of drugs ingested by the patient is essential to rational and effective treatment. This may be a matter of urgency for the treatment of overdose or for the detoxification of a patient who is experiencing withdrawal symptoms. It must be recognized, however, that the treatment of the underlying addictive disorder requires months or years of rehabilitation. The behavior patterns encoded in memory during thousands of prior drug ingestions do not disappear with detoxification from the drug, even after a typical 28-day inpatient rehabilitation program. Long periods of outpatient

treatment are necessary. There probably will be periods of relapse and remission. While complete abstinence is the preferred goal, in reality, most patients are at risk to resume drug-seeking behavior and require one or more periods of retreatment. Maintenance medication can be effective in some circumstances, such as methadone, buprenorphine, or naltrexone for opioid dependence, and disulfiram, naltrexone, or acamprosate for alcoholism. The process can best be compared to the treatment of other chronic disorders such as diabetes, asthma, or hypertension. Long-term medication may be necessary, and cures are not likely. When viewed in the context of chronic disease, the available treatments for addiction are quite successful in that the majority of patients improve, but improvement does not necessarily persist after treatment has ceased (McLellan et al., 2000; O'Brien, 1994).

Long-term treatment is accompanied by improvements in physical status as well as in mental, social, and occupational function. Unfortunately, there is general pessimism in the medical community about the benefits of treatment such that most of the therapeutic effort is directed at the complications of addiction, such as pulmonary, cardiac, and hepatic disorders. Prevention of these complications can be accomplished by addressing the underlying addictive disorder.

Regulation of Renal Function and Vascular Volume

Robert F. Reilly and Edwin K. Jackson

What engineer, wishing to regulate the composition of the internal environment of the body on which the function of every bone, gland, muscle, and nerve depends, would devise a scheme that operated by throwing the whole thing out 16 times a day and rely on grabbing from it, as it fell to earth, only those precious elements which he wanted to keep?

Homer Smith, *From Fish to Philosopher*

As the philosophizing physiologist, Homer Smith, noted, the kidney filters the extra cellular fluid volume across the renal glomeruli an average of 16 times a day, and the renal nephrons precisely regulate the fluid volume of the body and its electrolyte content via processes of secretion and reabsorption. Disease states such as hypertension, heart failure, renal failure, nephrotic syndrome, and cirrhosis may disrupt this balance. Diuretics increase the rate of urine flow and Na^+ excretion and are used to adjust the volume and/or composition of body fluids in these disorders. Precise regulation of body fluid osmolality is also essential. It is controlled by a finely tuned homeostatic mechanism that operates by adjusting both the rate of water intake and the rate of solute-free water excretion by the kidneys—that is, water balance. Abnormalities in this homeostatic system can result from genetic diseases, acquired diseases, or drugs and may cause serious and potentially life-threatening deviations in plasma osmolality.

This chapter first describes renal anatomy and physiology, then introduces diuretics with regard to chemistry, mechanism of action, site of action, effects on urinary composition, and effects on renal hemodynamics, and finally, integrates diuretic pharmacology with a discussion of mechanisms of edema formation and the role of diuretics in clinical medicine. Specific therapeutic applications of diuretics are presented in Chapters 27 (hypertension) and 28 (heart failure).

The second half of this chapter describes the physiological mechanisms that regulate plasma osmolality

and factors that perturb those mechanisms, and examines pharmacological approaches for treating disorders of water balance.

RENAL ANATOMY AND PHYSIOLOGY

The basic urine-forming unit of the kidney is the nephron, which consists of a filtering apparatus, the glomerulus, connected to a long tubular portion that reabsorbs and conditions the glomerular ultrafiltrate. Each human kidney is composed of ~1 million nephrons. The nomenclature for segments of the tubular portion of the nephron has become increasingly complex as renal physiologists have subdivided the nephron into shorter and shorter named segments. These subdivisions were based initially on the axial location of the segments but increasingly have been based on the morphology of the epithelial cells lining the various nephron segments. Figure 25–1 illustrates subdivisions of the nephron.

Glomerular Filtration. In the glomerular capillaries, a portion of plasma water is forced through a filter that has three basic components: the fenestrated capillary endothelial cells, a basement membrane lying just beneath the endothelial cells, and the filtration slit diaphragms formed by epithelial cells that cover the basement membrane on its urinary space side. Solutes of small size flow with filtered water (solvent drag) into the urinary (Bowman's) space, whereas formed elements and macromolecules are retained by the filtration barrier. For each nephron unit, the rate of filtration (single-nephron glomerular filtration rate [SNGFR]) is a function of the hydrostatic pressure in the glomerular capillaries (P_{GC}), the hydrostatic pressure in Bowman's space (which can be equated with pressure in the proximal tubule, P_T), the mean colloid osmotic pressure in the glomerular capillaries (Π_{GC}), the colloid osmotic pressure in the proximal tubule (Π_T), and the ultra-filtration coefficient (K_f), according to the equation

$$\text{SNGFR} = K_f[(p_{GC} - p_T) - (\Pi_{GC} - \Pi_T)] \quad (25-1)$$

If $P_{GC} - P_T$ is defined as the transcapillary hydraulic pressure difference (ΔP), and if Π_T is negligible (as it usually is because little protein is filtered), then

$$\text{SNGFR} = K_f(\Delta P - \Pi_{GC}) \quad (25-2)$$

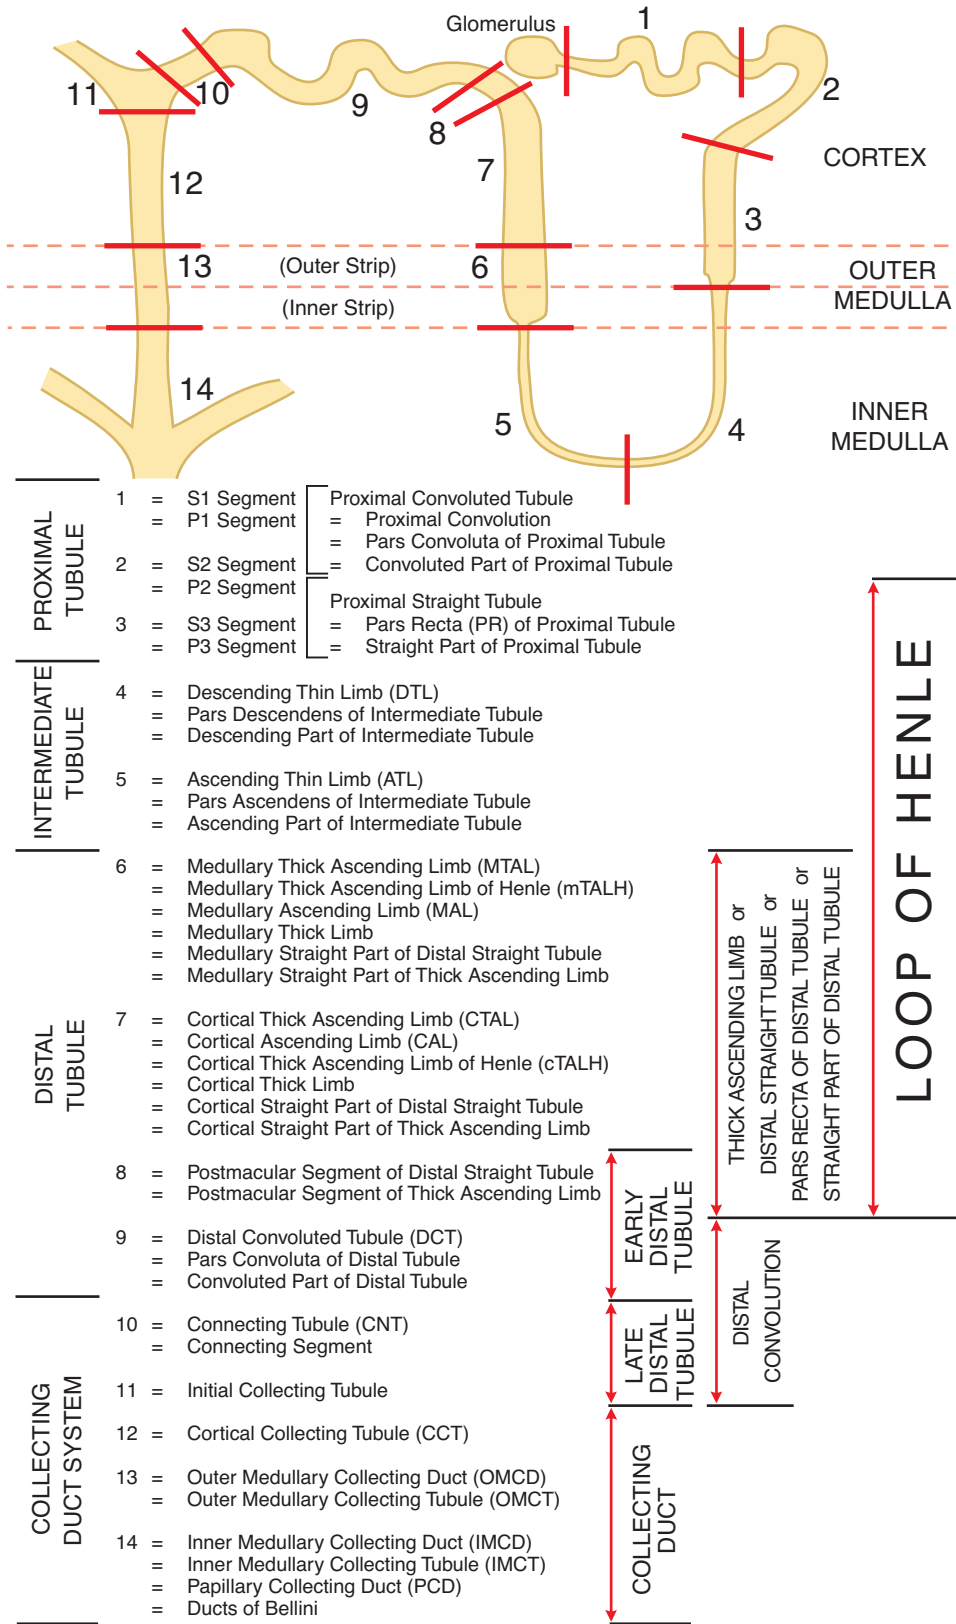

Figure 25–1. Anatomy and nomenclature of the nephron.

This latter equation succinctly expresses the three major determinants of SNGFR. However, each of these three determinants can be influenced by a number of other variables. K_f is determined by the physicochemical properties of the filtering membrane and by the surface area available for filtration. ΔP is determined primarily by the arterial blood pressure and by the proportion of the arterial pressure that is transmitted to the glomerular capillaries. This is governed by the relative resistances of preglomerular and postglomerular vessels. Π_{GC} is determined by two variables, the concentration of protein in the arterial blood entering the glomerulus and the single-nephron blood flow (Q_A). Q_A influences Π_{GC} because as blood transverses the glomerular capillary bed, filtration concentrates proteins in the capillaries, causing Π_{GC} to rise with distance along the glomerular bed. When Q_A is high, this effect is reduced; however, when Q_A is low, Π_{GC} may increase to the point that $\Pi_{GC} = \Delta P$, and filtration ceases (a condition known as *filtration equilibrium*).

Overview of Nephron Function. The kidney is designed to filter large quantities of plasma, reabsorb substances that the body must conserve, and leave behind and/or secrete substances that must be eliminated. The two kidneys in humans produce together ~120 mL of ultrafiltrate per minute, yet only 1 mL/min of urine is produced. Therefore, >99% of the glomerular ultrafiltrate is reabsorbed at a staggering energy cost. The kidneys consume 7% of total-body oxygen intake despite the fact that the kidneys make up only 0.5% of body weight.

The proximal tubule is contiguous with Bowman's capsule and takes a tortuous path until finally forming a straight portion that dives into the renal medulla. Based on the morphology of the epithelial cells lining the tubule, the proximal tubule has been subdivided into S1, S2, and S3 segments. Normally, ~65% of filtered Na^+ is reabsorbed in the proximal tubule, and since this part of the tubule is highly permeable to water, reabsorption is essentially isotonic.

Between the outer and inner strips of the outer medulla, the tubule abruptly changes morphology to become the descending thin limb (DTL), which penetrates the inner medulla, makes a hairpin turn, and then forms the ascending thin limb (ATL). At the juncture between the inner and outer medulla, the tubule once again changes morphology and becomes the thick ascending limb, which is made up of three segments: a medullary portion (MTAL), a cortical portion (CTAL), and a postmacular segment. Together the proximal straight tubule, DTL, ATL, MTAL, CTAL, and postmacular segment are known as the *loop of Henle*. The DTL is highly permeable to water, yet its permeability to NaCl and urea is low. In contrast, the ATL is permeable to NaCl and urea but is impermeable to water. The thick ascending limb actively reabsorbs NaCl but is impermeable to water and urea. Approximately 25% of filtered Na^+ is reabsorbed in the loop of Henle, mostly in the thick ascending limb, which has a large reabsorptive capacity.

The thick ascending limb passes between the afferent and efferent arterioles and makes contact with the afferent arteriole by means of a cluster of specialized columnar epithelial cells known as the *macula densa*. The macula densa is strategically located to sense concentrations of NaCl leaving the loop of Henle. If the concentration of NaCl is too high, the macula densa sends a chemical signal

(perhaps adenosine or ATP) to the afferent arteriole of the same nephron, causing it to constrict. This, in turn, causes a reduction in P_{GC} and Q_A and decreases SNGFR. This homeostatic mechanism, known as *tubuloglomerular feedback* (TGF), serves to protect the organism from salt and volume wasting. Besides mediating the TGF response, the macula densa also regulates renin release from the adjacent juxtaglomerular cells in the wall of the afferent arteriole.

Approximately 0.2 mm past the macula densa, the tubule changes morphology once again to become the distal convoluted tubule (DCT). The postmacular segment of the thick ascending limb and the distal convoluted tubule often are referred to as the *early distal tubule*. Like the thick ascending limb, the DCT actively transports NaCl and is impermeable to water. Since these characteristics impart the ability to produce a dilute urine, the thick ascending limb and the DCT are collectively called the *diluting segment of the nephron*, and the tubular fluid in the DCT is hypotonic regardless of hydration status. However, unlike the thick ascending limb, the DCT does not contribute to the countercurrent-induced hypertonicity of the medullary interstitium (described later in this section). There are marked species differences in transporter expression in the DCT. The DCT has been subdivided into DCT1 and DCT2. DCT1 expresses the thiazide-sensitive NaCl co-transporter but does not express genes involved in transepithelial Ca^{2+} transport such as the Ca^{2+} entry channel, TRPV5, and the $\text{Na}^+/\text{Ca}^{2+}$ exchanger. DCT2 expresses Ca^{2+} transport proteins and amiloride-sensitive epithelial Na^+ channels.

The collecting duct system (connecting tubule + initial collecting tubule + cortical collecting duct + outer and inner medullary collecting ducts—segments 10–14 in Figure 25–1) is an area of fine control of ultrafiltrate composition and volume. It is here that final adjustments in electrolyte composition are made, a process modulated by the adrenal steroid aldosterone. In addition, antidiuretic hormone modulates permeability of this part of the nephron to water.

The more distal portions of the collecting duct pass through the renal medulla, where the interstitial fluid is markedly hypertonic. In the absence of ADH, the collecting duct system is impermeable to water, and a dilute urine is excreted. In the presence of ADH, the collecting duct system is permeable to water, so water is reabsorbed. The movement of water out of the tubule is driven by the steep concentration gradient that exists between tubular fluid and medullary interstitium.

The hypertonicity of the medullary interstitium plays a vital role in the ability of mammals and birds to concentrate urine, and therefore is a key adaptation necessary for living in a terrestrial environment. This is accomplished by a combination of the unique topography of the loop of Henle and the specialized permeability features of the loop's subsegments. Although the precise mechanisms giving rise to the medullary hypertonicity have remained elusive, the "passive countercurrent multiplier hypothesis" is an intuitively attractive model that is qualitatively accurate. According to this hypothesis, the process begins with active transport in the thick ascending limb, which concentrates NaCl in the interstitium of the outer medulla. Since this segment of the nephron is impermeable to water, active transport in the ascending limb dilutes the tubular fluid. As the dilute fluid passes into the collecting-duct system, water is extracted if, and only if, ADH is present. Since the cortical and outer medullary collecting ducts have a low permeability to urea, urea is concentrated in the tubular fluid. The inner medullary collecting duct, however, is permeable to urea, so urea diffuses into the

Figure 25–2. Seven basic mechanisms for transmembrane transport of solutes. 1. Convective flow in which dissolved solutes are “dragged” by bulk water flow. 2. Simple diffusion of lipophilic solute across the membrane. 3. Diffusion of solute through a pore. 4. Transport of solute by carrier protein down electrochemical gradient. 5. Transport of solute by carrier protein against an electrochemical gradient with ATP hydrolysis providing driving force. 6,7. Co-transport and countertransport, respectively, of solutes, with one solute traveling uphill against an electrochemical gradient and the other solute traveling down an electrochemical gradient.

inner medulla, where it is trapped by countercurrent exchange in the vasa recta. Since the DTL is impermeable to salt and urea, the high urea concentration in the inner medulla extracts water from the DTL and concentrates NaCl in the tubular fluid of the DTL. As the tubular fluid enters the ATL, NaCl diffuses out of the salt-permeable ATL, thus contributing to the hypertonicity of the medullary interstitium.

General Mechanism of Renal Epithelial Transport. Figure 25–2 illustrates seven mechanisms by which solutes may cross renal epithelial cell membranes (see also Figure 5–4). If bulk water flow occurs across a membrane, solute molecules will be transferred by convection across the membrane, a process known as *solvent drag*. Solutes with sufficient lipid solubility also may dissolve in the membrane and diffuse across the membrane down their electrochemical gradients (simple diffusion). Many solutes, however, have limited lipid solubility, and transport must rely on integral proteins embedded in the cell membrane. In some cases the integral protein merely provides a conductive pathway (pore) through which the solute may diffuse passively (*channel-mediated diffusion*). In other cases the solute may bind to the integral protein and, owing to a conformational change in the protein, be transferred across the cell membrane down an electrochemical gradient (*carrier-mediated* or *facilitated diffusion*, also called *uniport*). However, this process will not result in net movement of solute against an electrochemical gradient. If solute must be moved “uphill” against an electrochemical gradient, then either primary active transport or secondary active transport is required. With primary active transport, ATP hydrolysis is coupled directly to conformational changes in the integral protein, thus providing the necessary free energy (*ATP-mediated transport*). Often, ATP-mediated transport is used to create an electrochemical gradient for a given solute, and the free energy of that solute gradient is then released to drive the “uphill” transport of other solutes. This process requires *symport* (co-transport of solute species in the same direction) or *antiport* (countertransport of solute species in opposite directions) and is known as *secondary active transport*.

The kinds of transport achieved in a particular nephron segment depend mainly on which transporters are present and whether they are embedded in the luminal or basolateral membrane. A general model of renal tubular transport is shown in Figure 25–3 and can be summarized as follows:

1. Na^+ , K^+ -ATPase (sodium pump) in the basolateral membrane hydrolyzes ATP, which results in the transport of Na^+ into the intercellular and interstitial spaces, the movement of K^+ into the cell, and the establishment and maintenance of an electrochemical gradient for Na^+ across the cell membrane directed inward. Although other ATPases exist in selected renal epithelial cells and participate in the transport of specific solutes (e.g., Ca^{2+} -ATPase and H^+ -ATPase), the bulk of all transport in the kidney is due to the abundant supply of Na^+ , K^+ -ATPase in the basolateral membranes of renal epithelial cells and the separation of Na^+ and K^+ across the cell membrane.
2. Na^+ may diffuse across the luminal membrane by means of Na^+ channels into the epithelial cell down the electrochemical gradient for Na^+ that is established by the basolateral Na^+ , K^+ -ATPase. In addition, free energy available in the electrochemical gradient for Na^+ is tapped by integral proteins in the luminal membrane, resulting in co-transport of various solutes against their electrochemical gradients by symporters (e.g., Na^+ -glucose, Na^+ - H_2PO_4^- , and Na^+ -amino acid). This process results in movement of Na^+ and co-transported solutes out of the tubular lumen into the cell. Also, antiporters (e.g., Na^+ - H^+) move Na^+ out of and some solutes into the tubular lumen.
3. Na^+ exits the basolateral membrane into the intercellular and interstitial spaces by means of the Na^+ pump or symporters or antiporters in the basolateral membrane.
4. The action of Na^+ -linked symporters in the luminal membrane causes the concentration of substrates for these symporters to rise in the epithelial cell. These electrochemical gradients then permit simple diffusion or mediated transport (e.g., symporters,

Figure 25–3. Generic mechanism of renal epithelial cell transport (see text for details). S, symporter; A, antiporter; CH, ion channel; WP, water pore; U, uniporter; ATPase, Na^+ , K^+ -ATPase (sodium pump); X and Y, transported solutes; P, membrane-permeable (reabsorbable) solutes; I, membrane-impermeable (nonreabsorbable) solutes; PD, potential difference across indicated membrane or cell.

antiporters, uniporters, and channels) of solutes into the intercellular and interstitial spaces.

- Accumulation of Na^+ and other solutes in the intercellular space creates a small osmotic pressure differential across the epithelial cell. In water-permeable epithelium, water moves into the intercellular spaces driven by the osmotic pressure differential. Water moves through aqueous pores in both the luminal and the basolateral cell membranes, as well as through tight junctions (paracellular pathway). Bulk water flow carries some solutes into the intercellular space by solvent drag.
- Movement of water into the intercellular space concentrates other solutes in the tubular fluid, resulting in an electrochemical gradient for these substances across the epithelium. Membrane-permeable solutes then move down their electrochemical gradients into the intercellular space by both the transcellular (e.g., simple diffusion, symporters, antiporters, uniporters, and channels) and paracellular pathways. Membrane-impermeable solutes remain in the tubular lumen and are excreted in the urine with an obligatory amount of water.

7. As water and solutes accumulate in the intercellular space, hydrostatic pressure increases, thus providing a driving force for bulk water flow. Bulk water flow carries solute (solute convection) out of the intercellular space into the interstitial space and, finally, into the peritubular capillaries. The movement of fluid into peritubular capillaries is governed by the same Starling forces that determine transcapillary fluid movement for any capillary bed.

Mechanism of Organic Acid and Organic Base Secretion. The kidney is a major organ involved in the elimination of organic chemicals from the body. Organic molecules may enter the renal tubules by glomerular filtration of molecules not bound to plasma proteins or may be actively secreted directly into tubules. The proximal tubule has a highly efficient transport system for organic acids and an equally efficient but separate transport system for organic bases. Current models for these secretory systems are illustrated in Figure 25–4. Both systems are powered by the sodium pump in the basolateral membrane, involve secondary and tertiary active transport, and use a facilitated-diffusion step. There are at least nine different organic acid and five different organic base transporters; the precise roles that these transporters play in organic acid and base transport remain ill defined (Dresser et al., 2001). A family of organic anion transporters (OATs) countertransport organic anions with dicarboxylates (Figure 25–4A). OATs most likely exist as α -helical dodecaspanns connected by short segments of ~ 10 or fewer amino acids, except for large interconnecting stretches of amino acids between helices 1 and 2 and helices 6 and 7 (Eraly et al., 2004); see Chapter 5.

Renal Handling of Specific Anions and Cations. Reabsorption of Cl^- generally follows reabsorption of Na^+ . In segments of the tubule with low-resistance tight junctions (i.e., “leaky” epithelium), such as the proximal tubule and thick ascending limb, Cl^- movement can occur paracellularly. With regard to transcellular Cl^- flux, Cl^- crosses the luminal membrane by antiport with formate and oxalate (proximal tubule), symport with Na^+/K^+ (thick ascending limb), symport with Na^+ (DCT), and antiport with HCO_3^- (collecting-duct system). Cl^- crosses the basolateral membrane by symport with K^+ (proximal tubule and thick ascending limb), antiport with $\text{Na}^+/\text{HCO}_3^-$ (proximal tubule), and Cl^- channels (thick ascending limb, DCT, collecting-duct system).

Eighty to ninety percent of filtered K^+ is reabsorbed in the proximal tubule (diffusion and solvent drag) and thick ascending limb (diffusion) largely through the paracellular pathway. In contrast, the DCT and collecting-duct system secrete variable amounts of K^+ by a conductive (channel-mediated) pathway. Modulation of the rate of K^+ secretion in the collecting-duct system, particularly by aldosterone, allows urinary K^+ excretion to be matched with dietary intake. The transepithelial potential difference (V_T), lumen-positive in the thick ascending limb and lumen-negative in the collecting-duct system, provides an important driving force for K^+ reabsorption and secretion, respectively.

Most of the filtered Ca^{2+} ($\sim 70\%$) is reabsorbed by the proximal tubule by passive diffusion through a paracellular route. Another 25% of filtered Ca^{2+} is reabsorbed by the thick ascending limb in part by a paracellular route driven by the lumen-positive V_T and in part by active transcellular Ca^{2+} reabsorption modulated by parathyroid hormone (PTH; see Chapter 44). Most of the remaining Ca^{2+} is

Figure 25–4. Mechanisms of organic acid (A) and organic base (B) secretion in the proximal tubule. The numbers 1, 2, and 3 refer to primary, secondary, and tertiary active transport. A^- , organic acid [anion]; C^+ , organic base [cation]; αKG^{2-} , α -ketoglutarate but also other dicarboxylates. BL and LM indicate basolateral and luminal membranes, respectively.

reabsorbed in DCT by a transcellular pathway. The transcellular pathway in the thick ascending limb and DCT involves passive Ca^{2+} influx across the luminal membrane through Ca^{2+} channels (TRPV5), followed by Ca^{2+} extrusion across the basolateral membrane by a Ca^{2+} -ATPase. Also, in DCT and CNT, Ca^{2+} crosses the basolateral membrane by $\text{Na}^+/\text{Ca}^{2+}$ exchanger (antiport).

Inorganic phosphate (P_i) is largely reabsorbed (80% of filtered load) by the proximal tubule. The Na^+/P_i symporter uses the free energy of the Na^+ electrochemical gradient to transport P_i into

the cell. The $\text{Na}^+\text{-P}_i$ symporter is inhibited by PTH. P_i exits the basolateral membrane down its electrochemical gradient by a poorly understood transport system.

Only 20–25% of Mg^{2+} is reabsorbed in the proximal tubule, and only 5% is reabsorbed by the DCT and collecting-duct system. The bulk of Mg^{2+} is reabsorbed in the thick ascending limb by a paracellular pathway driven by the lumen-positive V_T . However, transcellular movement of Mg^{2+} also may occur with basolateral exit by $\text{Na}^+\text{-Mg}^{2+}$ antiport or an $\text{Mg}^{2+}\text{-ATPase}$.

The renal tubules play an extremely important role in the reabsorption of HCO_3^- and secretion of protons (tubular acidification) and thus participate critically in the maintenance of acid-base balance. These processes are described in the section on carbonic anhydrase inhibitors.

PRINCIPLES OF DIURETIC ACTION

By definition, diuretics are drugs that increase the rate of urine flow; however, clinically useful diuretics also increase the rate of Na^+ excretion (natriuresis) and of an accompanying anion, usually Cl^- . NaCl in the body is the major determinant of extracellular fluid volume, and most clinical applications of diuretics are directed toward reducing extracellular fluid volume by decreasing total-body NaCl content. A sustained imbalance between dietary Na^+ intake and Na^+ loss is incompatible with life. A net positive Na^+ balance would result in volume overload with pulmonary edema, and a net negative Na^+ balance would result in volume depletion and cardiovascular collapse. Although continued diuretic administration causes a sustained net deficit in total-body Na^+ , the time course of natriuresis is finite because renal compensatory mechanisms bring Na^+ excretion in line with Na^+ intake, a phenomenon known as *diuretic braking*. These compensatory, or braking, mechanisms include activation of the sympathetic nervous system, activation of the renin–angiotensin–aldosterone axis, decreased arterial blood pressure (which reduces pressure natriuresis), renal epithelial cell hypertrophy, increased renal epithelial transporter expression, and perhaps alterations in natriuretic hormones such as atrial natriuretic peptide (Ellison, 1999). This is shown in Figure 25–5.

Historically, the classification of diuretics was based on a mosaic of ideas such as site of action (loop diuretics), efficacy (high-ceiling diuretics), chemical structure (thiazide diuretics), similarity of action with other diuretics (thiazide-like diuretics), and effects on K^+ excretion (K^+ -sparing diuretics). However, since the mechanism of action of each of the major classes of diuretics is now well understood, a classification scheme based on mechanism of action is used in this chapter.

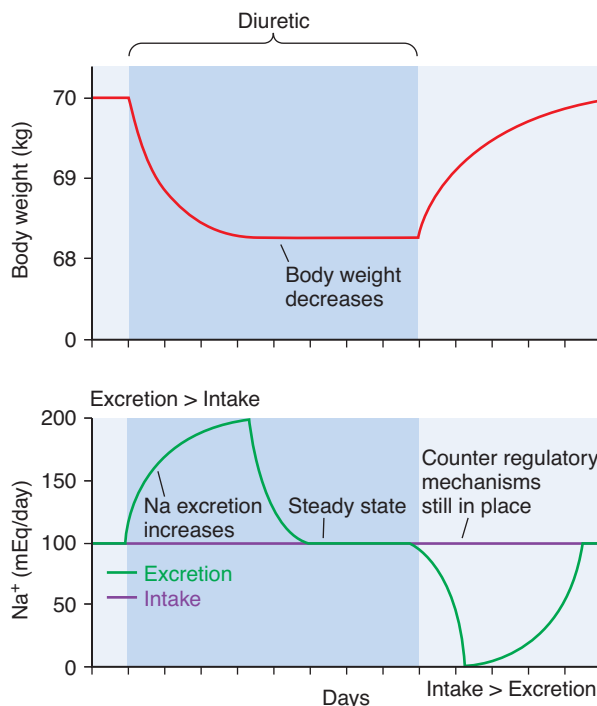

Figure 25–5. Changes in extracellular fluid volume and weight with diuretic therapy. The period of diuretic administration is shown in the shaded box along with its effects on body weight in the upper part of the figure and Na^+ excretion in the lower half of the figure. Initially, when Na^+ excretion exceeds intake, body weight and extracellular fluid volume (ECFV) decrease. Subsequently, a new steady state is achieved where Na^+ intake and excretion are equal but at a lower ECFV and body weight. This results from activation of the renin–angiotensin–aldosterone system (RAAS) and sympathetic nervous system (SNS), “the braking phenomenon.” When the diuretic is discontinued, body weight and ECFV rise during a period where Na^+ intake exceeds excretion. A new steady state is then reached as stimulation of the RAAS and SNS wane.

Diuretics not only alter the excretion of Na^+ but also may modify renal handling of other cations (e.g., K^+ , H^+ , Ca^{2+} , and Mg^{2+}), anions (e.g., Cl^- , HCO_3^- , and H_2PO_4^-), and uric acid. In addition, diuretics may alter renal hemodynamics indirectly. Table 25–1 gives a comparison of the general effects of the major diuretic classes.

INHIBITORS OF CARBONIC ANHYDRASE

Acetazolamide (DIAMOX, others) is the prototype of a class of agents that have limited usefulness as diuretics but have played a major role in the development of fundamental concepts of renal physiology and pharmacology.

Table 25–1

Excretory and Renal Hemodynamic Effects of Diuretics^a

Diuretic Mechanism (Primary site of action)	CATIONS					ANIONS			URIC ACID		RENAL HEMODYNAMICS			
	Na ⁺	K ⁺	H ⁺ ^b	Ca ²⁺	Mg ²⁺	Cl ⁻	HCO ₃ ⁻	H ₂ PO ₄ ⁻	Acute	Chronic	RBF	GFR	FF	TGF

^aExcept for uric acid, changes are for acute effects of diuretics in the absence of significant volume depletion, which would trigger complex physiological adjustments. ^bH⁺, titratable acid and NH₄⁺. ^cIn general, these effects are restricted to those individual agents that inhibit carbonic anhydrase. However, there are notable exceptions in which symport inhibitors increase bicarbonate and phosphate (e.g., metolazone, bumetanide). ++, +, (+), -, NC, V, V(+), V(-) and I indicate marked increase, mild to moderate increase, slight increase, decrease, no change, variable effect, variable increase, variable decrease, and insufficient data, respectively. For cations and anions, the indicated effects refer to absolute changes in fractional excretion.

RBF, renal blood flow; GFR, glomerular filtration rate; FF, filtration fraction; TGF, tubuloglomerular feedback; CA, carbonic anhydrase.

Chemistry. When sulfanilamide was introduced as a chemotherapeutic agent, metabolic acidosis was recognized as a side effect. This observation led to the demonstration that sulfanilamide is an inhibitor of carbonic anhydrase. Subsequently, an enormous number of sulfonamides were synthesized and tested for their ability to inhibit carbonic anhydrase; of these compounds, acetazolamide has been studied most extensively. There are three orally administered carbonic anhydrase inhibitors—acetazolamide, dichlorphenamide (not marketed in the U.S.), and methazolamide. The common molecular motif of available carbonic anhydrase inhibitors is an unsubstituted sulfonamide moiety (Table 25–2).

Mechanism and Site of Action. Proximal tubular epithelial cells are richly endowed with the zinc metalloenzyme carbonic anhydrase, which is found in the luminal and basolateral membranes (type IV carbonic

anhydrase, an enzyme tethered to the membrane by a glycosylphosphatidylinositol linkage), as well as in the cytoplasm (type II carbonic anhydrase). Carbonic anhydrase plays a key role in NaHCO₃ reabsorption and acid secretion.

In the proximal tubule, the free energy in the Na⁺ gradient established by the basolateral Na⁺ pump is used by an Na⁺-H⁺ antiporter (also referred to as an Na⁺-H⁺ exchanger [NHE]) in the luminal membrane to transport H⁺ into the tubular lumen in exchange for Na⁺ (Figure 25–6). In the lumen, H⁺ reacts with filtered HCO₃⁻ to form H₂CO₃, which decomposes rapidly to CO₂ and water in the presence of carbonic anhydrase in the brush border. Normally, the reaction occurs slowly, but carbonic anhydrase reversibly accelerates this reaction several thousand times. CO₂ is lipophilic and rapidly diffuses across the luminal membrane into the

Table 25–2

Inhibitors of Carbonic Anhydrase

Abbreviations: R, renal excretion of intact drug; M, metabolism; ID, insufficient data.

epithelial cell, where it reacts with water to form H_2CO_3 , a reaction catalyzed by cytoplasmic carbonic anhydrase (Figure 25–6). Continued operation of the $\text{Na}^+\text{-H}^+$ antiporter maintains a low proton concentration in the cell, so H_2CO_3 ionizes spontaneously to

form H^+ and HCO_3^- , creating an electrochemical gradient for HCO_3^- across the basolateral membrane. The electrochemical gradient for HCO_3^- is used by an $\text{Na}^+\text{-HCO}_3^-$ symporter (also referred to as the $\text{Na}^+\text{-HCO}_3^-$ co-transporter [NBC]) in the basolateral membrane to transport NaHCO_3 into the interstitial space. The net effect of this process is transport of NaHCO_3 from the tubular lumen to the interstitial space, followed by movement of water (isotonic reabsorption). Removal of water concentrates Cl^- in the tubular lumen, and consequently, Cl^- diffuses down its concentration gradient into the interstitium by the paracellular pathway.

Carbonic anhydrase inhibitors potently inhibit (IC_{50} for acetazolamide is 10 nM) both the membrane-bound and cytoplasmic forms of carbonic anhydrase, resulting in nearly complete abolition of NaHCO_3 reabsorption in the proximal tubule. Studies with a high-molecular-weight carbonic anhydrase inhibitor that inhibits only luminal enzyme because of limited cellular permeability indicate that inhibition of both membrane-bound and cytoplasmic pools of carbonic anhydrase contributes to the diuretic activity of carbonic anhydrase inhibitors. Because of the large excess of carbonic anhydrase in proximal tubules, a high percentage of enzyme activity must be inhibited before an effect on electrolyte excretion is observed. Although the proximal tubule is the major site of action of carbonic anhydrase inhibitors, carbonic anhydrase also is involved in secretion of titratable acid in the collecting duct system (a process that involves a proton pump); therefore, the collecting duct system is a secondary site of action for this class of drugs.

Figure 25–6. NaHCO_3 reabsorption in proximal tubule and mechanism of diuretic action of carbonic anhydrase inhibitors. The actual reaction catalyzed by carbonic anhydrase is $\text{OH}^- + \text{CO}_2 \rightarrow \text{HCO}_3^-$; however, $\text{H}_2\text{O} \rightarrow \text{OH}^- + \text{H}^+$, and $\text{HCO}_3^- + \text{H}^+ \rightarrow \text{H}_2\text{CO}_3$, so the net reaction is $\text{H}_2\text{O} + \text{CO}_2 \rightarrow \text{H}_2\text{CO}_3$. Numbers in parentheses indicate stoichiometry. A, antiporter; S, symporter; CH, ion channel; BL, basolateral membrane; LM, luminal membrane.

Effects on Urinary Excretion. Inhibition of carbonic anhydrase is associated with a rapid rise in urinary HCO_3^- excretion to ~35% of filtered load. This, along with inhibition of titratable acid and NH_4^+ secretion in the collecting-duct system, results in an increase in urinary pH to ~8 and development of a metabolic acidosis.

However, even with a high degree of inhibition of carbonic anhydrase, 65% of HCO_3^- is rescued from excretion by poorly understood mechanisms that may involve carbonic anhydrase-independent HCO_3^- reabsorption at downstream sites. Inhibition of the transport mechanism described in the preceding section results in increased delivery of Na^+ and Cl^- to the loop of Henle, which has a large reabsorptive capacity and captures most of the Cl^- and a portion of the Na^+ . Thus only a small increase in Cl^- excretion occurs, HCO_3^- being the major anion excreted along with the cations Na^+ and K^+ . The fractional excretion of Na^+ may be as much as 5%, and the fractional excretion of K^+ can be as much as 70%. The increased excretion of K^+ is in part secondary to increased delivery of Na^+ to the distal nephron. The mechanism by which increased distal Na^+ delivery enhances K^+ excretion is described in the section on inhibitors of Na^+ channels.

Other mechanisms contributing to enhanced K^+ excretion include flow-dependent enhancement of K^+ secretion by the collecting duct, nonosmotic vasopressin release, and activation of the renin-angiotensin-aldosterone axis. Carbonic anhydrase inhibitors increase phosphate excretion (mechanism unknown) but have little or no effect on Ca^{2+} or Mg^{2+} excretion. The effects of carbonic anhydrase inhibitors on renal excretion are self-limiting, probably because the resulting metabolic acidosis decreases the filtered load of HCO_3^- to the point that the uncatalyzed reaction between CO_2 and water is sufficient to achieve HCO_3^- reabsorption. Studies in rabbits show that the K_i for luminal carbonic anhydrase inhibition in outer medulla is increased >100-fold over the concentration required in control tubules. These results suggest that acidosis induces a conformational change in the protein making it less sensitive to inhibition by acetazolamide (Tsuroka, 1998).

Effects on Renal Hemodynamics. By inhibiting proximal reabsorption, carbonic anhydrase inhibitors increase delivery of solutes to the macula densa. This triggers TGF, which increases afferent arteriolar resistance and reduces renal blood flow (RBF) and glomerular filtration rate (GFR).

Other Actions. Carbonic anhydrase is present in a number of extrarenal tissues, including the eye, gastric mucosa, pancreas, central nervous system (CNS), and erythrocytes. Carbonic anhydrase in the ciliary processes of the eye mediates formation of large amounts of HCO_3^- in aqueous humor. Inhibition of carbonic anhydrase decreases the rate of formation of aqueous humor and consequently reduces intraocular pressure. Acetazolamide frequently causes paresthesias and somnolence, suggesting an action of carbonic anhydrase inhibitors in the CNS. The efficacy of acetazolamide in epilepsy is due in part to the production of metabolic acidosis; however, direct actions of acetazolamide in the CNS also contribute to its anticonvulsant action. Owing to interference with carbonic anhydrase activity in erythrocytes, carbonic anhydrase inhibitors increase CO_2 levels in

peripheral tissues and decrease CO_2 levels in expired gas. Large doses of carbonic anhydrase inhibitors reduce gastric acid secretion, but this has no therapeutic application. Acetazolamide causes vasodilation by opening vascular Ca^{2+} -activated K^+ channels; however, the clinical significance of this effect is unclear.

Absorption and Elimination. Carbonic anhydrase inhibitors are avidly bound by carbonic anhydrase, and accordingly, tissues rich in this enzyme will have higher concentrations of carbonic anhydrase inhibitors following systemic administration. See Table 25–2 for structures and pharmacokinetic data.

Toxicity, Adverse Effects, Contraindications, Drug Interactions. Serious toxic reactions to carbonic anhydrase inhibitors are infrequent; however, these drugs are sulfonamide derivatives and, like other sulfonamides, may cause bone marrow depression, skin toxicity, sulfonamide-like renal lesions, and allergic reactions in patients hypersensitive to sulfonamides. With large doses, many patients exhibit drowsiness and paresthesias. Most adverse effects, contraindications, and drug interactions are secondary to urinary alkalization or metabolic acidosis, including:

- diversion of ammonia of renal origin from urine into the systemic circulation, a process that may induce or worsen hepatic encephalopathy (the drugs are contraindicated in patients with hepatic cirrhosis)
- calculus formation and ureteral colic owing to precipitation of calcium phosphate salts in an alkaline urine
- worsening of metabolic or respiratory acidosis (the drugs are contraindicated in patients with hyperchloremic acidosis or severe chronic obstructive pulmonary disease)
- reduction of the urinary excretion rate of weak organic bases

Therapeutic Uses. Although acetazolamide is used for treatment of edema, the efficacy of carbonic anhydrase inhibitors as single agents is low, and carbonic anhydrase inhibitors are not employed widely in this regard. The combination of acetazolamide with diuretics that block Na^+ reabsorption at more distal sites in the nephron causes a marked natriuretic response in patients with low basal fractional excretion of Na^+ (<0.2%) who are resistant to diuretic monotherapy (Knauf and Mutschler, 1997). Even so, the long-term usefulness of carbonic anhydrase inhibitors often is compromised by the development of metabolic acidosis.

The major indication for carbonic anhydrase inhibitors is open-angle glaucoma. Two products developed specifically for this use are dorzolamide (TRUSOPT, others) and brinzolamide (AZOPT), which are available only as ophthalmic drops. Carbonic anhydrase inhibitors also may be employed for secondary glaucoma and preoperatively in acute angle-closure glaucoma to lower intraocular pressure before surgery (Chapter 64). Acetazolamide also is used for the treatment of epilepsy (Chapter 21). The rapid development of tolerance, however, may limit the usefulness of carbonic anhydrase inhibitors for epilepsy.

Acetazolamide can provide symptomatic relief in patients with *high-altitude illness* or *mountain sickness*; however, it is more appropriate to give acetazolamide as a prophylactic measure. Acetazolamide also is useful in patients with familial periodic paralysis. The mechanism for the beneficial effects of acetazolamide in altitude sickness and familial periodic paralysis is not clear, but it may be related to the induction of a metabolic acidosis. Other off-label clinical uses include the treatment of dural ectasia in individuals with Marfan syndrome, of sleep apnea, and of idiopathic intracranial hypertension. Finally, carbonic anhydrase inhibitors can be useful for correcting a metabolic alkalosis, especially one caused by diuretic-induced increases in H⁺ excretion.

OSMOTIC DIURETICS

Osmotic diuretics are agents that are freely filtered at the glomerulus, undergo limited reabsorption by the renal tubule, and are relatively inert pharmacologically. Osmotic diuretics are administered in doses large enough to increase significantly the osmolality of plasma and tubular fluid. Table 25–3 lists four osmotic diuretics—glycerin (OSMOGLYN), isosorbide, mannitol (OSMITROL, others), and urea (currently not available in the U.S.).

Mechanism and Site of Action. For many years it was thought that osmotic diuretics act primarily in the proximal tubule as nonreabsorbable solutes that limit the osmosis of water into the interstitial space and thereby

reduce luminal Na⁺ concentration to the point that net Na⁺ reabsorption ceases. Although early micropuncture studies supported this concept, subsequent studies suggested that this mechanism, while operative, may be of only secondary importance and that the major site of action of osmotic diuretics is the loop of Henle.

By extracting water from intracellular compartments, osmotic diuretics expand extracellular fluid volume, decrease blood viscosity, and inhibit renin release. These effects increase RBF, and the increase in renal medullary blood flow removes NaCl and urea from the renal medulla, thus reducing medullary tonicity. Under some circumstances, prostaglandins may contribute to the renal vasodilation and medullary washout induced by osmotic diuretics. A reduction in medullary tonicity causes a decrease in the extraction of water from the DTL, which in turn limits the concentration of NaCl in the tubular fluid entering the ATL. This latter effect diminishes the passive reabsorption of NaCl in the ATL. In addition, the marked ability of osmotic diuretics to inhibit Mg²⁺ reabsorption, a cation that is reabsorbed mainly in the thick ascending limb, suggests that osmotic diuretics also interfere with transport processes in the thick ascending limb. The mechanism of this effect is unknown.

In summary, osmotic diuretics act both in proximal tubule and loop of Henle, with the latter being the primary site of action. Also, osmotic diuretics probably act by an osmotic effect in the tubules and by reducing medullary tonicity.

Table 25–3

Osmotic Diuretics

DRUG	STRUCTURE	ORAL AVAILABILITY	t _{1/2} (HOURS)	ROUTE OF ELIMINATION

Mannitol (OSMITROL)		Negligible	0.25-1.7 ^a	~80% R ~20% M + B
Urea (UREAPHIL)		Negligible	ID	R

^aIn renal failure, 6–36. *Abbreviations:* R, renal excretion of intact drug; M, metabolism; B, excretion of intact drug into bile; U, unknown pathway of elimination; ID, insufficient data.

682 Effects on Urinary Excretion. Osmotic diuretics increase urinary excretion of nearly all electrolytes, including Na^+ , K^+ , Ca^{2+} , Mg^{2+} , Cl^- , HCO_3^- , and phosphate.

Effects on Renal Hemodynamics. Osmotic diuretics increase RBF by a variety of mechanisms. Osmotic diuretics dilate the afferent arteriole, which increases P_{GC} , and dilute the plasma, which decreases Π_{GC} . These effects would increase GFR were it not for the fact that osmotic diuretics also increase P_{T} . In general, superficial SNGFR is increased, but total GFR is little changed.

Absorption and Elimination. Pharmacokinetic data on the osmotic diuretics are listed in Table 25–3. Glycerin and isosorbide can be given orally, whereas mannitol and urea must be administered intravenously.

Toxicity, Adverse Effects, Contraindications, and Drug Interactions. Osmotic diuretics are distributed in the extracellular fluid and contribute to the extracellular osmolality. Thus, water is extracted from intracellular compartments, and the extracellular fluid volume becomes expanded. In patients with heart failure or pulmonary congestion, this may cause frank pulmonary edema. Extraction of water also causes hyponatremia, which may explain the common adverse effects, including headache, nausea, and vomiting. On the other hand, loss of water in excess of electrolytes can cause hypernatremia and dehydration. Osmotic diuretics are contraindicated in patients who are anuric owing to severe renal disease. Urea may cause thrombosis or pain if extravasation occurs, and it should not be administered to patients with impaired liver function because of the risk of elevation of blood ammonia levels. Both mannitol and urea are contraindicated in patients with active cranial bleeding. Glycerin is metabolized and can cause hyperglycemia.

Therapeutic Uses. One use for mannitol is in the treatment of dialysis disequilibrium syndrome. Too rapid a removal of solutes from the extracellular fluid by hemodialysis results in a reduction in the osmolality of extracellular fluid. Consequently, water moves from the extracellular compartment into the intracellular compartment, causing hypotension and CNS symptoms (headache, nausea, muscle cramps, restlessness, CNS depression, and convulsions). Osmotic diuretics increase the osmolality of the extracellular fluid compartment and thereby shift water back into the extracellular compartment.

By increasing the osmotic pressure of plasma, osmotic diuretics extract water from the eye and brain. All osmotic diuretics are used to control intraocular pressure during acute attacks of glaucoma and for short-term reductions in intraocular pressure both preoperatively and postoperatively in patients who require ocular surgery. Also, mannitol and urea are used to reduce cerebral edema and brain mass before and after neurosurgery.

INHIBITORS OF $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ SYMPORT (LOOP DIURETICS, HIGH-CEILING DIURETICS)

Drugs in this group of diuretics inhibit activity of the $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symporter in the thick ascending limb of the loop of Henle; hence these diuretics also are referred to as *loop diuretics*. Although the proximal tubule reabsorbs ~65% of filtered Na^+ , diuretics acting only in the proximal tubule have limited efficacy because the thick ascending limb has a great reabsorptive capacity and reabsorbs most of the rejectate from the proximal tubule. Diuretics acting predominantly at sites past the thick ascending limb also have limited efficacy because only a small percentage of the filtered Na^+ load reaches these more distal sites. In contrast, inhibitors of $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symport in thick ascending limb are highly efficacious, and for this reason, they sometimes are called *high-ceiling diuretics*. The efficacy of inhibitors of $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symport in the thick ascending limb of the loop of Henle is due to a combination of two factors: (1) approximately 25% of the filtered Na^+ load normally is reabsorbed by the thick ascending limb, and (2) nephron segments past the thick ascending limb do not possess the reabsorptive capacity to rescue the flood of rejectate exiting the thick ascending limb.

Chemistry. Inhibitors of $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symport are a chemically diverse group (Table 25–4). Only furosemide (LASIX, others), bumetanide (BUMEX, others), ethacrynic acid (EDECRIN, others), and torsemide (DEMADEX, others) are available currently in the U.S. Furosemide and bumetanide contain a sulfonamide moiety. Ethacrynic acid is a phenoxyacetic acid derivative and torsemide is a sulfonyleurea.

Mechanism and Site of Action. Inhibitors of $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symport act primarily in the thick ascending limb. Micropuncture of the DCT demonstrates that loop diuretics increase delivery of solutes out of the loop of Henle. Also, *in situ* microperfusion of the loop of Henle and *in vitro* microperfusion of CTAL indicate inhibition of transport by low concentrations of furosemide in the perfusate. Some inhibitors of $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symport may have additional effects in the proximal tubule; however, the significance of these effects is unclear.

It was thought initially that Cl^- was transported by a primary active electrogenic transporter in the luminal membrane independent of Na^+ . Discovery of furosemide-sensitive $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symport in other tissues prompted a more careful investigation of the Na^+ dependence of Cl^- transport in isolated perfused rabbit CTAL. Scrupulous removal of Na^+ from the luminal perfusate demonstrated the dependence of Cl^- transport on Na^+ .

It is now well accepted that flux of Na^+ , K^+ , and Cl^- from the lumen into epithelial cells in thick ascending limb is mediated by an

Na⁺-K⁺-2Cl⁻ symporter (Figure 25-7). This symporter captures free energy in the Na⁺ electrochemical gradient established by the basolateral Na⁺ pump and provides for “uphill” transport of K⁺ and Cl⁻ into the cell. K⁺ channels in the luminal membrane (called ROMK) provide a conductive pathway for the apical recycling of this cation, and basolateral Cl⁻ channels (called CLC-Kb) provide a basolateral

exit mechanism for Cl⁻. Luminal membranes of epithelial cells in thick ascending limb have a large conductive pathway (channels) for K⁺; therefore, apical membrane voltage is determined by the equilibrium potential for K⁺ (E_K) and is hyperpolarized. In contrast, the basolateral membrane has a large conductive pathway (channels) for Cl⁻, so the basolateral membrane voltage is less negative than E_K ;

Figure 25–7. *NaCl* reabsorption in thick ascending limb and mechanism of diuretic action of Na^+ - K^+ - 2Cl^- symport inhibitors. Numbers in parentheses indicate stoichiometry. Designated voltages are the potential differences across the indicated membrane or cell. The mechanisms illustrated here apply to the medullary, cortical, and postmacular segments of the thick ascending limb. S, symporter; CH, ion channel; BL, basolateral membrane; LM, luminal membrane.

that is, conductance for Cl^- depolarizes the basolateral membrane. Hyperpolarization of the luminal membrane and depolarization of the basolateral membrane result in a transepithelial potential difference of ~ 10 mV, with the lumen positive with respect to the interstitial space. This lumen-positive potential difference repels cations (Na^+ , Ca^{2+} , and Mg^{2+}) and thereby provides an important driving force for the paracellular flux of these cations into the interstitial space.

Inhibitors of Na^+ - K^+ - 2Cl^- symport bind to the Na^+ - K^+ - 2Cl^- symporter in the thick ascending limb and block its function, bringing salt transport in this segment of the nephron to a virtual standstill. The molecular mechanism by which this class of drugs blocks the Na^+ - K^+ - 2Cl^- symporter is unknown, but evidence suggests that these drugs attach to the Cl^- binding site located in the symporter's transmembrane domain (Iseuring and Forbush, 1997). Inhibitors of Na^+ - K^+ - 2Cl^- symport also inhibit Ca^{2+} and Mg^{2+} reabsorption in the thick ascending limb by abolishing the transepithelial potential difference that is the dominant driving force for reabsorption of these cations.

Na^+ - K^+ - 2Cl^- symporters are an important family of transport molecules found in many secretory and absorbing epithelia. The rectal gland of the dogfish shark is a particularly rich source of the protein, and a cDNA encoding an Na^+ - K^+ - 2Cl^- symporter was isolated from a cDNA library obtained from the dogfish shark rectal gland by screening with antibodies to the shark symporter (Xu et al., 1994). Molecular cloning revealed a deduced amino acid sequence of 1191 residues containing 12 putative membrane-spanning domains

flanked by long N and C termini in the cytoplasm. Expression of this protein resulted in Na^+ - K^+ - 2Cl^- symport that was sensitive to bumetanide. The shark rectal gland Na^+ - K^+ - 2Cl^- symporter cDNA was used subsequently to screen a human colonic cDNA library, and this provided Na^+ - K^+ - 2Cl^- symporter cDNA probes from this tissue. These latter probes were used to screen rabbit renal cortical and renal medullary libraries, which allowed cloning of the rabbit renal Na^+ - K^+ - 2Cl^- symporter (Payne and Forbush, 1994). This symporter is 1099 amino acids in length, is 61% identical to the dogfish shark secretory Na^+ - K^+ - 2Cl^- symporter, has 12 predicted transmembrane helices, and contains large N- and C-terminal cytoplasmic regions. Subsequent studies demonstrated that Na^+ - K^+ - 2Cl^- symporters are of two varieties (Kaplan et al., 1996). The “absorptive” symporter (called *ENCC2*, *NKCC2*, or *BSC1*) is expressed only in the kidney, is localized to the apical membrane and subapical intracellular vesicles of the thick ascending limb, and is regulated by cyclic AMP/PKA (Obermüller et al., 1996; Plata et al., 1999). At least six different isoforms of the absorptive symporter are generated by alternative mRNA splicing (Mount et al., 1999), and alternative splicing of the absorptive symporter determines the dependency of transport on K^+ (Plata et al., 2001). The “secretory” symporter (called *ENCC3*, *NKCC1*, or *BSC2*) is a “housekeeping” protein that is expressed widely and, in epithelial cells, is localized to the basolateral membrane. The affinity of loop diuretics for the secretory symporter is somewhat less than for the absorptive symporter (e.g., 4-fold difference for bumetanide). A model of Na^+ - K^+ - 2Cl^- symport has been proposed based on ordered binding of ions to the symporter (Lytle et al., 1998). Mutations in genes coding for the absorptive Na^+ - K^+ - 2Cl^- symporter, the apical K^+ channel, the basolateral Cl^- channel, or the chloride channel subunit Barttin are causes of Bartter syndrome (inherited hypokalemic alkalosis with salt wasting and hypotension) (Simon and Lifton, 1998).

Effects on Urinary Excretion. Owing to blockade of the Na^+ - K^+ - 2Cl^- symporter, loop diuretics increase urinary Na^+ and Cl^- excretion profoundly (i.e., up to 25% of the filtered Na^+ load). Abolition of the transepithelial potential difference also results in marked increases in Ca^{2+} and Mg^{2+} excretion. Given in excessive amounts, loop diuretics can lead to dehydration and electrolyte depletion. Some (e.g., furosemide) but not all (e.g., bumetanide) sulfonamide-based loop diuretics have weak carbonic anhydrase-inhibiting activity. Drugs with carbonic anhydrase-inhibiting activity increase urinary excretion of HCO_3^- and phosphate. The mechanism by which inhibition of carbonic anhydrase increases phosphate excretion is not known. All inhibitors of Na^+ - K^+ - 2Cl^- symport increase urinary K^+ and titratable acid excretion. This effect is due in part to increased Na^+ delivery to the distal tubule. The mechanism by which increased distal Na^+ delivery enhances K^+ and H^+ excretion is discussed in the section on Na^+ channel inhibitors. Other mechanisms contributing to enhanced K^+ and H^+ excretion include flow-dependent enhancement of ion secretion by the collecting duct,

nonosmotic vasopressin release, and activation of the renin–angiotensin–aldosterone axis.

Acutely, loop diuretics increase uric acid excretion, whereas chronic administration of these drugs results in reduced uric acid excretion. Chronic effects of loop diuretics on uric acid excretion may be due to enhanced proximal tubule transport or secondary to volume depletion, leading to increased uric acid reabsorption, or to competition between diuretic and uric acid for the organic acid secretory mechanism in proximal tubule, leading to reduced uric acid secretion. Asymptomatic hyperuricemia is a common consequence of loop diuretics, but painful episodes of gout are rarely reported.

By blocking active NaCl reabsorption in the thick ascending limb, inhibitors of $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symport interfere with a critical step in the mechanism that produces a hypertonic medullary interstitium. Therefore, loop diuretics block the kidney's ability to concentrate urine during hyponemia. Also, since the thick ascending limb is part of the diluting segment, inhibitors of $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symport markedly impair the kidney's ability to excrete a dilute urine during water diuresis.

Effects on Renal Hemodynamics. If volume depletion is prevented by replacing fluid losses, inhibitors of $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symport generally increase total RBF and redistribute RBF to the midcortex. However, the effects on RBF are variable. The mechanism of the increase in RBF is not known but may involve prostaglandins. Nonsteroidal anti-inflammatory drugs (NSAIDs) attenuate the diuretic response to loop diuretics in part by preventing prostaglandin-mediated increases in RBF. Loop diuretics block TGF by inhibiting salt transport into the macula densa so that the macula densa no longer can detect NaCl concentrations in the tubular fluid. Therefore, unlike carbonic anhydrase inhibitors, loop diuretics do not decrease GFR by activating TGF. Loop diuretics are powerful stimulators of renin release. This effect is due to interference with NaCl transport by the macula densa and, if volume depletion occurs, to reflex activation of the sympathetic nervous system and stimulation of the intrarenal baroreceptor mechanism. Prostaglandins, particularly prostacyclin, may play an important role in mediating the renin-release response to loop diuretics.

Other Actions. Loop diuretics may cause direct vascular effects. Loop diuretics, particularly furosemide, acutely increase systemic venous capacitance and thereby decrease left ventricular filling pressure. This effect, which may be mediated by prostaglandins and requires intact kidneys, benefits patients with pulmonary edema even before diuresis ensues. Furosemide and ethacrynic acid can inhibit $\text{Na}^+\text{-K}^+\text{-ATPase}$, glycolysis, mitochondrial respiration, the microsomal Ca^{2+} pump, adenylyl cyclase, phosphodiesterase, and prostaglandin dehydrogenase; however, these effects do not have therapeutic implications. *In vitro*, high doses of inhibitors of $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symport can inhibit electrolyte transport in many tissues. Only in the inner ear, where alterations in the electrolyte composition of endolymph may contribute to drug-induced ototoxicity, is this effect important clinically. Irreversible ototoxicity is more common at high doses, with rapid IV administration, and during

concomitant therapy with other drugs known to be ototoxic (e.g., aminoglycoside antibiotics, cisplatin, vancomycin).

Absorption and Elimination. The oral bioavailabilities, plasma $t_{1/2}$, and routes of elimination of inhibitors of $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symport are listed in Table 25–4. Because furosemide, bumetanide, ethacrynic acid, and torsemide are bound extensively to plasma proteins, delivery of these drugs to the tubules by filtration is limited. However, they are secreted efficiently by the organic acid transport system in the proximal tubule, and thereby gain access to their binding sites on the $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symport in the luminal membrane of the thick ascending limb. Probenecid shifts the plasma concentration-response curve to furosemide to the right by competitively inhibiting furosemide secretion by the organic acid transport system.

Approximately 65% of furosemide is excreted unchanged in urine, and the remainder is conjugated to glucuronic acid in the kidney. Thus, in patients with renal but not liver disease, the elimination $t_{1/2}$ of furosemide is prolonged. In contrast, bumetanide and torsemide have significant hepatic metabolism, so the elimination $t_{1/2}$ of these loop diuretics are prolonged by liver but not renal disease.

Although average oral availability of furosemide is ~60%, bioavailability varies (10–100%). In contrast, oral availabilities of bumetanide and torsemide are reliably high. Heart failure patients have fewer hospitalizations and better quality of life with torsemide than with furosemide, perhaps because of its more reliable absorption.

As a class, loop diuretics have short elimination $t_{1/2}$, and prolonged-release preparations are not available. Consequently, often the dosing interval is too short to maintain adequate levels of loop diuretics in the tubular lumen. Note that torsemide has a longer $t_{1/2}$ than other agents available in the U.S. (Table 25–4). As the concentration of loop diuretic in the tubular lumen declines, nephrons begin to avidly reabsorb Na^+ , which often nullifies the overall effect of the loop diuretic on total-body Na^+ . This phenomenon of “postdiuretic Na^+ retention” can be overcome by restricting dietary Na^+ intake or by more frequent administration of the loop diuretic (Ellison, 1999). Furosemide, with its short $t_{1/2}$, often produces a poor response when administered only once daily, a common clinical error.

Toxicity, Adverse Effects, Contraindications, Drug Interactions. Adverse effects unrelated to diuretic efficacy are rare, and most adverse effects are due to abnormalities of fluid and electrolyte balance. Overzealous use of loop diuretics can cause serious depletion of total-body Na^+ .

This may manifest as hyponatremia and/or extracellular fluid volume depletion associated with hypotension, reduced GFR, circulatory collapse, thromboembolic episodes, and in patients with liver disease, hepatic encephalopathy. Increased Na^+ delivery to the distal tubule, particularly when combined with activation of the renin–angiotensin system, leads to increased urinary K^+ and H^+ excretion, causing a hypochloremic alkalosis. If dietary K^+ intake is not sufficient, hypokalemia may develop, and this may induce

cardiac arrhythmias, particularly in patients taking cardiac glycosides. Increased Mg^{2+} and Ca^{2+} excretion may result in hypomagnesemia (a risk factor for cardiac arrhythmias) and hypocalcemia (rarely leading to tetany). Recent evidence suggests that loop diuretics should be avoided in postmenopausal osteopenic women, in whom increased Ca^{2+} excretion may have deleterious effects on bone metabolism (Rejnmark et al., 2003).

Loop diuretics can cause ototoxicity that manifests as tinnitus, hearing impairment, deafness, vertigo, and a sense of fullness in the ears. Hearing impairment and deafness are usually, but not always, reversible. Ototoxicity occurs most frequently with rapid intravenous administration and least frequently with oral administration. Ethacrynic acid appears to induce ototoxicity more often than do other loop diuretics and should be reserved for use only in patients who cannot tolerate other loop diuretics. Loop diuretics also can cause hyperuricemia (occasionally leading to gout) and hyperglycemia (infrequently precipitating diabetes mellitus) and can increase plasma levels of low-density lipoprotein (LDL) cholesterol and triglycerides while decreasing plasma levels of high-density lipoprotein (HDL) cholesterol. Other adverse effects include skin rashes, photosensitivity, paresthesias, bone marrow depression, and GI disturbances. Glucose intolerance frequently can be demonstrated but precipitation of diabetes mellitus has been reported only rarely.

Contraindications to the use of loop diuretics include severe Na^+ and volume depletion, hypersensitivity to sulfonamides (for sulfonamide-based loop diuretics), and anuria unresponsive to a trial dose of loop diuretic.

Drug interactions may occur when loop diuretics are co-administered with:

- aminoglycosides, carboplatin, paclitaxel and several other agents (synergism of ototoxicity)
- anticoagulants (increased anticoagulant activity)
- digitalis glycosides (increased digitalis-induced arrhythmias)
- lithium (increased plasma levels of lithium)
- propranolol (increased plasma levels of propranolol)
- sulfonyleureas (hyperglycemia)
- cisplatin (increased risk of diuretic-induced ototoxicity)
- NSAIDs (blunted diuretic response and salicylate toxicity when given with high doses of salicylates)
- probenecid (blunted diuretic response)
- thiazide diuretics (synergism of diuretic activity of both drugs leading to profound diuresis)
- amphotericin B (increased potential for nephrotoxicity and toxicity and intensification of electrolyte imbalance)

Therapeutic Uses. All loop diuretics except torsemide are available as oral and injectable formulations. Bumetanide is labeled for once daily administration and may be used in patients allergic to furosemide (the bumetanide:furosemide conversion ratio is approximately 1:40). A major use of loop diuretics is in the treatment of acute pulmonary edema. A rapid increase in venous capacitance in conjunction with a brisk natriuresis reduces left ventricular filling pressures and thereby rapidly relieves pulmonary edema. Loop diuretics also are used widely for treatment of chronic congestive

heart failure when diminution of extracellular fluid volume is desirable to minimize venous and pulmonary congestion (Chapter 28). In this regard, a meta-analysis of randomized clinical trials demonstrates that diuretics cause a significant reduction in mortality and the risk of worsening heart failure, as well as an improvement in exercise capacity (Faris et al., 2002).

Diuretics are used widely for treatment of hypertension (Chapter 28), and controlled clinical trials demonstrating reduced morbidity and mortality have been conducted with Na^+-Cl^- symport (thiazides and thiazide-like diuretics) but not $Na^+-K^+-2Cl^-$ symport inhibitors. Nonetheless, $Na^+-K^+-2Cl^-$ symport inhibitors appear to lower blood pressure as effectively as Na^+-Cl^- symport inhibitors while causing smaller perturbations in the lipid profile. However, the relative potency and short elimination half-lives of loop diuretics render them less useful for hypertension than thiazide-type diuretics.

The edema of nephrotic syndrome often is refractory to less potent diuretics, and loop diuretics often are the only drugs capable of reducing the massive edema associated with this renal disease. Loop diuretics also are employed in the treatment of edema and ascites of liver cirrhosis; however, care must be taken not to induce volume contraction. In patients with a drug overdose, loop diuretics can be used to induce a forced diuresis to facilitate more rapid renal elimination of the offending drug. Loop diuretics, combined with isotonic saline administration to prevent volume depletion, are used to treat hypercalcemia. Loop diuretics interfere with the kidney's capacity to produce a concentrated urine. Consequently, loop diuretics combined with hypertonic saline are useful for the treatment of life-threatening hyponatremia.

Loop diuretics also are used to treat edema associated with chronic kidney disease. Higher doses of loop diuretics are often required in patients with chronic kidney disease. The dose-response curve is shifted to the right (Figure 25–8). Animal studies have demonstrated that loop diuretics increase P_{GC} by activating the renin-angiotensin system, an effect that could accelerate renal injury (Lane et al., 1998). Most patients with ARF receive a trial dose of a loop diuretic in an attempt to convert oliguric ARF to nonoliguric ARF. However, there is no evidence that loop diuretics prevent ATN or improve outcome in patients with ARF, and as mentioned earlier, the appearance of undesired effects increases with dose.

INHIBITORS OF Na^+-Cl^- SYMPORT (THIAZIDE AND THIAZIDE-LIKE DIURETICS)

Benzothiadiazides were synthesized in an effort to enhance the potency of inhibitors of carbonic anhydrase. However, unlike carbonic anhydrase inhibitors (that primarily increase $NaHCO_3$ excretion), benzothia diazides predominantly increase $NaCl$ excretion, an effect shown to be independent of carbonic anhydrase inhibition.

Figure 25–8. Dose-response curve of furosemide in chronic kidney disease. With chronic kidney disease the dose-response curve of furosemide and other loop diuretics shifts to the right. This may occur as a result of impaired proximal tubular secretion of the diuretic into the tubular lumen. This can occur for at least two reasons: (1) competition for peritubular uptake and luminal secretion by organic anions that accumulate in uremia such as urate and (2) metabolic acidosis.

Chemistry. Inhibitors of $\text{Na}^+\text{-Cl}^-$ symport are sulfonamides (Table 25–5), and many are analogs of 1,2,4-benzothiadiazine-1,1-dioxide. Because the original inhibitors of $\text{Na}^+\text{-Cl}^-$ symport were benzothiadiazine derivatives, this class of diuretics became known as *thiazide diuretics*. Subsequently, drugs that are pharmacologically similar to thiazide diuretics but are not thiazides were developed and are called *thiazide-like diuretics*. The term *thiazide diuretics* is used here to refer to all members of the class of inhibitors of $\text{Na}^+\text{-Cl}^-$ symport.

Mechanism and Site of Action. Some studies using split-droplet and stationary-microperfusion techniques described reductions in proximal tubule reabsorption by thiazide diuretics; however, free-flow micropuncture studies have not consistently demonstrated increased solute delivery out of the proximal tubule following administration of thiazides. In contrast, micropuncture and *in situ* microperfusion studies clearly indicate that thiazide diuretics inhibit NaCl transport in DCT. The DCT expresses thiazide binding sites and is accepted as the primary site of action of thiazide diuretics; the proximal tubule may represent a secondary site of action.

Figure 25–9 illustrates the current model of electrolyte transport in DCT. As with other nephron segments, transport is powered by a Na^+ pump in the basolateral membrane. Free energy in the electrochemical gradient for Na^+ is harnessed by an $\text{Na}^+\text{-Cl}^-$ symporter in the luminal membrane that moves Cl^- into the epithelial cell against its electrochemical gradient. Cl^- then exits the basolateral

membrane passively by a Cl^- channel. Thiazide diuretics inhibit the $\text{Na}^+\text{-Cl}^-$ symporter. In this regard, Na^+ or Cl^- binding to the $\text{Na}^+\text{-Cl}^-$ symporter modifies thiazide-induced inhibition of the symporter, suggesting that the thiazide-binding site is shared or altered by both Na^+ and Cl^- .

Using a functional expression strategy (Cl^- -dependent Na^+ uptake in *Xenopus* oocytes), Gamba and colleagues (1993) isolated a cDNA clone from the urinary bladder of the winter flounder that codes for an $\text{Na}^+\text{-Cl}^-$ symporter. This $\text{Na}^+\text{-Cl}^-$ symporter is inhibited by a number of thiazide diuretics (but not by furosemide, acetazolamide, or an amiloride derivative) and has 12 putative membrane-spanning domains, and its sequence is 47% identical to the cloned dogfish shark rectal gland $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symporter. Subsequently, the rat and human $\text{Na}^+\text{-Cl}^-$ symporters were cloned. The human $\text{Na}^+\text{-Cl}^-$ symporter has a predicted sequence of 1021 amino acids, 12 transmembrane domains, and 2 intracellular hydrophilic amino and carboxyl termini and maps to chromosome 16q13. The $\text{Na}^+\text{-Cl}^-$ symporter (called *ENCC1* or *TSC*) is expressed predominantly in kidney and is localized to the apical membrane of DCT epithelial cells (Bachmann et al., 1995). Expression of the $\text{Na}^+\text{-Cl}^-$ symporter is regulated by aldosterone (Velázquez et al., 1996). Mutations in the $\text{Na}^+\text{-Cl}^-$ symporter cause a form of inherited hypokalemic alkalosis called Gitelman syndrome (Simon and Lifton, 1998).

Effects on Urinary Excretion. As would be expected from their mechanism of action, inhibitors of $\text{Na}^+\text{-Cl}^-$ symport increase Na^+ and Cl^- excretion. However, thiazides are only moderately efficacious (i.e., maximum excretion of filtered Na^+ load is only 5%) because ~90% of the filtered Na^+ load is reabsorbed before reaching the DCT. Some thiazide diuretics also are weak inhibitors of carbonic anhydrase, an effect that increases HCO_3^- and phosphate excretion and probably accounts for their weak proximal tubular effects. Like inhibitors of $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symport, inhibitors of $\text{Na}^+\text{-Cl}^-$ symport increase K^+ and titratable acid excretion by the same mechanisms discussed for loop diuresis. Acute thiazide administration increases uric acid excretion. However, uric acid excretion is reduced following chronic administration by the same mechanisms discussed for loop diuretics. The acute effects of inhibitors of $\text{Na}^+\text{-Cl}^-$ symport on Ca^{2+} excretion are variable; when administered chronically, thiazide diuretics decrease Ca^{2+} excretion. The mechanism involves increased proximal reabsorption owing to volume depletion, as well as direct effects of thiazides to increase Ca^{2+} reabsorption in the DCT. Thiazide diuretics may cause a mild magnesuria by a poorly understood mechanism, and there is increasing awareness that long-term use of thiazide diuretics may cause magnesium deficiency, particularly in the elderly. Since inhibitors of $\text{Na}^+\text{-Cl}^-$ symport inhibit transport in the cortical diluting segment, thiazide diuretics attenuate the kidney's ability to excrete dilute urine during water

Table 25-5

Inhibitors of Na⁺-Cl⁻ Symport (Thiazide and Thiazide-like Diuretics)

DRUG	STRUCTURE	RELATIVE POTENCY	ORAL AVAILABILITY	t _{1/2} (HOURS)	ROUTE OF ELIMINATION
Bendroflumethiazide (NATURETIN)	R ₂ = H, R ₃ = CH ₂ -  , R ₆ = CF ₃	10	~100%	3-3.9	~30% R, ~70% M
Chlorothiazide (DIURIL)	(Unsaturated between C3 and N4)	0.1	9-56% (dose-dependent)	~1.5	R
Hydrochlorothiazide (HYDRODIURIL)		1	~70%	~2.5	R
Hydroflumethiazide (SALURON)		1	~50%	~17	40-80% R, 20-60% M
Methyclothiazide (ENDURON)		10	ID	ID	M
Polythiazide (RENESE)	R ₂ = CH ₃ , R ₃ = CH ₂ SCH ₂ CF ₃ , R ₆ = Cl	25	~100%	~25	~25% R, ~75% U
Trichlormethiazide (NAQUA)		25	ID	2.3-7.3	R
Chlorthalidone (HYGROTON)		1	~65%	~47	~65% R, ~10% B, ~25% U
Indapamide (LOZOL)		20	~93%	~14	M
Metolazone (MYKROX, ZAROXOLYN)		10	~65%	ID	~80% R, ~10% B, ~10% M
Quinethazone (HYDROMOX)		1	ID	ID	ID

Abbreviations: R, renal excretion of intact drug; M, metabolism; B, excretion of intact drug into bile; U, unknown pathway of elimination; ID, insufficient data.

Figure 25–9. NaCl reabsorption in distal convoluted tubule and mechanism of diuretic action of Na⁺-Cl⁻ symport inhibitors. Numbers in parentheses indicate stoichiometry. S, symporter; CH, ion channel; BL, basolateral membrane; LM, luminal membrane.

diuresis. However, since the DCT is not involved in the mechanism that generates a hypertonic medullary interstitium, thiazide diuretics do not alter the kidney's ability to concentrate urine during hydropenia.

Effects on Renal Hemodynamics. In general, inhibitors of Na⁺-Cl⁻ symport do not affect RBF and only variably reduce GFR owing to increases in intratubular pressure. Since thiazides act at a point past the macula densa, they have little or no influence on TGF.

Other Actions. Thiazide diuretics may inhibit cyclic nucleotide phosphodiesterases, mitochondrial O₂ consumption, and renal uptake of fatty acids; however, these effects are not clinically significant.

Absorption and Elimination. Pharmacokinetic parameters of Na⁺-Cl⁻ symport inhibitors are listed in Table 25–5.

Note the wide range of half-lives for this class of drugs. Sulfonamides are organic acids and therefore are secreted into the proximal tubule by the organic acid secretory pathway. Since thiazides must gain access to the tubular lumen to inhibit the Na⁺-Cl⁻ symporter, drugs such as probenecid can attenuate the diuretic response to thiazides by competing for transport into proximal tubule. However, plasma protein binding varies considerably among thiazide diuretics, and this parameter determines the contribution that filtration makes to tubular delivery of a specific thiazide.

Toxicity, Adverse Effects, Contraindications, Drug Interactions. Thiazide diuretics rarely cause CNS (e.g., vertigo, headache, paresthesias, xanthopsia, and weakness), GI (e.g., anorexia, nausea, vomiting, cramping, diarrhea, constipation, cholecystitis, and pancreatitis), hematological (e.g., blood dyscrasias), and dermatological (e.g., photosensitivity and skin rashes) disorders. The incidence of erectile

dysfunction is greater with Na⁺-Cl⁻ symport inhibitors than with several other antihypertensive agents (e.g., β adrenergic receptor antagonists, Ca²⁺-channel blockers, or angiotensin converting enzyme inhibitors) (Grimm et al., 1997), but usually is tolerable. As with loop diuretics, most serious adverse effects of thiazides are related to abnormalities of fluid and electrolyte balance. These adverse effects include extracellular volume depletion, hypotension, hypokalemia, hyponatremia, hypochloremia, metabolic alkalosis, hypomagnesemia, hypercalcemia, and hyperuricemia. Thiazide diuretics have caused fatal or near-fatal hyponatremia, and some patients are at recurrent risk of hyponatremia when rechallenged with thiazides.

Thiazide diuretics also decrease glucose tolerance, and latent diabetes mellitus may be unmasked during therapy. Recent concerns have also been raised in randomized prospective blood-pressure lowering trials regarding an increased incidence of type II diabetes mellitus compared to other antihypertensive agents such as angiotensin-converting enzyme inhibitors and angiotensin receptor blockers. The mechanism of impaired glucose tolerance is not completely understood but appears to involve reduced insulin secretion and alterations in glucose metabolism. Hyperglycemia may be related in some way to K⁺ depletion, in that hyperglycemia is reduced when K⁺ is given along with the diuretic. In addition to contributing to hyperglycemia, thiazide-induced hypokalemia impairs its antihypertensive effect and cardiovascular protection (Franse et al., 2000) afforded by thiazides in patients with hypertension. Thiazide diuretics also may increase plasma levels of LDL cholesterol, total cholesterol, and total triglycerides. Thiazide diuretics are contraindicated in individuals who are hypersensitive to sulfonamides.

With regard to drug interactions, thiazide diuretics may diminish the effects of anticoagulants, uricosuric agents used to treat gout, sulfonyleureas, and insulin and may increase the effects of anesthetics, diazoxide, digitalis glycosides, lithium, loop diuretics, and vitamin D. The effectiveness of thiazide diuretics may be reduced by NSAIDs, nonselective or selective COX-2 inhibitors, and bile acid sequestrants (reduced absorption of thiazides). Amphotericin B and corticosteroids increase the risk of hypokalemia induced by thiazide diuretics.

A potentially lethal drug interaction warranting special emphasis is that involving thiazide diuretics and quinidine. Prolongation of the QT interval by quinidine can lead to the development of polymorphic ventricular tachycardia (torsades de pointes) owing to triggered activity originating from early after-depolarizations (Chapter 29). Torsades de pointes may deteriorate into fatal ventricular fibrillation. Hypokalemia increases the risk of quinidine-induced torsades de pointes, and thiazide diuretics cause hypokalemia. Thiazide diuretic-induced K⁺ depletion may account for many cases of quinidine-induced torsades de pointes. In addition, alkalinization of the urine by thiazides increases the systemic exposure to quinidine by reducing its elimination.

Therapeutic Uses. Thiazide diuretics are used for the treatment of edema associated with heart (congestive heart failure), liver (hepatic cirrhosis), and renal (nephrotic syndrome, chronic renal failure, and acute glomerulonephritis) disease. With the possible exceptions of metolazone and indapamide, most thiazide diuretics are ineffective when the GFR is <30–40 mL/min.

Thiazide diuretics decrease blood pressure in hypertensive patients by increasing the slope of the renal pressure-natriuresis relationship (Figure 26–7), and thiazide diuretics are used widely for the treatment of hypertension either alone or in combination with other antihypertensive drugs (Chapter 28). In this regard, thiazide diuretics are inexpensive, as efficacious as other classes of antihypertensive agents, and well tolerated. Thiazides can be administered once daily, do not require dose titration, and have few contraindications. Moreover, thiazides have additive or synergistic effects when combined with other classes of antihypertensive agents. A common dose for hypertension is 25 mg/day of hydrochlorothiazide or the dose equivalent of another thiazide. The ALLHAT study (ALLHAT Officers and Coordinators for the ALLHAT Collaborative Research Group, 2002) provides strong evidence that thiazide diuretics are the best initial therapy for uncomplicated hypertension, a conclusion endorsed by the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (Chobanian et al., 2003) (Chapter 27). Studies also suggest that the antihypertensive response to thiazides is influenced by polymorphisms in the angiotensin-converting enzyme and α -adducin genes (Sciarrone et al., 2003).

Thiazide diuretics, which reduce urinary Ca^{2+} excretion, sometimes are employed to treat Ca^{2+} nephrolithiasis and may be useful for treatment of osteoporosis (Chapter 44). Thiazide diuretics also are the mainstay for treatment of nephrogenic diabetes insipidus, reducing urine volume by up to 50%. Although it may seem counterintuitive to treat a disorder of increased urine volume with a diuretic, thiazides reduce the kidney's ability to excrete free water. They do so by increasing proximal tubular water reabsorption (secondary to volume contraction) and by blocking the ability of the distal convoluted tubule to form dilute urine. This latter effect results in an increase in urine osmolality. Since other halides are excreted by renal processes similar to those for Cl^- , thiazide diuretics may be useful for the management of Br^- intoxication.

INHIBITORS OF RENAL EPITHELIAL Na^+ CHANNELS (K^+ -SPARING DIURETICS)

Triamterene (DYRENIUM) and amiloride (MIDAMOR, others) are the only two drugs of this class in clinical use. Both drugs cause small increases in NaCl excretion and usually are employed for their antikaliuretic actions to offset the effects of other diuretics that increase K^+ excretion. Consequently, triamterene and amiloride, along with spironolactone (described in the next section), often are classified as *potassium (K^+)-sparing diuretics*.

Chemistry. Amiloride is a pyrazinoylguanidine derivative, and triamterene is a pteridine (Table 25–6). Both drugs are organic bases and are transported by the organic base secretory mechanism in proximal tubule.

Mechanism and Site of Action. Available data suggest that triamterene and amiloride have similar mechanisms of action, which is illustrated in Figure 25–10.

Principal cells in the late distal tubule and collecting duct have, in their luminal membranes, epithelial Na^+ channels that provide a conductive pathway for Na^+ entry into the cell down the electrochemical gradient created by the basolateral Na^+ pump. The higher permeability of the luminal membrane for Na^+ depolarizes the luminal membrane but not the basolateral membrane, creating a lumen-negative transepithelial potential difference. This transepithelial voltage provides an important driving force for the secretion of K^+ into the lumen by K^+ channels (ROMK) in the luminal membrane. Carbonic anhydrase inhibitors, loop diuretics, and thiazide diuretics increase Na^+ delivery to the late distal tubule and collecting duct, a situation that often is associated with increased K^+ and H^+ excretion. It is likely that the elevation in luminal Na^+ concentration in distal nephron induced by such diuretics augments depolarization

Table 25–6

Inhibitors of Renal Epithelial Na^+ Channels (K^+ -Sparing Diuretics)

DRUG	STRUCTURE	RELATIVE POTENCY	ORAL AVAILABILITY	$t_{1/2}$ (HOURS)	ROUTE OF ELIMINATION
Amiloride (DYRENIUM)		1	15–25%	~21	R
Triamterene (MIDAMOR)		0.1	~50%	~4	M

Abbreviations: R, renal excretion of intact drug; M, metabolism; however, triamterene is transformed into an active metabolite that is excreted in the urine.

Figure 25–10. Na^+ reabsorption in late distal tubule and collecting duct and mechanism of diuretic action of epithelial Na^+ -channel inhibitors. Cl^- reabsorption (not shown) occurs both paracellularly and transcellularly, and the precise mechanism of Cl^- transport appears to be species-specific. Numbers in parentheses indicate stoichiometry. Designated voltages are the potential differences across the indicated membrane or cell. A, antiporter; CH, ion channel; CA, carbonic anhydrase; BL, basolateral membrane; LM, luminal membrane.

of the luminal membrane and thereby enhances the lumen-negative V_T , which facilitates K^+ excretion. In addition to principal cells, the collecting duct also contains type A intercalated cells that mediate H^+ secretion into the tubular lumen. Tubular acidification is driven by a luminal H^+ -ATPase (proton pump), and this pump is aided by partial depolarization of the luminal membrane. The luminal H^+ -ATPase is of the vacuolar-type and is distinct from the gastric H^+ - K^+ -ATPase that is inhibited by drugs such as omeprazole. However, increased distal Na^+ delivery is not the only mechanism by which diuretics increase K^+ and H^+ excretion. Activation of the renin-angiotensin-aldosterone axis by diuretics also contributes to diuretic-induced K^+ and H^+ excretion, as discussed later in the section on mineralocorticoid antagonists.

Considerable evidence indicates that amiloride blocks epithelial Na^+ channels in the luminal membrane of principal cells in late distal tubule and collecting duct. The amiloride-sensitive Na^+ channel (called *ENaC*) consists of three subunits (α , β , and γ) (Kleyman et al., 1999). Although the α subunit is sufficient for channel activity, maximal Na^+ permeability is induced when all three subunits are coexpressed in the same cell, probably forming a tetrameric structure consisting of two α subunits, one β subunit, and one γ subunit.

Studies in *Xenopus* oocytes expressing *ENaC* suggest that triamterene and amiloride bind *ENaC* by similar mechanisms. The K_i of amiloride for *ENaC* is submicromolar, and molecular studies identified critical domains in *ENaC* that participate in amiloride binding (Kleyman et al., 1999). Liddle syndrome is an autosomal dominant form of low-renin, volume-expanded hypertension that is due to mutations in the β or γ subunits, leading to increased basal *ENaC* activity.

Effects on Urinary Excretion. Since the late distal tubule and collecting duct have a limited capacity to reabsorb solutes, Na^+ channel blockade in this part of the nephron only mildly increases Na^+ and Cl^- excretion rates (~2% of filtered load). Blockade of Na^+ channels hyperpolarizes the luminal membrane, reducing the lumen-negative transepithelial voltage. Since the lumen-negative potential difference normally opposes cation reabsorption and facilitates cation secretion, attenuation of the lumen-negative voltage decreases K^+ , H^+ , Ca^{2+} , and Mg^{2+} excretion rates. Volume contraction may increase reabsorption of uric acid in the proximal tubule; hence chronic administration of amiloride and triamterene may decrease uric acid excretion.

Effects on Renal Hemodynamics. Amiloride and triamterene have little or no effect on renal hemodynamics and do not alter TGF.

Other Actions. Amiloride, at concentrations higher than needed to elicit therapeutic effects, also blocks the Na^+ - H^+ and Na^+ - Ca^{2+} antiporters and inhibits Na^+ , K^+ -ATPase.

Absorption and Elimination. Pharmacokinetic data for amiloride and triamterene are listed in Table 25–6.

Amiloride is eliminated predominantly by urinary excretion of intact drug. Triamterene is metabolized extensively to an active metabolite, 4-hydroxytriamterene sulfate, and this metabolite is excreted in urine. The pharmacological activity of 4-hydroxytriamterene sulfate is comparable with that of the parent drug. Therefore, triamterene toxicity may be enhanced in both hepatic disease (decreased metabolism of triamterene) and renal failure (decreased urinary excretion of active metabolite).

Toxicity, Adverse Effects, Contraindications, Drug Interactions. The most dangerous adverse effect of renal Na^+ -channel inhibitors is hyperkalemia, which can be life-threatening. Consequently, amiloride and triamterene are contraindicated in patients with hyperkalemia, as well as in patients at increased risk of developing hyperkalemia (e.g., patients with renal failure, patients receiving other K^+ -sparing diuretics, patients taking angiotensin-converting enzyme inhibitors, or patients taking K^+ supplements). Even NSAIDs can increase the likelihood of hyperkalemia in patients receiving Na^+ -channel inhibitors.

Pentamidine and high-dose trimethoprim are used often to treat *Pneumocystis jirovecii* pneumonia in patients with acquired immune deficiency syndrome (AIDS). Because these compounds are weak inhibitors of ENaC, they too may cause hyperkalemia. Risk with trimethoprim is related to both the dosage employed and the underlying level of renal function. It was first reported with high-dose therapy (200 mg/kg/day) in 1983. Subsequent reports of hyperkalemia occurred in HIV-infected patients with normal renal function on high doses of the drug. In one series of 30 such patients, 50% developed a serum K⁺ concentration >5.0 mEq/L and 10% >6.0 mEq/L. In a prospective study of otherwise healthy outpatients, the frequency was lower with a serum K⁺ concentration >5.5 mEq/L in only 6%. Within 3-10 days after onset of treatment, 10-21% of patients develop a K⁺ concentration >5.5 mEq/L (Perazella, 2000). Risk factors for severe hyperkalemia are older age, high-dose therapy, renal impairment, hypoaldosteronism, and treatment with other drugs that impair renal K⁺ excretion (e.g., NSAIDs and ACE inhibitors). Serum K⁺ concentration should be monitored after 3-4 days of trimethoprim treatment especially in those at increased risk. Likewise, routine monitoring of the serum K⁺ level is essential in patients receiving K⁺-sparing diuretics. Cirrhotic patients are prone to megaloblastosis because of folic acid deficiency, and triamterene, a weak folic acid antagonist, may increase the likelihood of this adverse event. Triamterene also can reduce glucose tolerance and induce photosensitization and has been associated with interstitial nephritis and renal stones. Both drugs can cause CNS, GI, musculoskeletal, dermatological, and hematological adverse effects. The most common adverse effects of amiloride are nausea, vomiting, diarrhea, and headache; those of triamterene are nausea, vomiting, leg cramps, and dizziness.

Therapeutic Uses. Because of the mild natriuresis induced by Na⁺-channel inhibitors, these drugs seldom are used as sole agents in treatment of edema or hypertension. Rather, their major utility is in combination with other diuretics; indeed, each is marketed in a fixed-dose combination with a thiazide: triamterene/hydrochlorothiazide (DYAZIDE, MAXZIDE, others), amiloride/hydrochlorothiazide (generic).

Co-administration of an Na⁺-channel inhibitor augments the diuretic and antihypertensive response to thiazide and loop diuretics. More important, the ability of Na⁺-channel inhibitors to reduce K⁺ excretion tends to offset the kaliuretic effects of thiazide and loop diuretics; consequently, the combination of an Na⁺-channel inhibitor with a thiazide or loop diuretic tends to result in normal plasma K⁺ values. Liddle syndrome can be treated effectively with Na⁺-channel inhibitors. Approximately 5% of people of African origin carry a *T594M* polymorphism in the β subunit of ENaC, and amiloride is particularly effective in lowering blood pressure in patients with hypertension who carry this polymorphism (Baker et al., 2002). Aerosolized amiloride has been shown to improve mucociliary clearance in patients with cystic fibrosis. By inhibiting Na⁺ absorption from the surfaces of airway epithelial cells, amiloride augments hydration of respiratory secretions and thereby improves mucociliary clearance. Amiloride also is useful for lithium-induced nephrogenic diabetes insipidus because it blocks Li⁺ transport into collecting tubule cells.

ANTAGONISTS OF MINERALOCORTICOID RECEPTORS (ALDOSTERONE ANTAGONISTS, K⁺-SPARING DIURETICS)

Mineralocorticoids cause salt and water retention and increase K⁺ and H⁺ excretion by binding to specific mineralocorticoid receptors. Early studies indicated that some spiro lactones block the effects of mineralocorticoids; this finding led to the synthesis of specific antagonists for the mineralocorticoid receptor (MR). Currently, two MR antagonists are available in the U.S., spironolactone (a 17-spirolactone; ALDACTONE, others) and eplerenone (INSPIRA, others); two others are available elsewhere (Table 25-7).

Mechanism and Site of Action. Epithelial cells in late distal tubule and collecting duct contain cytosolic MRs with a high aldosterone affinity. MRs are members of the superfamily of receptors for steroid hormones, thyroid hormones, vitamin D, and retinoids. Aldosterone enters the epithelial cell from the basolateral membrane and binds to MRs; the MR-aldosterone complex translocates to the nucleus, where it binds to specific sequences of DNA (hormone-responsive elements) and thereby regulates the expression of multiple gene products called *aldosterone-induced proteins* (AIPs). Consequently, transepithelial NaCl transport is enhanced, and the lumen-negative transepithelial voltage is increased. The latter effect increases the driving force for K⁺ and H⁺ secretion into the tubular lumen.

The discovery of gene mutation responsible for rare monogenic diseases that cause hypertension such as Liddle syndrome and apparent mineralocorticoid excess helped clarify how aldosterone regulates Na⁺ transport in the distal nephron (Figure 25-11). Mutations in the carboxy-terminal PY motif of either the β or γ subunits of ENaC are associated with Liddle syndrome. The PY motif is an area involved in protein-protein interaction. The PY motif of ENaC interacts with the ubiquitin ligase Nedd4-2, a protein that ubiquitinates ENaC. This then results in internalization of ENaC and proteasome-mediated degradation. Subsequent studies revealed that Nedd4-2 is phosphorylated and inactivated by SGK1 (serum and glucocorticoid-stimulated kinase) and that SGK1 is up-regulated after ~30 minutes by aldosterone. By tracing back the pathophysiologic mechanism of Liddle syndrome, one of the mechanisms whereby aldosterone acts in the collecting duct was identified. Aldosterone up-regulates SGK1, which phosphorylates and inactivates Nedd4-2. As a result, ENaC is not ubiquitinated and removed from the membrane, thereby increasing Na⁺ reabsorption. When the mineralocorticoid receptor was cloned and tested *in vitro* it was noted to have equal affinity for mineralocorticoid and glucocorticoids. It had been assumed that the mineralocorticoid receptor would have specificity for mineralocorticoids, but surprisingly this was not the case. Given that glucocorticoids circulate at 100- to 1000-fold

Table 25-7

Mineralocorticoid Receptor Antagonists (Aldosterone Antagonists, Potassium-Sparing Diuretics)

DRUG	STRUCTURE	ORAL AVAILABILITY	$t_{1/2}$ (HOURS)	ROUTE OF ELIMINATION
Spironolactone (ALDACTONE)		~65%	~1.6	M
Canrenone ^a		ID	~16.5	M
Potassium canrenoate ^a		ID	ID	M
Eplerenone (INSPIRA)		ID	~5	M

^aNot available in United States. M, metabolism; ID, insufficient data.

higher concentration than mineralocorticoids, it was unclear how mineralocorticoids would ever bind to their receptor. The mineralocorticoid receptor would be predominantly occupied by glucocorticoids. This mystery was solved with the cloning of the enzyme type II 11- β -hydroxysteroid dehydrogenase (HSD). Mineralocorticoid target tissues express type II 11- β -HSD, which converts cortisol to the inactive cortisone. This allows mineralocorticoids to bind to the receptor. The type II 11- β -HSD enzyme is genetically absent in the inherited disorder of apparent mineralocorticoid excess.

Drugs such as spironolactone and eplerenone competitively inhibit the binding of aldosterone to the MR. Unlike the MR-aldosterone complex, the MR-spironolactone complex is not able to induce the synthesis of AIPs. Since spironolactone and eplerenone

block biological effects of aldosterone, these agents also are referred to as *aldosterone antagonists*.

MR antagonists are the only diuretics that do not require access to the tubular lumen to induce diuresis.

Effects on Urinary Excretion. The effects of MR antagonists on urinary excretion are very similar to those induced by renal epithelial Na⁺-channel inhibitors. However, unlike Na⁺-channel inhibitors, the clinical efficacy of MR antagonists is a function of endogenous aldosterone levels. The higher the endogenous

LATE DISTAL TUBULE
AND COLLECTING DUCT

Figure 25–11. Effects of aldosterone on late distal tubule and collecting duct and diuretic mechanism of aldosterone antagonists. **A.** Cortisol also has affinity for the mineralocorticoid receptor (MR), but is inactivated in the cell by 11- β -hydroxysteroid dehydrogenase (HSD) type II. **B.** Serum and glucocorticoid-regulated kinase (SGK)-1 is upregulated after ~30 minutes by aldosterone. SGK-1 phosphorylates and inactivates Nedd4-2 a ubiquitin-protein ligase that acts on ENaC, leading to its degradation. Phosphorylated Nedd4-2 no longer interacts with the PY motif of ENaC. As a result, the protein is not ubiquitinated and remains in the membrane, the end result of which is increased Na^+ entry into the cell. 1. Activation of membrane-bound Na^+ channels. 2. Na^+ channel (ENaC) removal from the membrane is inhibited. 3. *De novo* synthesis of Na^+ channels. 4. Activation of membrane-bound Na^+ , K^+ -ATPase. 5. Redistribution of Na^+ , K^+ -ATPase from cytosol to membrane. 6. *De novo* synthesis of Na^+ , K^+ -ATPase. 7. Changes in permeability of tight junctions. 8. Increased mitochondrial production of ATP. AIP, aldosterone-induced proteins; ALDO, aldosterone; MR, mineralocorticoid receptor; CH, ion channel; BL, basolateral membrane; LM, luminal membrane.

aldosterone level, the greater the effects of MR antagonists on urinary excretion.

Effects on Renal Hemodynamics. MR antagonists have little or no effect on renal hemodynamics and do not alter TGF.

Other Actions. Spironolactone has some affinity toward progesterone and androgen receptors and thereby induces side effects such as gynecomastia, impotence, and menstrual irregularities. Owing to the 9,11-epoxide group, eplerenone has very low affinity for progesterone and androgen receptors (<1% and <0.1%, respectively) compared with spironolactone. High spironolactone concentrations were reported to interfere with steroid biosynthesis by inhibiting steroid hydroxylases (e.g., CYPs 11A1, 11B1, 11B2, and C21; see Chapters 40 and 41). These effects have limited clinical relevance.

Absorption and Elimination. Spironolactone is absorbed partially (~65%), is metabolized extensively (even during

its first passage through the liver), undergoes enterohepatic recirculation, is highly protein bound, and has a short $t_{1/2}$ (~1.6 hours). The $t_{1/2}$ is prolonged to 9 hours in patients with cirrhosis.

Spironolactone undergoes metabolism by both deacylation and dethioacetylation to a variety of metabolites with prolonged $t_{1/2}$; of these, 7 α thiomethyl spironolactone is the primary active metabolite.

Although not available in the U.S., canrenone and the K^+ salt of canrenoate also are in clinical use. Canrenoate is not active *per se* but is converted to canrenone. Eplerenone has good oral availability and is eliminated primarily by metabolism by CYP3A4 to inactive metabolites, with a $t_{1/2}$ of ~5 hours.

Toxicity, Adverse Effects, Contraindications, Drug Interactions. As with other K^+ -sparing diuretics, MR antagonists may cause life-threatening hyperkalemia. Indeed, hyperkalemia is the principal risk of MR

antagonists. Therefore, these drugs are contraindicated in patients with hyperkalemia and in those at increased risk of developing hyperkalemia either because of disease or administration of other medications. MR antagonists also can induce metabolic acidosis in cirrhotic patients.

Salicylates may reduce the tubular secretion of canrenone and decrease diuretic efficacy of spironolactone, and spironolactone may alter the clearance of digitalis glycosides. Owing to its affinity for other steroid receptors, spironolactone may cause gynecomastia, impotence, decreased libido, hirsutism, deepening of the voice, and menstrual irregularities. Spironolactone also may induce diarrhea, gastritis, gastric bleeding, and peptic ulcers (the drug is contraindicated in patients with peptic ulcers). CNS adverse effects include drowsiness, lethargy, ataxia, confusion, and headache. Spironolactone may cause skin rashes and, rarely, blood dyscrasias. Breast cancer has occurred in patients taking spironolactone chronically (cause and effect not established), and high doses of spironolactone are associated with malignant tumors in rats. Whether or not therapeutic spironolactone doses can induce malignancies remains an open question. Strong inhibitors of CYP3A4 may increase plasma levels of eplerenone, and such drugs should not be administered to patients taking eplerenone, and vice versa. Other than hyperkalemia and GI disorders, the rate of adverse events for eplerenone is similar to that of placebo (Pitt et al., 2003).

Therapeutic Uses. As with other K^+ -sparing diuretics, spironolactone often is coadministered with thiazide or loop diuretics in the treatment of edema and hypertension, and spironolactone in combination with hydrochlorothiazide (ALDACTAZIDE, others) is marketed. Such combinations result in increased mobilization of edema fluid while causing lesser perturbations of K^+ homeostasis. Spironolactone is particularly useful in the treatment of resistant hypertension due to primary hyperaldosteronism (adrenal adenomas or bilateral adrenal hyperplasia) and of refractory edema associated with secondary aldosteronism (cardiac failure, hepatic cirrhosis, nephrotic syndrome, and severe ascites). Spironolactone is considered the diuretic of choice in patients with hepatic cirrhosis. Spironolactone, added to standard therapy, substantially reduces morbidity and mortality (Pitt et al., 1999) and ventricular arrhythmias (Ramires et al., 2000) in patients with heart failure (Chapter 28).

Clinical experience with eplerenone is less than that with spironolactone. Eplerenone appears to be a safe and effective antihypertensive drug (Ouzan et al., 2002). It is somewhat more specific for the MR and therefore the incidence of progesterone-related adverse effects (e.g., gynecomastia) is lower than with spironolactone. In patients with acute myocardial infarction complicated by left ventricular systolic dysfunction, addition of eplerenone to optimal medical therapy significantly reduces morbidity and mortality (Pitt et al., 2003).

INHIBITORS OF THE NONSPECIFIC CATION CHANNEL: ATRIAL NATRIURETIC PEPTIDES

The inner medullary collecting duct (IMCD) is a major site of action of natriuretic peptides. Although five different natriuretic peptides exist, only four are relevant with respect to human physiology: atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP), C-type natriuretic peptide (CNP), and urodilatin. ANP and BNP are produced by the heart in response to wall stretch, CNP is of endothelial and renal cell origin, while urodilatin is found in urine and acts as a paracrine regulator of Na^+ transport (Lee and Burnett, 2007). Human recombinant ANP (carperitide, available only in Japan) and BNP (nesiritide [NATRECOR]) are currently available therapeutic agents of this class.

Mechanism and Site of Action. The IMCD is the final site along the nephron where Na^+ is reabsorbed. Up to 5% of the filtered Na^+ load can be reabsorbed here. Na^+ enters the IMCD cell across the apical membrane down an electrochemical gradient through Na^+ channels and exits via the Na^+/K^+ -ATPase (Figure 25–12). Two types of Na^+

Figure 25–12. Inner medullary collecting duct (IMCD) Na^+ transport and its regulation. Na^+ enters the IMCD cell in one of two ways. The first is via ENaC, and the second is through a cyclic nucleotide gated nonspecific cation channel (CNGC) that transports Na^+ , K^+ , and NH_4^+ and is gated by cyclic GMP. Na^+ then exits the cell via the Na^+ , K^+ -ATPase. It is the CNGC that is the primary pathway for Na^+ entry, and is inhibited by natriuretic peptides. Atrial natriuretic peptides (ANP) bind to surface receptors (natriuretic peptide receptors A, B, and C). The A and B receptors are isoforms of particulate guanylate cyclase that catalyze the conversion of GTP to cyclic GMP. Cyclic GMP inhibits the CNGC directly, and indirectly through PKG. PKG activation also inhibits Na^+ exit via the Na^+ , K^+ -ATPase.

channels are expressed in IMCD. The first is an amiloride-sensitive, 28pS, nonselective, cyclic nucleotide gated cation (CNG) channel. This channel is highly selective for cations over anions, has equal permeability for Na⁺ and K⁺, and is inhibited by cGMP, PKG, PKC, ATP, and atrial natriuretic peptides via their capacity to stimulate membrane-bound guanylyl cyclase activity and elevate cellular cGMP. Its open probability is increased by rises in intracellular Ca²⁺ concentration. CNG channels are expressed in all nephron segments with the possible exception of the thin limb of Henle's loop. The second type of Na⁺ channel expressed in the IMCD is the low-conductance 4 pS highly-selective Na⁺ channel ENaC. It appears that the majority of Na⁺ reabsorption in the IMCD is mediated via the CNG channel.

ANP has a 17 amino acid core ring and a cysteine bridge. It is produced in the cardiac atria in response to wall stretch. It binds to the natriuretic peptide receptor (NPR) A and increases intracellular cyclic GMP resulting in inhibition of the CNG channel and natriuresis. It also inhibits production of renin and aldosterone. BNP is produced in the ventricle, also binds to the NPR-A receptor and acts in a similar fashion as ANP. CNP binds to the NPR-B receptor and increases cGMP in vascular smooth muscle and mediates vasodilation. Urodilatin arises from the same precursor molecule as ANP but has four additional amino acids at the N terminus. It binds with lower affinity than ANP to the NPR-B receptor and has effects in glomeruli and IMCD. As a result of these effects, natriuretic peptides have been utilized to treat congestive heart failure. Human recombinant ANP (carperitide) is available in Japan but not yet in the U.S., where human recombinant BNP (nesiritide) is available. Urodilatin (ularitide) remains in preclinical trials in the U.S. and Europe. Only the use of nesiritide is discussed in the following sections. Nesiritide effects renal Na⁺ excretion by inhibiting the CNG nonspecific-cation channel, as well as through inhibiting both the renin-angiotensin-aldosterone system and endothelin production.

Effects on Urinary Excretion. Nesiritide inhibits Na⁺ transport in both the proximal and distal nephron but its primary effect is in the IMCD. Urinary Na⁺ excretion increases with nesiritide but the effect may be attenuated by upregulation of Na⁺ reabsorption in upstream segments of the nephron.

Effects on Renal Hemodynamics. GFR increases administered nesiritide in normal subjects, but in treated patients with congestive heart failure GFR may increase, decrease, or remain unchanged.

Other Actions. Administration of nesiritide decreases systemic and pulmonary resistances and left ventricular filling pressure, and induces a secondary increase in cardiac output. In one study, mean arterial pressure, pulmonary capillary wedge pressure, and right atrial pressure declined 17%, 48%, and 56%, respectively. Declines in blood pressure with administration are dose related.

Elimination. Natriuretic peptides are administered intravenously and have short $t_{1/2}$ values. Nesiritide has a distribution $t_{1/2}$ of 2 minutes and a mean terminal $t_{1/2}$ of 18 minutes. Its volume of distribution is small, 0.19 L/kg. It is cleared via three mechanisms: binding to the NPR-C receptor, degradation via a neutral endopeptidase, and renal excretion. There is no need to adjust the dose for renal insufficiency.

Toxicity, Adverse Effects, Contraindications, Drug Interactions.

There are concerns about adverse renal effects and reports of increased short-term mortality in patients treated with nesiritide. Increases in serum creatinine concentration may be related to decreases in extracellular fluid volume, higher doses of diuretics used, decreases in blood pressure, and activation of the renin-angiotensin-aldosterone system. The Vasodilation in the Management of Acute CHF (VAMC) trial showed no increased risk with low or moderate doses of diuretics but an increased risk with high-dose diuretics (>160 mg furosemide), rising with increasing doses. The risk of hypotension was 4.4% and lasted an average of 2.2 hours. Oral ACE inhibitors may increase the risk of hypotension with nesiritide. Data on whether 30-day mortality is increased by nesiritide are conflicting. There are no data to suggest that nesiritide reduces mortality in the short term or long term in patients with acute decompensated CHF.

Therapeutic Uses. Use of nesiritide should be limited to patients with acutely decompensated CHF with shortness of breath at rest; the drug should not be used in place of diuretics. Nesiritide reduces symptoms and improves hemodynamic parameters in those with dyspnea at rest who are not hypotensive. Nesiritide is available for administration as a continuous intravenous infusion; there is little experience with administering nesiritide for longer than 48 hours.

CLINICAL USE OF DIURETICS

Site and Mechanism of Diuretic Action. An understanding of the sites and mechanisms of action of diuretics enhances comprehension of the clinical aspects of diuretic pharmacology. Figure 25–13 provides an overview of the sites and mechanisms of actions of diuretics. Much of the pharmacology of diuretics can be deduced from this figure.

Mechanism of Edema Formation. A complex set of interrelationships (Figure 25–14) exists among the cardiovascular system, kidneys, CNS (Na⁺ appetite, thirst regulation), and tissue capillary beds (distribution of extracellular fluid volume [ECFV]), so perturbations at one of these sites can affect all other sites. A primary law of the kidney is that Na⁺ excretion is a steep function of mean arterial blood pressure (MABP), such that small increases in MABP cause marked increases in Na⁺ excretion (Guyton, 1991). Over any given time interval, the net change in total-body Na⁺ (either positive or negative) is simply the dietary Na⁺ intake minus the urinary excretion rate minus other losses (e.g., sweating, fecal losses, and vomiting). When a net positive Na⁺ balance occurs, the Na⁺ concentration in the extracellular fluid (ECF) will increase, stimulating water intake (thirst) and reducing urinary water output

Figure 25–13. Summary of the site and mechanism of action of diuretics. Three important features of this summary figure are worth special note. 1. Transport of solute across epithelial cells in all nephron segments involves highly specialized proteins, which for the most part are apical and basolateral membrane integral proteins. 2. Diuretics target and block the action of epithelial proteins involved in solute transport. 3. The site and mechanism of action of a given class of diuretics are determined by the specific protein inhibited by the diuretic. CA, carbonic anhydrase; MR, mineralocorticoid receptor; MRA, mineralocorticoid receptor antagonist; Aldo, aldosterone.

(by ADH release). Opposite changes occur during a net negative Na^+ balance.

Changes in water intake and output adjust ECFV toward normal, thereby expanding or contracting total ECFV. Total ECFV is distributed among many body compartments; however, since ECF volume on the arterial side of the circulation pressurizes the arterial tree, it is this fraction of ECFV that determines MABP, and it is this fraction of ECFV that is “sensed” by the cardiovascular system and kidneys. Since MABP is a major determinant of Na^+ output, a closed loop is established (Figure 25–14). This loop cycles until net Na^+ accumulation is zero; i.e., in the long run, Na^+ intake must equal Na^+ loss.

The preceding discussion implies that three fundamental types of perturbations contribute to venous congestion and/or edema formation:

1. A shift to the right in the renal pressure-natriuresis relationship (e.g., chronic renal failure) causes

reduced Na^+ excretion for any level of MABP. If all other factors remain constant, this would increase total-body Na^+ , ECFV, and MABP. The additional ECFV would be distributed throughout various body compartments according to the state of cardiac function and prevailing Starling forces and would predispose toward venous congestion and/or edema. Even so, in the absence of any other predisposing factors for venous congestion and/or edema, a rightward shift in the renal pressure-natriuresis curve generally causes hypertension with only a slight (usually immeasurable) increase in ECFV. As elucidated by Guyton (1991), ECFV expansion triggers a series of events: expanded ECFV \rightarrow augmented cardiac output \rightarrow enhanced vascular tone (i.e., total-body autoregulation) \rightarrow increased total peripheral resistance \rightarrow elevated MABP \rightarrow pressure natriuresis \rightarrow reduction of ECFV and cardiac output toward normal. Most likely, a

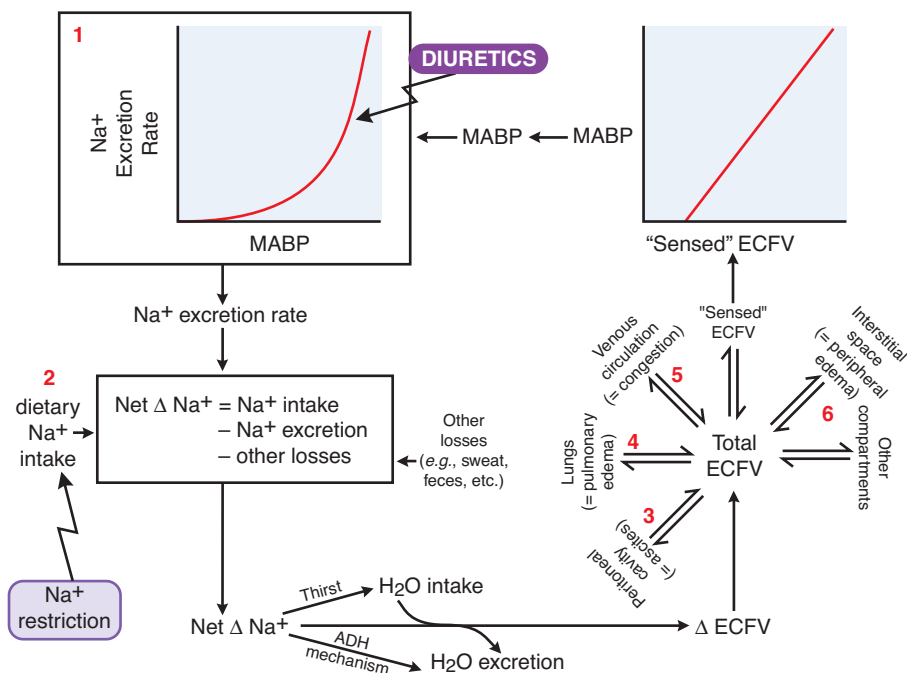

Figure 25–14. Interrelationships among renal function, Na^+ intake, water homeostasis, distribution of extracellular fluid volume, and mean arterial blood pressure. Pathophysiological mechanisms of edema formation. 1. Rightward shift of renal pressure natriuresis curve. 2. Excessive dietary Na^+ intake. 3. Increased distribution of extracellular fluid volume (ECFV) to peritoneal cavity (e.g., liver cirrhosis with increased hepatic sinusoidal hydrostatic pressure) leading to ascites formation. 4. Increased distribution of ECFV to lungs (e.g., left-sided heart failure with increased pulmonary capillary hydrostatic pressure) leading to pulmonary edema. 5. Increased distribution of ECFV to venous circulation (e.g., right-sided heart failure) leading to venous congestion. 6. Peripheral edema caused by altered Starling forces causing increased distribution of ECFV to interstitial space (e.g., diminished plasma proteins in nephrotic syndrome, severe burns, and liver disease).

sustained rightward shift in the renal pressure-natriuresis curve is a necessary and sufficient condition for long-term hypertension but is only a predisposing factor for venous congestion and/or edema.

- An increase in dietary Na^+ intake would have the same effects as a rightward shift in the renal pressure-natriuresis relationship (i.e., increased MABP and predisposition to venous congestion/edema). However, changes in salt intake may have minimal or large effects depending on the shape of the patient's renal pressure-natriuresis curve.
- Any pathophysiological alterations in the forces that govern the distribution of ECFV among the various body compartments would cause abnormal amounts of ECFV to be trapped at the site of altered forces. This would deplete the "sensed" ECFV, which would be restored back to normal by the mechanisms described earlier. ECFV may be trapped at several sites by different mechanisms. For instance, cirrhosis of the liver increases lymph in the space of Disse, leading to spillover by the glissonian wall into the peritoneal cavity (ascites). Left-sided heart

failure, both acute and chronic, increases hydrostatic pressure in the lung capillaries, leading to pulmonary edema. Chronic right-sided heart failure redistributes ECFV from the arterial to the venous circulation, resulting in venous, hepatic, and splenic congestion and peripheral tissue edema. Decreased plasma protein levels, particularly albumin (e.g., in nephrotic syndrome, severe burns, and hepatic disease), increase the distribution of ECFV into interstitial spaces, causing generalized peripheral edema. Peripheral edema also may be "idiopathic" owing to unknown alterations in Starling forces at the capillary bed.

The Role of Diuretics in Clinical Medicine. Another implication of the mechanisms illustrated in Figure 25–14 is that three fundamental strategies exist for mobilizing edema fluid:

- Correction of the underlying disease
- Restriction of Na^+ intake
- Administration of diuretics

The most desirable course of action would be to correct the primary disease; however, this often is impossible. For instance, increased hepatic sinusoidal pressure in cirrhosis of the liver and urinary loss of protein in nephrotic syndrome are due to structural alterations in the portal circulation and glomeruli, respectively, that may not be remediable.

Restriction of Na^+ intake is the favored nonpharmacologic approach to treatment of edema and hypertension and should be attempted; however, compliance is a major obstacle. Diuretics, therefore, remain the cornerstone for treatment of edema or volume overload, particularly that owing to congestive heart failure, ascites, chronic renal failure, and nephrotic syndrome.

Whether a patient should receive diuretics and, if so, what therapeutic regimen should be used (type of diuretic, dose, route of administration, and speed of mobilization of edema fluid) depend on the clinical situation. Massive pulmonary edema in patients with acute left-sided heart failure is a medical emergency requiring rapid, aggressive therapy including intravenous administration of a loop diuretic. In this setting, use of oral diuretics or diuretics with lesser efficacy is inappropriate. On the other hand, mild pulmonary and venous congestion associated with chronic heart failure is best treated with an oral loop or thiazide diuretic, the dosage of which should be titrated carefully to maximize the benefit-to-risk ratio. As mentioned previously, meta-analysis indicates that loop and thiazide diuretics decrease morbidity and mortality in heart failure patients (Faris et al., 2002), and two randomized clinical trials with MR antagonists also demonstrate reduced morbidity and mortality in heart failure patients receiving optimal therapy with other drugs (Pitt et al., 1999, 2003). Periodic administration of diuretics to cirrhotic patients with ascites may eliminate the necessity for or reduce the interval between paracenteses, adding to patient comfort and sparing protein reserves that are lost during the paracenteses. Although diuretics can reduce edema associated with chronic renal failure, increased doses of more powerful loop diuretics usually are required. In nephrotic syndrome, diuretic response often is disappointing. In chronic renal failure and cirrhosis, edema will not pose an immediate health risk. Even so, uncomfortable, oppressive, and/or disfiguring edema can greatly reduce quality of life, and the decision to treat will be based in part on quality-of-life issues. In such cases, only partial removal of edema fluid should be attempted, and fluid should be mobilized slowly using a diuretic regimen that accomplishes the task with minimal perturbation of normal physiology. Brater (1998) provides a logically compelling

algorithm for diuretic therapy (specific recommendations for drug, dose, route, and drug combinations) in patients with edema caused by renal, hepatic, or cardiac disorders. The basic features of “Brater’s algorithm” are summarized in Figure 25–15.

In many clinical situations, edema is not caused by abnormal Na^+ intake or by an altered renal Na^+ handling. Rather, edema is the result of altered Starling forces at the capillary beds—a “Starling trap.” Use of diuretics in these clinical settings represents a judicious compromise between the edematous state and the hypovolemic state. In such conditions, reducing total ECFV with diuretics will decrease edema but also will cause depletion of “sensed” ECFV, possibly leading to hypotension, malaise, and asthenia.

Diuretic resistance refers to edema that is or has become refractory to a given diuretic. If diuretic resistance develops against a less efficacious diuretic, a more efficacious diuretic should be substituted, such as a loop diuretic for a thiazide. However, resistance to loop diuretics is not uncommon and can be due to several causes.

NSAID co-administration is a common preventable cause of diuretic resistance. An estimated 10% of the elderly each year have periods when NSAID and diuretic prescriptions overlap. Prostaglandin production, especially PGE_2 , is an important counter-regulatory mechanism in states of reduced renal perfusion such as volume contraction, congestive heart failure, and cirrhosis characterized by activation of the renin-angiotensin-aldosterone (RAA) and sympathetic nervous systems. Prostaglandins reduce NaCl reabsorption in the distal nephron, antagonize effects of ADH, and redistribute blood flow from cortex to juxtamedullary regions in this setting. NSAID administration can block these prostaglandin-mediated effects that counterbalance the RAA and sympathetic nervous system, resulting in salt and water retention. Interaction between NSAIDs and diuretics can result in important clinical consequences such as development or exacerbation of congestive heart failure. NSAIDs can also increase blood pressure, especially in the elderly. In one study of patients over age 55, the relative risk of hospitalization for congestive heart failure (CHF) during periods of concomitant diuretic and NSAID use was increased 2.2-fold over that with diuretic use alone. The majority of these admissions occurred in the first month of simultaneous use, most in the first 20 days. After 40 days, risk was similar to that before simultaneous use. This appeared to be a class effect with no significant differences between individual NSAIDs. Diuretic resistance also occurs with COX-2-selective inhibitors.

In chronic renal failure, a reduction in RBF decreases delivery of diuretics to the kidney, and accumulation of endogenous organic acids competes with loop diuretics for transport at the proximal tubule. Consequently, diuretic concentration at the active site in the tubular lumen is diminished. In nephrotic syndrome, binding of diuretics to luminal albumin was postulated to limit response; however, the validity of this concept has been challenged (Agarwal et al., 2000). In hepatic cirrhosis, nephrotic syndrome, and heart failure,

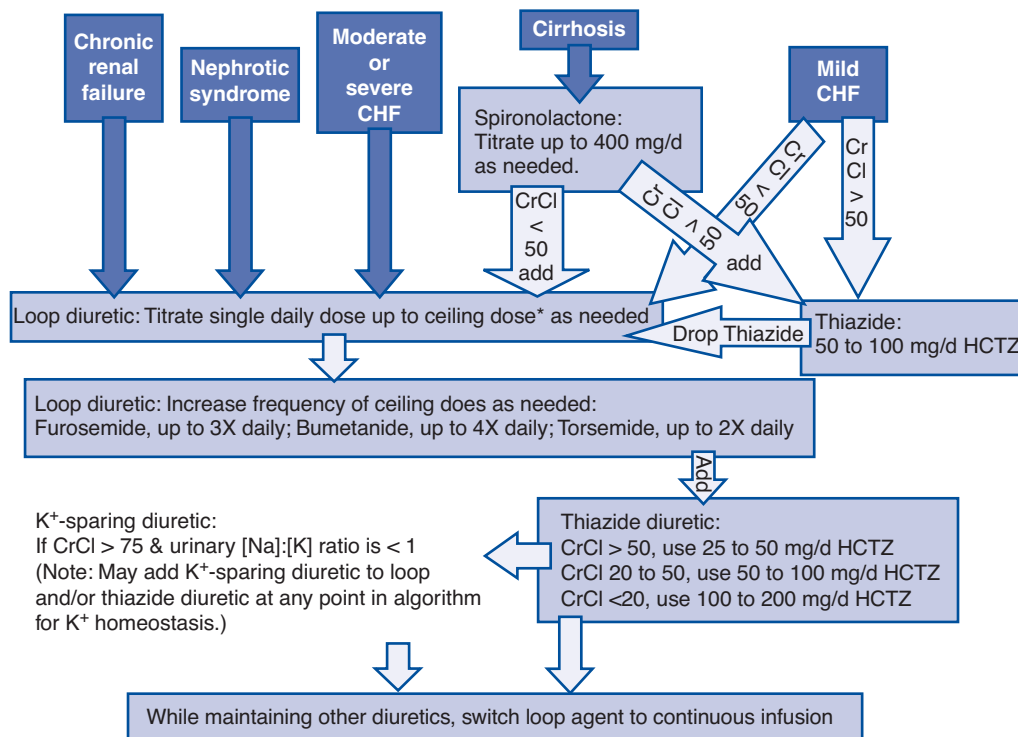

Figure 25–15. “Brater’s algorithm” for diuretic therapy of chronic renal failure, nephrotic syndrome, congestive heart failure, and cirrhosis. Follow algorithm until adequate response is achieved. If adequate response is not obtained, advance to the next step. For illustrative purposes, the thiazide diuretic used in Brater’s algorithm is hydrochlorothiazide (HCTZ). An alternative thiazide-type diuretic may be substituted with appropriate dosage adjustment so as to be pharmacologically equivalent to the recommended dose of HCTZ. Do not combine two K⁺-sparing diuretics because of the risk of hyperkalemia. CrCl indicates creatinine clearance in mL/min, and ceiling dose refers to the smallest dose of diuretic that produces a near-maximal effect. Ceiling doses of loop diuretics and dosing regimens for continuous intravenous infusions of loop diuretics are disease-state-specific. In this regard, see Brater (1998) for recommended dosages. Doses are for adults only.

nephrons may have diminished diuretic responsiveness because of increased proximal tubular Na⁺ reabsorption, leading to diminished Na⁺ delivery to distal nephron segments (Knauf and Mutschler, 1997).

Faced with resistance to loop diuretics, the clinician has several options:

1. Bed rest may restore drug responsiveness by improving the renal circulation.
2. An increase in dose of loop diuretic may restore responsiveness; however, nothing is gained by increasing the dose above that which causes a near-maximal effect (the ceiling dose) of the diuretic.
3. Administration of smaller doses more frequently or a continuous intravenous infusion of a loop diuretic (Ferguson et al., 1997) will increase the length of time that an effective diuretic concentration is at the active site.
4. Use of combination therapy to sequentially block more than one site in the nephron may result in a

synergistic interaction between two diuretics. For instance, a combination of a loop diuretic with a K⁺-sparing or a thiazide diuretic may improve therapeutic response; however, nothing is gained by the administration of two drugs of the same type.

Thiazide diuretics with significant proximal tubular effects (e.g., metolazone) are particularly well suited for sequential blockade when co-administered with a loop diuretic. This combination should be used with caution and the patient followed closely in the first few weeks of therapy. Significant complications may ensue, including severe hyponatremia, hypokalemia, and volume depletion. The patient should be warned to stop both drugs and contact his or her physician if weight loss exceeds 5 pounds per week.

5. Reducing salt intake will diminish postdiuretic Na⁺ retention that can nullify previous increases in Na⁺ excretion.
6. Scheduling of diuretic administration shortly before food intake will provide effective diuretic concentration in the tubular lumen when salt load is highest.

All currently available diuretics perturb K^+ homeostasis. However, studies in animals established that blockade of adenosine A_1 receptors induces a brisk natriuresis without significantly increasing urinary K^+ excretion (Kuan et al., 1993). Two clinical studies with FK453, a highly selective A_1 -receptor antagonist, confirm that blockade of A_1 receptors induces natriuresis in humans with minimal effects on K^+ excretion (van Buren et al., 1993). The natriuretic mechanism of this novel class of diuretics has been partially elucidated (Takeda et al., 1993). Elevated intracellular cyclic AMP reduces basolateral $Na^+HCO_3^-$ symport in proximal tubular cells. Endogenous adenosine normally acts on A_1 receptors in these cells to inhibit adenylyl cyclase and reduce cyclic AMP accumulation. Blockade of A_1 receptors removes this inhibition, permits cellular cyclic AMP to rise, and results in reduced activity of the $Na^+HCO_3^-$ symporter. Because A_1 receptors are involved in TGF, A_1 receptor antagonists uncouple increased distal Na^+ delivery from activation of TGF. Other mechanisms, including an effect in the collecting tubules, contribute to the natriuretic response to A_1 -receptor antagonists; however, it is not known why this class of diuretics has little effect on K^+ excretion. In some patients, loop diuretics may compromise renal hemodynamics and actually reduce GFR, a phenomenon known as *diuretic intolerance*. Importantly, A_1 receptor antagonists tend to improve GFR in the setting of diuretic intolerance. A_1 receptor antagonists such as rolofylline are in clinical trials. However, the future utility of this class of diuretics is doubtful: the large PROTECT trial showed in 2009 that rolofylline was not superior to placebo in patients with acute heart failure; rolofylline also increased the incidence of seizures, an expected side-effect of A_1 receptor antagonists.

WATER HOMEOSTASIS

Arginine vasopressin (the antidiuretic hormone in humans) is the main hormone that regulates body fluid osmolality. Many diseases of water homeostasis and many pharmacological strategies for correcting such disorders involve vasopressin. This section of the chapter focuses on vasopressin, including (1) chemistry of vasopressin agonists and vasopressin antagonists; (2) physiology (anatomical considerations; the synthesis, transport, and storage of vasopressin; and regulation of vasopressin secretion); (3) basic pharmacology (vasopressin receptors and their signal-transduction pathways, renal actions of vasopressin, pharmacological modification of the antidiuretic response to vasopressin, and nonrenal actions of vasopressin); (4) diseases affecting the vasopressin system (diabetes insipidus, syndrome of inappropriate secretion of antidiuretic hormone [SIADH], and other water-retaining states); and (5) clinical pharmacology of vasopressin peptides. A small number of other drugs can be used to treat abnormalities of water balance; a discussion of these agents is integrated into the section on diseases affecting the vasopressin system.

Genes encoding vasopressin-like peptides probably evolved >700 million years ago. Immunoreactive vasopressin occurs in neurons from organisms belonging to the first animal phylum with a nervous system (e.g., *Hydra attenuata*), and vasopressin-like peptides have been isolated and characterized from both mammalian and nonmammalian vertebrates, as well as from invertebrates (Table 25–8). With the emergence of life on land, vasopressin became the mediator of a remarkable regulatory system for water conservation. The hormone is released by the posterior pituitary whenever water deprivation causes an increased plasma osmolality or whenever the cardiovascular system is challenged by hypovolemia and/or hypotension. In amphibians, target organs for vasopressin are skin and urinary bladder, whereas in other vertebrates, including humans, vasopressin acts primarily in the renal collecting duct. In each of these target tissues, vasopressin increases the water permeability of the cell membrane, thus permitting water to move passively down an osmotic gradient across skin, bladder, or collecting duct into the extracellular compartment.

In view of the long evolutionary history of vasopressin, it is not surprising that vasopressin acts at sites in the nephron other than the collecting duct and on tissues other than kidney. Vasopressin is a potent vasopressor; indeed, its name was chosen originally in recognition of this vasoconstrictor action. Vasopressin is a neurotransmitter; among its actions in the CNS are apparent roles in the secretion of adrenocorticotrophic hormone (ACTH) and in regulation of the cardiovascular system, temperature, and other visceral functions. Vasopressin also promotes release of coagulation factors by vascular endothelium and increases platelet aggregability.

PHYSIOLOGY OF VASOPRESSIN

Anatomy. The antidiuretic mechanism in mammals involves two anatomical components: a CNS component for synthesis, transport, storage, and release of vasopressin and a renal collecting-duct system composed of epithelial cells that respond to vasopressin by increasing their water permeability. The CNS component of the antidiuretic mechanism is called the *hypothalamic-neurohypophyseal system* and consists of neurosecretory neurons with perikarya located predominantly in two specific hypothalamic nuclei, the supraoptic nucleus (SON) and paraventricular nucleus (PVN). Long axons of magnocellular neurons in SON and PVN transverse the external zone of the median eminence to terminate in the neural lobe of the posterior pituitary (neurohypophysis), where they release vasopressin and oxytocin. In addition, axons of parvicellular neurons

Synthesis. Vasopressin and oxytocin are synthesized mainly in the perikarya of magnocellular neurons in the SON and PVN; the two hormones are synthesized predominantly in separate neurons. Parvocellular neurons in the PVN also synthesize vasopressin. Vasopressin synthesis appears to be regulated solely at the transcriptional level. In humans, a 168-amino acid preprohormone (Figure 25–16) is synthesized, and a signal peptide (residues –23 to –1) ensures incorporation of the nascent polypeptide into ribosomes. During synthesis, the signal peptide is removed to form vasopressin prohormone, which then is processed and incorporated into the Golgi compartment and then into membrane-associated granules. The prohormone contains three domains: vasopressin (residues 1–9), vasopressin (VP)-neurophysin (residues 13–105), and VP-glycopeptide (residues 107–145). The vasopressin domain is linked to the VP-neurophysin domain through a glycine-lysine-arginine-processing signal, and the VP-neurophysin is linked to the VP-glycopeptide domain by an arginine-processing signal. In secretory granules, an endopeptidase, exopeptidase, monooxygenase, and lyase act sequentially on the prohormone to produce vasopressin, VP-neurophysin (sometimes referred to as neurophysin II or MSEL-neurophysin), and VP-glycopeptide (sometimes called copeptin). The synthesis and transport of vasopressin depend on the preprohormone conformation. In particular, VP-neurophysin binds vasopressin and is critical

to correct processing, transport, and storage of vasopressin. Genetic mutations in either the signal peptide or VP-neurophysin give rise to central diabetes insipidus.

Transport and Storage. The process of axonal transport of vasopressin- and oxytocin-containing granules is rapid, and these hormone-laden granules arrive at their destinations within 30 minutes, ready for release by exocytosis when the magnocellular or parvocellular neurons are stimulated appropriately.

Maximal release of vasopressin occurs when impulse frequency is ~12 spikes per second for 20 seconds. Higher frequencies or longer periods of stimulation lead to diminished hormone release (fatigue). Appropriately, vasopressin-releasing cells demonstrate an atypical pattern of spike activity characterized by rapid phasic bursts (5–12 spikes per second for 15–60 seconds) separated by quiescent periods (15–60 seconds in duration). This pattern is orchestrated by activation and inactivation of ion channels in magnocellular neurons and provides for optimal vasopressin release.

Vasopressin Synthesis Outside the CNS. Vasopressin also is synthesized by heart and adrenal gland. In heart, elevated wall stress increases vasopressin synthesis severalfold. Cardiac synthesis of vasopressin is predominantly vascular and perivascular and may contribute to impaired ventricular relaxation and coronary vasoconstriction. Vasopressin synthesis in the adrenal medulla stimulates catecholamine secretion from chromaffin cells and may promote adrenal cortical growth and stimulate aldosterone synthesis.

Figure 25–16. Processing of the 168-amino acid human 8-arginine vasopressin (AVP) preprohormone to AVP, vasopressin (VP)-neurophysin, and VP-glycopeptide. More than 40 mutations in the single gene on chromosome 20 that encodes AVP preprohormone give rise to central diabetes insipidus. *Boxes indicate mutations leading to central diabetes insipidus.

Regulation of Vasopressin Secretion. An increase in plasma osmolality is the principal physiological stimulus for vasopressin secretion by the posterior pituitary (Bankir, 2001). Severe hypovolemia/hypotension also is a powerful stimulus for vasopressin release. In addition, pain, nausea, and hypoxia can stimulate vasopressin secretion, and several endogenous hormones and pharmacological agents can modify vasopressin release.

Hyperosmolality. The relationship between plasma osmolality and plasma vasopressin concentration is shown in Figure 25–17A, and the relationship between plasma vasopressin levels and urine osmolality is illustrated in Figure 25–17B. The osmolality threshold for secretion is ~ 280 mOsm/kg. Below the threshold, vasopressin is barely detectable in plasma, and above the threshold, vasopressin levels are a steep and relatively linear function of plasma osmolality. A small increase in plasma osmolality leads to enhanced vasopressin secretion. Indeed, a 2% elevation in plasma osmolality causes a 2- to 3-fold increase in plasma vasopressin levels, which in turn causes increased solute-free water reabsorption, with an increase in urine osmolality. Increases in plasma osmolality above 290 mOsm/kg lead to an intense desire for water (thirst). Thus, the vasopressin system affords the organism longer thirst-free periods and, in the event that water is unavailable, allows the organism to survive longer periods of water deprivation. It is important to point out, however, that above a plasma osmolality of ~ 290 mOsm/kg, plasma vasopressin levels exceed 5 pM. Since urinary concentration is maximal (~ 1200 mOsm/kg) when vasopressin levels exceed 5 pM, further defense against hypertonicity depends entirely on water intake rather than on decreases in water loss.

Several CNS structures are involved in osmotic stimulation of vasopressin release by the posterior pituitary; these structures are collectively referred to as the *osmoreceptive complex*. Although magnocellular neurons in SON and PVN are osmosensitive, afferent inputs

from other components of the osmoreceptive complex are required for a normal vasopressin response. The SON and PVN receive projections from the subfornical organ (SFO) and the organum vasculosum of the lamina terminalis (OVLT) either directly or indirectly by means of the median preoptic nucleus (MnPO). Subgroups of neurons in the SFO, OVLT, and MnPO are either osmoreceptors or osmosponders (i.e., are stimulated by osmoreceptive neurons located at other sites). Thus, a web of interconnecting neurons contributes to osmotically induced vasopressin secretion.

Aquaporin 4, a water-selective channel, is associated with CNS structures involved in osmoregulation and may confer osmosensitivity. In the CNS, aquaporin 4 resides on glial and ependymal cells rather than on neurons, suggesting that osmotic status may be communicated to the neuronal cell by a glial-neuron interaction (Wells, 1998).

Hepatic Portal Osmoreceptors. An oral salt load activates hepatic portal osmoreceptors leading to increased vasopressin release. This mechanism augments plasma vasopressin levels even before the oral salt load increases plasma osmolality.

Hypovolemia and Hypotension. Vasopressin secretion also is regulated hemodynamically by changes in effective blood volume and/or arterial blood pressure (Robertson, 1992). Regardless of the cause (e.g., hemorrhage, Na^+ depletion, diuretics, heart failure, hepatic cirrhosis with ascites, adrenal insufficiency, or hypotensive drugs), reductions in effective blood volume and/or arterial blood pressure may be associated with high circulating vasopressin concentrations. However, unlike osmoregulation, hemodynamic regulation of vasopressin secretion is exponential; i.e., small decreases (5%) in blood volume and/or pressure have little effect on vasopressin secretion, whereas larger decreases (20–30%) can increase vasopressin levels to 20–30 times normal (exceeding the vasopressin concentration required to induce maximal antidiuresis). Vasopressin is one of the most potent vasoconstrictors

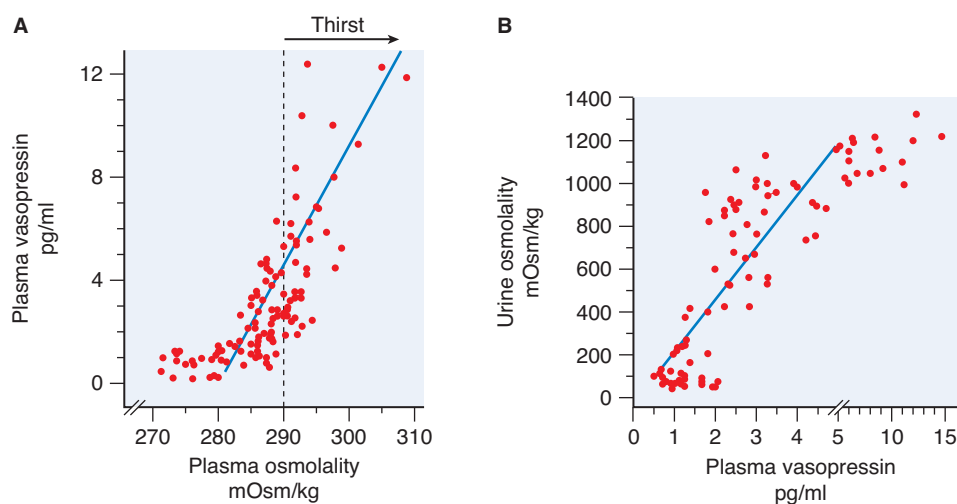

Figure 25–17. **A.** The relationship between plasma osmolality and plasma vasopressin levels. Plasma osmolality range associated with thirst is indicated by arrow. **B.** The relationship between plasma vasopressin levels and urine osmolality. known, and the vasopressin response to hypovolemia or hypotension serves as a mechanism to stave off cardiovascular collapse during periods of severe blood loss and/or hypotension. Hemodynamic regulation of vasopressin secretion does not disrupt osmotic regulation; rather, hypovolemia/hypotension alters the set point and slope of the plasma osmolality-plasma vasopressin relationship (Figure 25-18).

Neuronal pathways that mediate hemodynamic regulation of vasopressin release are different from those involved in osmoregulation. Baroreceptors in left atrium, left ventricle, and pulmonary veins sense blood volume (filling pressures), and baroreceptors in carotid sinus and aorta monitor arterial blood pressure. Nerve impulses reach brainstem nuclei predominantly through the vagal trunk and glossopharyngeal nerve; these signals are relayed to the solitary tract nucleus, then to the A_1 -noradrenergic cell group in the caudal ventrolateral medulla, and finally to the SON and PVN.

Hormones and Neurotransmitters. Vasopressin-synthesizing magnocellular neurons have a large array of receptors on both perikarya and nerve terminals; therefore, vasopressin release can be accentuated or attenuated by chemical agents acting at both ends of the magnocellular neuron. Also, hormones and neurotransmitters can modulate vasopressin secretion by stimulating or inhibiting neurons in nuclei that project, either directly or indirectly, to the SON and PVN. Because of these complexities, results of any given investigation may depend critically on route of administration of the agent and on the experimental paradigm. In many cases, the precise mechanism by which a given agent modulates vasopressin secretion is either unknown or controversial, and the physiological relevance of the modulation of vasopressin secretion by most hormones and neurotransmitters is unclear.

Nonetheless, several agents are known to stimulate vasopressin secretion, including acetylcholine (by nicotinic receptors), histamine (by H_1 receptors), dopamine (by both D_1 and D_2 receptors),

glutamine, aspartate, cholecystokinin, neuropeptide Y, substance P, vasoactive intestinal polypeptide, prostaglandins, and angiotensin II (AngII). Inhibitors of vasopressin secretion include atrial natriuretic peptide, γ -aminobutyric acid, and opioids (particularly dynorphin *via* κ receptors). The effects of AngII have received the most attention. AngII, applied directly to magnocellular neurons in the SON and PVN, increases neuronal excitability; when applied to the MnPO, AngII indirectly stimulates magnocellular neurons in the SON and PVN. In addition, AngII stimulates angiotensin-sensitive neurons in the OVLT and SFO (circumventricular nuclei lacking a blood-brain barrier) that project to the SON/PVN. Thus, AngII synthesized in the brain and circulating AngII may stimulate vasopressin release. Inhibition of the conversion of AngII to AngIII blocks AngII-induced vasopressin release, suggesting that AngIII is the main effector peptide of the brain renin-angiotensin system controlling vasopressin release (Reaux et al., 2001).

Pharmacological Agents. A number of drugs alter urine osmolality by stimulating or inhibiting vasopressin secretion. In some cases the mechanism by which a drug alters vasopressin secretion involves direct effects on one or more CNS structures that regulate vasopressin secretion. In other cases vasopressin secretion is altered indirectly by the effects of a drug on blood volume, arterial blood pressure, pain, or nausea. In most cases the mechanism is not known. Stimulators of vasopressin secretion include vincristine, cyclophosphamide, tricyclic antidepressants, nicotine, epinephrine, and high doses of morphine. Lithium, which inhibits the renal effects of vasopressin, also enhances vasopressin secretion. Inhibitors of vasopressin secretion include ethanol, phenytoin, low doses of morphine, glucocorticoids, fluphenazine, haloperidol, promethazine, oxilofan, and butorphanol. Carbamazepine has a renal action to produce antidiuresis in patients with central diabetes insipidus but actually inhibits vasopressin secretion by a central action.

BASIC PHARMACOLOGY OF VASOPRESSIN

Vasopressin Receptors. Cellular vasopressin effects are mediated mainly by interactions of the hormone with the three types of receptors, V_{1a} , V_{1b} , and V_2 . The V_{1a} receptor is the most widespread subtype of vasopressin receptor; it is found in vascular smooth muscle, adrenal gland, myometrium, bladder, adipocytes, hepatocytes, platelets, renal medullary interstitial cells, vasa recta in the renal microcirculation, epithelial cells in the renal cortical collecting-duct, spleen, testis, and many CNS structures. V_{1b} receptors have a more limited distribution and are found in the anterior pituitary, several brain regions, pancreas, and adrenal medulla. V_2 receptors are located predominantly in principal cells of the renal collecting-duct system but also are present on epithelial cells in thick ascending limb and on vascular endothelial cells. Although originally defined by pharmacological criteria, vasopressin receptors now are defined by their primary amino acid sequences. The cloned vasopressin receptors

are typical heptahelical GPCRs. Manning and co-workers (1999) synthesized novel hypotensive vasopressin peptide agonists that do not interact with V_{1a} , V_{1b} , or V_2 receptors and may stimulate a putative vasopressin vasodilatory receptor.

Two additional putative receptors for vasopressin have been cloned. A vasopressin-activated Ca^{2+} -mobilizing receptor with one transmembrane domain binds vasopressin and increases intracellular Ca^{2+} (Serradeil-Le Gal et al., 2002). A dual AngII-vasopressin heptahelical receptor activates adenylyl cyclase in response to both AngII and vasopressin (Serradeil-Le Gal et al., 2002). The physiological roles of these putative vasopressin receptors are unclear.

V_1 Receptor-Effector Coupling. Figure 25–19 summarizes the current model of V_1 receptor-effector coupling. Vasopressin binding to V_1 receptors activates the

G_q -PLC-IP₃ pathway, thereby mobilizing intracellular Ca^{2+} and activating PKC, ultimately causing biological effects that include immediate responses (e.g., vasoconstriction, glycogenolysis, platelet aggregation, and ACTH release) and growth responses in smooth muscle cells. Other effects of V_1 -receptor activation may be mediated by stimulation of small G proteins, activation of PLD and PLA₂, and activation of V_1 -sensitive Ca^{2+} influx. Some effects of V_1 -receptor activation are secondary to synthesis of prostaglandins and epoxyeicosatrienoic acids (Chapter 33).

V_2 Receptor-Effector Coupling. Principal cells in renal collecting duct have V_2 receptors on their basolateral membranes that couple to G_s to stimulate adenylyl cyclase activity (Figure 25–20) when vasopressin binds to V_2 receptors. The resulting increase in cellular cyclic AMP and PKA activity triggers an increased rate of

Figure 25–19. Mechanism of V_1 receptor-effector coupling. Binding of 8-arginine vasopressin (AVP) to V_1 vasopressin receptors (V_1) stimulates several membrane-bound phospholipases. Stimulation of the G_q -PLC $_{\beta}$ pathway results in IP₃ formation, mobilization of intracellular Ca^{2+} , and activation of PKC. Activation of V_1 receptors also causes influx of extracellular Ca^{2+} by an unknown mechanism. PKC and Ca^{2+} /calmodulin-activated protein kinases phosphorylate cell-type-specific proteins leading to cellular responses. A further component of the AVP response derives from the production of eicosanoids secondary to the activation of PLA₂; the resulting mobilization of arachidonic acid (AA) provides substrate for eicosanoid synthesis by the cyclooxygenase (COX) and lipoxygenase (LOX) pathways, leading to local production of prostaglandins (PG), thromboxanes (TX), and leukotrienes (LT), which may activate a variety of signaling pathways, including those linked to G_s and G_q . Biological effects mediated by the V_1 receptor include vasoconstriction, glycogenolysis, platelet aggregation, ACTH release, and growth of vascular smooth muscle cells. The effects of vasopressin on cell growth involve transcriptional regulation by the FOS/JUN AP-1 transcription complex.

Figure 25–20. Mechanism of V_2 receptor-effector coupling. Binding of vasopressin (AVP) to the V_2 receptor activates the G_s -adenylyl cyclase-cAMP-PKA pathway and shifts the balance of aquaporin 2 trafficking toward the apical membrane of the principal cell of the collecting duct, thus enhancing water permeability. Although phosphorylation of serine 256 of aquaporin 2 is involved in V_2 receptor signaling, other proteins located both in the water channel-containing vesicles and the apical membrane of the cytoplasm also may be involved.

insertion of water channel-containing vesicles (WCVs) into the apical membrane and a decreased rate of endocytosis of WCVs from the apical membrane (Snyder et al., 1992). Distribution of WCVs between the cytosolic compartment and apical membrane compartment is thus shifted in favor of the apical membrane compartment (Nielsen et al., 1999). Because WCVs contain preformed

functional water channels (aquaporin 2), their net shift into apical membranes in response to V_2 -receptor stimulation greatly increases water permeability of the apical membrane (see Figures 25–20 and 25–21).

Figure 25–21. Structure of aquaporins. Aquaporins have six transmembrane domains, and the NH_2 and COOH termini are intracellular. Loops B and E each contain an asparagine-proline-alanine (NPA) sequence. Aquaporins fold with transmembrane domains 1, 2, and 6 in close proximity and transmembrane domains 3, 4 and 5 in juxtaposition. The long B and E loops dip into the membrane, and the NPA sequences align to create a pore through which water can diffuse. Most likely aquaporins form a tetrameric oligomer. At least seven aquaporins are expressed at distinct sites in the kidney. Aquaporin 1, abundant in the proximal tubule and descending thin limb, is essential for concentration of urine. Aquaporin 2, exclusively expressed in the principal cells of the connecting tubule and collecting duct, is the major vasopressin-regulated water channel. Aquaporin 3 and aquaporin 4 are expressed in the basolateral membranes of collecting-duct principal cells and provide exit pathways for water reabsorbed apically by aquaporin 2. Aquaporin 7 is in the apical brush border of the straight proximal tubule. Aquaporins 6 to 8 are also expressed in kidney; their functions remain to be clarified. Vasopressin regulates water permeability of the collecting duct by influencing the trafficking of aquaporin 2 from intracellular vesicles to the apical plasma membrane (Figure 25–20). AVP-induced activation of the cAMP-PKA pathway also enhances expression of aquaporin 2 mRNA and protein; chronic dehydration thus causes up-regulation of aquaporin 2 and water transport in the collecting duct.

For maximum concentration of urine, large amounts of urea must be deposited in the interstitium of the inner medulla. It is not surprising, therefore, that V_2 -receptor activation also increases urea permeability by 400% in the terminal portions of the inner medullary collecting duct. V_2 receptors increase urea permeability by activating a vasopressin-regulated urea transporter (termed *VRUT*, *UT1*, or *UT-A1*), most likely by PKA-induced phosphorylation (Sands, 2003). Kinetics of vasopressin-induced water and urea permeability differ, and vasopressin-induced regulation of *VRUT* does not entail vesicular trafficking to the plasma membrane (Inoue et al., 1999).

In addition to increasing water permeability of the collecting duct and urea permeability of the inner medullary collecting duct, V_2 -receptor activation also increases Na^+ transport in thick ascending limb and collecting duct. Increased Na^+ transport in thick ascending limb is mediated by three mechanisms that affect the $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symporter: rapid phosphorylation of the symporter, translocation of the symporter into the luminal membrane, and increased expression of symporter protein (Ecelbarger et al., 2001). Enhanced Na^+ transport in collecting duct is mediated by increased expression of subunits of the epithelial Na^+ channel (Ecelbarger et al., 2001). The multiple mechanisms by which vasopressin increases water reabsorption are summarized in Figure 25–22.

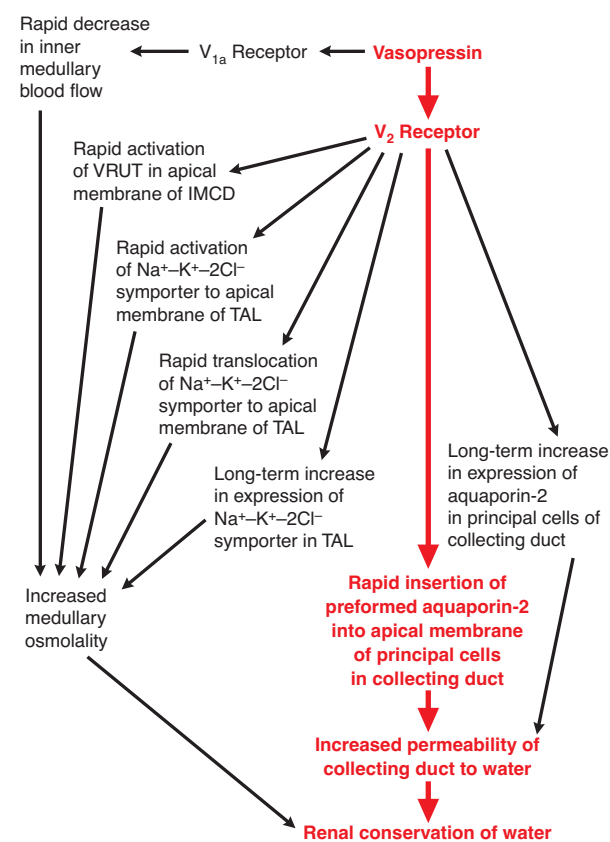

Figure 25–22. Mechanisms by which vasopressin increases the renal conservation of water. Red and black arrows denote major and minor pathways, respectively. IMCD, inner medullary collecting duct; TAL, thick ascending limb; VRUT, vasopressin-regulated urea transporter.

Renal Actions of Vasopressin. Several sites of vasopressin action in kidney involve both V_1 and V_2 receptors (Bankir, 2001). V_1 receptors mediate contraction of mesangial cells in the glomerulus and contraction of vascular smooth muscle cells in vasa recta and efferent arteriole. V_1 -receptor-mediated reduction of inner medullary blood flow contributes to the maximum concentrating capacity of the kidney (Franchini and Cowley, 1996) (Figure 25–22). V_1 receptors also stimulate prostaglandin synthesis by medullary interstitial cells. Since PGE_2 inhibits adenylyl cyclase in collecting duct, stimulation of prostaglandin synthesis by V_1 receptors may counterbalance V_2 -receptor-mediated antidiuresis. V_1 receptors on principal cells in cortical collecting duct may inhibit V_2 -receptor-mediated water flux by activation of PKC. V_2 receptors mediate the most prominent response to vasopressin, which is increased water permeability of the collecting duct. Indeed, vasopressin can increase water permeability in collecting duct at concentrations as low as 50 fM. Thus, V_2 -receptor-mediated effects of vasopressin occur at concentrations far lower than are required to engage V_1 -receptor-mediated actions. This differential sensitivity may not be due to differences in receptor affinities because cloned rat V_{1a} and V_2 receptors have similar affinities for vasopressin ($K_d = 0.7$ and 0.4 nM, respectively) but rather may be due to differential amplification of their signal-transduction pathways.

The collecting-duct system is critical for water conservation. By the time tubular fluid arrives at the cortical collecting duct, it has been rendered hypotonic by the upstream diluting segments of the nephron that reabsorb NaCl without reabsorbing water. In the well-hydrated subject, plasma osmolality is in the normal range, concentrations of vasopressin are low, the entire collecting duct is relatively impermeable to water, and the urine is dilute. Under conditions of dehydration, plasma osmolality is increased, concentrations of vasopressin are elevated, and the collecting duct becomes permeable to water. The osmotic gradient between dilute tubular urine and hypertonic renal interstitial fluid (which becomes progressively more hypertonic in deeper regions of the renal medulla) provides for osmotic flux of water out of the collecting duct. The final osmolality of urine may be as high as 1200 mOsm/kg in humans, and a significant saving of solute-free water thus is possible.

Other renal actions mediated by V_2 receptors include increased urea transport in inner medullary collecting duct and increased Na^+ transport in thick ascending limb; both effects contribute to the urine-concentrating ability of the kidney (Figure 25–22). V_2 receptors also increase Na^+ transport in cortical collecting duct (Ecelbarger et al., 2001), and this may synergize with aldosterone to enhance Na^+ reabsorption during hypovolemia.

Pharmacological Modification of the Antidiuretic Response to Vasopressin. Nonsteroidal anti-inflammatory drugs (NSAIDs), particularly indomethacin, enhance the

antidiuretic response to vasopressin. Since prostaglandins attenuate antidiuretic responses to vasopressin and NSAIDs inhibit prostaglandin synthesis, reduced prostaglandin production probably accounts for potentiation of vasopressin's antidiuretic response. Carbamazepine and chlorpropamide also enhance antidiuretic effects of vasopressin by unknown mechanisms. In rare instances, chlorpropamide can induce water intoxication.

A number of drugs inhibit the antidiuretic actions of vasopressin. Lithium is of particular importance because of its use in the treatment of manic-depressive disorders. Acutely, Li^+ appears to reduce V_2 -receptor-mediated stimulation of adenylyl cyclase. Also, Li^+ increases plasma levels of parathyroid hormone, a partial antagonist to vasopressin. In most patients, the antibiotic demeclocycline attenuates the antidiuretic effects of vasopressin, probably owing to decreased accumulation and action of cyclic AMP.

Nonrenal Actions of Vasopressin. Vasopressin and related peptides are ancient hormones in evolutionary terms, and they are found in species that do not concentrate urine. Thus, it is not surprising that vasopressin has nonrenal actions in mammals.

Cardiovascular System. The cardiovascular effects of vasopressin are complex, and vasopressin's role in physiological situations is ill-defined. Vasopressin is a potent vasoconstrictor (V_1 receptor-mediated), and resistance vessels throughout the circulation may be affected. Vascular smooth muscle in the skin, skeletal muscle, fat, pancreas, and thyroid gland appear most sensitive, with significant vasoconstriction also occurring in GI tract, coronary vessels, and brain. Despite the potency of vasopressin as a direct vasoconstrictor, vasopressin-induced pressor responses in vivo are minimal and occur only with vasopressin concentrations significantly higher than those required for maximal antidiuresis. To a large extent, this is due to circulating vasopressin actions on V_1 receptors to inhibit sympathetic efferents and potentiate baroreflexes. In addition, V_2 receptors cause vasodilation in some blood vessels.

A large body of data supports the conclusion that vasopressin helps to maintain arterial blood pressure during episodes of severe hypovolemia/hypotension. At present, there is no convincing evidence for a role of vasopressin in essential hypertension in humans (Kawano et al., 1997).

The effects of vasopressin on heart (reduced cardiac output and heart rate) are largely indirect and result from coronary vasoconstriction, decreased coronary blood flow, and alterations in vagal and sympathetic tone. In humans, vasopressin effects on coronary blood flow can be demonstrated easily, especially if large doses are employed. The cardiac actions of the hormone are of more than academic interest. Some patients with coronary insufficiency experience angina even in response to the relatively small amounts of vasopressin required to control diabetes insipidus, and vasopressin-induced myocardial ischemia has led to severe reactions and even death.

CNS. It is likely that vasopressin plays a role as a neurotransmitter and/or neuromodulator. Vasopressin may participate in the acquisition

of certain learned behaviors, in the development of some complex social processes, and in the pathogenesis of specific psychiatric diseases such as depression. However, the physiological/pathophysiological relevance of these findings is controversial, and some actions of vasopressin on memory and learned behavior may be due to visceral autonomic effects. Many studies support a physiological role for vasopressin as a naturally occurring antipyretic factor. Although vasopressin can modulate CNS autonomic systems controlling heart rate, arterial blood pressure, respiration rate, and sleep patterns, the physiological significance of these actions is unclear. Finally, ACTH secretion is enhanced by vasopressin released from parvicellular neurons in the PVN and secreted into pituitary portal capillaries from axon terminals in the median eminence. Although vasopressin is not the principal corticotropin-releasing factor, vasopressin may provide for sustained activation of the hypothalamic-pituitary-adrenal axis during chronic stress. CNS effects of vasopressin appear to be mediated predominantly by V_1 receptors.

Blood Coagulation. Activation of V_2 receptors by desmopressin or vasopressin increases circulating levels of procoagulant factor VIII and of von Willebrand factor. These effects are mediated by extrarenal V_2 receptors (Bernat et al., 1997). Presumably, vasopressin stimulates secretion of von Willebrand factor and of factor VIII from storage sites in vascular endothelium. However, since release of von Willebrand factor does not occur when desmopressin is applied directly to cultured endothelial cells or to isolated blood vessels, intermediate factors are likely to be involved.

Other Nonrenal Effects of Vasopressin. At high concentrations, vasopressin stimulates smooth muscle contraction in uterus (by oxytocin receptors) and GI tract (by V_1 receptors). Vasopressin is stored in platelets, and activation of V_1 receptors stimulates platelet aggregation. Also, activation of V_1 receptors on hepatocytes stimulates glycogenolysis. The physiological significance of these effects of vasopressin is not known.

VASOPRESSIN RECEPTOR AGONISTS AND ANTAGONISTS

A number of vasopressin-like peptides occur naturally (Table 25–8). All are nonapeptides, contain cysteine residues in positions 1 and 6, have an intramolecular disulfide bridge between the two cysteine residues (essential for agonist activity), have additional conserved amino acids in positions 5, 7, and 9 (asparagine, proline, and glycine, respectively), contain a basic amino acid in position 8, and are amidated on the carboxyl terminus. In all mammals except swine, the neurohypophyseal peptide is 8-arginine vasopressin, and the terms vasopressin, arginine vasopressin (AVP), and antidiuretic hormone (ADH) are used interchangeably.

The chemical structure of oxytocin is closely related to that of vasopressin: oxytocin is [Ile^3 , Leu^8]AVP. Oxytocin binds to specific oxytocin receptors on myoepithelial cells in mammary gland and on

Table 25–8

smooth muscle cells in the uterus, causing milk ejection and uterine contraction, respectively. Inasmuch as vasopressin and oxytocin are structurally similar, it is not surprising that vasopressin and oxytocin agonists and antagonists can bind to each other's receptors. Therefore, most of the available peptide vasopressin agonists and antagonists have some affinity for oxytocin

receptors; at high doses, they may block or mimic the effects of oxytocin.

Many vasopressin analogs were synthesized with the goal of increasing duration of action and selectivity for vasopressin receptor subtypes (*V₁* versus *V₂* vasopressin receptors, which mediate pressor responses and antidiuretic responses, respectively). Deamination at position 1 increases duration of action and increases

antidiuretic activity without increasing vasopressor activity. Substitution of D-arginine for L-arginine greatly reduces vasopressor activity without reducing antidiuretic activity. Thus, the antidiuretic-to-vasopressor ratio for 1-deamino-8-D-arginine vasopressin (Table 25–8), also called desmopressin (DDAVP, MINIRIN, STIMATE, others), is ~3000 times greater than that for vasopressin, and desmopressin now is the preferred drug for the treatment of central diabetes insipidus. Substitution of valine for glutamine in position 4 further increases the antidiuretic selectivity, and the antidiuretic to vasopressor ratio for deamino [Val⁴, D-Arg⁸]AVP (Table 25–8) is ~11,000 times greater than that for vasopressin. Nakamura and colleagues (2000) synthesized a nonpeptide V₂-receptor agonist (Table 25–8).

Increasing V₁ selectivity has proved more difficult than increasing V₂ selectivity, but a limited number of agonists with modest selectivity for V₁ receptors have been developed (Table 25–8). Vasopressin receptors in the adenohypophysis that mediate vasopressin-induced ACTH release are neither classical V₁ nor V₂ receptors. Since vasopressin receptors in the adenohypophysis appear to share a common signal-transduction mechanism with classical V₁ receptors, and since many vasopressin analogs with vasoconstrictor activity release ACTH, V₁ receptors have been subclassified into V_{1a} (vascular/hepatic) and V_{1b} (pituitary) receptors. V_{1b} receptors are also called V₃ receptors. Vasopressin analogs that are agonists selective for V_{1a} or V_{1b} receptors have been described (Table 25–8).

Chemistry of Vasopressin Receptor Antagonists. The impetus for the development of specific vasopressin receptor antagonists is the belief that such drugs may be useful in a number of clinical settings. Based on receptor physiology, selective V_{1a} antagonists may be beneficial when total peripheral resistance is increased (e.g., congestive heart failure and hypertension), whereas selective V₂ antagonists could be useful whenever reabsorption of solute-free water is excessive (e.g., the syndrome of inappropriate secretion of antidiuretic hormone [SIADH] and hyponatremia associated with a reduced effective blood volume). Combined V_{1a}/V₂ receptor antagonists might be beneficial in diseases associated with a combination of increased peripheral resistance and dilutional hyponatremia (e.g., congestive heart failure).

Highly selective V₁ and V₂ peptide antagonists that are structural analogs of vasopressin have been synthesized (see Table 25–9 for examples), including both cyclic and linear peptides. [1-(β-Mercapto-β, β-cyclopentamethylenepropionic acid), 2-O-methyltyrosine] arginine vasopressin, also known as d(CH₂)₅[Tyr(Me)²]AVP, has a greater affinity for V_{1a} receptors than for either V_{1b} or V₂ receptors; this antagonist has been employed widely in physiological and pharmacological studies. Although [1-deaminopenicillamine, 2-O-methyltyrosine] arginine vasopressin, also called dP[Tyr(Me)²]AVP, is a potent V_{1b} receptor antagonist with little affinity for the V₂ receptor, it also blocks V_{1a} receptors. No truly selective peptide V_{1b}-receptor antagonist is available. Peptide antagonists have limited oral activity, and the potency of peptide V₂ antagonists is species dependent.

DISEASES AFFECTING THE VASOPRESSIN SYSTEM

Diabetes Insipidus (DI). DI is a disease of impaired renal water conservation owing either to inadequate

vasopressin secretion from the neurohypophysis (central DI) or to insufficient renal vasopressin response (nephrogenic DI). Very rarely, DI can be caused by an abnormally high degradation rate of vasopressin by circulating vasopressinases. Pregnancy may accentuate or reveal central and/or nephrogenic DI by increasing plasma levels of vasopressinase and by reducing renal sensitivity to vasopressin. Patients with DI excrete large volumes (>30 mL/kg per day) of dilute (<200 mOsm/kg) urine and, if their thirst mechanism is functioning normally, are polydipsic. In contrast to the sweet urine excreted by patients with diabetes mellitus, urine from patients with DI is tasteless, hence the name insipidus.

The urinary taste test for DI has been supplanted by the approach of observing whether the patient is able to reduce urine volume and increase urine osmolality after a period of carefully observed fluid deprivation. Central DI can be distinguished from nephrogenic DI by administration of desmopressin, which will increase urine osmolality in patients with central DI but have little or no effect in patients with nephrogenic DI. DI can be differentiated from primary polydipsia by measuring plasma osmolality, which will be low to low-normal in patients with primary polydipsia and high to high-normal in patients with DI. For a more complete discussion of diagnostic procedures, see Robertson (2001).

Central DI. Head injury, either surgical or traumatic, in the region of the pituitary and/or hypothalamus may cause central DI. Postoperative central DI may be transient, permanent, or triphasic (recovery followed by permanent relapse). Other causes include hypothalamic or pituitary tumors, cerebral aneurysms, CNS ischemia, and brain infiltrations and infections (Robertson, 2001). Central DI may also be idiopathic or familial. Familial central DI usually is autosomal dominant (chromosome 20), and vasopressin deficiency occurs several months or years after birth and worsens gradually. Autosomal dominant central DI is linked to mutations in the vasopressin prohormone gene that cause the prohormone to misfold and oligomerize improperly. The long-term result is accumulation of the mutant vasopressin precursor in the affected neuron because the precursor cannot move from the endoplasmic reticulum into the secretory pathway. Accumulation of mutant vasopressin precursor causes neuronal death, hence the dominant mode of inheritance (Robertson, 2001). Rarely, familial central DI is autosomal recessive owing to a mutation in the vasopressin peptide itself that gives rise to an inactive vasopressin mutant.

Antidiuretic peptides are the primary treatment for central DI, with desmopressin being the peptide of choice. For patients with central DI who cannot tolerate antidiuretic peptides because of side effects or allergic reactions, other treatment options are available.

Chlorpropamide, an oral sulfonylurea, potentiates the action of small or residual amounts of circulating vasopressin and will reduce urine volume in more than half of all patients with central DI. Doses of 125-500 mg daily appear effective in patients with partial central DI. If polyuria is not controlled satisfactorily with chlorpropamide alone, addition of a thiazide diuretic to the regimen usually results in an adequate reduction in urine volume. Carbamazepine (800-1000 mg daily in divided doses) also reduces urine volume in patients with central DI. Long-term use may induce serious adverse effects; therefore, carbamazepine is used rarely to treat central DI. The antidiuretic mechanisms of chlorpropamide, carbamazepine, and clofibrate (not available in the U.S.) are not clear. These agents are not effective in nephrogenic DI, which indicates that functional V_2 receptors are required for the antidiuretic effect. Since carbamazepine inhibits and chlorpropamide has little effect on vasopressin secretion, it is likely that carbamazepine and chlorpropamide act directly on the kidney to enhance V_2 -receptor-mediated antidiuresis.

Nephrogenic DI. Nephrogenic DI may be congenital or acquired. Hypercalcemia, hypokalemia, postobstructive renal failure, Li^+ , foscarnet, clozapine, demeclocycline, and other drugs can induce nephrogenic DI. As many as one in three patients treated with Li^+ may develop nephrogenic DI.

X-linked nephrogenic DI is caused by mutations in the gene encoding the V_2 receptor, which maps to Xq28. A number of missense, nonsense, and frame-shift mutations in the gene encoding the V_2 receptor were identified in patients with this disorder. Mutations in the V_2 -receptor gene may cause impaired routing of the V_2 receptor to the cell surface, defective coupling of the receptor to G proteins, or decreased receptor affinity for vasopressin. The effects of these mutations range from a complete loss of responsiveness to vasopressin to a shift to the left of the concentration-response curve. Autosomal recessive and dominant nephrogenic DI result from inactivating mutations in aquaporin 2. These findings indicate that aquaporin 2 is essential for the antidiuretic effect of vasopressin in humans.

Although the mainstay of treatment of nephrogenic DI is assurance of an adequate water intake, drugs also can be used to reduce polyuria. Amiloride blocks Li^+ uptake by the Na^+ channel in the collecting-duct system and may be effective in patients with mild to moderate concentrating defects. Patients with severe disease often do not respond. Thiazide *diuretics* reduce the polyuria of patients with DI and often are used to treat nephrogenic DI. The use of thiazide diuretics in infants with nephrogenic DI may be crucially important because uncontrolled polyuria may exceed the child's capacity to imbibe and absorb fluids. The antidiuretic mechanism of thiazides in DI is incompletely understood. It is possible that the natriuretic action of thiazides and resulting extracellular fluid volume depletion play an important role in thiazide-induced antidiuresis. In this regard, whenever extracellular fluid volume is reduced, compensatory mechanisms increase $NaCl$ reabsorption in proximal tubule, reducing the volume delivered to the distal tubule. Consequently, less free water can be formed, which should diminish polyuria. However, studies in rats with vasopressin-deficient DI challenge this hypothesis. Nonetheless, the antidiuretic effects appear to parallel the thiazide's ability to cause natriuresis, and the drugs are given in doses similar to those used to mobilize edema fluid. In

patients with DI, a 50% reduction of urine volume is a good response to thiazides. Moderate restriction of Na^+ intake can enhance the antidiuretic effectiveness of thiazides.

A number of case reports describe the effectiveness of indomethacin in the treatment of nephrogenic DI; however, other prostaglandin synthase inhibitors (e.g., ibuprofen) appear to be less effective. The mechanism of the effect may involve a decrease in glomerular filtration rate, an increase in medullary solute concentration, and/or enhanced proximal fluid reabsorption. Also, since prostaglandins attenuate vasopressin-induced antidiuresis in patients with at least a partially intact V_2 -receptor system, some of the antidiuretic response to indomethacin may be due to diminution of the prostaglandin effect and enhancement of vasopressin effects on the principal cells of collecting duct.

Syndrome of Inappropriate Secretion of Antidiuretic Hormone (SIADH). SIADH is a disease of impaired water excretion with accompanying hyponatremia and hypo-osmolality caused by the *inappropriate* secretion of vasopressin. Clinical manifestations of plasma hypotonicity resulting from SIADH may include lethargy, anorexia, nausea and vomiting, muscle cramps, coma, convulsions, and death. A multitude of disorders can induce SIADH (Robertson, 2001), including malignancies, pulmonary diseases, CNS injuries/diseases (e.g., head trauma, infections, and tumors), and general surgery.

The three drug classes most commonly implicated in drug-induced SIADH include psychotropic medications (e.g., selective serotonin reuptake inhibitors, haloperidol, and tricyclic antidepressants), sulfonylureas (e.g., chlorpropamide), and vinca alkaloids (e.g., vincristine and vinblastine). Other drugs strongly associated with SIADH include clonidine, cyclophosphamide, enalapril, felbamate, ifosfamide, and methyl dopa, pentamidine, and vinorelbine. In a normal individual, an elevation in plasma vasopressin *per se* does not induce plasma hypotonicity because the person simply stops drinking owing to an osmotically induced aversion to fluids. Therefore, plasma hypotonicity only occurs when excessive fluid intake (oral or intravenous) accompanies inappropriate secretion of vasopressin. Treatment of hypotonicity in the setting of SIADH includes water restriction, intravenous administration of hypertonic saline, loop diuretics (which interfere with kidney's concentrating ability), and drugs that inhibit the effect of vasopressin to increase water permeability in collecting ducts. To inhibit vasopressin's action in collecting ducts, demeclocycline, a tetracycline, has been the preferred drug, but tolvaptan and conivaptan, V_2 receptor antagonists, are now available (see next section and Table 25-9).

Although Li^+ can inhibit the renal actions of vasopressin, it is effective in only a minority of patients, may induce irreversible renal damage when used chronically, and has a low therapeutic index.

712 Therefore, Li^+ should be considered for use only in patients with symptomatic SIADH who cannot be controlled by other means or in whom tetracyclines are contraindicated (e.g., patients with liver disease). It is important to stress that the majority of patients with SIADH do not require therapy because plasma Na^+ stabilizes in the range of 125-132 mM; such patients usually are asymptomatic. Only when symptomatic hypotonicity ensues, generally when plasma Na^+ levels drop below 120 mM, should therapy with demeclocycline be initiated. Since hypotonicity, which causes an influx of water into cells with resulting cerebral swelling, is the cause of symptoms, the goal of therapy is simply to increase plasma osmolality toward normal. For a more complete description of the diagnosis and treatment of SIADH, see Robertson (2001).

Other Water-Retaining States. In patients with congestive heart failure, cirrhosis, or nephrotic syndrome, *effective* blood volume often is reduced, and hypovolemia frequently is exacerbated by the liberal use of diuretics. Since hypovolemia stimulates vasopressin release, patients may become hyponatremic owing to vasopressin-mediated retention of water. The development of potent orally active V_2 receptor antagonists and specific inhibitors of water channels in the collecting duct has provided a new therapeutic strategy not only in patients with SIADH but also in the more common setting of hyponatremia in patients with heart failure, liver cirrhosis, and nephrotic syndrome, as discussed in the next section.

CLINICAL PHARMACOLOGY OF VASOPRESSIN PEPTIDES

Agonists

Therapeutic Uses. Two antidiuretic peptides are available for clinical use in the U.S.:

- Vasopressin (synthetic 8-L-arginine vasopressin; PITRESSIN, others) is available as a sterile aqueous solution; it may be administered subcutaneously, intramuscularly, or intranasally.
- Desmopressin acetate (synthetic 1-deamino-8-D-arginine vasopressin; DDAVP, others) is available as a sterile aqueous solution packaged for intravenous or subcutaneous injection, in a solution for intranasal administration with either a nasal spray pump or rhinal tube delivery system, and in tablets for oral administration.

The therapeutic uses of vasopressin and its congeners can be divided into two main categories according to the type of vasopressin receptor involved.

V_1 receptor-mediated therapeutic applications are based on the rationale that V_1 receptors cause GI and vascular smooth muscle contraction. V_1 receptor-mediated GI smooth muscle contraction has been used to treat postoperative ileus and abdominal distension and to displace intestinal gas before abdominal roentgenography to

avoid interfering gas shadows. V_1 receptor-mediated vasoconstriction of the splanchnic arterial vessels reduces blood flow to the portal system and, thereby, attenuates pressure and bleeding in esophageal varices (Burroughs, 1998). Although endoscopic variceal banding ligation is the treatment of choice for bleeding esophageal varices, V_1 receptor agonists have been used in an emergency setting until endoscopy can be performed (Vlavianos and Westaby, 2001). Simultaneous administration of nitroglycerin with V_1 receptor agonists may attenuate the cardiotoxic effects of V_1 agonists while enhancing their beneficial splanchnic effects. Also, V_1 receptor agonists have been used during abdominal surgery in patients with portal hypertension to diminish the risk of hemorrhage during the procedure. Finally, V_1 receptor-mediated vasoconstriction has been used to reduce bleeding during acute hemorrhagic gastritis, burn wound excision, cyclophosphamide-induced hemorrhagic cystitis, liver transplant, cesarean section, and uterine myoma resection.

The applications of V_1 receptor agonists can be accomplished with vasopressin; however, the use of vasopressin for all these indications is no longer recommended because of significant adverse reactions. Terlipressin (LUCASSIN) is preferred for bleeding esophageal varices because of increased safety compared with vasopressin (Vlavianos and Westaby, 2001) and is designated as an orphan drug for this use. Moreover, terlipressin is effective in patients with hepatorenal syndrome, particularly when combined with albumin (Ortega et al., 2002). Terlipressin has been granted priority review, orphan drug status, and fast-track designation by the FDA for type I hepatorenal syndrome.

Vasopressin levels in patients with vasodilatory shock are inappropriately low, and such patients are extraordinarily sensitive to the pressor actions of vasopressin. The combination of vasopressin and norepinephrine is superior to norepinephrine alone in the management of catecholamine-resistant vasodilatory shock. However, recent clinical trials show that, in comparison to catecholamines alone, addition of vasopressin does not improve outcomes in either cardiac arrest or septic shock.

V_2 receptor-mediated therapeutic applications are based on the rationale that V_2 receptors cause water conservation and release of blood coagulation factors. Central but not nephrogenic DI can be treated with V_2 receptor agonists, and polyuria and polydipsia usually are well controlled by these agents. Some patients experience transient DI (e.g., in head injury or surgery in the area of the pituitary); however, therapy for most patients with DI is lifelong. Desmopressin is the drug of choice for the vast majority of patients, and numerous clinical trials demonstrated the efficacy and tolerability of desmopressin in both adults and children.

The duration of effect from a single intranasal dose is from 6-20 hours; twice-daily administration is effective in most patients. There is considerable variability in the intranasal dose of desmopressin required to maintain normal urine volume, and the dosage must be tailored individually. The usual intranasal dosage in adults

is 10–40 μg daily either as a single dose or divided into two or three doses. In view of the high cost of the drug and the importance of avoiding water intoxication, the schedule of administration should be adjusted to the minimal amount required. An initial dose of 2.5 μg can be used, with therapy first directed toward control of nocturia. An equivalent or higher morning dose controls daytime polyuria in most patients, although a third dose occasionally may be needed in the afternoon. In some patients, chronic allergic rhinitis or other nasal pathology may preclude reliable peptide absorption following nasal administration. Oral administration of desmopressin in doses 10–20 times the intranasal dose provides adequate desmopressin blood levels to control polyuria. Subcutaneous administration of 1–2 μg daily of desmopressin also is effective in central DI.

Vasopressin has little, if any, place in the long-term therapy of DI because of its short duration of action and V_1 receptor-mediated side effects. Vasopressin can be used as an alternative to desmopressin in the initial diagnostic evaluation of patients with suspected DI and to control polyuria in patients with DI who recently have undergone surgery or experienced head trauma. Under these circumstances, polyuria may be transient, and long-acting agents may produce water intoxication.

An additional V_2 receptor-mediated therapeutic application is the use of desmopressin in bleeding disorders (Mannucci, 1997). In most patients with type I von Willebrand's disease (vWD) and in some with type II vWD, desmopressin will elevate von Willebrand factor and shorten bleeding time. However, desmopressin generally is ineffective in patients with types IIa, IIb, and III vWD. Desmopressin may cause a marked transient thrombocytopenia in individuals with type IIb vWD and is contraindicated in such patients. Desmopressin also increases factor VIII levels in patients with mild to moderate hemophilia A. Desmopressin is not indicated in patients with severe hemophilia A, those with hemophilia B, or those with factor VIII antibodies. Using a test dose of nasal spray, the response of any given patient with type I vWD or hemophilia A to desmopressin should be determined at the time of diagnosis or 1–2 weeks before elective surgery to assess the extent of increase in factor VIII or von Willebrand factor. Desmopressin is employed widely to treat the hemostatic abnormalities induced by uremia. In patients with renal insufficiency, desmopressin shortens bleeding time and increases circulating levels of factor VIII coagulant activity, factor VIII-related antigen, and ristocetin cofactor. It also induces the appearance of larger von Willebrand factor multimers. Desmopressin is effective in some patients with liver cirrhosis-induced or drug-induced (e.g., heparin, hirudin, and antiplatelet agents) bleeding disorders. Desmopressin, given intravenously at a dose of 0.3 $\mu\text{g}/\text{kg}$, increases factor VIII and von Willebrand factor for > 6 hours. Desmopressin can be given at intervals of 12–24 hours depending on the clinical response and severity of bleeding. Tachyphylaxis to desmopressin usually occurs after several days (owing to depletion of factor VIII and von Willebrand factor storage sites) and limits its usefulness to preoperative preparation, postoperative bleeding, excessive menstrual bleeding, and emergency situations.

Another V_2 receptor-mediated therapeutic application is the use of desmopressin for primary nocturnal enuresis. Bedtime administration of desmopressin intranasal spray or tablets provides a high response rate

that is sustained with long-term use, that is safe, and that accelerates the cure rate. Finally, desmopressin has been found to relieve post-lumbar puncture headache probably by causing water retention and thereby facilitating rapid fluid equilibration in the CNS.

Pharmacokinetics. When vasopressin and desmopressin are given orally, they are inactivated quickly by trypsin, which cleaves the peptide bond between amino acids 8 and 9.

Inactivation by peptidases in various tissues (particularly liver and kidney) results in a plasma $t_{1/2}$ of vasopressin of 17–35 minutes. Following intramuscular or subcutaneous injection, antidiuretic effects of vasopressin last 2–8 hours. The plasma $t_{1/2}$ of desmopressin has two components, a fast component (~8 min) and a slow component (30–117 min). Only 3% and 0.15%, respectively, of intranasally and orally administered desmopressin is absorbed.

Toxicity, Adverse Effects, Contraindications, Drug Interactions. Most adverse effects are mediated through V_1 receptor activation on vascular and GI smooth muscle; consequently, such adverse effects are much less common and less severe with desmopressin than with vasopressin.

After injection of large doses of vasopressin, marked facial pallor owing to cutaneous vasoconstriction is observed commonly. Increased intestinal activity is likely to cause nausea, belching, cramps, and an urge to defecate. Most serious, however, is the effect on the coronary circulation. Vasopressin should be administered only at low doses and with extreme caution in individuals suffering from vascular disease, especially coronary artery disease. Other cardiac complications include arrhythmia and decreased cardiac output. Peripheral vasoconstriction and gangrene were encountered in patients receiving large doses of vasopressin.

The major V_2 receptor-mediated adverse effect is water intoxication, which can occur with desmopressin or vasopressin. In this regard, many drugs, including carbamazepine, chlorpropamide, morphine, tricyclic antidepressants, and NSAIDs, can potentiate the antidiuretic effects of these peptides. Several drugs such as Li^+ , demeclocycline, and ethanol can attenuate the antidiuretic response to desmopressin. Desmopressin and vasopressin should be used cautiously in disease states in which a rapid increase in extracellular water may impose risks (e.g., in angina, hypertension, and heart failure) and should not be used in patients with acute renal failure. Patients receiving desmopressin to maintain hemostasis should be advised to reduce fluid intake. Also, it is imperative that these peptides not be administered to patients with primary or psychogenic polydipsia because severe hypotonic hyponatremia will ensue.

Mild facial flushing and headache are the most common adverse effects associated with desmopressin. Allergic reactions ranging from urticaria to anaphylaxis may occur with desmopressin or vasopressin. Intranasal administration may cause local adverse effects in the nasal passages, such as edema, rhinorrhea, congestion, irritation, pruritus, and ulceration.

Vasopressin Receptor Antagonists

Table 25–9 lists the structures and selectivity of receptor antagonists.

Therapeutic Uses. When the kidney perceives the arterial blood volume to be low (as in the disease states of CHF, cirrhosis, and nephrosis), AVP perpetuates a state of total body salt and water excess. V_2 receptor (V_2R) antagonists or “aquaretics” may have a therapeutic role in these conditions, especially in patients with concomitant hyponatremia. They are also effective in hyponatremia associated with SIADH. Aquaretics increase renal free water excretion with little or no change in electrolyte excretion. Since they do not affect Na^+ reabsorption they do not stimulate the TGF mechanism with its associated consequence of reducing GFR. Conivaptan, a $V_{1a}R/V_2R$ antagonist, and tolvaptan, a selective V_2R antagonist, are FDA-approved for use in patients with euvolemic or hypervolemic hyponatremia associated with SIADH. The V_2R antagonist mozavaptan is approved in Japan for the treatment hyponatremia secondary to SIADH caused by malignancy. Although a large number of vasopressin receptor antagonists are in preclinical and clinical trials, we will discuss only the V_2R antagonists mozavaptan and tolvaptan, and the $V_{1a}R/V_2R$ antagonist conivaptan (Costello-Boerriqter et al., 2009).

Mozavaptan. Mozavaptan was the first nonpeptide V_2 receptor antagonist in clinical use. It was approved for treatment of SIADH secondary to cancer in Japan in 1996. Mozavaptan causes a dose-dependent increase in free water excretion with only slight increases in urinary Na^+ and K^+ excretion.

Tolvaptan. Tolvaptan (SAMSCA) is a selective oral V_2R antagonist developed through structural modifications of mozavaptan to create a more selective V_2R antagonist. In short-term clinical trials in patients with CHF and reduced ejection fraction, the drug decreased body weight and improved dyspnea. In long-term trials, there was no effect on all-cause mortality, cardiovascular death, or hospitalization for heart failure; losses in body weight and increases in Na^+ concentration were sustained over the course of the studies. Tolvaptan is approved for clinically significant hypervolemic and euvolemic hyponatremia. The drug is labeled with a

black box warning against too rapid correction of hyponatremia (can have serious and fatal consequences) and the recommendation to initiate therapy in a hospital setting capable of close monitoring of serum Na^+ . Tolvaptan is contraindicated in patients receiving drugs that inhibit CYP3A4.

Conivaptan. Conivaptan (VAPRISOL) is a nonselective $V_{1a}R/V_2R$ antagonist that is FDA-approved for the treatment of hospitalized patients with euvolemic hyponatremia and hypervolemic hyponatremia. The drug is available only for intravenous infusion. In CHF patients, conivaptan increases renal free water excretion without a change in systemic vascular resistance. The manufacturer recommends starting administration with a 20 mg loading dose given over 30 minutes followed by a continuous infusion of an additional 20 mg over the first 24 hours. The infusion is then continued at 20 mg/day for a maximum of three additional days. The dose can be increased to 40 mg/day if there is no response to the 20 mg dose. Doses higher than 40 mg/day have no additional benefit. Serum Na^+ concentration should not be increased >12 mEq/L in a 24-hour period.

Pharmacokinetics

Mozavaptan. Mozavaptan is available in 30-mg tablets. Few data are available regarding its pharmacokinetics. It binds to the V_2R with much higher affinity than $V_{1a}R$, K_i 9.42 ± 0.9 nM versus 150 ± 15 nM, respectively. Its peak effects occur 60–90 minutes after an oral dose.

Tolvaptan. Tolvaptan is available in 15 and 30 mg tablets and inhibits the V_2R with a K_i of 0.43 ± 0.06 nM and the $V_{1a}R$ with a K_i of 12.3 ± 0.8 nM. Tolvaptan is 29 times more selective for the V_2R than the $V_{1a}R$. Most of its effects on renal free water excretion occur in the first 6–8 hours after administration. Tolvaptan has a $t_{1/2}$ of 6–8 hours and $<1\%$ is excreted in the urine. The starting dose is 15 mg once daily, and this dose can be titrated up to a maximum of 60 mg daily. Tolvaptan is a substrate and inhibitor of P-glycoprotein and is eliminated entirely by CYP3A metabolism.

Conivaptan. Conivaptan inhibits the $V_{1a}R$ with a K_i of 6.3 ± 1.8 nM and the V_2R with a K_i of 1.1 ± 0.2 nM. Total body clearance is 9.5–10.1 L/hr. It is highly protein bound and has a terminal elimination $t_{1/2}$ of 5–12 hours. Conivaptan is metabolized via CYP3A4 and is partially excreted by the kidney. Caution should be exercised in those with hepatic and renal disease. At higher doses clearance may be reduced in the elderly.

Toxicity, Adverse Effects, Contraindications, Drug Interactions

Mozavaptan. Mozavaptan’s major side effects are dry mouth and abnormal liver function tests.

Tolvaptan. Tolvaptan is eliminated by CYP3A4. Plasma concentrations of the drug are increased by ketoconazole. There is no known affect on amiodarone, digoxin, or warfarin metabolism. Among the

V_2 antagonistic activity in rats; however, antagonistic activity may be less or nonexistent in other species. Also, with prolonged infusion may exhibit significant agonist activity. ^cAvailable for clinical use.

adverse effects listed for tolvaptan are GI effects, hyperglycemia, and pyrexia. Less common are cerebrovascular accident, deep vein thrombosis, disseminated intravascular coagulation, intracardiac thrombus, ventricular fibrillation, urethral hemorrhage, vaginal hemorrhage, pulmonary embolism, respiratory failure, diabetic ketoacidosis, ischemic colitis, increase in prothrombin time and rhabdomyolysis.

Conivaptan. Conivaptan is metabolized by CYP3A4 and as a result is associated with a variety of drug-drug interactions. It should not be administered in patients receiving ketoconazole, itraconazole, ritonavir, indinavir, clarithromycin, or other strong CYP3A4 inhibitors. Conivaptan increases levels of simvastatin, digoxin, amlodipine, and midazolam. It is not known to interact with warfarin or prolong the QT_c interval. Due to multiple drug-drug interactions conivaptan is no longer being developed for chronic long-term oral use. The most common adverse effect of conivaptan is an infusion site reaction. The manufacturer recommends that the drug only be infused into large veins and that infusion sites be changed daily. Other adverse effects have included headache, hypertension, hypokalemia, and pyrexia.

Future Directions in Vasopressin Analogs

Nonpeptide vasopressin receptor antagonists and agonists are being developed for a wide range of clinical indications, including for V_{1a} -selective antagonists: dysmenorrhea, preterm labor, and Raynaud's syndrome; for V_{1b} -selective antagonists: stress-related disorders, anxiety, depression, ACTH-secreting tumors, and Cushing's syndrome; for V_2 -selective and V_{1a}/V_2 -selective antagonists: heart failure, SIADH, cirrhosis, hyponatremia, brain edema, nephrotic syndrome, diabetic nephropathy, and glaucoma; and for V_2 -selective agonists: central DI, nocturnal enuresis, nocturnal polyuria, and urinary incontinence (Wong and Verbalis, 2001).

Preliminary data support several of the indications mentioned earlier for vasopressin receptor antagonists and agonists. Relcovaptan (SR 49059) is a V_{1a} -selective antagonist that has efficacy in primary dysmenorrhea (Brouard et al., 2000), and nelivaptan (SSR 149415) is a V_{1b} -selective antagonist that demonstrates anxiolytic activity in animal models of stress (Griebel et al., 2002). Aquaretics are drugs that increase free-water clearance with minimal effects on electrolyte excretion. The V_2 -selective antagonist lixivaptan (VPA-985) is an effective aquaretic in patients with hyponatremia of various etiologies (Wong et al., 2003). In contrast, the V_2 -selective agonist OPC-51803 has strong antidiuretic effects in animals and is being developed for central DI, nocturnal enuresis, and urinary incontinence (Nakamura et al., 2003). It is likely that more nonpeptide vasopressin receptor antagonists and agonists will become available clinically in the near future.

chapter

Renin and Angiotensin

Randa Hilal-Dandan

The renin–angiotensin system (RAS) participates significantly in the pathophysiology of hypertension, congestive heart failure, myocardial infarction, and diabetic nephropathy. This realization has led to a thorough exploration of the RAS and the development of new approaches for inhibiting its actions. This chapter discusses the biochemistry, molecular and cellular biology, and physiology of the RAS; the pharmacology of drugs that interrupt the RAS; and the clinical utility of inhibitors of the RAS. Therapeutic applications of drugs covered in this chapter are also discussed in Chapters 27 and 28.

THE RENIN–ANGIOTENSIN SYSTEM

History. In 1898, Tiegerstedt and Bergman found that crude saline extracts of the kidney contained a pressor substance that they named *renin*. In 1934, Goldblatt and his colleagues demonstrated that constriction of the renal arteries produced persistent hypertension in dogs. In 1940, Braun-Menéndez and his colleagues in Argentina and Page and Helmer in the U.S. reported that renin was an enzyme that acted on a plasma protein substrate to catalyze the formation of the actual pressor material, a peptide, that was named *hypertensin* by the former group and *angiotonin* by the latter. These two terms persisted for nearly 20 years until it was agreed to rename the pressor substance *angiotensin* and to call the plasma substrate *angiotensinogen*. In the mid-1950s, two forms of angiotensin were recognized, a decapeptide (angiotensin I [AngI]) and an octapeptide (angiotensin II [AngII]) formed by proteolytic cleavage of AngI by an enzyme termed *angiotensin-converting enzyme* (ACE). The octapeptide was shown to be the more active form, and its synthesis in 1957 by Schwyzler and by Bumpus made the material available for intensive study.

It was later shown that the kidneys are important for aldosterone regulation and that angiotensin potently stimulates the production of aldosterone in humans. Moreover, renin secretion increased with depletion of Na^+ . Thus, the RAS came to be recognized as a mechanism to stimulate aldosterone synthesis and secretion and an important homeostatic mechanism in the regulation of blood pressure and electrolyte composition.

In the early 1970s, polypeptides were discovered that either inhibited the formation of AngII or blocked AngII receptors. These inhibitors revealed important physiological and pathophysiological roles for the RAS and inspired the development of a new and broadly efficacious class of antihypertensive drugs: the orally active ACE inhibitors. Studies with ACE inhibitors uncovered roles for the RAS in the pathophysiology of hypertension, heart failure, vascular disease, and renal failure. Selective and competitive antagonists of AngII receptors were developed that yielded losartan, the first orally active, highly selective, and potent nonpeptide AngII receptor antagonist. Subsequently, many other AngII receptor antagonists have been developed. Recently aliskiren, a direct renin inhibitor, was approved for antihypertensive therapy (see Chapter 27).

Components of the Renin–Angiotensin System

Overview. AngII, the most active angiotensin peptide, is derived from angiotensinogen in two proteolytic steps. First, renin, an enzyme released from the kidneys, cleaves the decapeptide AngI from the amino terminus of angiotensinogen (renin substrate). Then, ACE removes the carboxy-terminal dipeptide of AngI to produce the octapeptide AngII. These enzymatic steps are summarized in Figure 26–1. AngII acts by binding to two heptahelical GPCRs, AT_1 and AT_2 .

The understanding of the RAS has expanded in recent years. The current view of the RAS also includes a local (tissue) RAS, alternative pathways for AngII synthesis (ACE independent), formation of other biologically active angiotensin peptides (AngIII, AngIV, Ang[1–7]), and additional angiotensin binding receptors (angiotensin subtypes 1, 2, and 4 [AT_1 , AT_2 , AT_4]; Mas) that participate in cell growth differentiation, hypertrophy, inflammation, fibrosis, and apoptosis. All components of the RAS are described in detail in a later section.

Renin. Renin is the major determinant of the rate of AngII production. It is synthesized, stored, and secreted by exocytosis into the

Figure 26–2. **A.** Schematic portrayal of the three major physiological pathways regulating renin release. See text for details. MD, macula densa; PGI₂/PGE₂, prostaglandins I₂ and E₂; NSAIDs, nonsteroidal antiinflammatory drugs; Ang II, angiotensin II; ACE, angiotensin-converting enzyme; AT₁ R, angiotensin subtype 1 receptor; NE/Epi, norepinephrine/epinephrine; JGCs, juxtaglomerular cells. **B.** Mechanisms by which the macula densa regulates renin release. Changes in tubular delivery of NaCl to the macula densa cause appropriate signals to be conveyed to the juxtaglomerular cells. Sodium depletion upregulates nNOS and COX-2 in the macula densa to enhance production of prostaglandins (PGs). PGs and catecholamines stimulate cyclic AMP production and thence renin release from the juxtaglomerular cells. Increased NaCl transport depletes ATP and increases adenosine (ADO) levels. Adenosine diffuses to the juxtaglomerular cells and inhibits cyclic AMP production and renin release via G_i-coupled A₁ receptors. Increased NaCl transport in the macula densa augments the efflux of ATP, which may inhibit renin release directly by binding to P2Y receptors and activating the G_q-PLC-IP₃-Ca²⁺ pathway in juxtaglomerular cells. Circulating AngII also inhibits renin release on juxtaglomerular cells via G_q-coupled AT₁ receptors.

Figure 26-3. Biological activation of prorenin and pharmacological inhibition of renin. Pro-renin (black segment) is inactive; accessibility of angiotensinogen (AGT) to the active is blocked by the propeptide (black segment). The blocked catalytic site can be activated non-proteolytically by the binding of prorenin to the (pro) renin receptor (PRR) or by proteolytic removal of the propeptide. The competitive renin inhibitor, aliskiren, has a higher affinity ($\sim 0.1 \mu\text{M}$) for the active site of renin than does AGT ($\sim 1 \mu\text{M}$).

The second mechanism controlling renin release is the *intrarenal baroreceptor pathway*. Increases and decreases in blood pressure or renal perfusion pressure in the preglomerular vessels inhibit and stimulate renin release, respectively. The immediate stimulus to secretion is believed to be reduced tension within the wall of the afferent arteriole. The release of renal prostaglandins and biomechanical coupling via stretch-activated ion channels may mediate in part the intrarenal baroreceptor pathway (Wang et al., 1999).

The third mechanism, the *β adrenergic receptor pathway*, is mediated by the release of norepinephrine from postganglionic sympathetic nerves; activation of β_1 receptors on juxtaglomerular cells enhances renin secretion.

The three mechanisms regulating renin release are embedded in a feedback regulation (Figure 26–2A). Increased renin secretion enhances the formation of AngII, which stimulates AT_1 receptors on juxtaglomerular cells to inhibit renin release, an effect termed *short-loop negative feedback*. AngII increases arterial blood via AT_1 receptors; this effect inhibits renin release by:

- activating high-pressure baroreceptors, thereby reducing renal sympathetic tone
- increasing pressure in the preglomerular vessels
- reducing NaCl reabsorption in the proximal tubule (pressure natriuresis), which increases tubular delivery of NaCl to the macula densa

The inhibition of renin release owing to AngII-induced increases in blood pressure has been termed *long-loop negative feedback*.

The physiological pathways regulating renin release are influenced by arterial blood pressure, dietary salt intake, and a number of pharmacological agents (Figure 26–2A). Loop diuretics stimulate renin release by decreasing arterial blood pressure and by blocking the reabsorption of NaCl at the macula densa. *Nonsteroidal anti-inflammatory drugs* (NSAIDs; see Chapter 34) inhibit prostaglandin synthesis and thereby decrease renin release. ACE inhibitors, angiotensin receptor blockers (ARBs), and renin inhibitors

interrupt both the short- and long-loop negative feedback mechanisms and therefore increase renin release. Increasing cyclic AMP in the juxtaglomerular cells stimulates renin. Centrally acting sympatholytic drugs (see Chapter 12), as well as β adrenergic receptor antagonists, decrease renin secretion by reducing activation of β adrenergic receptors on juxtaglomerular cells.

Angiotensinogen. The substrate for renin is angiotensinogen, an abundant globular glycoprotein (MW = 55,000–60,000). AngI is cleaved from the amino terminus of angiotensinogen. The human angiotensinogen contains 452 amino acids and is synthesized as pre-angiotensinogen, which has a 24- or 33-amino acid signal peptide. Angiotensinogen is synthesized and secreted primarily by the liver, although angiotensinogen transcripts also are abundant in fat, certain regions of the central nervous system (CNS), and the kidneys. Angiotensinogen synthesis is stimulated by inflammation, insulin, estrogens, glucocorticoids, thyroid hormone, and AngII. During pregnancy, plasma levels of angiotensinogen increase several-fold owing to increased estrogen.

Circulating levels of angiotensinogen are approximately equal to the K_m of renin for its substrate ($\sim 1 \mu\text{M}$). Consequently, the rate of AngII synthesis, and therefore blood pressure, can be influenced by changes in angiotensinogen levels. For instance, knockout mice lacking angiotensinogen are hypotensive, and there is a progressive relationship among the number of copies of the angiotensinogen gene, plasma levels of angiotensinogen, and arterial blood pressure. Oral contraceptives containing estrogen increase circulating levels of angiotensinogen and can induce hypertension. A missense mutation in the angiotensinogen gene (a methionine to threonine at position 235 of angiotensinogen) that increases plasma levels of angiotensinogen is associated with essential and pregnancy-induced hypertension (Sethi et al., 2003). Angiotensinogen shares sequence homologies that have anti-angiogenic properties with the serpin protein family (C  lerier et al., 2002).

Angiotensin-Converting Enzyme (ACE, Kininase II, Dipeptidyl Carboxypeptidase). ACE is an ectoenzyme and glycoprotein with

an apparent molecular weight of 170,000. Human ACE contains 1277 amino acid residues and has two homologous domains, each with a catalytic site and a Zn²⁺-binding region. ACE has a large amino-terminal extracellular domain, a short carboxyl-terminal intracellular domain, and a 17-amino acid hydrophobic region that anchors the ectoenzyme to the cell membrane. ACE is rather nonspecific and cleaves dipeptide units from substrates with diverse amino acid sequences. Preferred substrates have only one free carboxyl group in the carboxyl-terminal amino acid, and proline must not be the penultimate amino acid; thus, the enzyme does not degrade AngII. ACE is identical to kininase II, the enzyme that inactivates bradykinin and other potent vasodilator peptides. Although slow conversion of AngI to AngII occurs in plasma, the very rapid metabolism that occurs *in vivo* is due largely to the activity of membrane-bound ACE present on the luminal surface of endothelial cells throughout the vascular system.

The ACE gene contains an insertion/deletion polymorphism in intron 16 that explains 47% of the phenotypic variance in serum ACE levels. The deletion allele, associated with higher levels of serum ACE and increased metabolism of bradykinin, may confer an increased risk of hypertension, cardiac hypertrophy, atherosclerosis, and diabetic nephropathy (Hadjadj et al., 2001) but may be protective against Alzheimer's disease (Sayed-Tabatabaei et al., 2006; Castrop et al., 2010).

Angiotensin-Converting Enzyme 2. Two groups independently discovered a novel ACE-related carboxypeptidase, now termed ACE2 (Donoghue et al., 2000; Tipnis et al., 2000). Human ACE2 is 805 amino acids in length with a short putative signal sequence. ACE2 contains a single catalytic domain that is 42% identical to the two catalytic domains of ACE. ACE2 cleaves one amino acid from the carboxyl terminal to convert AngI to Ang(1–9) and AngII to Ang(1–7). AngII is the preferred substrate for ACE2 with 400-fold higher affinity than AngI. The physiological significance of ACE2 is still uncertain; it may serve as a counter-regulatory mechanism to oppose the effects of ACE. ACE2 regulates the levels of AngII and limits its effects by converting it to Ang(1–7), which binds to Mas receptors and elicits vasodilator and anti-proliferative responses (Varagic et al., 2008). ACE2 is not inhibited by the standard ACE inhibitors and has no effect on bradykinin. In animals, reduced expression of ACE2 is associated with hypertension, defects in cardiac contractility, and elevated levels of AngII (Crackower et al., 2002). Overexpression of the ACE2 gene prevents AngII-induced cardiac hypertrophy in hypertensive rats (Huentelman et al., 2005). ACE2 also serves as a receptor for the SARS coronavirus (Li et al., 2003).

Angiotensin Peptides. When given intravenously, AngI is rapidly converted to AngII. However, AngI *per se* is less than 1% as potent as AngII on smooth muscle, the heart, and the adrenal cortex. Angiotensin III (AngIII), also called Ang(2–8), can be formed either by the action of aminopeptidase on AngII or by the action of ACE on Ang(2–10). AngII and AngIII cause qualitatively similar effects. AngII and AngIII stimulate aldosterone secretion with equal potency; however, AngIII is only 25% and 10% as potent as AngII in elevating blood pressure and stimulating the adrenal medulla, respectively.

Ang(1–7) is formed by multiple pathways (Figure 26–1). AngI can be converted to Ang(1–7) by endopeptidases. AngII can be converted to Ang(1–7) by prolylcarboxypeptidase (Ferrario et al., 1997).

ACE2 converts AngI to Ang(1–9) and AngII to Ang(1–7); ACE metabolizes Ang(1–9) to Ang(1–7). In animal models, Ang(1–7) opposes many of the effects of AngII: it induces vasodilation, promotes NO production, potentiates the vasodilatory effects of bradykinin, and inhibits AngII-induced activation of ERK1/2; it has anti-angiogenic, anti-proliferative, and anti-thrombotic effects; and is cardioprotective in cardiac ischemia and heart failure. The effects of Ang(1–7) are mediated by a specific Mas receptor. The *Mas* proto-oncogene encodes an orphan G protein-coupled receptor (Santos et al., 2008; Varagic et al., 2008). Ferrario and colleagues (1997) proposed that Ang(1–7) serves to counterbalance the actions of AngII, which may depend on ACE-AngII/ACE2-Ang(1–7) activity ratio (Santos et al., 2008). ACE inhibitors increase tissue and plasma levels of Ang(1–7), both because AngI levels are increased and diverted away from AngII formation (Figure 26–1) and because ACE contributes to the plasma clearance of Ang(1–7). AT₁ receptor blockade boosts the levels of AngII that is converted to Ang(1–7) by ACE2.

Angiotensin IV (AngIV), also called Ang(3–8), is formed from AngIII through the catalytic action of aminopeptidase M and has potent effects on memory and cognition. Central and peripheral actions of AngIV are mediated through specific AT₄ receptors identified as insulin-regulated amino peptidases (IRAPs). AngIV binding to AT₄ receptors inhibits the catalytic activity of IRAPs and enables accumulation of various neuropeptides linked to memory potentiation. Other actions include renal vasodilation, natriuresis, neuronal differentiation, hypertrophy, inflammation, and extracellular matrix remodeling (Ruiz-Ortega et al., 2007). Analogs of angiotensin IV are being developed for their therapeutic potential in cognition in Alzheimer disease or head injury (Albiston et al., 2007).

Angiotensinases. These include aminopeptidases, endopeptidases, carboxypeptidases, and other peptidases that degrade and inactivate angiotensin peptides; none is specific.

Local (Tissue) Renin–Angiotensin Systems. The traditional view of the RAS as classical endocrine system is oversimplified. The modern view of the RAS also includes the local (tissue) RAS. Local (tissue) RAS is an AngII-producing system that is being recognized for its role in hypertrophy, inflammation, remodeling, and apoptosis. Activation of (tissue) RAS and local AngII production require the binding of renin or prorenin to the specific (pro)renin receptor (PRR), located on cell surfaces. In this regard, it is important to distinguish between *extrinsic* and *intrinsic* local RAS:

Extrinsic Local RAS. ACE is present on the luminal face of vascular endothelial cells throughout the circulation, and circulating renin of renal origin can be taken up by the arterial wall and by other tissues (Danser et al., 1994).

Intrinsic Local RAS. Many tissues—including the brain, pituitary, blood vessels, heart, kidney, and adrenal gland—express mRNAs for renin, angiotensinogen, and/or ACE, and various cells cultured from these tissues produce renin, angiotensinogen, ACE, and angiotensins I, II, and III. Thus, it appears that local RASs exist independently of the renal/hepatic-based system and may influence vascular, cardiac, and renal function and structure (Paul et al., 2006).

The (Pro)Renin Receptor. The PRR is the functional receptor, located on the cell surface, that binds prorenin and renin with high affinity (K_D ~6 and 20 nM, respectively) and specificity (Batenburg and Danser, 2008). Human PRR is a 350-amino acid protein that shares no homology with any membrane protein. The PRR gene is located

in the locus p11.4 of the X chromosome and is named ATP6ap2 (ATPase-associated protein). Knockout of the PRR gene is lethal. In humans, mutations in the PRR gene are associated with mental retardation and epilepsy, suggesting an important role in cognition, brain development, and survival (Nguyen and Danser, 2008; Ramser et al., 2005). Prorenin and renin also bind to mannose-6-phosphate receptor (M6P), an insulin-like growth factor II receptor that functions as a clearance receptor.

Binding of (pro)renin to PRR enhances the catalytic activity of renin by 4-5 fold and induces non-proteolytic activation of prorenin (Figure 26-3). Bound, activated (pro)renin catalyzes the conversion of angiotensinogen to AngI, which is subsequently converted to AngII by ACE located on the cell surface. Locally produced AngII binds to AT₁ receptors and activates intracellular signaling events that regulate cell growth, collagen deposition, fibrosis, inflammation, and apoptosis (Nguyen and Danser, 2008).

The binding of (pro)renin to PRR also induces AngII-independent signaling events that include activation of ERK1/2, p38, tyrosine kinases, TGF- β gene expression, and plasminogen activator inhibitor type 1 (PAI-1). These signaling pathways are not blocked by ACE inhibitors or AT₁ receptor antagonists and are reported to contribute to fibrosis, nephrosis, and organ damage (Kaneshiro et al., 2007; Nguyen and Danser, 2008; see Figure 26-4). PRR is abundant in the heart, brain, eye, adrenals, placenta, adipose tissue, liver, and kidneys. Overexpression of the human PRR in transgenic animals increases plasma aldosterone levels in the absence of changes in plasma renin levels and induces hypertension and nephropathy. Rats overexpressing PRR exhibit increased expression of COX-2 in the macula densa and develop proteinuria and glomerulosclerosis that increase with aging (Kaneshiro et al., 2006; Kaneshiro et al., 2007).

Prorenin is no longer considered the inactive precursor of renin. Prorenin is capable of activating local (tissue) RAS and AngII-dependent and independent events that may contribute to organ damage. Circulating plasma concentrations of prorenin are 10-fold higher than renin in healthy subjects but are elevated to 100-fold in diabetic patients and are associated with increased risk of nephropathy, renal fibrosis, and retinopathy (Danser and Deinum, 2005; Nguyen and Danser, 2008). The interaction of prorenin with PRR has become a target for therapeutic interventions.

Alternative Pathways for Angiotensin Biosynthesis. Angiotensinogen may be converted to AngI or directly to AngII by cathepsin G and tonin. Other enzymes that convert AngI to AngII include cathepsin G, chymostatin-sensitive AngII-generating enzyme, and heart chymase. Chymase contributes to the local tissue conversion of AngI to AngII, particularly in the heart and kidneys (Paul et al., 2006).

Angiotensin Receptors. AngII and AngIII couple to specific GPCRs designated AT₁ and AT₂ (de Gasparo et al., 2000). The AT₁ receptor has a 10,000-fold higher affinity for losartan (and related biphenyl tetrazole derivatives) than the AT₂ receptor. The AT₁ receptor (359 amino acids) and the AT₂ receptor (363 amino acids) share 34% sequence homology.

Most of the known biological effects of AngII are mediated by the AT₁ receptor. The AT₁ receptor gene contains a polymorphism (A-to-C transversion in position 1166) associated with hypertension, hypertrophic cardiomyopathy, and coronary artery vasoconstriction. Moreover, the C allele synergizes with the ACE deletion allele with

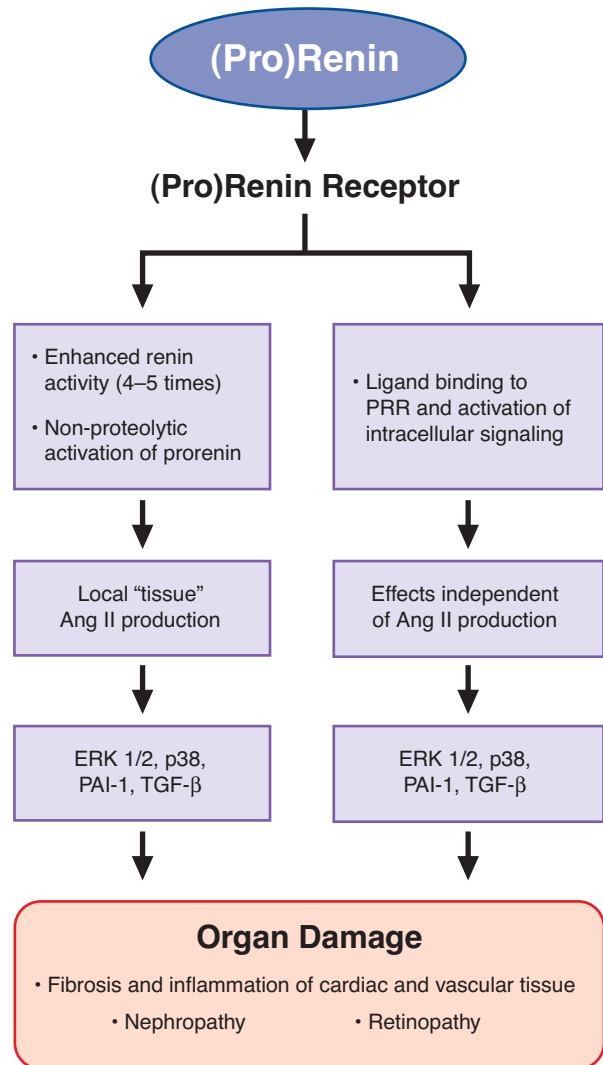

Figure 26-4. Ang II-dependent and Ang II-independent actions of prorenin. See text for details.

regard to increased risk of coronary artery disease (Álvarez et al., 1998). Preeclampsia is associated with the development of agonistic auto-antibodies against the AT₁ receptor (Wallukat et al., 1999).

Functional roles for the AT₂ receptors are less well defined, but they may counterbalance many of the effects of the AT₁ receptors by having antiproliferative, proapoptotic, vasodilatory, natriuretic, and antihypertensive effects (Jones et al., 2008; Carey et al., 2001). The AT₂ receptor is distributed widely in fetal tissues, but its distribution is more restricted in adults. Although the AT₂ receptor generally is conceptualized as a cardiovascular protective receptor, its overexpression and activation may contribute to myocyte hypertrophy and cardiac fibrosis (D'Amore et al., 2005; Ichihara et al., 2001). Expression of AT₂ receptors is upregulated in cardiovascular diseases, including heart failure, cardiac fibrosis, and ischemic heart disease; however, the significance of increased AT₂ receptor expression is unclear (Jones et al., 2008).

The Mas receptor mediates the effects of Ang(1–7), which include vasodilation and anti-proliferation. Deletion of the *Mas* gene in transgenic mice reveals cardiac dysfunction (Santos et al., 2008).

The AT₄ receptor (IRAP; see Figure 26-2) mediates the effects of AngIV. This receptor is a single transmembrane protein (1025 amino acids) that co-localizes with the glucose transporter GLUT4. AT₄ receptors are detectable in a number of tissues, such as heart, vasculature, adrenal cortex, and brain regions processing sensory and motor functions (Chai et al., 2004).

Angiotensin Receptor–Effector Coupling. AT₁ receptors activate a large array of signal-transduction systems to produce effects that vary with cell type and that are a combination of primary and secondary responses. AT₁ receptors couple to several heterotrimeric G proteins, including G_q, G_{12/13}, and G_i. In most cell types, AT₁ receptors couple to G_q to activate the PLCβ–IP₃–Ca²⁺ pathway. Secondary to G_q activation, activation of PKC, PLA₂, and PLD and eicosanoid production, as well as activation of Ca²⁺-dependent and MAP kinases and the Ca²⁺–calmodulin–dependent activation of NOS may occur. Activation of G_i may occur and will reduce the activity of adenylyl cyclase, lowering cellular cyclic AMP content; however, there also is evidence for G_q → G_s cross-talk such that activation of the AT₁–G_q–PLC pathway enhances cyclic AMP production (Meszaros et al., 2000; Epperson et al., 2004). The βγ subunits of G_i and activation of G_{12/13} lead to activation of tyrosine kinases and small G proteins such as Rho. Ultimately, the JAK/STAT pathway may be activated and a variety of transcriptional regulatory factors induced. By these mechanisms, angiotensin influences the expression of a host of gene products relating to cell growth and the production of components of the extracellular matrix. AT₁ receptors also stimulate the activity of a membrane-bound NADH/NADPH oxidase that generates reactive oxygen species (ROS). ROS may contribute to biochemical effects (activation of MAP kinase, tyrosine kinase, and phosphatases; inactivation of NO; and expression of monocyte chemoattractant protein-1) and physiological effects (acute effects on renal function, chronic effects on blood pressure, and vascular hypertrophy and inflammation) (Mehta and Griendling, 2007; Higuchi et al., 2007). The relative importance of these myriad signal-transduction pathways in mediating biological responses to AngII is tissue specific. The presence of other receptors may alter the response to AT₁ receptor activation. For example, AT₁ receptors heterodimerize with bradykinin B₂ receptors, a process that enhances AngII sensitivity in preeclampsia (AbdAlla et al., 2002).

Less is known about AT₂ receptor–effector coupling. Signaling from AT₂ receptors is mediated by G protein-dependent and independent pathways. Consequences of AT₂ receptor activation include activation of phosphoprotein phosphatases, K⁺ channels, synthesis of NO and cyclic GMP, bradykinin production, and inhibition of Ca²⁺ channel functions (Jones et al., 2008). AT₂ receptors may possess constitutive activity. Overexpression of AT₂ receptors has been reported to induce NO production in vascular smooth muscle cells and hypertrophy in cardiac myocytes through an intrinsic activity of the AT₂ receptor independent of angiotensin binding (D'Amore et al., 2005; Jones et al., 2008). Homo-oligomerization of AT₂ receptors also has been reported to induce apoptosis (Miura et al., 2005). The AT₂ receptor may bind directly to and antagonize the AT₁ receptor (AbdAlla et al., 2001) and can form heterodimers with the bradykinin B₂ receptor to enhance NO production (Abadir, 2006).

Functions and Effects of the Renin–Angiotensin System

The main effects of AngII on the cardiovascular system include:

- rapid pressor response
- slow pressor response
- vascular and cardiac hypertrophy and remodeling

Modest increases in plasma concentrations of AngII acutely raise blood pressure; on a molar basis, AngII is ~40 times more potent than NE (see Chapter 12); the EC₅₀ of AngII for acutely raising arterial blood pressure is ~0.3 nM. When a single moderate dose of AngII is injected intravenously, systemic blood pressure begins to rise within seconds, peaks rapidly, and returns to normal within minutes (Figure 26–5). This *rapid pressor response* to AngII is due to a swift increase in total peripheral resistance—a response that helps to maintain arterial blood pressure in the face of an acute hypotensive challenge (e.g., blood loss or vasodilation). Although AngII increases cardiac contractility directly (via opening voltage-gated Ca²⁺ channels in cardiac myocytes) and increases heart rate indirectly (via facilitation of sympathetic tone, enhanced adrenergic neurotransmission, and adrenal catecholamine release), the rapid increase in arterial blood pressure activates a baroreceptor reflex that decreases sympathetic tone and increases vagal tone. Thus, depending on the physiological

Figure 26–5. Effect of a bolus intravenous injection of AngII (0.05 μg/kg) on arterial blood pressure (BP) and renal blood flow (RBF) in a conscious dog. (Reproduced with permission, from Zimmerman BG. Absence of adrenergic mediation of agonist response to [Sar¹,Ala⁸] angiotensin II in conscious normotensive and hypertensive dogs. *Clin Sci*, 1979, 57:71–81. © the Biochemical Society.)

state, AngII may increase, decrease, or not change cardiac contractility, heart rate, and cardiac output. Changes in cardiac output therefore contribute little, if at all, to the rapid pressor response induced by AngII.

AngII also causes a *slow pressor response* that helps to stabilize arterial blood pressure over the long term. A continuous infusion of initially subpressor doses of AngII gradually increases arterial blood pressure, with the maximum effect requiring days to achieve. This slow pressor response probably is mediated by a decrement in renal excretory function that shifts the renal pressure–natriuresis curve to the right (see the next section). AngII stimulates the synthesis of endothelin-1 and superoxide anion, which may contribute to the slow pressor response.

In addition to its effects on arterial blood pressure, AngII stimulates remodeling of the cardiovascular system, causing hypertrophy of vascular and cardiac

cells and increased synthesis and deposition of collagen by cardiac fibroblasts.

Mechanisms by Which Angiotensin II Increases Total Peripheral Resistance. AngII increases total peripheral resistance (TPR) via direct and indirect effects on blood vessels (Figure 26–6).

Rapid Pressor Response

Direct Vasoconstriction. AngII constricts precapillary arterioles and, to a lesser extent, postcapillary venules by activating AT_1 receptors located on vascular smooth muscle cells and stimulating the G_q -PLC- IP_3 - Ca^{2+} pathway. AngII has differential effects on vascular beds. Direct vasoconstriction is strongest in the kidneys (Figure 26–5) and somewhat less in the splanchnic vascular bed; blood flow in these regions falls sharply when AngII is infused. AngII-induced vasoconstriction is much less in vessels of the brain and still weaker in

Figure 26–6. Summary of the three major effects of AngII and the mechanisms that mediate them. NE, norepinephrine.

those of the lung and skeletal muscle. Nevertheless, high circulating concentrations of AngII may decrease cerebral and coronary blood flow.

Enhancement of Peripheral Noradrenergic Neurotransmission.

AngII augments norepinephrine release from sympathetic nerve terminals by inhibiting the reuptake of norepinephrine into nerve terminals and by enhancing the vascular response to NE (see Chapter 12). High concentrations of the peptide stimulate ganglion cells directly.

Effects on the CNS. Small amounts of AngII infused into the vertebral arteries cause an increase in arterial blood pressure. This response—mediated by increased sympathetic outflow—reflects effects of the hormone on circumventricular nuclei that are not protected by a blood-brain barrier (e.g., area postrema, subfornical organ, organum vasculosum of the lamina terminalis). Circulating AngII also attenuates baroreceptor-mediated reductions in sympathetic discharge, thereby increasing arterial pressure. The CNS is affected both by bloodborne AngII and by AngII formed within the brain, where it may serve as a neurotransmitter. The brain contains all components of the RAS. In addition to increasing sympathetic tone, AngII also causes a centrally mediated dipsogenic (thirst) effect and enhances the release of vasopressin from the neurohypophysis.

Release of Catecholamines from the Adrenal Medulla.

AngII stimulates the release of catecholamines from the adrenal medulla by depolarizing chromaffin cells.

Slow Pressor Response

Alteration of Renal Function. AngII has pronounced effects on renal function, reducing the urinary excretion of Na^+ and water while increasing the excretion of K^+ . The overall effect of AngII on the kidneys is to shift the renal pressure–natriuresis curve to the right (Figure 26–7).

Direct Effects of Angiotensin II on Na^+ Reabsorption in the Renal Tubules.

Very low concentrations of AngII stimulate Na^+/H^+ exchange in the proximal tubule—an effect that increases Na^+ , Cl^- , and bicarbonate reabsorption. Approximately 20–30% of the bicarbonate handled by the nephron may be affected by this mechanism. AngII also increases the expression of the Na^+ –glucose symporter in the proximal tubule (Bautista et al., 2004). Paradoxically, at high concentrations, AngII may inhibit Na^+ transport in the proximal tubule. AngII also directly stimulates the Na^+ – K^+ – 2Cl^- symporter in the thick ascending limb. The proximal tubule secretes angiotensinogen, and the connecting tubule releases renin, so a paracrine tubular RAS may contribute to Na^+ reabsorption.

Figure 26–7. Pressure-natriuresis curve: effects of Na^+ intake on renin release (AngII formation) and arterial blood pressure. Inhibition of the renin-angiotensin system will cause a large drop in blood pressure in Na^+ -depleted individuals. (Modified with permission from Jackson EK, Branch RA, et al: Physiological functions of the renal prostaglandin, renin, and kalikrein systems, in Seldin DW, Giebisch GH, eds: *The Kidney: Physiology and Pathophysiology*, Vol 1. Philadelphia: Lippincott Williams & Wilkins, 1985, p 624. <http://lww.com>.)

Release of Aldosterone from the Adrenal Cortex. AngII stimulates the zona glomerulosa of the adrenal cortex to increase the synthesis and secretion of aldosterone, and augments responses to other stimuli (e.g., ACTH, K^+). Increased output of aldosterone is elicited by concentrations of AngII that have little or no acute effect on blood pressure. Aldosterone acts on the distal and collecting tubules to cause retention of Na^+ and excretion of K^+ and H^+ . The stimulant effect of AngII on aldosterone synthesis and release is enhanced under conditions of hyponatremia or hyperkalemia and is reduced when concentrations of Na^+ and K^+ in plasma are altered in the opposite directions.

Altered Renal Hemodynamics. AngII reduces renal blood flow and renal excretory function by directly constricting the renal vascular smooth muscle, by enhancing renal sympathetic tone (a CNS effect), and by facilitating renal adrenergic transmission (an intrarenal effect). AngII-induced vasoconstriction of preglomerular microvessels is enhanced by endogenous adenosine owing to signal-transduction systems activated by AT_1 and the adenosine A_1 receptor (Hansen et al., 2003).

AngII influences glomerular filtration rate (GFR) by means of several mechanisms:

- constriction of the afferent arterioles, which reduces intraglomerular pressure and tends to reduce GFR
- contraction of mesangial cells, which decreases the capillary surface area within the glomerulus available for filtration and also tends to decrease GFR
- constriction of efferent arterioles, which increases intraglomerular pressure and tends to increase GFR

Normally, GFR is slightly reduced by AngII; however, during renal artery hypotension, the effects of AngII on the efferent arteriole predominate so that AngII increases GFR. Thus, blockade of the RAS may cause acute renal failure in patients with bilateral renal artery stenosis or in patients with unilateral stenosis who have only a single kidney.

Vascular and Cardiac Hypertrophy and Remodeling.

Pathological alterations involving cardiac hypertrophy and remodeling increase morbidity and mortality. These morbid changes in cardiovascular structure are due to increased migration, proliferation (hyperplasia), and hypertrophy of cells, as well as to increased extracellular matrix. The cells involved include vascular smooth muscle cells, cardiac myocytes, and fibroblasts. In this regard, AngII:

- stimulates the migration, proliferation, and hypertrophy of vascular smooth muscle cells
- increases extracellular matrix production by vascular smooth muscle cells
- causes hypertrophy of cardiac myocytes
- increases extracellular matrix production by cardiac fibroblasts

These effects of AngII are mediated by acting directly on cells to induce the expression of specific proto-oncogenes (*c-fos*, *c-jun*, *c-myc*, and *egr-1*) that alter the expression of growth factors such as basic FGF, PDGF, and TGF- β . In addition, AngII alters extracellular matrix formation and degradation indirectly by increasing aldosterone.

Hemodynamically Mediated Effects of Angiotensin II on Cardiovascular Structure. In addition to the direct cellular effects of AngII on cardiovascular structure, changes in cardiac preload (volume expansion owing to Na⁺ retention) and afterload (increased arterial blood pressure) probably contribute to cardiac hypertrophy and remodeling. Arterial hypertension also contributes to hypertrophy and remodeling of blood vessels.

Role of the RAS in Long-Term Maintenance of Arterial Blood Pressure Despite Extremes in Dietary Na⁺ Intake. Arterial blood pressure is a major determinant of Na⁺ excretion. This is illustrated graphically by plotting urinary Na⁺ excretion versus mean arterial blood pressure (Figure 26–7), a plot known as the *renal pressure–natriuresis curve*. Over the long term, Na⁺ excretion must equal Na⁺ intake; therefore, the set point for long-term levels of arterial blood pressure can be

obtained as the intersection of a horizontal line representing Na⁺ intake with the renal pressure–natriuresis. As illustrated in Figure 26–7, the RAS plays a major role in maintaining a constant set point for long-term levels of arterial blood pressure despite extreme changes in dietary Na⁺ intake. When dietary Na⁺ intake is low, renin release is stimulated, and AngII acts on the kidneys to shift the renal pressure–natriuresis curve to the right. Conversely, when dietary Na⁺ is high, renin release is inhibited, and the withdrawal of AngII shifts the renal pressure–natriuresis curve to the left. When modulation of the RAS is blocked by drugs, changes in salt intake markedly affect long-term levels of arterial blood pressure.

Other Effects of the RAS. Expression of the RAS is required for the development of normal kidney morphology, particularly the maturational growth of the renal papilla (Niimura et al., 1995). AngII causes a marked anorexigenic effect and weight loss, and high circulating levels of AngII may contribute to the anorexia, wasting, and cachexia of heart failure (Brink et al., 1996).

Angiotensin and Vascular Disease

The RAS induces vascular disease by multiple mechanisms, including directly and indirectly (via aldosterone): stimulating vascular smooth muscle cell migration, proliferation, and extracellular matrix production; increasing the release of plasminogen activator inhibitor type 1 and enhancing the expression of monocyte chemoattractant protein 1; augmenting the expression of adhesion proteins (e.g., ICAM-1, integrins, and osteopontin) in vascular cells; and stimulating the production of inflammatory chemokines and cytokines that enhance the migration of inflammatory cells (Schmieder et al., 2007). AngII markedly accelerates the development of atherosclerosis in apolipoprotein E-deficient mice (Weiss et al., 2001), an animal model of atherosclerosis.

INHIBITORS OF THE RENIN–ANGIOTENSIN SYSTEM

Clinical interest focuses on developing inhibitors of the RAS. Three types of inhibitors are utilized therapeutically (Figure 26–8):

- ACE inhibitors (ACEIs)
- angiotensin receptor blockers (ARBs)
- direct renin inhibitors (DRIs)

Figure 26-8. Inhibitors of the RAS. ACE-I, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; DRI, direct renin inhibitor.

Angiotensin-Converting Enzyme Inhibitors

History. In the 1960s, Ferreira and colleagues found that the venoms of pit vipers contain factors that intensify vasodilator responses to bradykinin. These bradykinin-potentiating factors are a family of peptides that inhibit kininase II, an enzyme that inactivates bradykinin. Erdös and coworkers established that ACE and kininase II are the same enzyme, which catalyzes both the synthesis of AngII and the destruction of bradykinin. Based on these findings, the nonapeptide teprotide (snake venom peptide that inhibits kininase II and ACE) was later synthesized and tested in human subjects. It lowered blood pressure in many patients with essential hypertension and exerted beneficial effects in patients with heart failure.

The orally effective ACE inhibitor *captopril* was developed by a rational approach that involved analysis of the inhibitory action of teprotide, inference about the action of ACE on its substrates, and analogy with carboxypeptidase A, which was known to be inhibited by D-benzylsuccinic acid. Ondetti, Cushman, and colleagues argued that inhibition of ACE might be produced by succinyl amino acids that corresponded in length to the dipeptide cleaved by ACE. This led to the synthesis of a series of carboxy alkanoyl and mercapto alkanoyl derivatives that are potent competitive inhibitors of ACE. Most active was captopril (Vane, 1999).

Pharmacological Effects in Normal Laboratory Animals and Humans. The effect of ACE inhibitors on the RAS is to inhibit the conversion of AngI to the active AngII. Inhibition of AngII production will lower blood pressure and enhance natriuresis. ACE is an enzyme with

many substrates, and inhibition of ACE may also induce effects unrelated to reducing the levels of AngII. ACE inhibitors increase bradykinin levels and bradykinin stimulates prostaglandin biosynthesis; both may contribute to the pharmacological effects of ACE inhibitors. ACE inhibitors increase by 5-fold the circulating levels of the natural stem cell regulator *N*-acetyl-seryl-aspartyl-lysyl-proline, which may contribute to the cardioprotective effects of ACE inhibitors (Rhaleb et al., 2001). In addition, ACE inhibitors will increase renin release and the rate of formation of AngI by interfering with both short- and long-loop negative feedbacks on renin release (Figure 26–2A). Accumulating AngI is directed down alternative metabolic routes, resulting in the increased production of vasodilator peptides such as Ang(1–7). In healthy, Na⁺-replete animals and humans, a single oral dose of an ACE inhibitor has little effect on systemic blood pressure, but repeated doses over several days cause a small reduction in blood pressure. By contrast, even a single dose of these inhibitors lowers blood pressure substantially in normal subjects depleted of Na⁺ (Figure 26-7).

Clinical Pharmacology. ACE inhibitors can be classified into three broad groups based on chemical structure: (1) sulfhydryl-containing ACE inhibitors structurally related to captopril; (2) dicarboxyl-containing ACE inhibitors structurally related to enalapril (e.g., lisinopril, benazepril, quinapril, moexipril, ramipril, trandolapril, perindopril); and (3) phosphorus-containing ACE inhibitors structurally related to fosinopril. Many ACE inhibitors are ester-containing prodrugs that are 100–1000 times less potent but have a better oral bioavailability than the active molecules. Currently, 11 ACE inhibitors are available for clinical use in the U.S. (Figure 26–9). They differ with regard to potency, whether ACE inhibition is primarily a direct effect of the drug itself or the effect of an active metabolite, and pharmacokinetics.

With the exceptions of fosinopril and spirapril (which display balanced elimination by the liver and kidneys), ACE inhibitors are cleared predominantly by the kidneys. Impaired renal function significantly diminishes the plasma clearance of most ACE inhibitors, and dosages of these drugs should be reduced in patients with renal impairment. *Elevated plasma renin activity renders patients hyperresponsive to ACE inhibitor-induced hypotension, and initial dosages of all ACE inhibitors should be reduced in patients with high plasma levels of renin (e.g., patients with heart failure and salt-depleted patients).*

BENAZEPRIL

CAPTOPRIL

ENALAPRIL

ENALAPRILAT

FOSINOPRIL

LISINOPRIL

MOEXIPRIL

PERINDOPRIL

QUINAPRIL

RAMIPRIL

TRANDOLAPRIL

Figure 26–9. Chemical structures of selected ACE inhibitors. Captopril, lisinopril, and enalaprilat are active molecules. Benazepril, enalapril, fosinopril, moexipril, perindopril, quinapril, ramipril, and trandolapril are relatively inactive until converted to their corresponding diacids. The structures enclosed within red boxes are removed by esterases and replaced with a hydrogen atom to form the active molecule *in vivo* (e.g., enalapril to enalaprilat or ramipril to ramiprilat).

All ACE inhibitors block the conversion of AngI to AngII and have similar therapeutic indications, adverse-effect profiles, and contraindications. Although captopril and enalapril are indistinguishable with regard to antihypertensive efficacy and safety, the Quality-of-Life Hypertension Study Group reported that captopril may have a more favorable effect on quality of life (Testa et al., 1993). Because hypertension usually requires lifelong treatment, quality-of-life issues are an important consideration in comparing antihypertensive drugs. ACE inhibitors differ markedly in tissue distribution, and it is possible that this difference could be exploited to inhibit some local (tissue) RAS while leaving others relatively intact.

Captopril (CAPOTEN, others). Captopril, the first ACE inhibitor to be marketed, is a potent ACE inhibitor with a K_i of 1.7 nM. It is the only ACE inhibitor approved for use in the U.S. that contains a sulfhydryl moiety. Given orally, captopril is absorbed rapidly and has a bioavailability ~75%. Bioavailability is reduced by 25-30% with food, so captopril should be given 1 hour before meals. Peak concentrations in plasma occur within an hour, and the drug is cleared rapidly with a $t_{1/2}$ ~2 hours. Most of the drug is eliminated in urine, 40-50% as captopril and the rest as captopril disulfide dimers and captopril–cysteine disulfide. The oral dose of captopril ranges from 6.25-150 mg two to three times daily, with 6.25 mg

three times daily or 25 mg twice daily being appropriate for the initiation of therapy for heart failure or hypertension, respectively. Most patients should not receive daily doses in excess of 150 mg, although the maximum labeled dose for heart failure is 450 mg/day.

Enalapril (VASOTEC, others). Enalapril maleate is a prodrug that is hydrolyzed by esterases in the liver to produce the active dicarboxylic acid, enalaprilat. Enalaprilat is a highly potent inhibitor of ACE with a K_i of 0.2 nM. Although it also contains a “proline surrogate,” enalaprilat differs from captopril in that it is an analog of a tripeptide rather than of a dipeptide. Enalapril is absorbed rapidly when given orally and has an oral bioavailability of ~60% (not reduced by food). Although peak concentrations of enalapril in plasma occur within an hour, enalaprilat concentrations peak only after 3-4 hours. Enalapril has a $t_{1/2}$ ~1.3 hours, but enalaprilat, because of tight binding to ACE, has a plasma $t_{1/2}$ of ~11 hours. Nearly all the drug is eliminated by the kidneys as either intact enalapril or enalaprilat. The oral dosage of enalapril ranges from 2.5-40 mg daily (single or divided dose), with 2.5 and 5 mg daily being appropriate for the initiation of therapy for heart failure and hypertension, respectively.

Enalaprilat (VASOTEC INJECTION, others). Enalaprilat is not absorbed orally but is available for intravenous administration when oral therapy is not appropriate. For hypertensive patients, the dosage is 0.625-1.25 mg given intravenously over 5 minutes. This dosage may be repeated every 6 hours.

Lisinopril (PRINIVIL, ZESTRIL, others). Lisinopril is the lysine analog of enalaprilat; unlike enalapril, lisinopril itself is active. *In vitro*, lisinopril is a slightly more potent ACE inhibitor than is enalaprilat. Lisinopril is absorbed slowly, variably, and incompletely (~30%) after oral administration (not reduced by food); peak concentrations in plasma are achieved in ~7 hours. It is cleared as the intact compound by the kidney, and its $t_{1/2}$ in plasma is ~12 hours. Lisinopril does not accumulate in tissues. The oral dosage of lisinopril ranges from 5-40 mg daily (single or divided dose), with 5 and 10 mg daily being appropriate for the initiation of therapy for heart failure and hypertension, respectively. A daily dose of 2.5 mg and close medical supervision is recommended for patients with heart failure who are hyponatremic or have renal impairment.

Benazepril (LOTENSIN, others). Cleavage of the ester moiety by hepatic esterases transforms benazepril, a prodrug, into benazeprilat, an ACE inhibitor that *in vitro* is more potent than captopril, enalaprilat, or lisinopril. Benazepril is absorbed rapidly but incompletely (37%) after oral administration (only slightly reduced by food). Benazepril is nearly completely metabolized to benazeprilat and to the glucuronide conjugates of benazepril and benazeprilat, which are excreted into both the urine and bile; peak concentrations of benazepril and benazeprilat in plasma are achieved in 0.5-1 hour and 1-2 hours, respectively. Benazeprilat has an effective plasma $t_{1/2}$ of 10-11 hours. With the exception of the lungs, benazeprilat does not accumulate in tissues. The oral dosage of benazepril ranges from 5-80 mg daily (single or divided dose).

Fosinopril (MONOPRIL, others). Fosinopril is the only ACE inhibitor approved for use in the U.S. that contains a phosphinate group that binds to the active site of ACE. Cleavage of the ester moiety by hepatic esterases transforms fosinopril, a prodrug, into fosinoprilat, an ACE inhibitor that *in vitro* is more potent than captopril yet less

potent than enalaprilat. Fosinopril is absorbed slowly and incompletely (36%) after oral administration (rate but not extent reduced by food). Fosinopril is largely metabolized to fosinoprilat (75%) and to the glucuronide conjugate of fosinoprilat. These are excreted in both the urine and bile; peak concentrations of fosinoprilat in plasma are achieved in ~3 hours. Fosinoprilat has an effective plasma $t_{1/2}$ of ~11.5 hours; its clearance is not significantly altered by renal impairment. The oral dosage of fosinopril ranges from 10-80 mg daily (single or divided dose). The initial dose is reduced to 5 mg daily in patients with Na^+ or water depletion or renal failure.

Trandolapril (MAVIK, others). An oral dose of trandolapril is absorbed without reduction by food and produces plasma levels of trandolapril (10% bioavailability) and trandolaprilat (70% bioavailability). Trandolaprilat is ~8 times more potent than trandolapril as an ACE inhibitor. Trandolapril is metabolized to trandolaprilat and to inactive metabolites (mostly glucuronides of trandolapril and deesterification products), and these are recovered in the urine (33%, mostly trandolaprilat) and feces (66%). Peak concentrations of trandolaprilat in plasma are achieved in 4-10 hours. Trandolaprilat displays biphasic elimination kinetics with an initial $t_{1/2}$ of ~10 hours (the major component of elimination), followed by a more prolonged $t_{1/2}$ (owing to slow dissociation of trandolaprilat from tissue ACE). Plasma clearance of trandolaprilat is reduced by both renal and hepatic insufficiency. The oral dosage ranges from 1-8 mg daily (single or divided dose). The initial dose is 0.5 mg in patients who are taking a diuretic or who have renal impairment, and 2 mg for African-Americans.

Quinapril (ACCUPRIL, others). Cleavage of the ester moiety by hepatic esterases transforms quinapril, a prodrug, into quinaprilat, an ACE inhibitor that *in vitro* is about as potent as benazeprilat. Quinapril is absorbed rapidly (peak concentrations are achieved in 1 hour), and the rate, but not extent, of oral absorption (60%) may be reduced by food (delayed peak). Quinaprilat and other minor metabolites of quinapril are excreted in the urine (61%) and feces (37%). Peak concentrations of quinaprilat in plasma are achieved in ~2 hours. Conversion of quinapril to quinaprilat is reduced in patients with diminished liver function. The initial $t_{1/2}$ of quinaprilat is ~2 hours; a prolonged terminal $t_{1/2}$ ~25 hours may be due to high-affinity binding of the drug to tissue ACE. The oral dosage of quinapril ranges from 5-80 mg daily (single or divided dose).

Ramipril (ALTACE, others). Cleavage of the ester moiety by hepatic esterases transforms ramipril into ramiprilat, an ACE inhibitor that *in vitro* is about as potent as benazeprilat and quinaprilat. Ramipril is absorbed rapidly (peak concentrations are achieved in 1 hour), and the rate but not extent of its oral absorption (50-60%) is reduced by food. Ramipril is metabolized to ramiprilat and to inactive metabolites (glucuronides of ramipril and ramiprilat and the diketopiperazine ester and acid) that are excreted predominantly by the kidneys. Peak concentrations of ramiprilat in plasma are achieved in ~3 hours. Ramiprilat displays triphasic elimination kinetics with half-lives of 2-4 hours, 9-18 hours, and >50 hours. This triphasic elimination is due to extensive distribution to all tissues (initial $t_{1/2}$), clearance of free ramiprilat from plasma (intermediate $t_{1/2}$), and dissociation of ramiprilat from tissue ACE (long terminal $t_{1/2}$). The oral dosage of ramipril ranges from 1.25-20 mg daily (single or divided dose).

Moexipril (UNIVASC, others). Moexipril is another prodrug whose antihypertensive activity is almost entirely due to its deesterified

metabolite, moexiprilat. Moexipril is absorbed incompletely, with bioavailability as moexiprilat of ~13%. Bioavailability is markedly decreased by food. The time to peak plasma concentration of moexiprilat is almost 1.5 hours; the elimination $t_{1/2}$ varies between 2 and 12 hours. The recommended dosage range is 7.5-30 mg daily (single or divided doses). The dosage range is halved in patients who are taking diuretics or who have renal impairment.

Perindopril (ACEON). Perindopril erbumine is a prodrug, and 30-50% of systemically available perindopril is transformed to perindoprilat by hepatic esterases. Although the oral bioavailability of perindopril (75%) is not affected by food, the bioavailability of perindoprilat is reduced by ~35%. Perindopril is metabolized to perindoprilat and to inactive metabolites (glucuronides of perindopril and perindoprilat, dehydrated perindopril, and diastereomers of dehydrated perindoprilat) that are excreted predominantly by the kidneys. Peak concentrations of perindoprilat in plasma are achieved in 3-7 hours. Perindoprilat displays biphasic elimination kinetics with half-lives of 3-10 hours (the major component of elimination) and 30-120 hours (owing to slow dissociation of perindoprilat from tissue ACE). The oral dosage ranges from 2-16 mg daily (single or divided dose).

Therapeutic Uses of ACE Inhibitors and Clinical Summary. Drugs that interfere with the RAS play a prominent role in the treatment of cardiovascular disease, the major cause of mortality in modern Western societies.

ACE Inhibitors in Hypertension. Inhibition of ACE lowers systemic vascular resistance and mean, diastolic, and systolic blood pressures in various hypertensive states except when high blood pressure is due to primary aldosteronism (see Chapter 27). The initial change in blood pressure tends to be positively correlated with plasma renin activity (PRA) and AngII plasma levels prior to treatment. Some patients may show a sizable reduction in blood pressure that correlates poorly with pretreatment values of PRA. It is possible that increased local (tissue) production of AngII or increased responsiveness of tissues to normal levels of AngII makes some hypertensive patients sensitive to ACE inhibitors despite normal PRA.

The long-term fall in systemic blood pressure observed in hypertensive individuals treated with ACE inhibitors is accompanied by a leftward shift in the renal pressure–natriuresis curve (Figure 26–7) and a reduction in total peripheral resistance in which there is variable participation by different vascular beds. The kidney is a notable exception: because the renal vessels are extremely sensitive to the vasoconstrictor actions of AngII, ACE inhibitors increase renal blood flow via vasodilation of the afferent and efferent arterioles. Increased renal blood flow occurs without an increase in GFR; thus, the filtration fraction is reduced.

ACE inhibitors cause systemic arteriolar dilation and increase the compliance of large arteries, which

contributes to a reduction of systolic pressure. Cardiac function in patients with uncomplicated hypertension generally is little changed, although stroke volume and cardiac output may increase slightly with sustained treatment. Baroreceptor function and cardiovascular reflexes are not compromised, and responses to postural changes and exercise are little impaired. Even when a substantial lowering of blood pressure is achieved, heart rate and concentrations of catecholamines in plasma generally increase only slightly, if at all. This perhaps reflects an alteration of baroreceptor function with increased arterial compliance and the loss of the normal tonic influence of AngII on the sympathetic nervous system.

Aldosterone secretion is reduced, but not seriously impaired, by ACE inhibitors. Aldosterone secretion is maintained at adequate levels by other steroidogenic stimuli, such as ACTH and K^+ . The activity of these secretagogues on the zona glomerulosa of the adrenal cortex requires very small trophic or permissive amounts of AngII, which always are present because ACE inhibition never is complete. Excessive retention of K^+ is encountered in patients taking supplemental K^+ , in patients with renal impairment, or in patients taking other medications that reduce K^+ excretion.

ACE inhibitors alone normalize blood pressure in ~50% of patients with mild to moderate hypertension. Ninety percent of patients with mild to moderate hypertension will be controlled by the combination of an ACE inhibitor and either a Ca^{2+} channel blocker, a β adrenergic receptor blocker, or a diuretic. Diuretics augment the antihypertensive response to ACE inhibitors by rendering the patient's blood pressure renin dependent. Several ACE inhibitors are marketed in fixed-dose combinations with a thiazide diuretic or Ca^{2+} channel blocker for the management of hypertension.

ACE Inhibitors in Left Ventricular Systolic Dysfunction.

Unless contraindicated, ACE inhibitors should be given to all patients with impaired left ventricular systolic function whether or not they have symptoms of overt heart failure (see Chapter 28). Several large, randomized, placebo-controlled clinical studies demonstrate that inhibition of ACE in patients with systolic dysfunction prevents or delays the progression of heart failure, decreases the incidence of sudden death and myocardial infarction, decreases hospitalization, and improves quality of life. The more severe the ventricular dysfunction, the greater the benefit from ACE inhibition.

Inhibition of ACE commonly reduces afterload and systolic wall stress, and both cardiac output and

cardiac index increase, as do indices of stroke work and stroke volume. In systolic dysfunction, AngII decreases arterial compliance, and this is reversed by ACE inhibition (Lage et al., 2002). Heart rate generally is reduced. Systemic blood pressure falls, sometimes steeply at the outset, but tends to return toward initial levels. Renovascular resistance falls sharply, and renal blood flow increases. Natriuresis occurs as a result of the improved renal hemodynamics, the reduced stimulus to the secretion of aldosterone by AngII, and the diminished direct effects of AngII on the kidney. The excess volume of body fluids contracts, which reduces venous return to the right side of the heart. A further reduction results from venodilation and an increased capacity of the venous bed.

Although AngII has little acute venoconstrictor activity, long-term infusion of AngII increases venous tone, perhaps by central or peripheral interactions with the sympathetic nervous system. The response to ACE inhibitors also involves reductions of pulmonary arterial pressure, pulmonary capillary wedge pressure, and left atrial and left ventricular filling volumes and pressures. Consequently, preload and diastolic wall stress are diminished. The better hemodynamic performance results in increased exercise tolerance and suppression of the sympathetic nervous system. Cerebral and coronary blood flows usually are well maintained, even when systemic blood pressure is reduced.

In heart failure, ACE inhibitors reduce ventricular dilation and tend to restore the heart to its normal elliptical shape. ACE inhibitors may reverse ventricular remodeling via changes in preload/afterload, by preventing the growth effects of AngII on myocytes, and by attenuating cardiac fibrosis induced by AngII and aldosterone.

ACE Inhibitors in Acute Myocardial Infarction. The beneficial effects of ACE inhibitors in acute myocardial infarction are particularly large in hypertensive (Borghi et al., 1999) and diabetic (Zuanetti et al., 1997) patients (Chapter 27). Unless contraindicated (e.g., cardiogenic shock or severe hypotension), ACE inhibitors should be started immediately during the acute phase of myocardial infarction and can be administered along with thrombolytics, aspirin, and β adrenergic receptor antagonists (ACE Inhibitor Myocardial Infarction Collaborative Group, 1998). In high-risk patients (e.g., large infarct, systolic ventricular dysfunction), ACE inhibition should be continued long term.

ACE Inhibitors in Patients Who Are at High Risk of Cardiovascular Events. The HOPE study demonstrated that patients at high risk of cardiovascular events benefited considerably from treatment with ACE inhibitors (Heart Outcomes Prevention Study Investigators, 2000). ACE inhibition significantly decreased the rate

of myocardial infarction, stroke, and death in patients who did not have left ventricular dysfunction but had evidence of vascular disease or diabetes and one other risk factor for cardiovascular disease. The EUROPA trial demonstrated that in patients with coronary artery disease but without heart failure, ACE inhibition reduced cardiovascular disease death and myocardial infarction (European Trial, 2003).

ACE Inhibitors in Diabetes Mellitus and Renal Failure. Diabetes mellitus is the leading cause of renal disease. In patients with type 1 diabetes mellitus and diabetic nephropathy, captopril prevents or delays the progression of renal disease. Renoprotection in type 1 diabetes, as defined by changes in albumin excretion, also is observed with lisinopril. The renoprotective effects of ACE inhibitors in type 1 diabetes are in part independent of blood pressure reduction. In addition, ACE inhibitors may decrease retinopathy progression in type 1 diabetics and attenuate the progression of renal insufficiency in patients with a variety of nondiabetic nephropathies (Ruggenti et al., 2010).

Several mechanisms participate in the renal protection afforded by ACE inhibitors. Increased glomerular capillary pressure induces glomerular injury, and ACE inhibitors reduce this parameter both by decreasing arterial blood pressure and by dilating renal efferent arterioles. ACE inhibitors increase the permeability selectivity of the filtering membrane, thereby diminishing exposure of the mesangium to proteinaceous factors that may stimulate mesangial cell proliferation and matrix production, two processes that contribute to expansion of the mesangium in diabetic nephropathy. Because AngII is a growth factor, reductions in the intrarenal levels of AngII may further attenuate mesangial cell growth and matrix production.

ACE Inhibitors in Scleroderma Renal Crisis. The use of ACE inhibitors considerably improves survival of patients with scleroderma renal crisis (Steen and Medsger, 1990).

Adverse Effects of ACE Inhibitors. In general, ACE inhibitors are well tolerated. Metabolic side effects are rare during long-term therapy with ACE inhibitors. The drugs do not alter plasma concentrations of uric acid or Ca^{2+} and may improve insulin sensitivity in patients with insulin resistance and decrease cholesterol and lipoprotein (a) levels in proteinuric renal disease.

Hypotension. A steep fall in blood pressure may occur following the first dose of an ACE inhibitor in patients with elevated PRA. Care should be exercised in patients who are salt depleted, are on multiple antihypertensive drugs, or who have congestive heart failure.

Cough. In 5-20% of patients, ACE inhibitors induce a bothersome, dry cough mediated by the accumulation in the lungs of bradykinin, substance P, and/or prostaglandins. Thromboxane antagonism, aspirin, and iron supplementation reduce cough induced by ACE inhibitors. ACE dose reduction or switching to an ARB is sometimes

effective. Once ACE inhibitors are stopped, the cough disappears, usually within 4 days.

Hyperkalemia. Significant K^+ retention is rarely encountered in patients with normal renal function. However, ACE inhibitors may cause hyperkalemia in patients with renal insufficiency or diabetes or in patients taking K^+ -sparing diuretics, K^+ supplements, β receptor blockers, or NSAIDs.

Acute Renal Failure. AngII, by constricting the efferent arteriole, helps to maintain adequate glomerular filtration when renal perfusion pressure is low. Inhibition of ACE can induce acute renal insufficiency in patients with bilateral renal artery stenosis, stenosis of the artery to a single remaining kidney, heart failure, or volume depletion owing to diarrhea or diuretics.

Fetopathic Potential. The fetopathic effects may be due in part to fetal hypotension. Once pregnancy is diagnosed, it is imperative that ACE inhibitors be discontinued as soon as possible.

Skin Rash. ACE inhibitors occasionally cause a maculopapular rash that may itch, but that may resolve spontaneously or with antihistamines. Although initially attributed to the presence of the sulfhydryl group in captopril, a rash also may occur with other ACE inhibitors, albeit less frequently.

Angioedema. In 0.1-0.5% of patients, ACE inhibitors induce a rapid swelling in the nose, throat, mouth, glottis, larynx, lips, and/or tongue. Once ACE inhibitors are stopped, angioedema disappears within hours; meanwhile, the patient's airway should be protected, and if necessary, epinephrine, an antihistamine, and/or a glucocorticoid should be administered. African-Americans have a 4.5 times greater risk of ACE inhibitor-induced angioedema than Caucasians (Brown et al., 1996). Although rare, angioedema of the intestine (visceral angioedema) characterized by emesis, watery diarrhea, and abdominal pain also has been reported.

Other Side Effects. Extremely rare but reversible side effects include *dysgeusia* (an alteration in or loss of taste), *neutropenia* (symptoms include sore throat and fever), *glycosuria* (spillage of glucose into the urine in the absence of hyperglycemia), and *hepatotoxicity*.

Drug Interactions. Antacids may reduce the bioavailability of ACE inhibitors; capsaicin may worsen ACE inhibitor-induced cough; NSAIDs, including aspirin, may reduce the antihypertensive response to ACE inhibitors; and K^+ -sparing diuretics and K^+ supplements may exacerbate ACE inhibitor-induced hyperkalemia. ACE inhibitors may increase plasma levels of digoxin and lithium and may increase hypersensitivity reactions to allopurinol.

NON-PEPTIDE ANGIOTENSIN II RECEPTOR ANTAGONISTS

History. Attempts to develop therapeutically useful AngII receptor antagonists date to the early 1970s, and these initial endeavors concentrated on angiotensin peptide analog. Saralasin, 1-sarcosine, 8-isoleucine AngII, and other 8-substituted angiotensins were potent AngII receptor antagonists but were of no clinical value because of lack of oral bioavailability and unacceptable partial agonist activity.

A breakthrough came in the early 1980s with the synthesis and testing of a series of imidazole-5-acetic acid derivatives that attenuated pressor responses to AngII in rats. Two compounds,

S-8307 and S-8308, were found to be highly specific, albeit very weak, non-peptide AngII receptor antagonists that were devoid of partial agonist activity. Through a series of stepwise modifications, the orally active, potent, and selective non-peptide AT_1 receptor antagonist losartan was developed (Timmermans et al., 1993) and approved for clinical use in the U.S. in 1995. Since then, six additional AT_1 receptor antagonists (Figure 26-10) have been approved. Although these AT_1 receptor antagonists are devoid of partial agonist activity, structural modifications as minor as a methyl group can transform a potent antagonist into an agonist (Perlman et al., 1997).

Pharmacological Effects. The AngII receptor blockers bind to the AT_1 receptor with high affinity and are more than 10,000-fold selective for the AT_1 receptor over the AT_2 receptor. The rank-order affinity of the AT_1 receptor for ARBs is candesartan = olmesartan > irbesartan = eprosartan > telmisartan = valsartan = EXP 3174 (the active metabolite of losartan) > losartan. Although binding of ARBs to the AT_1 receptor is competitive, the inhibition by ARBs of biological responses to AngII often is insurmountable (the maximal response to AngII cannot be restored in the presence of the ARB regardless of the concentration of AngII added to the experimental preparation).

The mechanism of insurmountable antagonism by ARBs may be due to slow dissociation kinetics of the compounds from the AT_1 receptor; however, a number of other factors may contribute, such as ARB-induced receptor internalization and alternative binding sites for ARBs on the AT_1 receptor (McConnaughey et al., 1999). Insurmountable antagonism has the theoretical advantage of sustained receptor blockade even with increased levels of endogenous ligand and with missed doses of drug. Whether this advantage translates into an enhanced clinical performance remains to be determined.

ARBs potently and selectively inhibit most of the biological effects of AngII (Timmermans et al., 1993; Csajka et al., 1997), including AngII-induced (1) contraction of vascular smooth muscle, (2) rapid pressor responses, (3) slow pressor responses, (4) thirst, (5) vasopressin release, (6) aldosterone secretion, (7) release of adrenal catecholamines, (8) enhancement of noradrenergic neurotransmission, (9) increases in sympathetic tone, (10) changes in renal function, and (11) cellular hypertrophy and hyperplasia. ARBs reduce arterial blood pressure in animals with renovascular and genetic hypertension, as well as in transgenic animals overexpressing the renin gene. ARBs, however, have little effect on arterial blood pressure in animals with low-renin hypertension (e.g., rats with hypertension induced by NaCl and deoxycorticosterone).

Do ARBs have therapeutic efficacy equivalent to that of ACE inhibitors? Although both classes of drugs block the RAS, they differ in several important aspects:

Figure 26–10. AngII receptor antagonists. Structures within red boxes are removed by esterases and replaced with a hydrogen atom to form the active molecule *in vivo*. “~” indicates point of attachment to biphenyl core.

- ARBs reduce activation of AT₁ receptors more effectively than do ACE inhibitors. ACE inhibitors reduce the biosynthesis of AngII by the action of ACE, but do not inhibit alternative non-ACE AngII-generating pathways. ARBs block the actions of AngII via the AT₁ receptor regardless of the biochemical pathway leading to AngII formation.
- In contrast to ACE inhibitors, ARBs permit activation of AT₂ receptors. ACE inhibitors increase renin release, but block the conversion of AngI to AngII. ARBs also stimulate renin release; however, with ARBs, this translates into a several-fold increase in circulating levels of AngII. Because ARBs block AT₁ receptors, this increased level of AngII is available to activate AT₂ receptors.

- ACE inhibitors may increase Ang(1-7) levels more than do ARBs. ACE is involved in the clearance of Ang(1-7), so inhibition of ACE may increase Ang(1-7) levels more so than do ARBs.
- ACE inhibitors increase the levels of a number of ACE substrates, including bradykinin and Ac-SDKP.

Whether the pharmacological differences between ARBs and ACE inhibitors result in significant differences in therapeutic outcomes is an open question.

Clinical Pharmacology. Oral bioavailability of ARBs generally is low (<50%, except for irbesartan, with 70% available), and protein binding is high (>90%).

Candesartan Cilexetil (ATACAND). Candesartan cilexetil is an inactive ester prodrug that is completely hydrolyzed to the active form, candesartan, during absorption from the gastrointestinal tract. Peak plasma levels are obtained 3-4 hours after oral administration, and the plasma $t_{1/2}$ is ~9 hours. Plasma clearance of candesartan is due to renal elimination (33%) and biliary excretion (67%). The plasma clearance of candesartan is affected by renal insufficiency but not by mild-to-moderate hepatic insufficiency. Candesartan cilexetil should be administered orally once or twice daily for a total daily dose of 4-32 mg.

Eprosartan (TEVETEN). Peak plasma levels are obtained 1-2 hours after oral administration, and the plasma $t_{1/2}$ is 5-9 hours. Eprosartan is metabolized in part to the glucuronide conjugate. Clearance is by renal elimination and biliary excretion. The plasma clearance of eprosartan is affected by both renal insufficiency and hepatic insufficiency. The recommended dosage of eprosartan is 400-800 mg/day in one or two doses.

Irbesartan (AVAPRO). Peak plasma levels are obtained ~1.5-2 hours after oral administration, and the plasma $t_{1/2}$ is 11-15 hours. Irbesartan is metabolized in part to the glucuronide conjugate, and the parent compound and its glucuronide conjugate are cleared by renal elimination (20%) and biliary excretion (80%). The plasma clearance of irbesartan is unaffected by either renal or mild-to-moderate hepatic insufficiency. The oral dosage of irbesartan is 150-300 mg once daily.

Losartan (COZAAR). Approximately 14% of an oral dose of losartan is converted to the 5-carboxylic acid metabolite EXP 3174, which is more potent than losartan as an AT₁ receptor antagonist. The metabolism of losartan to EXP 3174 and to inactive metabolites is mediated by CYP2C9 and CYP3A4. Peak plasma levels of losartan and EXP 3174 occur ~1-3 hours after oral administration, respectively, and the plasma half-lives are 2.5 and 6-9 hours, respectively. The plasma clearances of losartan and EXP 3174 are due to renal clearance and hepatic clearance (metabolism and biliary excretion). The plasma clearance of losartan and EXP 3174 is affected by hepatic but not renal insufficiency. Losartan should be administered orally once or twice daily for a total daily dose of 25-100 mg. In addition to being an ARB, losartan is a competitive antagonist of the thromboxane A₂ receptor and attenuates platelet aggregation (Levy et al., 2000). Also, EXP 3179, a metabolite of losartan without angiotensin receptor effects, reduces COX-2 mRNA upregulation and COX-dependent prostaglandin generation (Krämer et al., 2002).

Olmesartan Medoxomil (BENICAR). Olmesartan medoxomil is an inactive ester prodrug that is completely hydrolyzed to the active form, olmesartan, during absorption from the gastrointestinal tract. Peak plasma levels are obtained 1.4-2.8 hours after oral administration, and the plasma $t_{1/2}$ is between 10 and 15 hours. Plasma clearance of

olmesartan is due to both renal elimination and biliary excretion. Although renal impairment and hepatic disease decrease the plasma clearance of olmesartan, no dose adjustment is required in patients with mild-to-moderate renal or hepatic impairment. The oral dosage of olmesartan medoxomil is 20-40 mg once daily.

Telmisartan (MICARDIS). Peak plasma levels are obtained 0.5-1 hour after oral administration, and the plasma $t_{1/2}$ is ~24 hours. Telmisartan is cleared from the circulation mainly by biliary secretion of intact drug. The plasma clearance of telmisartan is affected by hepatic but not renal insufficiency. The recommended oral dosage of telmisartan is 40-80 mg once daily.

Valsartan (DIOVAN). Peak plasma levels occur 2-4 hours after oral administration, and the plasma $t_{1/2}$ is ~9 hours. Food markedly decreases absorption. Valsartan is cleared from the circulation by the liver (~70% of total clearance). The plasma clearance of valsartan is affected by hepatic but not renal insufficiency. The oral dosage of valsartan is 80-320 mg once daily.

Therapeutic Uses of AngII Receptor Antagonists. All ARBs are approved for the treatment of hypertension. In addition, irbesartan and losartan are approved for diabetic nephropathy, losartan is approved for stroke prophylaxis, and valsartan is approved for heart failure and to reduce cardiovascular mortality in clinically stable patients with left ventricular failure or left ventricular dysfunction following myocardial infarction. The efficacy of ARBs in lowering blood pressure is comparable with that of ACE inhibitors and other established antihypertensive drugs, with a favorable adverse-effect profile. ARBs also are available as fixed-dose combinations with hydrochlorothiazide or amlodipine (Chapters 27 and 28).

Losartan is well tolerated in patients with heart failure and is comparable to enalapril with regard to improving exercise tolerance (Lang et al., 1997). The Evaluation of Losartan in the Elderly (ELITE) study reported that in elderly patients with heart failure, losartan was as effective as captopril in improving symptoms and better in reducing mortality (Pitt et al., 1997). However, the greater reduction in mortality by losartan was not confirmed in the larger Losartan Heart Failure Survival Study (ELITE II) trial (Pitt et al., 2000). The Valsartan in Acute Myocardial Infarction (VALIANT) trial demonstrated that valsartan is as effective as captopril in patients with myocardial infarction complicated by left ventricular systolic dysfunction with regard to all-cause-mortality (Pfeffer et al., 2003). Both valsartan and candesartan reduce mortality and morbidity in heart failure patients (Maggioni et al., 2002; Granger et al., 2003). Current recommendations are to use ACE inhibitors as first-line agents for the treatment of heart failure and to reserve ARBs for treatment of heart failure in patients who cannot tolerate or have an unsatisfactory response to ACE inhibitors.

At present, there is conflicting evidence regarding the advisability of combining an ARB and an ACE inhibitor in heart failure patients. The Candesartan in Heart Failure Assessment of Reduction in Mortality (CHARM-additive) and the Valsartan in Heart Failure (ValHeFt) studies indicate that a combination of ARB and ACE inhibitors decrease morbidity and mortality in patients with heart

failure (McMurray et al., 2003; Cohn and Tognoni, 2001). In contrast, the VALIANT and ONTARGET (Ongoing Telmisartan Alone and in Combination with Ramipril Global Endpoint) findings show no added benefits with combination therapy, which was associated with more adverse effects (Pfeffer et al., 2003; ONTARGET Investigators, 2008).

ARBs are renoprotective in type 2 diabetes mellitus, in part via blood pressure-independent mechanisms (Viberti et al., 2002). Based on these results, many experts now consider them the drugs of choice for renoprotection in diabetic patients. The Losartan Intervention For Endpoint (LIFE) Reduction in Hypertension Study demonstrated the superiority of an ARB compared with a β_1 adrenergic receptor antagonist with regard to reducing stroke in hypertensive patients with left ventricular hypertrophy (Dahlöf et al., 2002). Also, irebesartan appears to maintain sinus rhythm in patients with persistent, long-standing atrial fibrillation (Madrid et al., 2002). Losartan is reported to be safe and highly effective in the treatment of portal hypertension in patients with cirrhosis and portal hypertension (Schneider et al., 1999) without compromising renal function.

Adverse Effects. ARBs are generally well tolerated. The incidence of angioedema and cough with ARBs is less than that with ACE inhibitors. As with ACE inhibitors, ARBs have teratogenic potential and should be discontinued in pregnancy. In patients whose arterial blood pressure or renal function is highly dependent on the RAS (e.g., renal artery stenosis), ARBs can cause hypotension, oliguria, progressive azotemia, or acute renal failure. ARBs may cause hyperkalemia in patients with renal disease or in patients taking K^+ supplements or K^+ -sparing diuretics. ARBs enhance the blood pressure-lowering effect of other antihypertensive drugs, a desirable effect but one that may necessitate dosage adjustment. There are rare postmarketing reports of anaphylaxis, abnormal hepatic function, hepatitis, neutropenia, leukopenia, agranulocytosis, pruritus, urticaria, hyponatremia, alopecia, and vasculitis, including Henoch-Schönlein purpura.

DIRECT RENIN INHIBITORS

DRI is a novel class of antihypertensive drugs that inhibit the RAS at its origin. Angiotensinogen is the only specific substrate for renin, and its conversion to AngI presents a rate-limiting step for the generation of downstream components of the RAS.

Aliskiren (TEKTURNa) is the only DRI approved for clinical use.

History. The earlier renin inhibitors were orally inactive peptide analogs of the prorenin propeptide or analogs of renin-substrate cleavage site. Orally active, first-generation renin inhibitors (*enalkiren*, *zankiren*, *CGP38560A*, and *remikiren*) were effective in reducing AngII levels, but none of them made it past clinical trials due to their low potency, poor bioavailability, and short $t_{1/2}$. Low-molecular-weight renin inhibitors were designed based on molecular modeling and crystallographic structural information of renin-substrate interaction (Wood et al., 2003; Staessen et al., 2006). This led to the development of aliskiren, a second-generation renin inhibitor that was approved by the U.S. FDA in 2007 for the treatment of hypertension. Aliskiren has blood pressure-lowering effects similar to those of ACE inhibitors and ARBs.

Pharmacological Effects. Aliskiren is a low-molecular-weight non-peptide that is a potent competitive inhibitor of renin. It binds the active site of renin to block conversion of angiotensinogen to AngI, thus reducing the consequent production of AngII. Aliskiren has a 10,000-fold higher affinity to renin ($IC_{50} \sim 0.6$ nM) than to any other aspartic peptidases.

In healthy volunteers, aliskiren (40-640 mg/day) induces a dose-dependent decrease in blood pressure, reduces PRA and AngI and AngII levels, but increases plasma renin concentration by 16-34-fold due to the loss of the short-loop negative feedback by AngII. Aliskiren also decreases plasma and urinary aldosterone levels and enhances natriuresis (Nussberger et al., 2002).

Aliskiren binds with great specificity to human and primate renin, but is less specific for non-primate renins (e.g., dog, cat, rat, pig) and induces a dose-dependent reduction in blood pressure in Na^+ -depleted marmosets, equivalent to valsartan or benazepril (Wood et al., 2003; Wood et al., 2005). In double transgenic rats expressing human renin and human angiotensinogen genes, aliskiren is similar to the high dose of valsartan in lowering blood pressure, reducing albuminuria, normalizing serum creatinine, and protecting against end-organ damage (Pilz et al., 2005).

Clinical Pharmacology. Aliskiren is recommended as a single oral dose of 150 or 300 mg/day. Bioavailability of aliskiren is low ($\sim 2.5\%$), but its high affinity and potency compensate for the low bioavailability. Peak plasma concentrations are reached within 3-6 hours. The $t_{1/2}$ is 20-45 hours. Steady state in plasma is achieved in 5-8 days. Plasma protein binding is 50% and is independent of concentration. Aliskiren is a substrate for P-glycoprotein (Pgp), which accounts for low absorption. Fatty meals significantly decrease the absorption of aliskiren. Hepatic metabolism by CYP3A4 is minimal. Elimination is mostly as unchanged drug in feces. About 25% of the absorbed dose appears in the urine as parent drug. Aliskiren is well tolerated in the elderly population, in patients with hepatic disease and renal insufficiency, and in patients with type 2 diabetes (Vaidyanathan et al., 2008).

Therapeutic Uses of Aliskiren in Hypertension. Clinical studies confirm aliskiren as an effective antihypertensive agent that induces significant dose-dependent

(75-300 mg) reductions in blood pressure. Aliskiren is as effective as ACE inhibitors (ramipril), ARBs (losartan, irbesartan, valsartan), and hydrochlorothiazide (HCTZ) in lowering blood pressure in patients with mild-to-moderate hypertension (Oparil et al., 2007; Sanoski, 2009). Aliskiren also is as effective as lisinopril in lowering blood pressure in patients with severe hypertension (Strasser et al., 2007). The long $t_{1/2}$ of aliskiren allows its antihypertensive effects to be sustained for several days following termination of therapy (Oh et al., 2007).

Many short-term studies indicate that the effect of aliskiren in combination with ACE inhibitors, ARBs, and HCTZ is additive in lowering blood pressure. The antihypertensive effects of aliskiren in monotherapy and in combination therapy were evaluated in patients with mild-to-moderate hypertension. In these studies, supplementing aliskiren to ramipril, irbesartan, valsartan, or HCTZ induced additional decreases in systolic and diastolic blood pressure that were larger than that induced by any of the drugs alone. PRA is inhibited by aliskiren but significantly elevated with ramipril, irbesartan, and HCTZ (Table 26-1). Co-administration of aliskiren with ramipril, irbesartan, or HCTZ neutralized the increase in plasma renin activity to baseline levels (Staessen, 2006; Sanoski, 2009). Because plasma renin levels correlate with the capacity to generate AngII, the ability of aliskiren to neutralize plasma renin in combination therapy may contribute to better control of blood pressure than monotherapy.

The antihypertensive effect of aliskiren is significantly augmented in combination with HCTZ (Oparil et al., 2007). Fixed-dose combinations of aliskiren/HCTZ are marketed for antihypertensive therapy (Baldwin and Plosker, 2009).

Therapeutic Uses of Aliskiren in End-Organ Damage. The ability of aliskiren to inhibit the increased PRA caused

by ACE inhibitors and ARBs theoretically provides a more comprehensive blockade of the RAS and may limit activation of the local (tissue) RAS (Table 26-1). Studies are ongoing to address whether aliskiren provides better protection against end-organ damage in cardiovascular and renal diseases.

The ALLAY trial (Aliskiren in Left Ventricular Hypertrophy trial) compared the effect of aliskiren with losartan on left ventricular hypertrophy as a marker of end-organ damage. Both aliskiren and losartan were equivalent in reducing blood pressure and decreasing left ventricular mass, but there was no additional reduction in left ventricular mass with combination therapy (Solomon et al., 2009).

The ALOFT trial (Aliskiren Observation of Heart Failure Treatment) indicated that aliskiren was beneficial when added to ACE inhibitors in heart failure treatment (McMurray et al., 2008). Patients received aliskiren or placebo in addition to standard heart failure treatment (ACE inhibitors, ARBs, β blockers), and the primary outcome measured was changes in N-terminal proB type natriuretic peptide (BNP). Aliskiren caused a significant decrease in plasma BNP levels, urinary BNP, and aldosterone levels, indicating favorable neurohormonal effects of aliskiren in heart failure when added to standard therapy. A follow-up SPHERE trial (Aliskiren Trial to Mediate Outcome Prevention in Heart Failure) will address long-term outcome in heart failure patients.

The AVOID trial (Aliskiren in Evaluation of Proteinuria I Diabetes Trial) reported aliskiren to be renoprotective in patients with hypertension and type 2 diabetes. Patients were on the maximal dose of losartan for 3 months before adding aliskiren or placebo for 6 months. At the end of the study period, patients taking aliskiren had their mean urinary albumin-to-creatinine ratio significantly decreased by 20%, and the decrease was 50% or more in 24.7% of patients compared with placebo. The renoprotective effects of aliskiren were independent of blood pressure-lowering effects

Table 26-1

Effects of Anti-hypertensive Agents on Components of the RAS

	DIRECT RENIN INHIBITORS	ACE-INHIBITORS	ARBs	DIURETICS	Ca ²⁺ CHANNEL BLOCKERS	β BLOCKERS
PRC	↑	↑	↑	↑	↔	↓
PRA	↓	↑	↑	↑	↔	↓

Ang II	↓	↓	↑	↑	↔	↓
ACE	↔	↓	↔			
Bradykinin	↔	↑	↔			
AT ₁ receptors	↔	↔	inhibition			
AT ₂ receptors	↔	↔	stimulation			

PRC, plasma renin concentration; PRA, plasma renin activity; ACE, angiotensin converting enzyme; ARB, angiotensin receptor blocker.

(Parving et al., 2008). The long-term ALTITUDE study (Aliskiren Trial in Type 2 Diabetes Using Cardio-Renal Endpoints) is in progress to assess if aliskiren will reduce cardiovascular and renal morbidity and mortality when added to ACE inhibitors and ARBs. The study is expected to end in 2011 (Parving et al., 2009).

Aliskiren is an effective antihypertensive agent that is well tolerated in monotherapy and combination therapy. It has cardioprotective and renoprotective effects in combination therapy; however, long-term advantages still need to be established. Aliskiren is recommended in patients who are intolerant to other antihypertensive therapies or for use in combination with other drugs for further blood pressure control.

Adverse Events. Aliskiren is well tolerated, and adverse events are mild or comparable to placebo with no gender difference. Adverse effects include mild gastrointestinal symptoms such as diarrhea observed at high doses (600 mg daily), abdominal pain, dyspepsia, and gastroesophageal reflux; headache; nasopharyngitis; dizziness; fatigue; upper-respiratory tract infection; back pain; angioedema; and cough (cough was much less common than with ACE inhibitors). Other adverse effects reported for aliskiren that were slightly increased compared with placebo include rash, hypotension, hyperkalemia in diabetics on combination therapy, elevated uric acid, renal stones, and gout. Like other RAS inhibitors, aliskiren is not recommended in pregnancy.

Drug Interactions. Aliskiren does not interact with drugs that interact with CYPs. Aliskiren reduces absorption of furosemide by 50%. Irbesartan reduces the C_{max} of aliskiren by 50%. Aliskiren plasma levels are increased by drugs, such as ketoconazole, atorvastatin, and cyclosporine, that inhibit P-glycoprotein.

Pharmacological Lowering of Blood Pressures Alters Components of the RAS

The renin-angiotensin system responds to alterations in blood pressure with compensatory changes (Figure 26-2). Thus, pharmacological agents that lower blood pressure will alter the feedback loops that regulate the RAS and cause changes in the levels and activities of the system's components. These changes are summarized in Table 26-1.

chapter

Treatment of Myocardial Ischemia and Hypertension

Thomas Michel and
Brian B. Hoffman

PATHOPHYSIOLOGY OF ISCHEMIC HEART DISEASE

Angina pectoris, the primary symptom of ischemic heart disease, is caused by transient episodes of myocardial ischemia that are due to an imbalance in the myocardial oxygen supply–demand relationship. This imbalance may be caused by an increase in myocardial oxygen demand (which is determined by heart rate, ventricular contractility, and ventricular wall tension) or by a decrease in myocardial oxygen supply (primarily determined by coronary blood flow, but occasionally modified by the oxygen-carrying capacity of the blood) or sometimes by both (Figure 27–1). Because blood flow is inversely proportional to the fourth power of the artery’s luminal radius, the progressive decrease in vessel radius that characterizes coronary atherosclerosis can impair coronary blood flow and lead to symptoms of angina when myocardial O₂ demand increases, as with exertion (so-called typical angina pectoris). In some patients, anginal symptoms may occur without any increase in myocardial O₂ demand, but rather as a consequence of an abrupt reduction in blood flow, as might result from coronary thrombosis (unstable angina) or localized vasospasm (variant or Prinzmetal angina). Regardless of the precipitating factors, the sensation of angina is similar in most patients. Typical angina is experienced as a heavy, pressing substernal discomfort (rarely described as a “pain”), often radiating to the left shoulder, flexor aspect of the left arm, jaw, or epigastrium. However, a significant minority of patients note discomfort in a different location or of a different character. Women, the elderly, and diabetics are more likely to experience myocardial ischemia with atypical symptoms. In most patients with typical

angina, whose symptoms are provoked by exertion, the symptoms are relieved by rest or by administration of sublingual nitroglycerin.

Angina pectoris is a common symptom, affecting more than 9 million Americans (Rosamond et al., 2008). Angina pectoris may occur in a stable pattern over many years or may become unstable, increasing in frequency or severity and even occurring at rest. In typical stable angina, the pathological substrate is usually fixed atherosclerotic narrowing of an epicardial coronary artery, on which exertion or emotional stress superimposes an increase in myocardial O₂ demand. In variant angina, focal or diffuse coronary vasospasm episodically reduces coronary flow. Patients also may display a mixed pattern of angina with the addition of altered vessel tone on a background of atherosclerotic narrowing. In most patients with unstable angina, rupture of an atherosclerotic plaque, with consequent platelet adhesion and aggregation, decreases coronary blood flow. Superimposed thrombosis may lead to the complete abrogation of blood flow. Atherosclerotic plaques with thinner fibrous caps appear to be more “vulnerable” to rupture.

Myocardial ischemia also may be *silent*, with electrocardiographic, echocardiographic, or radionuclide evidence of ischemia appearing in the absence of symptoms. While some patients have only silent ischemia, most patients who have silent ischemia have symptomatic episodes as well. The precipitants of silent ischemia appear to be the same as those of symptomatic ischemia. We now know that the *ischemic burden* (i.e., the total time a patient is ischemic each day) is greater in many patients than was recognized previously. In most trials, the agents that are efficacious in typical angina also are efficacious in reducing silent ischemia. β Adrenergic

Figure 27–1. Pharmacological modification of the major determinants of myocardial O₂ supply. When myocardial O₂ requirements exceed O₂ supply, an ischemic episode results. This figure shows the primary hemodynamic sites of actions of pharmacological agents that can reduce O₂ demand (*left side*) or enhance O₂ supply (*right side*). Some classes of agents have multiple effects. Stents, angioplasty, and coronary bypass surgery are mechanical interventions that increase O₂ supply. Both pharmacotherapy and mechanotherapy attempt to restore a dynamic balance between O₂ demand and O₂ supply.

receptor antagonists appear to be more effective than the Ca²⁺ channel blockers in the prevention of episodes. Therapy directed at abolishing all silent ischemia has not been shown to be of additional benefit over conventional therapy.

This section describes the principal pharmacological agents used in the treatment of angina. The major drugs are nitrovasodilators, β adrenergic receptor antagonists (see Chapter 12), and Ca²⁺ channel antagonists. These anti-anginal agents improve the balance of myocardial O₂ supply and O₂ demand, increasing supply by dilating the coronary vasculature and/or decreasing demand by reducing cardiac work (Figure 27–1).

Other drugs also have efficacy in treatment of both stable and unstable angina, including antiplatelet agents (see Chapters 30) as well as statins (HMG CoA-reductase inhibitors) (see Chapter 31), which may have a role in stabilizing the vulnerable plaque. A new class of medications that appears to be effective in treatment of angina is exemplified by ranolazine (RANEXA) (Wilson et al., 2009), which has been approved for treatment of chronic angina. The mechanisms whereby ranolazine exerts its anti-anginal effect are incompletely understood, but the drug appears to exert direct effects on cardiac myocyte Na⁺ channels (Hasenfuss and Maier 2008; Nash and Nash 2008).

Increasing the cardiac extraction of O₂ from the blood has not been a practical therapeutic goal. Drugs used in typical angina function principally by reducing myocardial O₂ demand by decreasing heart rate, myocardial contractility, and/or ventricular wall stress. By contrast, the principal therapeutic goal in unstable angina is to increase myocardial blood flow; strategies include the use of antiplatelet agents and *heparin* to

reduce intracoronary thrombosis, often accompanied by efforts to restore flow by mechanical means, including percutaneous coronary interventions using coronary stents, or (less commonly) emergency coronary bypass surgery. The principal therapeutic aim in variant or Prinzmetal angina is to prevent coronary vasospasm.

Anti-anginal agents may provide prophylactic or symptomatic treatment, but β adrenergic receptor antagonists also reduce mortality apparently by decreasing the incidence of sudden cardiac death associated with myocardial ischemia and infarction. The chronic use of organic nitrate vasodilators, which are highly efficacious in treatment of angina, is not associated with improvements in cardiac mortality, and some investigators have suggested that chronic use of nitroglycerin may have adverse cardiovascular effects (Parker, 2004). It is unclear whether the new anti-anginal agent ranolazine may have beneficial effects on cardiovascular mortality, but this drug does appear to have salutary effects on glucose metabolism (Morrow et al., 2009).

The treatment of cardiac risk factors can reduce the progression or even lead to the regression of atherosclerosis. *Aspirin* is used routinely in patients with myocardial ischemia, and daily aspirin use reduces the incidence of clinical events (Gibbons et al., 2003). Other antiplatelet agents such as oral clopidogrel and intravenous anti-integrin drugs such as abciximab, tirofiban, and eptifibatid have been shown to reduce morbidity in patients with angina who undergo coronary artery stenting (Yeghiazarians et al., 2000). Lipid-lowering drugs such as the statins reduce mortality in patients with hypercholesterolemia with or without known coronary artery disease (Libby et al., 2002). Angiotensin-converting enzyme

(ACE) inhibitors (see Chapter 26) also reduce mortality in patients with coronary disease (Yusuf et al., 2000) and are particularly recommended for patients when there is concomitant impairment of cardiac systolic function (Gibbons et al., 2003).

Coronary artery bypass surgery and percutaneous coronary interventions such as angioplasty and coronary artery stent deployment can complement pharmacological treatment. In some subsets of patients, percutaneous or surgical revascularization may have a survival advantage over medical treatment alone. Intracoronary drug delivery using drug-eluting coronary stents represents an intersection of mechanical and pharmacological approaches in the treatment of coronary artery disease. Novel therapies that modify the expression of vascular or myocardial cell genes eventually may become an important part of the therapy of ischemic heart disease.

ORGANIC NITRATES

These agents are prodrugs that are sources of nitric oxide (NO). NO activates the soluble isoform of guanylyl cyclase, thereby increasing intracellular levels of cyclic GMP. In turn, cyclic GMP promotes the dephosphorylation of the myosin light chain and the reduction of cytosolic Ca^{2+} and leads to the relaxation of smooth muscle cells in a broad range of tissues. The NO-dependent relaxation of vascular smooth muscle leads to vasodilation; NO-mediated guanylyl cyclase activation inhibits platelet aggregation and relaxes smooth muscle in the bronchi and GI tract (Murad, 1996).

The broad biological response to nitrovasodilators reflects the existence of endogenous NO-modulated regulatory pathways. The endogenous synthesis of NO in humans is catalyzed by a family of NO synthases that oxidize the amino acid L-arginine to form NO, plus L-citrulline as a co-product. There are three distinct mammalian NO synthase isoforms termed *nNOS*, *eNOS*, and *iNOS* (see Chapter 3), and they are involved in processes as diverse as neurotransmission, vasomotion, and immunomodulation. In several vascular disease states, pathways of endogenous NO-dependent regulation appear to be deranged (reviewed in Dudzinski et al., 2006).

History. Nitroglycerin was first synthesized in 1846 by Sobrero, who observed that a small quantity placed on the tongue elicited a severe headache. The explosive properties of nitroglycerin also were soon noted, and control of this unstable compound for military and industrial use was not realized until Alfred Nobel devised a process to stabilize the nitroglycerin and patented a specialized detonator in 1863. The vast fortune that Nobel accrued from the nitroglycerin detonator patent provided the funds later used to establish the Nobel prizes. In 1857, T. Lauder Brunton of Edinburgh administered *amyl nitrite*, a known vasodepressor, by inhalation and noted that anginal pain was

relieved within 30-60 seconds. The action of amyl nitrite was transitory, however, and the dosage was difficult to adjust. Subsequently, William Murrell surmised that the action of nitroglycerin mimicked that of amyl nitrite and established the use of sublingual nitroglycerin for relief of the acute anginal attack and as a prophylactic agent to be taken prior to exertion. The empirical observation that organic nitrates could dramatically and safely alleviate the symptoms of angina pectoris led to their widespread acceptance by the medical profession. Indeed, Alfred Nobel himself was prescribed nitroglycerin by his physicians when he developed angina in 1890. Basic investigations defined the role of NO in both the vasodilation produced by nitrates and endogenous vasodilation. The importance of NO as a signaling molecule in the cardiovascular system and elsewhere was recognized by the awarding of the 1998 Nobel Prize in medicine/physiology to the pharmacologists Robert Furchgott, Louis Ignarro, and Ferid Murad.

Chemistry. Organic nitrates are polyol esters of nitric acid, whereas organic nitrites are esters of nitrous acid (Table 27-1). Nitrate esters ($-\text{C}-\text{O}-\text{NO}_2$) and nitrite esters ($-\text{C}-\text{O}-\text{NO}$) are characterized by a sequence of carbon-oxygen-nitrogen, whereas nitro compounds possess carbon-nitrogen bonds ($\text{C}-\text{NO}_2$). Thus glyceryl trinitrate is not a nitro compound, and it is erroneously called nitroglycerin; however, this nomenclature is both widespread and official. Amyl nitrite is a highly volatile liquid that must be administered by inhalation and is of limited therapeutic utility. Organic nitrates of low molecular mass (such as nitroglycerin) are moderately volatile, oily liquids, whereas the high-molecular-mass nitrate esters (e.g., erythrityl tetranitrate, isosorbide dinitrate, and isosorbide mononitrate) are solids. In the pure form (without an inert carrier such as lactose), nitroglycerin is explosive. The organic nitrates and nitrites, collectively termed *nitrovasodilators*, must be metabolized (reduced) to produce gaseous NO, which appears to be the active principle of this class of compounds. Nitric oxide gas also can be directly administered by inhalation (Bloch et al., 2007).

Pharmacological Properties

Mechanism of Action. Nitrites, organic nitrates, nitroso compounds, and a variety of other nitrogen oxide-containing substances (including *nitroprusside*; see later in the chapter) lead to the formation of the reactive gaseous free radical NO and related NO-containing compounds. Nitric oxide gas also may be administered by inhalation. The exact mechanism(s) of denitration of the organic nitrates to liberate NO remains an active area of investigation (Chen et al., 2002).

Phosphorylation of the myosin light chain regulates the maintenance of the contractile state in smooth muscle. NO can activate guanylyl cyclase, increase the cellular level of cyclic GMP, activate PKG, and modulate the activities of cyclic nucleotide phosphodiesterases (PDEs 2, 3, and 5) in a variety of cell types. In smooth muscle, the net result is reduced phosphorylation of myosin light chain, reduced Ca^{2+} concentration in the cytosol, and relaxation. One important

Table 27-1

Organic Nitrates Available for Clinical Use

NONPROPRIETARY NAMES AND TRADE NAMES	CHEMICAL STRUCTURE	PREPARATIONS, USUAL DOSES, AND ROUTES OF ADMINISTRATION ^a
Nitroglycerin (glyceryl trinitrate; NITRO-BID, NITROSTAT, NITROL, NITRO-DUR, others)	$\begin{array}{c} \text{H}_2\text{C}-\text{O}-\text{NO}_2 \\ \\ \text{HC}-\text{O}-\text{NO}_2 \\ \\ \text{H}_2\text{C}-\text{O}-\text{NO}_2 \end{array}$	T: 0.3-0.6 mg as needed S: 0.4 mg per spray as needed C: 2.5-9 mg 2-4 times daily B: 1 mg every 3-5 h O: 2.5-5 cm, topically to skin every 4-8 h D: 1 disc (2.5-15 mg) for 12-16 h per day IV: 10-20 $\mu\text{g}/\text{min}$; increments of 10 $\mu\text{g}/\text{min}$ to a maximum of 400 $\mu\text{g}/\text{min}$
Isosorbide dinitrate (ISORDIL, SORBITRATE, DILATRATE-SR, others)		T: 2.5-10 mg every 2-3 h T(C): 5-10 mg every 2-3 h T(O): 5-40 mg every 8 h C: 40-80 mg every 12 h
Isosorbide-5-mononitrate (IMDUR, ISMO, others)		T: 10-40 mg twice daily C: 60-120 mg daily

^aB, buccal (transmucosal) tablet; C, sustained-release capsule or tablet; D, transdermal disc or patch; IV, intravenous injection; O, ointment; S, lingual spray; T, tablet for sublingual use; T(C), chewable tablet; T(O), oral tablet or capsule.

consequence of the NO-mediated increase in intracellular cyclic GMP is the activation of PKG, which catalyzes the phosphorylation of various proteins in smooth muscle. Another important target of this kinase is the myosin light-chain phosphatase, which is activated on binding PKG and leads to dephosphorylation of the myosin light chain and thereby promotes vasorelaxation and smooth muscle relaxation in many other tissues.

The pharmacological and biochemical effects of the nitrovasodilators appear to be identical to those of an endothelium-derived relaxing factor now known to be NO. Although the soluble isoform of guanylyl cyclase remains the most extensively characterized molecular “receptor” for NO, it is increasingly clear that NO also forms specific adducts with thiol groups in proteins and with reduced glutathione to form nitrosothiol

compounds with distinctive biological properties (Stamler et al., 2001). Mitochondrial aldehyde dehydrogenase has been shown to catalyze the reduction of nitroglycerin to yield bioactive NO metabolites (Chen et al., 2002), providing a potentially important clue to the biotransformation of organic nitrates in intact tissues. The regulation and pharmacology of eNOS have been reviewed (Dudzinski et al., 2006).

Cardiovascular Effects Hemodynamic Effects. The nitrovasodilators promote relaxation of vascular smooth muscle. Low concentrations of nitroglycerin preferentially dilate veins more than arterioles. This venodilation decreases venous return, leading to a fall in left and right ventricular chamber size and end-diastolic pressures, but usually results in little change in systemic vascular resistance. Systemic arterial pressure may fall slightly, and heart rate is unchanged or may increase slightly in response to a

decrease in blood pressure. Pulmonary vascular resistance and cardiac output are slightly reduced. Doses of nitroglycerin that do not alter systemic arterial pressure may still produce arteriolar dilation in the face and neck, resulting in a facial flush, or dilation of meningeal arterial vessels, causing headache. The molecular basis for the differential response of arterial versus venous tissues to nitroglycerin remains incompletely understood.

Higher doses of organic nitrates cause further venous pooling and may decrease arteriolar resistance as well, thereby decreasing systolic and diastolic blood pressure and cardiac output and causing pallor, weakness, dizziness, and activation of compensatory sympathetic reflexes. The reflex tachycardia and peripheral arteriolar vasoconstriction tend to restore systemic vascular resistance; this is superimposed on sustained venous pooling. Coronary blood flow may increase transiently as a result of coronary vasodilation but may decrease subsequently if cardiac output and blood pressure decrease sufficiently.

In patients with autonomic dysfunction and an inability to increase sympathetic outflow (multiple-system atrophy and pure autonomic failure are the most common forms, much less commonly seen in the autonomic dysfunction associated with diabetes), the fall in blood pressure consequent to the venodilation produced by nitrates cannot be compensated. In these clinical contexts, nitrates may reduce arterial pressure and coronary perfusion pressure significantly, producing potentially life-threatening hypotension and even aggravating angina. The appropriate therapy in patients with orthostatic angina and normal coronary arteries is to correct the orthostatic hypotension by expanding volume (*fludrocortisone* and a high-sodium diet), to prevent venous pooling with fitted support garments, and to carefully titrate use of oral vasopressors. Because patients with autonomic dysfunction occasionally may have coexisting coronary artery disease, the coronary anatomy should be defined before therapy is undertaken.

Effects on Total and Regional Coronary Blood Flow. Myocardial ischemia is a powerful stimulus to coronary vasodilation, and regional blood flow is adjusted by autoregulatory mechanisms. In the presence of atherosclerotic coronary artery narrowing, ischemia distal to the lesion stimulates vasodilation; if the stenosis is severe, much of the capacity to dilate is used to maintain resting blood flow. When demand increases, further dilation may not be possible. After demonstration of direct coronary artery vasodilation in experimental animals, it became generally accepted that nitrates relieved anginal pain by dilating coronary arteries and thereby increasing coronary blood flow. In the presence of significant coronary stenoses, there is a disproportionate reduction in blood flow to the subendocardial regions of the heart, which are subjected to the

greatest extravascular compression during systole; organic nitrates tend to restore blood flow in these regions toward normal.

The hemodynamic mechanisms responsible for these effects are not entirely clear. Most hypotheses have focused on the ability of organic nitrates to cause dilation and prevent vasoconstriction of large epicardial vessels without impairing autoregulation in the small vessels, which are responsible for ~90% of the overall coronary vascular resistance. The vessel diameter is an important determinant of the response to nitroglycerin; vessels >200 μm in diameter are highly responsive, whereas those >100 μm respond minimally. Experimental evidence in patients undergoing coronary bypass surgery indicates that nitrates do have a relaxant effect on large coronary vessels. Collateral flow to ischemic regions also is increased. Moreover, analyses of coronary angiograms in humans have shown that sublingual nitroglycerin can dilate epicardial stenoses and reduce the resistance to flow through such areas (Brown et al., 1981; Feldman et al., 1981). The resulting increase in blood flow would be distributed preferentially to ischemic myocardial regions as a consequence of vasodilation induced by autoregulation. An important indirect mechanism for a preferential increase in subendocardial blood flow is the nitroglycerin-induced reduction in intracavitary systolic and diastolic pressures that oppose blood flow to the subendocardium (see below). To the extent that organic nitrates decrease myocardial requirements for O_2 (see the next section), the increased blood flow in ischemic regions could be balanced by decreased flow in nonischemic areas, and an overall increase in coronary artery blood flow need not occur. Dilation of cardiac veins may improve the perfusion of the coronary microcirculation. Such redistribution of blood flow to subendocardial tissue is *not* typical of all vasodilators. *Dipyridamole*, e.g., dilates resistance vessels nonselectively by distorting autoregulation and is ineffective in patients with typical angina.

In patients with angina owing to coronary artery spasm, the ability of organic nitrates to dilate epicardial coronary arteries, and particularly regions affected by spasm, may be the primary mechanism by which they are of benefit.

Effects on Myocardial O_2 Requirements. By their effects on the systemic circulation, the organic nitrates also can reduce myocardial O_2 demand. The major determinants of myocardial O_2 consumption include left ventricular wall tension, heart rate, and myocardial contractility. Ventricular wall tension is affected by a number of factors that may be considered under the categories of preload and afterload. *Preload* is determined by the diastolic pressure that distends the ventricle (ventricular end-diastolic pressure). Increasing end-diastolic volume augments the ventricular wall tension (by the law of Laplace, tension is proportional to pressure times radius). Increasing venous capacitance with nitrates decreases venous return to the heart, decreases ventricular end-diastolic volume, and thereby decreases O_2

consumption. An additional benefit of reducing preload is that it increases the pressure gradient for perfusion across the ventricular wall, which favors subendocardial perfusion. *Afterload* is the impedance against which the ventricle must eject. In the absence of aortic valvular disease, afterload is related to peripheral resistance. Decreasing peripheral arteriolar resistance reduces afterload and thus myocardial work and O_2 consumption.

Organic nitrates decrease both preload and afterload as a result of respective dilation of venous capacitance and arteriolar resistance vessels. Organic nitrates do not appear to significantly alter the inotropic or chronotropic state of the heart, although NO synthesized by cardiac myocytes and fibroblasts may play a role in the modulation of cyclic nucleotide metabolism and may thereby alter autonomic responses (Gustafsson and Brunton, 2002). Because nitrates affect several of the primary determinants of myocardial O_2 demand, their net effect usually is to decrease myocardial O_2 consumption. In addition, an improvement in the lusitropic state of the heart may be seen with more rapid early diastolic filling. This may be secondary to the relief of ischemia rather than primary, or it may be due to a reflex increase in sympathetic activity. Nitrovasodilators also increase cyclic GMP in platelets, with consequent inhibition of platelet function (Loscalzo, 2001) and decreased deposition of platelets in animal models of arterial wall injury (Lam et al., 1988). While this may contribute to their anti-anginal efficacy, the effect appears to be modest and in some settings may be confounded by the potential of nitrates to alter the pharmacokinetics of heparin, reducing its anti-thrombotic effect.

When nitroglycerin is injected or infused directly into the coronary circulation of patients with coronary artery disease, anginal attacks (induced by electrical pacing) are not aborted even when coronary blood flow is increased. However, sublingual administration of nitroglycerin does relieve anginal pain in the same patients. Furthermore, venous phlebotomy that is sufficient to reduce left ventricular end-diastolic pressure can mimic the beneficial effect of nitroglycerin.

Patients can exercise for considerably longer periods after the administration of nitroglycerin. Nevertheless, with or without nitroglycerin, angina occurs at the same value of the *triple product* (aortic pressure \times heart rate \times ejection time, which is roughly proportional to myocardial consumption of O_2). The observation that angina occurs at the same level of myocardial O_2 consumption suggests that the beneficial effects of nitroglycerin result from reduced cardiac O_2 demand rather than an increase

in the delivery of O_2 to ischemic regions of myocardium. However, these results do not preclude the possibility that a favorable redistribution of blood flow to ischemic subendocardial myocardium may contribute to relief of pain in a typical anginal attack, nor do they preclude the possibility that direct coronary vasodilation may be the major effect of nitroglycerin in situations where vasospasm compromises myocardial blood flow.

Mechanism of Relief of Symptoms of Angina Pectoris. The ability of nitrates to dilate epicardial coronary arteries, even in areas of atherosclerotic stenosis, is modest, and the preponderance of evidence continues to favor a reduction in myocardial work, and thus in myocardial O_2 demand, as their primary effect in chronic stable angina.

Paradoxically, high doses of organic nitrates may reduce blood pressure to such an extent that coronary flow is compromised; reflex tachycardia and adrenergic enhancement of contractility also occur. These effects may override the beneficial action of the drugs on myocardial O_2 demand and can aggravate ischemia. Additionally, sublingual nitroglycerin administration may produce bradycardia and hypotension, probably owing to activation of the Bezold-Jarisch reflex.

Other Effects. The nitrovasodilators act on almost all smooth muscle tissues. Bronchial smooth muscle is relaxed irrespective of the preexisting tone. The muscles of the biliary tract, including those of the gallbladder, biliary ducts, and sphincter of Oddi, are effectively relaxed. Smooth muscle of the GI tract, including that of the esophagus, can be relaxed and its spontaneous motility decreased by nitrates both *in vivo* and *in vitro*. The effect may be transient and incomplete *in vivo*, but abnormal “spasm” frequently is reduced. Indeed, many incidences of atypical chest pain and “angina” are due to biliary or esophageal spasm, and these too can be relieved by nitrates. Similarly, nitrates can relax ureteral and uterine smooth muscle, but these responses are of uncertain clinical significance.

Absorption, Fate, and Excretion. More than a century after the first use of organic nitrates to treat angina pectoris, their biotransformation remains the subject of active investigation. Studies in the 1970s suggested that nitroglycerin is reductively hydrolyzed by hepatic glutathione–organic nitrate reductase. More recent studies have implicated a mitochondrial aldehyde dehydrogenase enzyme in the biotransformation of nitroglycerin (Chen et al., 2002). Other enzymatic and nonenzymatic pathways also may contribute to the biotransformation of nitrovasodilators. Despite uncertainties about the quantitative importance of the various pathways involved in nitrovasodilator metabolism, the pharmacokinetic properties of nitroglycerin and isosorbide dinitrate have been studied in some detail (Parker and Parker, 1998).

Preparations

Nitroglycerin. In humans, peak concentrations of nitroglycerin are found in plasma within 4 minutes of sublingual administration; the

drug has a $t_{1/2}$ of 1-3 minutes. The onset of action of nitroglycerin may be even more rapid if it is delivered as a sublingual spray rather than as a sublingual tablet. Glyceryl dinitrate metabolites, which have about one-tenth the vasodilator potency, appear to have half-lives of ~40 minutes.

Isosorbide Dinitrate. The major route of metabolism of isosorbide dinitrate in humans appears to be by enzymatic denitration followed by glucuronide conjugation. Sublingual administration produces maximal plasma concentrations of the drug by 6 minutes, and the fall in concentration is rapid ($t_{1/2}$ of ~45 minutes). The primary initial metabolites, isosorbide-2-mononitrate and isosorbide-5-mononitrate, have longer half-lives (3-6 hours) and are presumed to *contribute to the therapeutic efficacy of the drug*.

Isosorbide-5-Mononitrate. This agent is available in tablet form. It does not undergo significant first-pass metabolism and so has excellent bioavailability after oral administration. The mononitrate has a significantly longer $t_{1/2}$ than does isosorbide dinitrate and has been formulated as a plain tablet and as a sustained-release preparation; both have longer durations of action than the corresponding dosage forms of isosorbide dinitrate.

Inhaled NO. Nitric oxide gas administered by inhalation appears to exert most of its therapeutic effects on the pulmonary vasculature because of the rapid inactivation of NO by hemoglobin in the blood. The selective pulmonary vasodilation observed when NO is administered by inhalation has formed the basis for the widespread use of inhaled NO to treat pulmonary hypertension in hypoxemic neonates, where inhaled NO has been shown to significantly reduce morbidity and mortality (Bloch et al., 2007). The efficacy of inhaled NO in adults for other clinical situations that are characterized by elevated pulmonary vascular pressures (acute lung injury and primary pulmonary hypertension, among other disease states) has not yet been established, and therapies using inhaled NO remain under active investigation.

Correlation of Plasma Concentrations of Drug and Biological Activity. Intravenous administration of nitroglycerin or long-acting organic nitrates in anesthetized animals produces the same transient (1-4 minutes) decrease in blood pressure. Because denitration markedly reduces the activity of the organic nitrates, their rapid clearance from blood indicates that the transient duration of action under these conditions correlates with the concentrations of the parent compounds. The rate of hepatic denitration is characteristic of each nitrate and is influenced by hepatic blood flow or the presence of hepatic disease. In experimental animals, injection of moderate amounts of organic nitrates into the portal vein results in little or no vasodepressor activity, indicating that a substantial fraction of drug can be inactivated by first-pass metabolism in the liver (isosorbide mononitrate is an exception).

Tolerance

Sublingual organic nitrates should be taken at the time of an anginal attack or in anticipation of exercise or stress. Such intermittent treatment provides reproducible cardiovascular effects. However, frequently repeated or continuous exposure to high doses of organic nitrates leads to a marked attenuation in the

magnitude of most of their pharmacological effects. The magnitude of tolerance is a function of dosage and frequency of use.

Tolerance may result from a reduced capacity of the vascular smooth muscle to convert nitroglycerin to NO, *true vascular tolerance*, or to the activation of mechanisms extraneous to the vessel wall, *pseudotolerance* (Münzel et al., 1995). Multiple mechanisms have been proposed to account for nitrate tolerance, including volume expansion, neurohumoral activation, cellular depletion of sulfhydryl groups, and the generation of free radicals (Parker and Parker, 1998). Inactivation of mitochondrial aldehyde dehydrogenase, an enzyme implicated in biotransformation of nitroglycerin, is seen in models of nitrate tolerance (Sydow et al., 2004), potentially associated with oxidative stress (Parker, 2004). A reactive intermediate formed during the generation of NO from organic nitrates may itself damage and inactivate the enzymes of the activation pathway; tolerance could involve endothelium-derived reactive oxygen species (Münzel et al., 1995; Parker 2004). Clinical data relating to the ability of agents that modify the renin-angiotensin-aldosterone system to prevent nitrate tolerance are contradictory (Parker and Parker, 1998). Important to the interpretation of clinical trials, factors that may influence the ability of such modification to prevent nitrate tolerance include the dose, whether the ACE inhibitors or angiotensin receptor antagonists were administered prior to the initiation of nitrates, and the tissue specificity of the agent. Despite experimental evidence that depletion of sulfhydryl groups may lead to impaired biotransformation of nitrates to NO and thereby result in nitrate tolerance, experimental results to date with sulfhydryl donors have been disappointing. Other changes that are observed in the setting of nitroglycerin tolerance include an enhanced response to vasoconstrictors such as angiotensin II (AngII), serotonin, and phenylephrine. Administration of nitroglycerin is associated with plasma volume expansion, which may be reflected by a decrease in hematocrit. Although diuretic therapy with hydrochlorothiazide can improve a patient's exercise duration, appropriately designed crossover trials have failed to demonstrate an effect of diuretics on nitrate tolerance (Parker et al., 1996).

A more effective approach to restoring responsiveness is to interrupt therapy for 8-12 hours each day, which allows the return of efficacy. It is usually most convenient to omit dosing at night in patients with exertional angina either by adjusting dosing intervals of oral or buccal preparations or by removing cutaneous nitroglycerin. However, patients whose anginal pattern suggests its precipitation by increased left ventricular filling pressures (i.e., occurring in association with orthopnea or paroxysmal nocturnal dyspnea) may benefit from continuing nitrates at night and omitting them during a quiet period of the day. Tolerance also has been seen with isosorbide-5-mononitrate; an eccentric twice-daily dosing schedule appears to maintain efficacy (Parker and Parker, 1998).

While these approaches appear to be effective, some patients develop an increased frequency of nocturnal

angina when a nitrate-free interval is employed using nitroglycerin patches; such patients may require another class of anti-anginal agent during this period. Tolerance is not universal, and some patients develop only partial tolerance. The problem of anginal rebound during nitrate-free intervals is especially problematic in the treatment of unstable angina with intravenous nitroglycerin. As tolerance develops, increasing doses are required to achieve the same therapeutic effects; eventually, despite dose escalation, the drug loses efficacy.

A special form of nitroglycerin tolerance is observed in individuals exposed to nitroglycerin in the manufacture of explosives. If protection is inadequate, workers may experience severe headaches, dizziness, and postural weakness during the first several days of employment. Tolerance then develops, but headache and other symptoms may reappear after a few days away from the job—the “Monday disease.” The most serious effect of chronic exposure is a form of organic nitrate dependence. Workers without demonstrable organic vascular disease have been reported to have an increase in the incidence of acute coronary syndromes during the 24-72-hour periods away from the work environment (Parker et al., 1995). Coronary and digital arteriospasm during withdrawal and its relaxation by nitroglycerin also have been demonstrated radiographically. Because of the potential problem of nitrate dependence, it seems prudent not to withdraw nitrates abruptly from a patient who has received such therapy chronically.

Toxicity and Untoward Responses

Untoward responses to the therapeutic use of organic nitrates are almost all secondary to actions on the cardiovascular system. Headache is common and can be severe. It usually decreases over a few days if treatment is continued and often can be controlled by decreasing the dose. Transient episodes of dizziness, weakness, and other manifestations associated with postural hypotension may develop, particularly if the patient is standing immobile, and may progress occasionally to loss of consciousness, a reaction that appears to be accentuated by alcohol. It also may be seen with very low doses of nitrates in patients with autonomic dysfunction. Even in severe nitrate syncope, positioning and other measures that facilitate venous return are the only therapeutic measures required. All the organic nitrates occasionally can produce drug rash.

Interaction of Nitrates with PDE5 Inhibitors. Erectile dysfunction is a frequently encountered problem whose risk factors parallel those of coronary artery disease. Thus many men desiring therapy for erectile dysfunction already may be receiving (or may require, especially if they increase physical activity) anti-anginal therapy. The combination of sildenafil and other phosphodiesterase 5

(PDE5) inhibitors with organic nitrate vasodilators can cause extreme hypotension.

Cells in the corpus cavernosum produce NO during sexual arousal in response to nonadrenergic, noncholinergic neurotransmission (Burnett et al., 1992). NO stimulates the formation of cyclic GMP, which leads to relaxation of smooth muscle of the corpus cavernosum and penile arteries, engorgement of the corpus cavernosum, and erection. The accumulation of cyclic GMP can be enhanced by inhibition of the cyclic GMP-specific PDE5 family. Sildenafil (VIA-GRA, REVATIO) and congeners inhibit PDE5 and have been demonstrated to improve erectile function in patients with erectile dysfunction. Not surprisingly, PDE5 inhibitors have assumed the status of widely used recreational drugs. Since the introduction of sildenafil, two additional PDE5 inhibitors have been developed for use in therapy of erectile dysfunction. Tadalafil (CIALIS, ADCIRCA) and vardenafil (LEVITRA) share similar therapeutic efficacy and side-effect profiles with sildenafil; tadalafil has a longer time to onset of action and a longer therapeutic $t_{1/2}$ than the other PDE5 inhibitors. Sildenafil has been the most thoroughly characterized of these compounds, but all three PDE5 inhibitors are contraindicated for patients taking organic nitrate vasodilators, and the PDE5 inhibitors should be used with caution in patients taking α or β adrenergic receptor antagonists (see Chapter 12).

The side effects of sildenafil and other PDE5 inhibitors are largely predictable on the basis of their effects on PDE5. Headache, flushing, and rhinitis may be observed, as well as dyspepsia owing to relaxation of the lower esophageal sphincter. Sildenafil and vardenafil also weakly inhibit PDE6, the enzyme involved in photoreceptor signal transduction (Chapters 3 and 64), and can produce visual disturbances, most notably changes in the perception of color hue or brightness. In addition to visual disturbances, sudden one-sided hearing loss has also been reported. Tadalafil inhibits PDE11, a widely distributed PDE isoform, but the clinical importance of this effect is not clear. The most important toxicity of all these PDE5 inhibitors is hemodynamic. When given alone to men with severe coronary artery disease, these drugs have modest effects on blood pressure, producing >10% fall in systolic, diastolic, and mean systemic pressures and in pulmonary artery systolic and mean pressures (Herrmann et al., 2000). However, sildenafil, tadalafil, and vardenafil all have a significant and potentially dangerous interaction with organic nitrates, the therapeutic actions of which are mediated via their conversion to NO with resulting increases in cyclic GMP. In the presence of a PDE5 inhibitor, nitrates cause profound increases in cyclic GMP and can produce dramatic reductions in blood pressure. Compared with controls, healthy male subjects pretreated with sildenafil or the other PDE5 inhibitors exhibit a much greater decrease in systolic blood pressure when treated with sublingual glyceryl trinitrate, and in many subjects a fall of more than 25 mm Hg was detected. This drug class toxicity is the basis for the warning that PDE5 inhibitors should not be prescribed to patients receiving any form of nitrate (Cheitlin et al., 1999) and dictates that patients should be questioned about the use of PDE5 inhibitors within 24 hours before nitrates are administered. A period of longer than 24 hours may be needed following administration of a PDE5 inhibitor for safe use of nitrates, especially with tadalafil because of its prolonged $t_{1/2}$. In the event that patients develop significant hypotension following combined administration of sildenafil and

a nitrate, fluids and α -adrenergic receptor agonists, if needed, should be used for support (Cheitlin et al., 1999). These same hemodynamic responses to PDE5 inhibition also may underlie the efficacy of sildenafil in the treatment of patients with primary pulmonary hypertension, in whom chronic treatment with the drug appears to result in enhanced exercise capacity associated with a decrease in pulmonary vascular resistance (Tsai and Kass, 2009). PDE5 inhibitors also are being studied in patients with congestive heart failure and cardiac hypertrophy (see Chapter 28).

Sildenafil, tadalafil, and vardenafil are metabolized via CYP3A4, and their toxicity may be enhanced in patients who receive other substrates of this enzyme, including macrolide and imidazole antibiotics, some statins, and antiretroviral agents (see individual chapters and Chapter 6). PDE5 inhibitors also may prolong cardiac repolarization by blocking the I_{Kr} . Although these interactions and effects are important clinically, the overall incidence and profile of adverse events observed with PDE5 inhibitors, when used without nitrates, are consistent with the expected background frequency of the same events in the treated population. In patients with coronary artery disease whose exercise capacity indicates that sexual activity is unlikely to precipitate angina and who are not currently taking nitrates, the use of PDE5 inhibitors can be considered. Such therapy needs to be individualized, and appropriate warnings must be given about the risk of toxicity if nitrates are taken subsequently for angina; this drug interaction may persist for approximately 24 hours for sildenafil and vardenafil and for considerably longer with tadalafil. Alternative non-nitrate anti-anginal therapy, such as β adrenergic receptor antagonists, should be used during these time periods (Cheitlin et al., 1999).

Therapeutic Uses

Angina. Diseases that predispose to angina should be treated as part of a comprehensive therapeutic program with the primary goal being to prolong life. Conditions such as hypertension, anemia, thyrotoxicosis, obesity, heart failure, cardiac arrhythmias, and acute anxiety can precipitate anginal symptoms in many patients. Patients should be counseled to stop smoking, lose weight, and maintain a low-fat, high-fiber diet; hypertension and hyperlipidemia should be corrected; and daily aspirin (or clopidogrel if aspirin is not tolerated) (see Chapter 30) should be prescribed. Exposure to sympathomimetic agents (e.g., those in nasal decongestants and other sources) probably should be avoided. The use of drugs that modify the perception of pain is a poor approach to the treatment of angina because the underlying myocardial ischemia is not relieved.

Table 27–1 lists the preparations and dosages of the nitrites and organic nitrates. The rapidity of onset, the duration of action, and the likelihood of developing tolerance are related to the method of administration.

Sublingual Administration. Because of its rapid action, long-established efficacy, and low cost, nitroglycerin is the most useful drug of the organic nitrates given sublingually. The onset of action is within 1–2 minutes, but the effects are undetectable by 1 hour after

administration. An initial dose of 0.3 mg nitroglycerin often relieves pain within 3 minutes. Absorption may be limited in patients with dentures or with dry mouths. Nitroglycerin tablets are stable but should be dispensed in glass containers and protected from moisture, light, and extremes of temperature. Active tablets usually produce a burning sensation under the tongue, but the absence of this sensation does not reliably predict loss of activity; elderly patients especially may be unable to detect the burning sensation. Anginal pain may be prevented when the drug is used prophylactically immediately prior to exercise or stress. The smallest effective dose should be prescribed. Patients should be instructed to seek medical attention immediately if three tablets taken over a 15-minute period do not relieve a sustained attack because this situation may be indicative of myocardial infarction (MI), unstable angina, or another cause of the pain. Patients also should be advised that there is no virtue in trying to avoid taking sublingual nitroglycerin for anginal pain. Other nitrates that can be taken sublingually do not appear to be longer acting than nitroglycerin because their half-lives depend only on the rate at which they are delivered to the liver. They are no more effective than nitroglycerin and often are more expensive.

Oral Administration. Oral nitrates often are used to provide prophylaxis against anginal episodes in patients who have more than occasional angina. They must be given in sufficient dosage to provide effective plasma levels after first-pass hepatic degradation. Low doses (e.g., 5–10 mg isosorbide dinitrate) are no more effective than placebo in decreasing the frequency of anginal attacks or increasing exercise tolerance. Higher doses of either isosorbide dinitrate (e.g., 20 mg or more orally every 4 hours) or sustained-release preparations of nitroglycerin decrease the frequency of anginal attacks and improve exercise tolerance. Effects peak at 60–90 minutes and last for 3–6 hours. Under these circumstances, the activities of less potent metabolites also may contribute to the therapeutic effect. Chronic oral administration of isosorbide dinitrate (120–720 mg daily) results in persistence of the parent compound and higher plasma concentrations of metabolites. However, these doses are more likely to cause troublesome side effects and lead to tolerance. Administration of isosorbide mononitrate (typically starting at 20 mg) once or twice daily (in the latter case, with the doses administered 7 hours apart) is efficacious in the treatment of chronic angina, and once-daily dosing or an eccentric twice-daily dosing schedule can minimize the development of tolerance.

Cutaneous Administration. Application of nitroglycerin ointment can relieve angina, prolong exercise capacity, and reduce ischemic ST-segment depression with exercise for 4 hours or more. Nitroglycerin ointment (2%) is applied to the skin (2.5–5 cm) as it is squeezed from the tube and then spread in a uniform layer; the dosage must be adjusted for each patient. Effects are apparent within 30–60 minutes (although absorption is variable) and last for 4–6 hours. The ointment is particularly useful for controlling nocturnal angina, which commonly develops within 3 hours after the patient goes to sleep. Transdermal nitroglycerin disks use a nitroglycerin-impregnated polymer (bonded to an adhesive bandage) that permits gradual absorption and a continuous plasma nitrate concentration over 24 hours. The onset of action is slow, with peak effects occurring at 1–2 hours. To avoid tolerance, therapy should be interrupted for at least 8 hours each day. With this regimen, long-term prophylaxis of ischemic episodes often can be attained.

754 Transmucosal or Buccal Nitroglycerin. This formulation is inserted under the upper lip above the incisors, where it adheres to the gingiva and dissolves gradually in a uniform manner. Hemodynamic effects are seen within 2-5 minutes, and it is therefore useful for short-term prophylaxis of angina. Nitroglycerin continues to be released into the circulation for a prolonged period, and exercise tolerance may be enhanced for up to 5 hours.

Congestive Heart Failure. The utility of nitrovasodilators to relieve pulmonary congestion and to increase cardiac output in congestive heart failure is addressed in Chapter 28.

Unstable Angina Pectoris and Non-ST-Segment-Elevation Myocardial Infarction. The term *unstable angina pectoris* has been used to describe a broad spectrum of clinical entities characterized by an acute or subacute worsening in a patient's anginal symptoms. The variable prognosis of unstable angina no doubt reflects the broad range of clinical entities subsumed by the term. More recently, efforts have been directed toward identifying patients with unstable angina on the basis of their risks for subsequent adverse outcomes such as MI or death. The term *acute coronary syndrome* has been useful in this context: Common to most clinical presentations of acute coronary syndrome is disruption of a coronary plaque, leading to local platelet aggregation and thrombosis at the arterial wall, with subsequent partial or total occlusion of the vessel. There is some variability in the pathogenesis of unstable angina, with gradually progressive atherosclerosis accounting for some cases of new-onset exertional angina. Less commonly, vasospasm in minimally atherosclerotic coronary vessels may account for some cases where rest angina has not been preceded by symptoms of exertional angina. For the most part, the pathophysiological principles that underlie therapy for exertional angina—which are directed at decreasing myocardial oxygen demand—have limited efficacy in the treatment of acute coronary syndromes characterized by an insufficiency of myocardial oxygen (blood) supply.

Notably, the degree of coronary stenosis correlates poorly with the likelihood of plaque rupture. Drugs that reduce myocardial O₂ consumption by reducing ventricular preload (nitrates) or by reducing heart rate and ventricular contractility (using β adrenergic receptor antagonists) are efficacious, but additional therapies are directed at the atherosclerotic plaque itself and the consequences (or prevention) of its rupture. As discussed later, these therapies include combinations of:

- anti-platelet agents, including aspirin and thienopyridines such as clopidogrel or prasugrel
- anti-thrombin agents such as heparin and the thrombolytics

- anti-integrin therapies that directly inhibit platelet aggregation mediated by glycoprotein (GP)IIb/IIIa
- mechano-pharmacological approaches with percutaneously deployed intracoronary stents
- coronary bypass surgery for selected patients

Along with nitrates and β adrenergic receptor antagonists, antiplatelet agents represent the cornerstone of therapy for acute coronary syndrome (Hillis and Lange, 2009). Aspirin (see later in the chapter) inhibits platelet aggregation and improves survival (Yeghiazarians et al., 2000). Heparin (either unfractionated or low-molecular-weight) also appears to reduce angina and prevent infarction. These and related agents are discussed in detail in Chapters 34 and 30. Anti-integrin agents directed against the platelet integrin GPIIb/IIIa (including abciximab, tirofiban, and eptifibatid) are effective in combination with heparin, as discussed later. Nitrates are useful both in reducing vasospasm and in reducing myocardial O₂ consumption by decreasing ventricular wall stress. Intravenous administration of nitroglycerin allows high concentrations of drug to be attained rapidly. Because nitroglycerin is degraded rapidly, the dose can be titrated quickly and safely using intravenous administration. If coronary vasospasm is present, intravenous nitroglycerin is likely to be effective, although the addition of a Ca²⁺ channel blocker may be required to achieve complete control in some patients. Because of the potential risk of profound hypotension, nitrates should be withheld and alternate anti-anginal therapy administered if patients have consumed a PDE5 inhibitor within 24 hours (discussed earlier).

Acute Myocardial Infarction. Therapeutic maneuvers in MI are directed at reducing the size of the infarct, preserving or retrieving viable tissue by reducing the O₂ demand of the myocardium, and preventing ventricular remodeling that could lead to heart failure.

Nitroglycerin is commonly administered to relieve ischemic pain in patients presenting with MI, but evidence that nitrates improve mortality in MI is sparse. Because they reduce ventricular preload through vasodilation, nitrates are effective in relief of pulmonary congestion. A decreased ventricular preload should be avoided in patients with right ventricular infarction because higher right-sided heart filling pressures are needed in this clinical context. Nitrates are relatively contraindicated in patients with systemic hypotension. According to the American Heart Association/American College of Cardiology (AHA/ACC) guidelines, “nitrates should not be used if hypotension limits the administration of β blockers, which have more powerful salutary effects” (Antman et al., 2004).

Because the proximate cause of MI is intracoronary thrombosis, reperfusion therapies are critically important, employing, when possible, direct percutaneous coronary interventions (PCIs) for acute MI, usually using drug-eluting intracoronary stents (Antman et al., 2004). Thrombolytic agents are administered at

hospitals where emergency PCI is not performed, but outcomes are better with direct PCI than with thrombolytic therapy (Antman et al., 2004) (see discussion of thrombolytic and antiplatelet therapies in Chapter 30).

Variant (Prinzmetal) Angina. The large coronary arteries normally contribute little to coronary resistance. However, in variant angina, coronary constriction results in reduced blood flow and ischemic pain. Multiple mechanisms have been proposed to initiate vasospasm, including endothelial cell injury. Whereas long-acting nitrates alone are occasionally efficacious in abolishing episodes of variant angina, additional therapy with Ca^{2+} channel blockers usually is required. Ca^{2+} channel blockers, but not nitrates, have been shown to influence mortality and the incidence of MI favorably in variant angina; they should generally be included in therapy.

Ca^{2+} CHANNEL ANTAGONISTS

Voltage-sensitive Ca^{2+} channels (L-type or slow channels) mediate the entry of extracellular Ca^{2+} into smooth muscle and cardiac myocytes and sinoatrial (SA) and atrioventricular (AV) nodal cells in response to electrical depolarization. In both smooth muscle and cardiac myocytes, Ca^{2+} is a trigger for contraction, albeit by different mechanisms. Ca^{2+} channel antagonists, also called *Ca²⁺ entry blockers*, inhibit Ca^{2+} channel function. In vascular smooth muscle, this leads to relaxation, especially in arterial beds. These drugs also may produce negative inotropic and chronotropic effects in the heart.

History. The work in the 1960s of Fleckenstein, Godfraind, and their colleagues led to the concept that drugs can alter cardiac and smooth muscle contraction by blocking the entry of Ca^{2+} into myocytes. Godfraind and associates showed that the effect of the diphenylpiperazine analogs in preventing agonist-induced vascular smooth muscle contraction could be overcome by raising the concentration of Ca^{2+} in the extracellular medium (Godfraind et al., 1986).

Hass and Hartfelder reported in 1962 that verapamil, a coronary vasodilator, possessed negative inotropic and chronotropic effects that were not seen with other vasodilatory agents, such as nitroglycerin. In 1967, Fleckenstein suggested that the negative inotropic effect resulted from inhibition of excitation–contraction coupling and that the mechanism involved reduced movement of Ca^{2+} into cardiac myocytes. Verapamil was the first clinically available calcium-channel blocker; it is a congener of papaverine. Many other calcium entry blockers with a wide range of structures are now available. Other compounds, such as nifedipine and diltiazem, also were shown to block the movement of Ca^{2+} through the cardiac myocyte Ca^{2+} channel, or the slow channel (see Chapter 29), and thereby alter the plateau phase of the cardiac action potential. Subsequently, drugs in several chemical classes have been shown to alter cardiac and

smooth muscle contraction by blocking or “antagonizing” the entry of Ca^{2+} through channels in the myocyte membrane.

Chemistry. The multiple Ca^{2+} channel antagonists that are approved for clinical use in the U.S. have diverse chemical structures. Clinically used Ca^{2+} channel antagonists include the phenylalkylamine compound verapamil, the benzothiazepine diltiazem, and numerous dihydropyridines, including nifedipine, amlodipine, felodipine, isradipine, nicardipine, nisoldipine, and nimodipine. The structures and specificities of several of these drugs are shown in Table 27–2. Although these drugs are commonly grouped together as “calcium channel blockers,” there are fundamental differences among verapamil, diltiazem, and the dihydropyridines, especially with respect to pharmacological characteristics, drug interactions, and toxicities.

Mechanisms of Action. An increased concentration of cytosolic Ca^{2+} causes increased contraction in both cardiac and vascular smooth muscle cells. The entry of extracellular Ca^{2+} is more important in initiating the contraction of cardiac myocytes (Ca^{2+} -induced Ca^{2+} release). The release of Ca^{2+} from intracellular storage sites also contributes to contraction of vascular smooth muscle, particularly in some vascular beds. Cytosolic Ca^{2+} concentrations can be increased by diverse contractile stimuli in vascular smooth muscle cells. Many hormones and autocooids increase Ca^{2+} influx through so-called receptor-operated channels, whereas increases in external concentrations of K^+ and depolarizing electrical stimuli increase Ca^{2+} influx through voltage-sensitive, or “potential operated,” channels. The Ca^{2+} channel antagonists produce their effects by binding to the α_1 subunit of the L-type Ca^{2+} channels and reducing Ca^{2+} flux through the channel. The vascular and cardiac effects of some of the Ca^{2+} channel blockers are summarized in the next section and in Table 27–2.

Voltage-sensitive channels contain domains of homologous sequence that are arranged in tandem within a single large subunit. In addition to the major channel-forming subunit (termed α_1), Ca^{2+} channels contain several other associated subunits (termed α_2 , β , γ , and δ) (Schwartz, 1992). Voltage-sensitive Ca^{2+} channels have been divided into at least three subtypes based on their conductances and sensitivities to voltage (Schwartz, 1992; Tsien et al., 1988). The channels best characterized to date are the L, N, and T subtypes. Only the L-type channel is sensitive to the dihydropyridine Ca^{2+} channel blockers. All approved Ca^{2+} channel blockers bind to the α_1 subunit of the L-type Ca^{2+} channel, which is the main pore-forming unit of the channel. This ~250,000-Da subunit is associated with a disulfide-linked $\alpha_2\delta$ subunit of ~140,000 Da and a smaller intracellular β subunit. The α_1 subunits share a common topology of four homologous domains, each of which is composed of six putative transmembrane segments (S1–S6). The α_2 , δ , and β subunits modulate the α_1 subunit (see Figure 14–2). The phenylalkylamine Ca^{2+} channel blocker verapamil binds to transmembrane segment 6 of domain IV (IVS6), the benzothiazepine Ca^{2+} channel blocker diltiazem

Table 27-2

Ca²⁺ Channel Blockers: Chemical Structures and Some Relative Cardiovascular Effects^a

CHEMICAL STRUCTURE Generic name (trade name)	VASODILATION (CORONARY FLOW)	SUPPRESSION OF CARDIAC CONTRACTILITY	SUPPRESSION OF AUTOMATICITY (SA NODE)	SUPPRESSION OF CONDUCTION (AV NODE)

binds to the cytoplasmic bridge between domain III (IIS) and domain IV (IVS), and the dihydropyridine Ca^{2+} channel blockers (nifedipine and several others) bind to transmembrane segments of both domains III and IV. These three separate receptor sites are linked allosterically.

Pharmacological Properties

Cardiovascular Effects. Actions in Vascular Tissue. Although there is some involvement of Na^+ currents, depolarization of vascular smooth muscle cells depends primarily on the influx of Ca^{2+} . At least three distinct mechanisms may be responsible for contraction of vascular smooth muscle cells. First, voltage-sensitive Ca^{2+} channels open in response to depolarization of the membrane, and extracellular Ca^{2+} moves down its electrochemical gradient into the cell. After closure of Ca^{2+} channels, a finite period of time is required before the channels can open again in response to a stimulus. Second, agonist-induced contractions that occur without depolarization of the membrane result from stimulation of the G_q -PLC- IP_3 pathway, resulting in the release of intracellular Ca^{2+} from the sarcoplasmic reticulum (Chapter 3). This receptor-mediated release of intracellular Ca^{2+} may trigger further influx of extracellular Ca^{2+} . Third, receptor-operated Ca^{2+} channels allow the entry of extracellular Ca^{2+} in response to receptor occupancy.

An increase in cytosolic Ca^{2+} results in enhanced binding of Ca^{2+} to calmodulin. The Ca^{2+} -calmodulin complex in turn activates myosin light-chain kinase, with resulting phosphorylation of the myosin light chain. Such phosphorylation promotes interaction between actin and myosin and leads to contraction of smooth muscle. Ca^{2+} channel antagonists inhibit the voltage-dependent Ca^{2+} channels in vascular smooth muscle at significantly lower concentrations than are required to interfere with the release of intracellular Ca^{2+} or to block receptor-operated Ca^{2+} channels. All Ca^{2+} channel blockers relax arterial smooth muscle, but they have a less pronounced effect on most venous beds and hence do not affect cardiac preload significantly.

Actions in Cardiac Cells. The mechanisms involved in excitation-contraction coupling in the cardiac muscle differ from those in vascular smooth muscle in that a portion of the two inward currents is carried by Na^+ through the fast channel in addition to that carried by Ca^{2+} through the slow channel. Within the cardiac myocyte, Ca^{2+} binds to troponin, relieving the inhibitory effect of troponin on the contractile apparatus and permitting a productive interaction of actin and myosin, leading to contraction. Thus, Ca^{2+} channel blockers can produce a negative inotropic effect. Although this is true

of all classes of Ca^{2+} channel blockers, the greater degree of peripheral vasodilation seen with the dihydropyridines is accompanied by a sufficient baroreflex-mediated increase in sympathetic tone to overcome the negative inotropic effect. Diltiazem also may inhibit mitochondrial Na^+ - Ca^{2+} exchange (Schwartz, 1992).

In the SA and AV nodes, depolarization largely depends on the movement of Ca^{2+} through the slow channel. The effect of a Ca^{2+} channel blocker on AV conduction and on the rate of the sinus node pacemaker depends on whether or not the agent delays the recovery of the slow channel (Schwarz, 1992). Although nifedipine reduces the slow inward current in a dose-dependent manner, it does not affect the rate of recovery of the slow Ca^{2+} channel. The channel blockade caused by nifedipine and related dihydropyridines also shows little dependence on the frequency of stimulation. At doses used clinically, nifedipine does not affect conduction through the AV node. In contrast, verapamil not only reduces the magnitude of the Ca^{2+} current through the slow channel but also decreases the rate of recovery of the channel. In addition, channel blockade caused by verapamil (and to a lesser extent by diltiazem) is enhanced as the frequency of stimulation increases, a phenomenon known as *frequency dependence* or *use dependence*. Verapamil and diltiazem depress the rate of the sinus node pacemaker and slow AV conduction; the latter effect is the basis for their use in the treatment of supraventricular tachyarrhythmias (see Chapter 29). Bepridil, like verapamil, inhibits both slow inward Ca^{2+} current and fast inward Na^+ current. It has a direct negative inotropic effect. Its electrophysiological properties lead to slowing of the heart rate, prolongation of the AV nodal effective refractory period, and importantly, prolongation of the QTc interval. Particularly in the setting of hypokalemia, the last effect can be associated with *torsades de pointes*, a potentially lethal ventricular arrhythmia (see Chapter 29).

Hemodynamic Effects. All the Ca^{2+} channel blockers approved for clinical use decrease coronary vascular resistance and can lead to an increase in coronary blood flow. The dihydropyridines are more potent vasodilators *in vivo* and *in vitro* than verapamil, which is more potent than diltiazem. The hemodynamic effects of these agents vary depending on the route of administration and the extent of left ventricular dysfunction.

Nifedipine given intravenously increases forearm blood flow with little effect on venous pooling; this indicates a selective dilation of arterial resistance vessels. The decrease in arterial blood pressure elicits sympathetic reflexes, with resulting tachycardia and positive inotropy. Nifedipine also has direct negative inotropic effects *in vitro*. However, nifedipine relaxes vascular smooth muscle at significantly lower concentrations than those required for prominent direct effects on the heart. Thus, arteriolar resistance and blood pressure are lowered, contractility and segmental ventricular function are improved, and heart rate and cardiac output are

758 increased modestly. After oral administration of nifedipine, arterial dilation increases peripheral blood flow; venous tone does not change.

The other dihydropyridines—amlodipine, felodipine, isradipine, nicardipine, nisoldipine, nimodipine, and clevidipine—share many of the cardiovascular effects of nifedipine.

Amlodipine is a dihydropyridine that has a slow absorption and a prolonged effect. With a plasma $t_{1/2}$ of 35-50 hours, plasma levels and effect increase over 7-10 days of daily administration of a constant dose. Amlodipine produces both peripheral arterial vasodilation and coronary dilation, with a hemodynamic profile similar to that of nifedipine. However, there is less reflex tachycardia with amlodipine, possibly because the long $t_{1/2}$ produces minimal peaks and troughs in plasma concentrations (van Zwieten and Pfaffendorf, 1993). Felodipine may have even greater vascular specificity than does nifedipine or amlodipine. At concentrations producing vasodilation, there is no negative inotropic effect. Like nifedipine, felodipine indirectly activates the sympathetic nervous system, leading to an increase in heart rate. Nicardipine has anti-anginal properties similar to those of nifedipine and may have selectivity for coronary vessels. Isradipine also produces the typical peripheral vasodilation seen with other dihydropyridines, but because of its inhibitory effect on the SA node, little or no rise in heart rate is seen. This inhibitory effect does not extend to the cardiac myocytes, however, because no cardiodepressant effect is seen.

Despite the negative chronotropic effect, isradipine appears to have little effect on the AV node, so it may be used in patients with AV block or combined with a β adrenergic receptor antagonist. In general, because of their lack of myocardial depression and, to a greater or lesser extent, lack of negative chronotropic effect, dihydropyridines are less effective as monotherapy in stable angina than are verapamil, diltiazem, or a β adrenergic receptor antagonist. Nisoldipine is more than 1000 times more potent in preventing contraction of human vascular smooth muscle than in preventing contraction of human cardiac muscle *in vitro*, suggesting a high degree of vascular selectivity (Godfraind et al., 1992). Although nisoldipine has a short elimination $t_{1/2}$, a sustained-release preparation that is efficacious as an anti-anginal agent has been developed. Nimodipine has high lipid solubility and was developed as an agent to relax the cerebral vasculature. It is effective in inhibiting cerebral vasospasm and has been used primarily to treat patients with neurological defects associated with cerebral vasospasm after subarachnoid hemorrhage.

Clevidipine is a novel dihydropyridine L-type Ca^{2+} channel blocker—available for intravenous administration—that has a very rapid ($t_{1/2}$ ~2 minutes) onset and offset of action. It is metabolized by esterases in blood, similar to the fate of esmolol. Clevidipine preferentially affects arterial smooth muscle compared to targeting veins or the heart. It may be useful in controlling blood pressure in severe or perioperative hypertension when oral therapy is not possible or desirable. Infusions are typically started at a rate of 1-2 $\mu\text{g}/\text{kg}/\text{min}$ and titrated to the desired effect on blood pressure. Cumulative experience with the drug in clinical settings is relatively limited.

Verapamil is a less potent vasodilator *in vivo* than are the dihydropyridines. Like dihydropyridines,

verapamil causes little effect on venous resistance vessels at concentrations that produce arteriolar dilation. With doses of verapamil sufficient to produce peripheral arterial vasodilation, there are more direct negative chronotropic, dromotropic, and inotropic effects than with the dihydropyridines. Intravenous verapamil causes a decrease in arterial blood pressure owing to a decrease in vascular resistance, but the reflex tachycardia is blunted or abolished by the direct negative chronotropic effect of the drug. This intrinsic negative inotropic effect is partially offset by both a decrease in afterload and the reflex increase in adrenergic tone. Thus, in patients without congestive heart failure, ventricular performance is not impaired and actually may improve, especially if ischemia limits performance. In contrast, in patients with congestive heart failure, intravenous verapamil can cause a marked decrease in contractility and left ventricular function. Oral administration of verapamil reduces peripheral vascular resistance and blood pressure, often with minimal changes in heart rate. The relief of pacing-induced angina seen with verapamil is due primarily to a reduction in myocardial oxygen demand.

Intravenous administration of diltiazem can result initially in a marked decrease in peripheral vascular resistance and arterial blood pressure, which elicits a reflex increase in heart rate and cardiac output. Heart rate then falls below initial levels because of the direct negative chronotropic effect of the agent. Oral administration of diltiazem decreases both heart rate and mean arterial blood pressure. While diltiazem and verapamil produce similar effects on the SA and AV nodes, the negative inotropic effect of diltiazem is more modest.

The effects of Ca^{2+} channel blockers on diastolic ventricular relaxation (the lusitropic state of the ventricle) are complex. The direct effect of several of these agents, especially when given into the coronary arteries, is to impair relaxation (Walsh and O'Rourke, 1985). Clinical studies suggest an improvement in peak left ventricular filling rates when verapamil, nifedipine, nisoldipine, or nicardipine are given systemically, but one must be cautious in extrapolating this change in filling rates to enhancement of relaxation. Because ventricular relaxation is so complex, the effect of even a single agent may be pleiotropic. If reflex stimulation of sympathetic tone increases cyclic AMP levels in myocytes, increased lusitropy will result that may outweigh a direct negative lusitropic effect. Likewise, a reduction in afterload will improve the lusitropic state. In addition, if ischemia is improved, the negative lusitropic effect of asymmetrical left ventricular contraction will be reduced. The sum total of these effects in any given patient cannot be determined *a priori*. Thus, caution should be exercised in the use of Ca^{2+} channel blockers for this purpose; the ideal is to determine the end result objectively before committing the patient to therapy.

Absorption, Fate, and Excretion. Although the absorption of these agents is nearly complete after oral administration, their bioavailability is reduced, in some cases markedly, by first-pass hepatic metabolism. The effects of these drugs are evident within 30-60 minutes of an oral dose, with the exception of the more slowly absorbed and longer-acting agents amlodipine, isradipine, and felodipine. Sustained-release forms of the Ca^{2+} channel blockers are used clinically to reduce the number of daily doses needed to maintain therapeutic drug levels, and in the case of nifedipine, sustained-release forms of the drug appear to mitigate the reflex tachycardia sometimes seen following oral administration. Intravenous administration of diltiazem or verapamil leads to a rapid therapeutic response.

These agents all are bound extensively to plasma proteins (70-98%); their elimination half-lives vary widely and range from 1.3-64 hours. During repeated oral administration, bioavailability and $t_{1/2}$ may increase because of saturation of hepatic metabolism. The bioavailability of some of these drugs may be increased by grapefruit juice, likely through inhibition of enzyme CYP3A4 expressed in the small bowel. A major metabolite of diltiazem is desacetyldiltiazem, which has about one-half of diltiazem's potency as a vasodilator. *N*-Demethylation of verapamil results in production of norverapamil, which is biologically active but much less potent than the parent compound. The $t_{1/2}$ of norverapamil is ~10 hours. The metabolites of the dihydropyridines are inactive or weakly active. In patients with hepatic cirrhosis, the bioavailabilities and half-lives of the Ca^{2+} channel blockers may be increased, and dosage should be decreased accordingly. The half-lives of these agents also may be longer in older patients. Except for diltiazem and nifedipine, all the Ca^{2+} channel blockers are administered as racemic mixtures (Abernethy and Schwartz, 1999).

Toxicity and Untoward Responses. The profile of adverse reactions to the Ca^{2+} channel blockers varies among the drugs in this class. Patients receiving immediate-release capsules of nifedipine develop headache, flushing, dizziness, and peripheral edema. However, short-acting formulations of nifedipine are not appropriate in the long-term treatment of angina or hypertension. Dizziness and flushing are much less of a problem with the sustained-release formulations and with the dihydropyridines having a long $t_{1/2}$ and relatively constant concentrations of drug in plasma. Peripheral edema may occur in some patients with Ca^{2+} channel blockers but is not the result of generalized fluid retention; it most likely results from increased hydrostatic pressure in the lower extremities owing to precapillary dilation and reflex postcapillary constriction (Epstein and Roberts, 2009). Some other adverse effects of these drugs are due to actions in nonvascular smooth muscle. Contraction of the lower esophageal sphincter is inhibited by the Ca^{2+} channel blockers. For example, Ca^{2+} channel blockers can cause or aggravate gastroesophageal reflux. Constipation is a common side effect of verapamil, but it occurs less frequently with other Ca^{2+} channel blockers. Urinary retention is a rare adverse effect. Uncommon adverse effects include rash and elevations of liver enzymes. Worsened myocardial ischemia has been observed with nifedipine (Egstrup and Andersen, 1993). Worsening

of angina was observed in patients with an angiographically demonstrable coronary collateral circulation. The worsening of angina may have resulted from excessive hypotension and decreased coronary perfusion, selective coronary vasodilation in nonischemic regions of the myocardium in a setting where vessels perfusing ischemic regions were already maximally dilated (i.e., coronary steal), or an increase in O_2 demand owing to increased sympathetic tone and excessive tachycardia. In a study of monotherapy with an immediate-release formulation of nisoldipine, the dihydropyridine was not superior to placebo and was associated with a trend toward an increased incidence of serious adverse events, a process termed *proischemia* (Waters, 1991).

Although bradycardia, transient asystole, and exacerbation of heart failure have been reported with verapamil, these responses usually have occurred after intravenous administration of verapamil in patients with disease of the SA node or AV nodal conduction disturbances or in the presence of β blockade. The use of intravenous verapamil with an intravenous β adrenergic receptor antagonist is contraindicated because of the increased propensity for AV block and/or severe depression of ventricular function. Patients with ventricular dysfunction, SA or AV nodal conduction disturbances, and systolic blood pressures below 90 mm Hg should not be treated with verapamil or diltiazem, particularly intravenously. Some Ca^{2+} channel antagonists can cause an increase in the concentration of digoxin in plasma, although toxicity from the cardiac glycoside rarely develops. The use of verapamil to treat digitalis toxicity thus is contraindicated; AV nodal conduction disturbances may be exacerbated.

Several studies have raised concerns about the long-term safety of short-acting nifedipine (Opie et al., 2000). The proposed mechanism for this adverse effect lies in abrupt vasodilation with reflex sympathetic activation. There does not appear to be either significant reflex tachycardia or long-term adverse outcomes from treatment with sustained-release forms of nifedipine or with the dihydropyridine Ca^{2+} blockers such as amlodipine or felodipine, which have more favorable (slower) pharmacokinetics.

Important drug-drug interactions may be encountered with Ca^{2+} channel blockers. Verapamil blocks the P-glycoprotein drug transporter. Both the renal and hepatic disposition of digoxin occurs via this transporter. Accordingly, verapamil inhibits the elimination of digoxin and other drugs that are cleared from the body by the P-glycoprotein (see Chapter 5). When used with quinidine, Ca^{2+} channel blockers may cause excessive hypotension, particularly in patients with idiopathic hypertrophic subaortic stenosis.

Therapeutic Uses

Variant Angina. Variant angina results from reduced blood flow (a consequence of transient localized vasoconstriction) rather than increased oxygen demand. Controlled clinical trials have demonstrated efficacy of the Ca^{2+} channel blocking agents for the treatment of variant angina (Gibbons et al., 2003). These drugs can attenuate ergonovine-induced vasospasm in patients with variant angina, which suggests that protection in variant angina is due to coronary dilation rather than to alterations in peripheral hemodynamics.

Exertional Angina. Ca^{2+} channel antagonists also are effective in the treatment of exertional, or exercise-induced, angina. Their utility may result from an increase in blood flow owing to coronary arterial dilation, from a decrease in myocardial oxygen demand (secondary to a decrease in arterial blood pressure, heart rate, or contractility), or both. Numerous double-blind, placebo-controlled studies have shown that these drugs decrease the number of anginal attacks and attenuate exercise-induced ST-segment depression.

The *double product*, calculated as heart rate \times systolic blood pressure, is an approximate if easily measured index of myocardial O_2 demand. Because these agents reduce the level of the double product at a given external workload, and because the value of the double product at peak exercise is not altered, the beneficial effect of Ca^{2+} channel blockers likely is due primarily to a decrease in O_2 demand rather than to an increase in coronary flow.

As described earlier, Ca^{2+} channel antagonists, particularly the dihydropyridines, may aggravate anginal symptoms in some patients when used without a β adrenergic receptor antagonist. This adverse effect is not prominent with verapamil or diltiazem because of their limited ability to induce marked peripheral vasodilation and reflex tachycardia. Concurrent therapy with nifedipine and the β receptor antagonist propranolol or with amlodipine and any of several β receptor antagonists has proven more effective than either agent given alone in exertional angina, presumably because the β antagonist suppresses reflex tachycardia (Gibbons et al., 2003). This concurrent drug therapy is particularly attractive because the dihydropyridines, unlike verapamil and diltiazem, do not delay AV conduction and will not enhance the negative dromotropic effects associated with β receptor blockade. Although concurrent administration of verapamil or diltiazem with a β receptor antagonist also may reduce angina, the potential for AV block, severe bradycardia, and decreased left ventricular function requires that these combinations be used judiciously, especially if left ventricular function is compromised prior to therapy. Amlodipine produces less reflex tachycardia than does nifedipine probably because of a flatter plasma concentration profile. Isradipine, approximately equivalent to nifedipine in enhancing exercise tolerance, also produces less rise in heart rate, possibly because of its slower onset of action.

Unstable Angina. Medical therapy for unstable angina involves the administration of aspirin, which reduces mortality, nitrates, β adrenergic receptor blocking agents, and heparin, which are effective in controlling ischemic episodes and angina. Because vasospasm occurs in some patients with unstable angina (Yeghiazarians et al., 2000), Ca^{2+} channel blockers may offer an additional approach to the treatment of unstable angina. However, there is insufficient evidence to assess whether such treatment decreases mortality except when the underlying

mechanism is vasospasm. In a randomized, double-blind clinical trial, the short-acting dihydropyridine nifedipine was found to be less effective than metoprolol, and there are no studies supporting the administration of a dihydropyridine to patients with unstable angina. In contrast, therapy directed toward reduction of platelet function and thrombotic episodes clearly decreases morbidity and mortality in patients with unstable angina (see Chapters 34 and 30), and administration of statins also can reduce adverse cardiac events.

Myocardial Infarction. There is no evidence that Ca^{2+} channel antagonists are of benefit in the early treatment or secondary prevention of acute MI. In several trials, higher doses of the short-acting formulation of the dihydropyridine nifedipine had a detrimental effect on mortality (Opie et al., 2000; Furberg et al., 1995). Diltiazem and verapamil may reduce the incidence of reinfarction in patients with myocardial infarction who are not candidates for a β adrenergic receptor antagonist (Gibbons et al., 2003), but β adrenergic receptor antagonists remain the drugs of first choice. Again, administration of statins can lead to improvements in the rate of adverse cardiac events, apparently independent of changes in serum lipid levels.

Other Uses. The use of Ca^{2+} channel antagonists as antiarrhythmic agents is discussed in Chapter 29; their use for the treatment of hypertension is discussed later; and use of amlodipine in the treatment of heart failure is reviewed in Chapter 28. Clinical trials are under way to evaluate the capacity of Ca^{2+} channel blockers to slow the progression of renal failure and to protect the transplanted kidney. Verapamil has been demonstrated to improve left ventricular outflow obstruction and symptoms in patients with hypertrophic cardiomyopathy. Verapamil also has been used in the prophylaxis of migraine headaches. While several studies suggest that dihydropyridines may suppress the progression of mild atherosclerosis, there is no evidence that this alters mortality or reduces the incidence of ischemic events. Nimodipine has been approved for use in patients with neurological deficits secondary to cerebral vasospasm after the rupture of a congenital intracranial aneurysm. Nifedipine, diltiazem, amlodipine, and felodipine appear to provide symptomatic relief in Raynaud's disease. The Ca^{2+} channel antagonists cause relaxation of the myometrium *in vitro* and may be effective in stopping preterm uterine contractions in preterm labor (see Chapter 66).

β ADRENERGIC RECEPTOR ANTAGONISTS

β Adrenergic receptor antagonists are effective in reducing the severity and frequency of attacks of exertional angina and in improving survival in patients who have had an MI. In contrast, these agents are not useful for vasospastic angina and, if used in isolation, may worsen the condition. Most β adrenergic receptor antagonists apparently are equally effective in the treatment of

exertional angina (Gibbons et al., 2003). *Timolol*, metoprolol, *atenolol*, and propranolol have been shown to exert cardioprotective effects. The effectiveness of β adrenergic receptor antagonists in the treatment of exertional angina is attributable primarily to a fall in myocardial O_2 consumption at rest and during exertion, although there also is some tendency for increased flow toward ischemic regions. The decrease in myocardial O_2 consumption is due to a negative chronotropic effect (particularly during exercise), a negative inotropic effect, and a reduction in arterial blood pressure (particularly systolic pressure) during exercise. Not all actions of β adrenergic receptor antagonists are beneficial in all patients. The decreases in heart rate and contractility cause increases in the systolic ejection period and left ventricular end-diastolic volume; these alterations tend to increase O_2 consumption. However, the net effect of β receptor blockade usually is to decrease myocardial O_2 consumption, particularly during exercise. Nevertheless, in patients with limited cardiac reserve who are critically dependent on adrenergic stimulation, β receptor blockade can result in profound decreases in left ventricular function. Despite this, several β adrenergic receptor antagonists have been shown to reduce mortality in patients with congestive heart failure, and treatment of patients with heart failure with β adrenergic antagonist drugs has become standard therapy for many such patients (see Chapters 12 and 28). Numerous β receptor antagonists are approved for clinical use in the U.S. Their pharmacology and the criteria for choosing a β_1 -selective agent, an agent with intrinsic sympathomimetic activity, or a nonspecific agent are considered in detail in Chapter 12.

Therapeutic Uses

Unstable Angina. β Adrenergic receptor antagonists are effective in reducing recurrent episodes of ischemia and the risk of progression to acute MI (Braunwald et al., 2002). Clinical trials have lacked sufficient statistical power to demonstrate beneficial effects of β receptor antagonists on mortality. On the other hand, if the underlying pathophysiology is coronary vasospasm, nitrates and Ca^{2+} channel blockers may be effective, and β receptor antagonists should be used with caution. In some patients, there is a combination of severe fixed disease and superimposed vasospasm; if adequate anti-platelet therapy and vasodilation have been provided by other agents and angina continues, the addition of a β receptor antagonist may be helpful.

Myocardial Infarction. β Adrenergic receptor antagonists that do not have intrinsic sympathomimetic activity improve mortality in MI. They should be given early and continued indefinitely in patients who can tolerate them (Gibbons et al., 2003).

COMPARISON OF ANTI-ANGINAL THERAPEUTIC STRATEGIES

In evaluating trials in which different forms of anti-anginal therapy are compared, careful attention must be paid to the patient population studied and to the pathophysiology and stage of the disease. An important placebo effect may be seen in these trials. The efficacy of anti-anginal treatment will depend on the severity of angina, the presence of coronary vasospasm, and myocardial O_2 demand. Optimally, the dose of each agent should be titrated to maximum benefit.

Task forces from the ACC and the AHA (Gibbons et al., 2003; updated in 2007) have published guidelines that are useful in the selection of appropriate initial therapy for patients with chronic stable angina pectoris. Patients with coronary artery disease should be treated with aspirin and a β receptor blocking drug (particularly if there is a history of prior MI). The ACC/AHA guidelines also note that solid data support the use of ACE inhibitors in patients with coronary artery disease who also have left ventricular dysfunction and/or diabetes. Therapy of hypercholesterolemia also is indicated. Nitrates, for treatment of angina symptoms, and Ca^{2+} antagonists also may be used (Gibbons et al., 2003). Table 27–3 summarizes the issues that the ACC/AHA task force considered to be relevant in choosing between β receptor antagonists and Ca^{2+} channel blockers in patients with angina and other medical conditions. A meta-analysis of publications that compared two or more anti-anginal therapies has been conducted (Heidenreich et al., 1999). Comparison of β adrenergic receptor antagonists with Ca^{2+} channel blockers showed that β receptor antagonists are associated with fewer episodes of angina per week and a lower rate of withdrawal because of adverse events. However, there were no differences in time to ischemia during exercise or in the frequency of adverse events when Ca^{2+} channel blockers other than nifedipine were compared with β adrenergic receptor antagonists. There were no significant differences in outcome between the studies comparing long-acting nitrates and Ca^{2+} channel blockers and the studies comparing long-acting nitrates with β receptor antagonists.

Table 27–3

Recommended Drug Therapy for Angina in Patients with Other Medical Conditions

CONDITION	RECOMMENDED TREATMENT (AND ALTERNATIVES) FOR ANGINA	DRUGS TO AVOID
Medical Conditions		
Systemic hypertension	β receptor antagonists (Ca ²⁺ channel antagonists)	
Migraine or vascular headaches	β receptor antagonists (Ca ²⁺ channel antagonists)	
Asthma or chronic obstructive pulmonary disease with bronchospasm	Verapamil or diltiazem	β receptor antagonists
Hyperthyroidism	β receptor antagonists	
Raynaud's syndrome	Long-acting, slow-release Ca ²⁺ antagonists	β receptor antagonists
Insulin-dependent diabetes mellitus	β receptor antagonists (particularly if prior MI) or long-acting, slow-release Ca ²⁺ channel antagonists	
Non-insulin-dependent diabetes mellitus	β receptor antagonists or long-acting, slow-release Ca ²⁺ channel antagonists	
Depression	Long-acting, slow-release Ca ²⁺ channel antagonists	β receptor antagonists
Mild peripheral vascular disease	β receptor antagonists or Ca ²⁺ channel antagonists	
Severe peripheral vascular disease with rest ischemia	Ca ²⁺ channel antagonists	β receptor antagonists
Cardiac Arrhythmias and Conduction Abnormalities		
Sinus bradycardia	Dihydropyridine Ca ²⁺ channel antagonists	β receptor antagonists, diltiazem, verapamil
Sinus tachycardia (not due to heart failure)	β receptor antagonists	
Supraventricular tachycardia	Verapamil, diltiazem, or β receptor antagonists	
Atrioventricular block	Dihydropyridine Ca ²⁺ channel antagonists	β receptor antagonists, diltiazem, verapamil
Rapid atrial fibrillation (with digitalis)	Verapamil, diltiazem, or β receptor antagonists	
Ventricular arrhythmias	β receptor antagonists	
Left Ventricular Dysfunction		
Congestive heart failure		
Mild (LVEF \geq 40%)	β receptor antagonists	
Moderate to severe (LVEF <40%)	Amlodipine or felodipine (nitrates)	
Left-sided valvular heart disease		
Mild aortic stenosis	β receptor antagonists	
Aortic insufficiency	Long-acting, slow-release dihydropyridines	
Mitral regurgitation	Long-acting, slow-release dihydropyridines	
Mitral stenosis	β receptor antagonists	
Hypertrophic cardiomyopathy	β receptor antagonists, non-dihydropyridine Ca ²⁺ channel antagonists	Nitrates, dihydropyridine Ca ²⁺ channel antagonists

MI, myocardial infarction; LVEF, left ventricular ejection fraction. (Gibbons RJ, Chatterjee K, Daley J, Douglas JS, Fihn SD, Gardin JM, Grunwald MA, Levy D, Lytle BW, O'Rourke RA, Schafer WP, Williams SV. ACC/AHA/ACP-ASIM. Guidelines for the management of patients with chronic stable angina: a report of the American College of Cardiology/ American Heart Association Task Force on Practice Guidelines (Committee on the Management of Patients With Chronic Stable Angina). *J Am Coll Cardiol* 1999; 33:2092–197. Combination Therapy and New Anti-Anginal Drugs.

Because the different categories of anti-anginal agents have different mechanisms of action, it has been suggested that combinations of these agents would allow the use of lower doses, increasing effectiveness and reducing the incidence of side effects. However, despite the predicted advantages, combination therapy rarely achieves this potential and may be accompanied by serious side effects. The new anti-anginal agent ranolazine elicits its therapeutic effects by different and incompletely understood mechanisms that distinguish this new drug from the “classical” classes of anti-anginal drugs (organic nitrates, β adrenergic blockers and Ca^{2+} channel blockers). Some studies have suggested that ranolazine may have additional efficacy in combination with other anti-anginal agents (Chaitman et al., 2004), and the effects of ranolazine on cardiac arrhythmias and glucose metabolism may identify indications for this drug independent of its role as an anti-anginal agent (Morrow et al., 2009). Indeed, most of the anti-anginal drugs have broader indications in cardiovascular therapeutics, including (among others): β blockers for treatment of hypertension, arrhythmias, and heart failure; dihydropyridine calcium channel blockers in treatment of hypertension and heart failure; and diltiazem and verapamil to treat cardiac arrhythmias and hypertension. Table 27–3 shows some of the important indications and contraindications for use of anti-anginal agents in the context of other disease states.

Nitrates and β Adrenergic Receptor Antagonists. The concurrent use of organic nitrates and β adrenergic receptor antagonists can be very effective in the treatment of typical exertional angina. The additive efficacy primarily is a result of the blockade by one drug of a reflex effect elicited by the other. β Adrenergic receptor antagonists can block the baroreceptor-mediated reflex tachycardia and positive inotropic effects that are sometimes associated with nitrates, whereas nitrates, by increasing venous capacitance, can attenuate the increase in left ventricular end-diastolic volume associated with β receptor blockade. Concurrent administration of nitrates also can alleviate the increase in coronary vascular resistance associated with blockade of β adrenergic receptors.

Ca^{2+} Channel Blockers and β Receptor Antagonists. Because there is a proven mortality benefit from the use of β adrenergic receptor antagonists in patients with heart disease, this class of drugs represents the first line of therapy. However, when angina is not controlled adequately by a β receptor antagonist plus nitrates, additional improvement

sometimes can be achieved by the addition of a Ca^{2+} channel blocker, especially if there is a component of coronary vasospasm. The differences among the chemical classes of Ca^{2+} channel blockers can lead to important adverse or salutary drug interactions with β receptor antagonists. If the patient already is being treated with maximal doses of verapamil or diltiazem, it is difficult to demonstrate any additional benefit of β receptor blockade, and excessive bradycardia, heart block, or heart failure may ensue. However, in patients treated with a dihydropyridine such as nifedipine or with nitrates, substantial reflex tachycardia often limits the effectiveness of these agents. A β receptor antagonist may be a helpful addition in this situation, resulting in a lower heart rate and blood pressure with exercise. The efficacy of amlodipine is improved by combination with a β adrenergic receptor antagonist. However, in the Total Ischaemic Burden European Trial (TIBET), which compared the effects of atenolol, a sustained-release form of nifedipine, and their combination on exercise parameters and ambulatory ischemia in patients with mild angina, there were no differences between the agents, either singly or in combination, on any of the measured ischemic parameters (Fox et al., 1996). On the other hand, in studies of patients with more severe but still stable angina, atenolol and propranolol were shown to be superior to nifedipine, and the combination of propranolol and nifedipine was more effective than a β receptor antagonist alone.

Relative contraindications to the use of β receptor antagonists for treatment of angina—bronchospasm, Raynaud’s syndrome, or Prinzmetal angina—may lead to a choice to initiate therapy with a Ca^{2+} channel blocker. Fluctuations in coronary tone are important determinants of variant angina. It is likely that episodes of increased tone, such as those precipitated by cold and by emotion, superimposed on fixed disease have a role in the variable anginal threshold seen in some patients with otherwise chronic stable angina. Increased coronary tone also may be important in the anginal episodes occurring early after MI and after coronary angioplasty, and it probably accounts for those patients with unstable angina who respond to dihydropyridines. Atherosclerotic arteries have abnormal vasomotor responses to a number of stimuli (Dudzinski et al., 2006), including exercise, other forms of sympathetic activation, and cholinergic agonists; in such vessels, stenotic segments actually may become more severely stenosed during exertion. This implies that the normal exercise-induced increase in coronary flow is lost in atherosclerosis. Similar exaggerated vascular contractile responses are seen in hyperlipidemia, even before anatomical evidence of atherosclerosis develops. Because of this, coronary vasodilators (nitrates and/or Ca^{2+} channel blockers) are an important part of the therapeutic program in the majority of patients with ischemic heart disease.

Ca^{2+} Channel Blockers and Nitrates. In severe exertional or vasospastic angina, the combination of a nitrate and

a Ca^{2+} channel blocker may provide additional relief over that obtained with either type of agent alone. Because nitrates primarily reduce preload, whereas Ca^{2+} channel blockers reduce afterload, the net effect on reduction of O_2 demand should be additive. However, excessive vasodilation and hypotension can occur. The concurrent administration of a nitrate and nifedipine has been advocated in particular for patients with exertional angina with heart failure, the sick-sinus syndrome, or AV nodal conduction disturbances, but excessive tachycardia may be seen.

Ca^{2+} Channel Blockers, β Receptor Antagonists, and Nitrates. In patients with exertional angina that is not controlled by the administration of two types of anti-anginal agents, the use of all three may provide improvement, although the incidence of side effects increases significantly. The dihydropyridines and nitrates dilate epicardial coronary arteries, the dihydropyridines decrease afterload, the nitrates decrease preload, and the β receptor antagonists decrease heart rate and myocardial contractility. Therefore, there is theoretical, and sometimes real, benefit with their combination, although adverse drug interactions may lead to clinically important events. For example, combining verapamil or diltiazem with a β receptor antagonist greatly increases the risk of conduction system and left ventricular dysfunction-related side effects and should be undertaken only with extreme caution and only if no other alternatives exist.

ANTI-PLATELET, ANTI-INTEGRIN, AND ANTI-THROMBOTIC AGENTS

Aspirin reduces the incidence of MI and death in patients with unstable angina. In addition, low doses of aspirin appear to reduce the incidence of MI in patients with chronic stable angina. Aspirin, given in doses of 160-325 mg at the onset of treatment of MI, reduces mortality in patients presenting with unstable angina. The addition of the thienopyridine clopidogrel to aspirin therapy reduces mortality in patients with acute coronary syndromes (Hillis and Lange, 2009); a related thienopyridine, prasugrel, has been approved for treatment of acute coronary syndromes (Wiviott et al., 2007). Heparin, in its unfractionated form and as low-molecular-weight heparin, also reduces symptoms and prevents infarction in unstable angina (Yeghiazarians et al., 2000). Thrombin inhibitors, such as hirudin or bivalirudin, directly inhibit even clot-bound thrombin, are not affected by circulating inhibitors, and function

independently of antithrombin III. Thrombolytic agents, on the other hand, are of no benefit in unstable angina (Yeghiazarians et al., 2000). Intravenous inhibitors of the platelet GPIIb/IIIa receptor (abciximab, tirofiban, and eptifibatide) are effective in preventing the complications of PCIs and in the treatment of some patients presenting with acute coronary syndromes (Hillis and Lange, 2009).

TREATMENT OF CLAUDICATION AND PERIPHERAL VASCULAR DISEASE

Most patients with peripheral vascular disease also have coronary artery disease, and the therapeutic approaches for peripheral and coronary arterial diseases overlap. Mortality in patients with peripheral vascular disease is most commonly due to cardiovascular disease (Regensteiner and Hiatt, 2002), and treatment of coronary disease remains the central focus of therapy. Many patients with advanced peripheral arterial disease are more limited by the consequences of peripheral ischemia than by myocardial ischemia. In the cerebral circulation, arterial disease may be manifest as stroke or transient ischemic attacks. The painful symptoms of peripheral arterial disease in the lower extremities (claudication) typically are provoked by exertion, with increases in skeletal muscle O_2 demand exceeding blood flow impaired by proximal stenoses. When flow to the extremities becomes critically limiting, peripheral ulcers and rest pain from tissue ischemia can become debilitating.

Most of the therapies shown to be efficacious for treatment of coronary artery disease also have a salutary effect on progression of peripheral artery disease (Hirsch et al., 2005). Reductions in cardiovascular morbidity and mortality in patients with peripheral arterial disease have been documented with anti-platelet therapy using aspirin, clopidogrel, or ticlopidine, administration of ACE inhibitors, and treatment of hyperlipidemia (Regensteiner and Hiatt, 2002). Interestingly, neither intensive treatment of diabetes mellitus nor antihypertensive therapy appears to alter the progression of symptoms of claudication. Other risk factor and lifestyle modifications remain cornerstones of therapy for patients with claudication: Physical exercise, rehabilitation, and smoking cessation have proven efficacy. Drugs used specifically in the treatment of lower-extremity claudication include pentoxifylline and cilostazol (Hiatt, 2001). Pentoxifylline is a methylxanthine derivative that is called a *rheologic modifier* for its effects on increasing the deformability of red blood cells. However, the

effects of pentoxifylline on lower-extremity claudication appear to be modest. Cilostazol is an inhibitor of PDE3 and promotes accumulation of intracellular cyclic AMP in many cells, including blood platelets. Cilostazol-mediated increases in cyclic AMP inhibit platelet aggregation and promote vasodilation. The drug is metabolized by CYP3A4 and has important drug interactions with other drugs metabolized via this pathway (see Chapter 6). Cilostazol treatment improves symptoms of claudication but has no effect on cardiovascular mortality.

As a PDE3 inhibitor, cilostazol is in the same drug class as milrinone, which had been used orally as an inotropic agent for patients with heart failure. Milrinone therapy was associated with an increase in sudden cardiac death, and the oral form of the drug was withdrawn from the market. Concerns about several other inhibitors of PDE3 (inamrinone, flecainide) followed. Cilostazol, therefore, is labeled as being contraindicated in patients with heart failure, although it is not clear that cilostazol itself leads to increased mortality in such patients. Cilostazol has been reported to increase non-sustained ventricular tachycardia; headache is the most common side effect. Other treatments for claudication, including naftidrofuryl, propionyl levocarnitine, and prostaglandins, have been explored in clinical trials, and there is some evidence that some of these therapies may be efficacious.

MECHANO-PHARMACOLOGICAL THERAPY: DRUG-ELUTING ENDOVASCULAR STENTS

Intracoronary stents can ameliorate angina and reduce adverse events in patients with acute coronary syndromes. However, the long-term efficacy of intracoronary stents is limited by subacute luminal restenosis within the stent, which occurs in a substantial minority of patients. The pathways that lead to “in-stent restenosis” are complex, but smooth muscle proliferation within the lumen of the stented artery is a common pathological finding. Local antiproliferative therapies at the time of stenting have been explored over many years, and the development of drug-eluting stents has had an important impact on clinical practice (Moses et al., 2003; Stone et al., 2004). Two drugs are currently being used in intravascular stents: paclitaxel and sirolimus. Paclitaxel is a tricyclic diterpene that inhibits cellular proliferation by binding to and stabilizing polymerized microtubules. Sirolimus is a hydrophobic macrolide that binds to the cytosolic immunophilin FKBP12; the FKBP12–sirolimus complex inhibits the mammalian kinase target of rapamycin (mTOR), thereby inhibiting cell cycle progression (see Chapter 60). Paclitaxel and sirolimus differ markedly in their mechanisms of action but share common chemical

properties as hydrophobic small molecules. Differences in the intracellular targets of these two drugs are associated with marked differences in their distribution in the vascular wall (Levin et al., 2004). Stent-induced damage to the vascular endothelial cell layer can lead to thrombosis; patients typically are treated with antiplatelet agents, including clopidogrel (for up to 6 months) and aspirin (indefinitely), sometimes in conjunction with intravenous heparin and/or GPIIb/IIIa inhibitors administered at the time of the revascularization procedure. The inhibition of cellular proliferation by paclitaxel and sirolimus not only affects vascular smooth muscle cell proliferation but also attenuates the formation of an intact endothelial layer within the stented artery. Therefore, antiplatelet therapy (typically with clopidogrel) is continued for several months after intracoronary stenting with drug-eluting stents. The rate of restenosis with drug-eluting stents is reduced markedly compared with “bare metal” stents, and the ongoing development of mechanopharmacological approaches likely will lead to novel approaches in intravascular therapeutics.

An important caveat in the use of drug-eluting stents is that stent thrombosis can occur even many months after placement of the stent, sometimes temporally associated with discontinuation of antiplatelet therapy with clopidogrel (Hillis and Lange, 2009). Long-term therapy with clopidogrel added to lifelong therapy with aspirin may be considered for many patients with drug-eluting stents; such long-term therapy carries an increased risk of bleeding. In some patients, the risk-benefit ratio between bare metal and drug-eluting stents may lead to the choice of a bare metal stent. The relative efficacy, morbidity, and mortality of percutaneous coronary revascularization versus surgical coronary artery bypass grafting are topics of active investigation and debate, well beyond the scope of this chapter. Mechano-pharmacological therapies influence this important ongoing discussion.

THERAPY OF HYPERTENSION

Hypertension is the most common cardiovascular disease. The prevalence of hypertension increases with advancing age; for example, about 50% of people between the ages of 60 and 69 years old have hypertension, and the prevalence is further increased beyond age 70 (Chobanian et al., 2003).

Elevated arterial pressure causes pathological changes in the vasculature and hypertrophy of the left ventricle. As a consequence, hypertension is the principal cause of stroke; a major risk factor for coronary artery disease and its attendant complications, MI and sudden cardiac death; and a major contributor to cardiac failure, renal insufficiency, and dissecting aneurysm of the aorta.

Hypertension is defined conventionally as a sustained increase in blood pressure $\geq 140/90$ mm Hg, a criterion that characterizes a group of patients whose risk of hypertension-related cardiovascular disease is high enough to merit medical attention. Actually, the risk of both fatal and nonfatal cardiovascular disease in adults is lowest with systolic blood pressures of <120 mm Hg and diastolic BP <80 mm Hg; these risks increase progressively with higher systolic and diastolic blood pressures. Recognition of this continuously increasing risk provides a simple definition of hypertension (Chobanian et al., 2003) (Table 27–4). Although many of the clinical trials classify the severity of hypertension by diastolic pressure, progressive elevations of systolic pressure are similarly predictive of adverse cardiovascular events; at every level of diastolic pressure, risks are greater with higher levels of systolic blood pressure. Indeed, beyond age 50 years, systolic blood pressure predicts outcome better than diastolic blood pressure. Systolic blood pressure tends to rise disproportionately greater in the elderly due to decreased compliance in blood vessels associated with aging and atherosclerosis. Isolated systolic hypertension (sometimes defined as systolic BP >140 – 160 mm Hg with diastolic BP <90 mm Hg) is largely confined to people older than 60 years of age.

At very high blood pressures (systolic ≥ 210 mm Hg and/or diastolic ≥ 120 mm Hg), a subset of patients develops fulminant arteriopathy characterized by endothelial injury and a marked proliferation of cells in the intima, leading to intimal thickening and ultimately to arteriolar occlusion. This is the pathological basis of the syndrome of immediately life-threatening hypertension, which is associated with rapidly progressive microvascular occlusive disease in the kidney (with renal failure), brain (hypertensive encephalopathy), congestive heart failure, and pulmonary edema. These patients typically require in-hospital management on an emergency basis for prompt lowering of blood pressure. Interestingly, isolated retinal changes with papilledema in an otherwise asymptomatic patient with very high blood pressure (formerly called “malignant hypertension”) may benefit from a more gradual lowering of blood pressure over days rather than hours.

Table 27–4

Criteria for Hypertension in Adults

CLASSIFICATION	BLOOD PRESSURE (mm Hg)	
	SYSTOLIC	DIASTOLIC
Normal	<120	and <80
Prehypertension	120–139	or 80–89
Hypertension, stage 1	140–159	or 90–99
Hypertension, stage 2	≥ 160	or ≥ 100

The presence of pathological changes in certain target organs heralds a worse prognosis than the same level of blood pressure in a patient lacking these findings. Consequently, retinal hemorrhages, exudates, and papilledema in the eyes indicate a far worse short-term prognosis for a given level of blood pressure. Left ventricular hypertrophy defined by electrocardiogram, or more sensitively by echocardiography, is associated with a substantially worse long-term outcome that includes a higher risk of sudden cardiac death. The risk of cardiovascular disease, disability, and death in hypertensive patients also is increased markedly by concomitant cigarette smoking, diabetes, or elevated low-density lipoprotein; the coexistence of hypertension with these risk factors increases cardiovascular morbidity and mortality to a degree that is compounded by each additional risk factor. Because the purpose of treating hypertension is to decrease cardiovascular risk, other dietary and pharmacological interventions may be required to treat these conditions.

Pharmacological treatment of patients with hypertension decreases morbidity and mortality from cardiovascular disease. Effective antihypertensive therapy markedly reduces the risk of strokes, cardiac failure, and renal insufficiency due to hypertension. However, reduction in risk of MI may be less impressive.

Principles of Antihypertensive Therapy. Nonpharmacological therapy is an important component of treatment of all patients with hypertension. In some stage 1 hypertensives (see Table 27–4), blood pressure may be adequately controlled by a combination of weight loss (in overweight individuals), restricting sodium intake, increasing aerobic exercise, and moderating consumption of alcohol. These lifestyle changes, though difficult for many to implement, may facilitate pharmacological control of blood pressure in patients whose responses to lifestyle changes alone are insufficient.

Arterial pressure is the product of cardiac output and peripheral vascular resistance. Drugs lower blood pressure by actions on peripheral resistance, cardiac output, or both. Drugs may decrease the cardiac output by inhibiting myocardial contractility or by decreasing ventricular filling pressure. Reduction in ventricular filling pressure may be achieved by actions on the venous tone or on blood volume via renal effects. Drugs can decrease peripheral resistance by acting on smooth muscle to cause relaxation of resistance vessels or by interfering with the activity of systems that produce constriction of resistance vessels (e.g., the sympathetic nervous system, the renin–angiotensin system [RAS]). In patients with isolated systolic hypertension, complex hemodynamics in a rigid arterial system contribute to increased blood pressure; drug effects may be mediated by changes in peripheral resistance but also via effects on large artery stiffness (Franklin, 2000). Antihypertensive drugs can

Table 27–5

Classification of Antihypertensive Drugs by Their Primary Site or Mechanism of Action

Diuretics (Chapter 25)

1. Thiazides and related agents (hydrochlorothiazide, chlorthalidone, chlorothiazide, indapamide, methylclothiazide, metolazone)
2. Loop diuretics (furosemide, bumetanide, torsemide, ethacrynic acid)
3. K⁺-sparing diuretics (amiloride, triamterene, spironolactone)

Sympatholytic drugs (Chapter 12)

1. β receptor antagonists (metoprolol, atenolol, betaxolol, bisoprolol, carteolol, esmolol, nadolol, nebivolol, penbutolol, pindolol, propranolol, timolol)
2. α receptor antagonists (prazosin, terazosin, doxazosin, phenoxybenzamine, phentolamine)
3. Mixed α - β receptor antagonists (labetalol, carvedilol)
4. Centrally acting adrenergic agents (methyldopa, clonidine, guanabenz, guanfacine)
5. Adrenergic neuron blocking agents (guanadrel, reserpine)

Ca²⁺ channel blockers (verapamil, diltiazem, nisoldipine, felodipine, nifedipine, nicardipine, isradipine, amlodipine, clevidipine, nifedipine^e)

Angiotensin-converting enzyme inhibitors (Chapter 26; captopril, enalapril, lisinopril, quinapril, ramipril, benazepril, fosinopril, moexipril, perindopril, trandolapril)

AngII receptor antagonists (Chapter 26; losartan, candesartan, irbesartan, valsartan, telmisartan, eprosartan, olmesartan)

Direct Renin Inhibitor (Chapter 26; aliskiren)

Vasodilators

1. Arterial (hydralazine, minoxidil, diazoxide, fenoldopam)
2. Arterial and venous (nitroprusside)

^eExtended-release nifedipine is approved for hypertension.

be classified according to their sites or mechanisms of action (Table 27–5).

The hemodynamic consequences of long-term treatment with antihypertensive agents (Table 27–6) provide a rationale for potential complementary effects of concurrent therapy with two or more drugs. The simultaneous use of drugs with similar mechanisms of action and hemodynamic effects often produces little additional benefit. However, concurrent use of drugs from different classes is a strategy for achieving effective control of blood pressure while minimizing dose-related adverse effects.

It generally is not possible to predict the responses of individuals with hypertension to any specific drug. For example, for some antihypertensive drugs, on average about two-thirds of patients will have a meaningful clinical response, whereas about one-third of patients will not respond to the same drug. Racial origin and age may have modest influence on the likelihood of a favorable response to a particular class of drugs. There is considerable interest in identifying genetic variation to improve selection of antihypertensive drugs in individual patients. Polymorphisms in a number of genes involved in the metabolism of antihypertensive drugs have been identified, for example in the CYP family (phase I metabolism) and

in phase II metabolism, such as catechol-*O*-methyltransferase (see Chapters 6 and 7). While these polymorphisms change the pharmacokinetics of specific drugs, it is not clear that there will be substantial differences in efficacy given the dose range available clinically for these drugs. Consequently, identification of polymorphisms that influence pharmacodynamic responses to antihypertensive drugs are of considerable interest. Polymorphisms influencing the actions of a number of classes of antihypertensive drugs, including ACE inhibitors and diuretics, have been identified; so far, individual genes have not been found to have a major impact on pharmacodynamic responses. Genome-wide scanning may lead to identification of novel genes that are more clinically significant. Likewise, treatment may benefit from an increased understanding of the molecular and genetic bases of hypertension (Charchar et al., 2008; Shih and O'Connor, 2008).

DIURETICS

An early strategy for the management of hypertension was to alter Na⁺ balance by restriction of salt in the diet. Pharmacological alteration of Na⁺ balance became practical with the development of the orally active thiazide diuretics (see Chapter 25). These and related diuretic agents have antihypertensive effects when used

Table 27–6

Hemodynamic Effects of Long-Term Administration of Antihypertensive Agents

	HEART RATE	CARDIAC OUTPUT	TOTAL PERIPHERAL RESISTANCE	PLASMA VOLUME	PLASMA RENIN ACTIVITY
Diuretics	↔	↔	↓	↓	↑
Sympatholytic agents					
Centrally acting	–↓	–↓	↓	–↑	–↓

↑, increased; ↓, decreased; –↑, increased or no change; –↓, decreased or no change; ↔, unchanged. ACE, angiotensin-converting enzyme; AT₁, the type 1 receptor for angiotensin II; ISA, intrinsic sympathomimetic activity.

alone, and they enhance the efficacy of virtually all other antihypertensive drugs. On account of these considerations, coupled with the very large favorable experience with diuretics in randomized trials in patients with hypertension, this class of drugs remains very important in the treatment of hypertension.

The exact mechanism for reduction of arterial blood pressure by diuretics is not certain. The initial action of these drugs decreases extracellular volume by interacting with a thiazide-sensitive NaCl co-transporter (NCC; gene symbol SLC12A3) expressed in the distal convoluted tubule in the kidney, enhancing Na⁺ excretion in the urine, and leading to a fall in cardiac output. However, the hypotensive effect is maintained during long-term therapy due to decreased vascular resistance; cardiac output returns to pretreatment values and extracellular volume returns almost to normal due to compensatory responses such as activation of the RAS. The explanation for the long-term vasodilation induced by these drugs is unknown. Thiazides directly promote vasodilation in isolated arteries *in vitro*. On the other hand, there is suggestive evidence that vasodilation may occur as an indirect consequence of action of the drugs on the kidneys (Ellison and Loffing, 2009).

Hydrochlorothiazide may open Ca²⁺-activated K⁺ channels, leading to hyperpolarization of vascular smooth muscle cells, which

leads in turn to closing of L-type Ca²⁺ channels and lower probability of opening, resulting in decreased Ca²⁺ entry and reduced vasoconstriction. Hydrochlorothiazide also inhibits vascular carbonic anhydrase, which hypothetically may alter smooth-cell systolic pH and thereby cause opening of Ca²⁺-activated K⁺ channels with the consequences noted above (Pickkers et al., 1999). The relevance of these findings—largely assessed *in vitro*—to the observed antihypertensive effects of thiazides is speculative. The major action of these drugs on SLC12A3—expressed predominantly in the distal convoluted tubules and not in vascular smooth muscle or the heart—has contributed to repeated suggestions that these drugs decrease peripheral resistance as an indirect effect of negative sodium balance. That thiazides lose efficacy in treating hypertension in patients with co-existing renal insufficiency is compatible with this hypothesis. Moreover, carriers of rare functional mutations in SLC12A3 that decrease renal Na⁺ reabsorption have lower blood pressure than appropriate controls (Ji et al., 2008); in a sense, this is an experiment of nature that may mimic the therapeutic effect of thiazides. Nonetheless, sorting out direct versus indirect actions of thiazides in promoting decreased peripheral resistance requires further experimental testing (Ellison and Loffing, 2009).

Benzothiadiazines and Related Compounds

Benzothiadiazines (“thiazides”) and related diuretics are the most frequently used class of antihypertensive agents in the U.S. Following the discovery of *chlorothiazide*, a number of oral diuretics were developed that

have an arylsulfonamide structure and block the NaCl co-transporter. Some of these are not benzothiadiazines but have structural features and molecular functions that are similar to the original benzothiadiazine compounds; consequently, they are designated as members of the thiazide class of diuretics. For example, chlorthalidone, one of the non-benzothiadiazines, is widely used in the treatment of hypertension, as is indapamide.

Regimen for Administration of the Thiazide-Class Diuretics in Hypertension. Because members of the thiazide class have similar pharmacological effects, they generally have been viewed as interchangeable with appropriate adjustment of dosage (see Chapter 25). However, the pharmacokinetics and pharmacodynamics of these drugs may differ, so they may not necessarily have the same clinical efficacy in treating hypertension (Carter et al., 2004). Indeed, there has been renewed debate about whether or not this group of diuretics should be considered as a class in terms of capacity to lower blood pressure and also decrease adverse clinical events due to hypertension (Sicca, 2006).

A direct comparison using 24-hour ambulatory blood pressure monitoring suggested that the antihypertensive efficacy of chlorthalidone is more favorable than that of hydrochlorothiazide (Ernst et al., 2006). Interestingly, the differences were primarily due to greater antihypertensive efficacy during the night and not with routine daytime office measurements of blood pressure. It is possible that the greater effect at night arises on account of the much longer $t_{1/2}$ of chlorthalidone (>24 hours) compared to hydrochlorothiazide (several hours). In light of the considerable clinical trial data supporting the capacity of chlorthalidone to diminish adverse cardiovascular events—in comparison to that available for currently used low doses of hydrochlorothiazide—there is a growing concern that chlorthalidone may be an underutilized drug in hypertensives requiring a diuretic.

When a thiazide-class diuretic is utilized as the sole antihypertensive drug (monotherapy), its dose-response curve for lowering blood pressure in patients with hypertension should be kept in mind. Antihypertensive effects can be achieved in many patients with as little as 12.5 mg daily of chlorthalidone or hydrochlorothiazide. Furthermore, when used as monotherapy, the maximal daily dose of thiazide-class diuretics usually should not exceed 25 mg of hydrochlorothiazide or chlorthalidone (or equivalent). Even though more diuresis can be achieved with higher doses of these diuretics, some evidence suggests that doses higher than this are not generally more efficacious in lowering blood pressure in patients with normal renal function. For example, a large study comparing 25 and 50 mg of hydrochlorothiazide daily in an elderly population did not show a greater decrease in blood pressure with the larger dose (Medical

Research Council Working Party, 1987). However, these conclusions are based on conventional rather than ambulatory blood pressure measurements. Other studies suggest that low doses of hydrochlorothiazide have inadequate effects on blood pressure when monitored in this more detailed manner (Lacourcière et al., 1995). In summary, recent critical attention has been focused on whether low doses of hydrochlorothiazide are as efficacious as low doses of chlorthalidone and whether low doses of hydrochlorothiazide are efficacious as monotherapy in protecting against the cardiovascular complications of hypertension. Relatively low doses of either thiazide are not at the top of the dose-response curve for adverse effects such as K^+ wasting and inhibition of uric acid excretion, emphasizing the importance of knowledge about the dose-response relationships for both beneficial and adverse effects.

In the clinical trials of antihypertensive therapy in the elderly that demonstrated the best outcomes in cardiovascular morbidity and mortality, 25 mg of hydrochlorothiazide or chlorthalidone was the maximum dose given; if this dose did not achieve the target blood pressure reduction, treatment with a second drug was initiated (SHEP Cooperative Research Group, 1991; Dahlöf et al., 1991; Medical Research Council Working Party, 1992). With respect to safety, a case-control study (Siscovick et al., 1994) found a dose-dependent increase in the occurrence of sudden death at doses of hydrochlorothiazide >25 mg daily. This finding supports the hypothesis proposed by the Multiple Risk Factor Intervention Trial Research Group (1982), suggesting that increased cardiovascular mortality is associated with higher diuretic doses. Taken together, clinical studies indicate that if adequate blood pressure reduction is not achieved with the 25-mg daily dose of hydrochlorothiazide or chlorthalidone, a second drug should be added rather than increasing the dose of diuretic. There is some concern that thiazide diuretics, especially at higher doses and in the absence of K^+ -sparing diuretics or K^+ supplements, may increase the risk of sudden death. However, their overall therapeutic benefits are well established.

Urinary K^+ loss can be a problem with thiazides. ACE inhibitors and angiotensin receptor antagonists will attenuate diuretic-induced loss of K^+ to some degree, and this is a consideration if a second drug is required to achieve further blood pressure reduction beyond that attained with the diuretic alone. Because the diuretic and hypotensive effects of these drugs are greatly enhanced when they are given in combination, care should be taken to initiate combination therapy with low doses of each of these drugs. Administration of ACE inhibitors or angiotensin receptor antagonists together with other K^+ -sparing agents or with K^+ supplements requires great caution; combining K^+ -sparing agents with each other or with K^+ supplementation can cause potentially dangerous hyperkalemia in some patients.

In contrast to the limitation on the dose of thiazide-class diuretics used as monotherapy, the treatment of severe hypertension that is unresponsive to three or more drugs may require larger doses of the thiazide-class diuretics. Indeed, hypertensive patients may become

refractory to drugs that block the sympathetic nervous system or to vasodilator drugs, because these drugs engender a state in which the blood pressure is very volume dependent. Therefore, it is appropriate to consider the use of thiazide-class diuretics in doses of 50 mg of daily hydrochlorothiazide equivalent when treatment with appropriate combinations and doses of three or more drugs fails to yield adequate control of the blood pressure. Alternatively, there may be a need to use higher-capacity diuretics such as furosemide, especially if renal function is not normal, in some of these patients. Dietary Na⁺ restriction is a valuable adjunct to the management of such refractory patients and will minimize the dose of diuretic that is required. This can be achieved by a modest restriction of Na⁺ intake to 2 g daily. More stringent Na⁺ restriction is not feasible for most patients. Because the degree of K⁺ loss relates to the amount of Na⁺ delivered to the distal tubule, such restriction of Na⁺ can minimize the development of hypokalemia and alkalosis. The effectiveness of thiazides as diuretics or antihypertensive agents is progressively diminished when the glomerular filtration rate falls below 30 mL/min. One exception is metolazone, which retains efficacy in patients with this degree of renal insufficiency.

Most patients will respond to thiazide diuretics with a reduction in blood pressure within about 4–6 weeks. Therefore, doses should not be increased more often than every 4–6 weeks. There is no way to predict the antihypertensive response from the duration or severity of the hypertension in a given patient, although diuretics are unlikely to be effective as sole therapy in patients with stage 2 hypertension (Table 27–4). Because the effect of thiazide diuretics is additive with that of other antihypertensive drugs, combination regimens that include these diuretics are common and rational. A wide range of fixed-dose combination products containing a thiazide are marketed for this purpose. Diuretics also have the advantage of minimizing the retention of salt and water that is commonly caused by vasodilators and some sympatholytic drugs. Omitting or underutilizing a diuretic is a frequent cause of “resistant hypertension.”

Adverse Effects and Precautions. The adverse effects of diuretics are discussed in Chapter 25. Some of these determine whether patients can tolerate and adhere to diuretic treatment.

Erectile dysfunction is a troublesome adverse effect of the thiazide-class diuretics, and physicians should inquire specifically regarding its occurrence in conjunction with treatment with these drugs. Gout may be a consequence of the hyperuricemia induced by these diuretics. The occurrence of either of these adverse effects is

a reason for considering alternative approaches to therapy. However, precipitation of acute gout is relatively uncommon with low doses of diuretics. Hydrochlorothiazide may cause rapidly developing, severe hyponatremia in some patients. Thiazides inhibit renal Ca²⁺ excretion, occasionally leading to hypercalcemia; although generally mild, this can be more severe in patients subject to hypercalcemia, such as those with primary hyperparathyroidism. The thiazide-induced decreased Ca²⁺ excretion may be used therapeutically in patients with osteoporosis or hypercalciuria.

Some other effects of thiazide diuretics are laboratory observations that are of concern primarily because they are putative *surrogate markers* for adverse drug effects on morbidity and mortality. The effects of diuretic drugs on several surrogate markers for adverse outcomes merit consideration. The K⁺ depletion produced by thiazide-class diuretics is dose dependent and is variable among individuals, such that a subset of patients may become substantially K⁺ depleted on diuretic drugs. Given chronically, even small doses lead to some K⁺ depletion.

There are two types of ventricular arrhythmias that are thought to be enhanced by K⁺ depletion. One of these is polymorphic ventricular tachycardia (torsades de pointes), which is induced by a number of drugs, including quinidine. Drug-induced polymorphic ventricular tachycardia is initiated by abnormal ventricular repolarization; because K⁺ currents normally mediate repolarization, drugs that produce K⁺ depletion potentiate polymorphic ventricular tachycardia. Accordingly, thiazide diuretics should not be given together with drugs that can cause polymorphic ventricular tachycardia (see Chapter 29).

The most important concern regarding K⁺ depletion is its influence on ischemic ventricular fibrillation, the leading cause of sudden cardiac death and a major contributor to cardiovascular mortality in treated hypertensive patients. Studies in experimental animals have demonstrated that K⁺ depletion lowers the threshold for electrically induced ventricular fibrillation in the ischemic myocardium and also increases spontaneous ischemic ventricular fibrillation (Curtis and Hearse, 1989). There is a positive correlation between diuretic dose and sudden cardiac death, and an inverse correlation between the use of adjunctive K⁺-sparing agents and sudden cardiac death (Siscovick et al., 1994). One controlled clinical trial demonstrated a significantly greater occurrence of sudden cardiac death in patients treated with 50 mg of hydrochlorothiazide daily in comparison with the β receptor antagonist metoprolol (Medical Research Council Working Party, 1992).

Thiazide diuretics have been associated with changes in plasma lipids and glucose tolerance that have led to some concern. The clinical significance of the changes has been disputed. Nonetheless, clinical studies demonstrate the efficacy of the thiazide diuretics in reducing cardiovascular risk (ALLHAT Officers, 2002).

All of the thiazide-like drugs cross the placenta, but they have not been shown to have direct adverse effects on the fetus. However, if administration of a thiazide is begun during pregnancy, there is a risk of transient volume depletion that may result in placental hypoperfusion. Because the thiazides appear in breast milk, they should be avoided by nursing mothers.

Other Diuretic Antihypertensive Agents

The thiazide diuretics are more effective antihypertensive agents than are the loop diuretics, such as

furosemide and bumetanide, in patients who have normal renal function. This differential effect is most likely related to the short duration of action of loop diuretics, such that a single daily dose does not cause a significant net loss of Na^+ for an entire 24-hour period. Indeed, loop diuretics are frequently and inappropriately prescribed as a once-a-day medication in the treatment not only of hypertension, but also of congestive heart failure and ascites. The spectacular efficacy of the loop diuretics in producing a rapid and profound natriuresis can be detrimental for the treatment of hypertension. When a loop diuretic is given twice daily, the acute diuresis can be excessive and lead to more side effects than occur with a slower-acting, milder thiazide diuretic. Loop diuretics may be particularly useful in patients with azotemia or with severe edema associated with a vasodilator such as minoxidil.

Amiloride is a K^+ -sparing diuretic that has some efficacy in lowering blood pressure in patients with hypertension. Another K^+ -sparing diuretic, spironolactone, also lowers blood pressure but has some significant adverse effects, especially in men (e.g., erectile dysfunction, gynecomastia, benign prostatic hyperplasia). Eplerenone is a newer aldosterone receptor antagonist that does not have the sexually related adverse effects induced by spironolactone. As a result of their capacity to inhibit loss of K^+ in the urine, these drugs are used in the medical treatment of patients with hyperaldosteronism, a syndrome that can lead to hypokalemia. Triamterene is a K^+ -sparing diuretic that decreases the risk of hypokalemia in patients treated with a thiazide diuretic but does not have efficacy in lowering blood pressure by itself. These agents should be used cautiously with frequent measurements of K^+ concentrations in plasma in patients predisposed to hyperkalemia. Patients taking spironolactone, amiloride, or triamterene should be cautioned regarding the possibility that concurrent use of K^+ -containing salt substitutes could produce hyperkalemia. Renal insufficiency is a relative contraindication to the use of K^+ -sparing diuretics. *Concomitant use of an ACE inhibitor or an angiotensin receptor antagonist magnifies the risk of hyperkalemia with these agents.*

Diuretic-Associated Drug Interactions

Because the antihypertensive effects of diuretics are frequently additive with those of other antihypertensive agents, a diuretic commonly is used in combination with other drugs. The K^+ - and Mg^{2+} -depleting effects of the thiazides and loop diuretics also can potentiate arrhythmias that arise from digitalis toxicity. Corticosteroids can amplify the hypokalemia produced by the diuretics. All

diuretics can decrease the clearance of Li^+ , resulting in increased plasma concentrations of Li^+ and potential toxicity. Nonsteroidal anti-inflammatory drugs (NSAIDs; see Chapter 34) that inhibit the synthesis of prostaglandins reduce the antihypertensive effects of diuretics. The effects of selective cyclooxygenase-2 (COX-2) inhibitors on renal prostaglandin synthesis and function are similar to those of the traditional NSAIDs. NSAIDs, β receptor antagonists, and ACE inhibitors reduce plasma concentrations of aldosterone and can potentiate the hyperkalemic effects of a K^+ -sparing diuretic.

SYMPATHOLYTIC AGENTS

With the demonstration in 1940 that bilateral excision of the thoracic sympathetic chain could lower blood pressure, there was a search for effective chemical sympatholytic agents. Many of the early sympathetic drugs were poorly tolerated and had adverse side effects. A number of sympathetic agents are currently in use (Table 27–5). Antagonists of α and β adrenergic receptors have been mainstays of antihypertensive therapy.

β Adrenergic Receptor Antagonists

β Adrenergic receptor antagonists were not expected to have antihypertensive effects when they were first investigated in patients with angina, their primary indication. However, *pronethalol*, a drug that was never marketed, was found to reduce arterial blood pressure in hypertensive patients with angina pectoris. This antihypertensive effect was subsequently demonstrated for *propranolol* and all other β adrenergic receptor antagonists. The pharmacology of these drugs is discussed in Chapter 12; characteristics relevant to their use in hypertension are described here.

Locus and Mechanism of Action. Antagonism of β adrenergic receptors affects the regulation of the circulation through a number of mechanisms, including a reduction in myocardial contractility, heart rate, and cardiac output (see Chapter 26). An important consequence is blockade of the β receptors of the juxtaglomerular complex, reducing renin secretion and thereby diminishing production of circulating AngII. This action likely contributes to the antihypertensive action of this class of drugs, in concert with the cardiac effects. β receptor antagonists may lower blood pressure by other mechanisms. Some members of this large, heterogeneous class of drugs have additional effects unrelated to their capacity to bind to β adrenergic receptors. For example, *labetalol* is an α receptor antagonist, and *nebivolol*

772 promotes endothelial cell dependent vasodilation via activation of the NO pathway (Pedersen and Cockcroft, 2006).

Pharmacological Effects. The β adrenergic blockers vary in their selectivity for the β_1 receptor subtype, presence of partial agonist or intrinsic sympathomimetic activity, and vasodilating capacity. Despite these differences, all of the β receptor antagonists are effective as antihypertensive agents. However, these differences do influence the clinical pharmacokinetics and spectrum of adverse effects of the various drugs. Drugs without intrinsic sympathomimetic activity produce an initial reduction in cardiac output and a reflex-induced rise in peripheral resistance, generally with no net change in arterial pressure. In patients who respond with a reduction in blood pressure, peripheral resistance gradually returns to pretreatment values or less. Generally, persistently reduced cardiac output and possibly decreased peripheral resistance accounts for the reduction in arterial pressure. Drugs with intrinsic sympathomimetic activity produce lesser decreases in resting heart rate and cardiac output; the fall in arterial pressure correlates with a fall in vascular resistance below pretreatment levels, possibly because of stimulation of vascular β_2 receptors that mediate vasodilation.

The clinical significance, if any, of these differences is uncertain. However, there is increasing concern that some β receptor blockers, particularly atenolol, may have less efficacy as monotherapy for hypertension than some other drug classes in terms of decreasing risk of adverse cardiovascular consequences of hypertension, particularly due to stroke and coronary artery disease (Carlberg et al., 2004; Kaplan, 2008; Pedersen and Cockcroft, 2009). Particular interest has focused on evidence suggesting that atenolol-based therapy may not lower central (aortic) blood pressure as effectively as it appears when conventionally measured in the brachial artery using a standard arm cuff (CAFE Investigators, 2006). However, teasing out the comparative efficacy of the various classes of antihypertensive drugs represents a complex undertaking. Results of a detailed meta-analysis of 147 randomized trials of blood pressure reduction showed that, regardless of blood pressure before treatment, lowering systolic blood pressure by 10 mm Hg or diastolic blood pressure by 5 mm Hg using any of the main classes of antihypertensive drugs significantly reduces coronary events and stroke without an increase in nonvascular mortality (Law et al., 2009).

Adverse Effects and Precautions. The adverse effects of β adrenergic blocking agents are discussed in Chapter 12. These drugs should be avoided in patients with reactive airway disease (asthma) or with SA or AV nodal dysfunction or in combination with other drugs that inhibit AV conduction, such as verapamil. The risk of hypoglycemic reactions may be increased in diabetics taking insulin. β Receptor antagonists without intrinsic sympathomimetic activity increase concentrations of triglycerides in plasma and lower those of HDL cholesterol without changing total cholesterol concentrations. β receptor blocking agents with intrinsic sympathomimetic activity have little or

no effect on blood lipids or increase HDL cholesterol. The long-term consequences of these effects are unknown.

Sudden discontinuation of β adrenergic blockers can produce a withdrawal syndrome that is likely due to upregulation of β receptors during blockade, causing enhanced tissue sensitivity to endogenous catecholamines; this can exacerbate the symptoms of coronary artery disease. The result, especially in active patients, can be rebound hypertension. Thus, β adrenergic blockers should not be discontinued abruptly except under close observation; dosage should be tapered gradually over 10-14 days prior to discontinuation.

NSAIDs such as *indomethacin* can blunt the antihypertensive effect of propranolol and probably other β receptor antagonists. This effect may be related to inhibition of vascular synthesis of prostacyclin, as well as to retention of Na^+ (Beckmann et al., 1988).

Epinephrine. can produce severe hypertension and bradycardia when a nonselective β antagonist is present. The hypertension is due to the unopposed stimulation of α adrenergic receptors when vascular β_2 receptors are blocked; the bradycardia is the result of reflex vagal stimulation. Such paradoxical hypertensive responses to β receptor antagonists have been observed in patients with hypoglycemia or pheochromocytoma, during withdrawal from *clonidine*, following administration of epinephrine as a therapeutic agent, or in association with the illicit use of cocaine.

Therapeutic Uses. The β receptor antagonists provide effective therapy for all grades of hypertension. Despite marked differences in their pharmacokinetic properties, the antihypertensive effect of all the β blockers is of sufficient duration to permit once- or twice-daily administration. Populations that tend to have a lesser antihypertensive response to β blocking agents include the elderly and African-Americans. However, intraindividual differences in antihypertensive efficacy are generally much larger than statistical evidence of differences between racial or age-related groups. Consequently, these observations should not discourage the use of these drugs in individual patients in groups reported to be less responsive.

The β receptor antagonists usually do not cause retention of salt and water, and administration of a diuretic is not necessary to avoid edema or the development of tolerance. However, diuretics do have additive antihypertensive effects when combined with β blockers. The combination of a β receptor antagonist, a diuretic, and a vasodilator is effective for patients who require a third drug. β receptor antagonists are highly preferred drugs for hypertensive patients with conditions such as MI, ischemic heart disease, or congestive heart failure. However, for other hypertensive patients, enthusiasm for their early use in treatment has diminished, as noted earlier.

α_1 Adrenergic Receptor Antagonists

The availability of drugs that selectively block α_1 adrenergic receptors without affecting α_2 adrenergic receptors adds another group of antihypertensive

agents. The pharmacology of these drugs is discussed in detail in Chapter 12. Prazosin, terazosin, and doxazosin are the agents that are available for the treatment of hypertension.

Pharmacological Effects. Initially, α_1 adrenergic receptor antagonists reduce arteriolar resistance and increase venous capacitance; this causes a sympathetically mediated reflex increase in heart rate and plasma renin activity. During long-term therapy, vasodilation persists, but cardiac output, heart rate, and plasma renin activity return to normal. Renal blood flow is unchanged during therapy with an α_1 receptor antagonist. The α_1 adrenergic blockers cause a variable amount of postural hypotension, depending on the plasma volume. Retention of salt and water occurs in many patients during continued administration, and this attenuates the postural hypotension. α_1 Receptor antagonists reduce plasma concentrations of triglycerides and total LDL cholesterol and increase HDL cholesterol. These potentially favorable effects on lipids persist when a thiazide-type diuretic is given concurrently. The long-term consequences of these small, drug-induced changes in lipids are unknown.

Adverse Effects. The use of doxazosin as monotherapy for hypertension increased the risk for developing congestive heart failure (ALLHAT Officers, 2002). This may be a class effect that represents an adverse effect of all of the α_1 receptor antagonists. However, this interpretation of the outcome of the ALLHAT study is controversial.

A major precaution regarding the use of the α_1 receptor antagonists for hypertension is the so-called first-dose phenomenon, in which symptomatic orthostatic hypotension occurs within 30-90 minutes (or longer) of the initial dose of the drug or after a dosage increase. This effect may occur in up to 50% of patients, especially in patients who are already receiving a diuretic or an α receptor antagonist. After the first few doses, patients develop a tolerance to this marked hypotensive response.

Therapeutic Uses. α_1 Receptor antagonists are not recommended as monotherapy for hypertensive patients primarily as a consequence of the ALLHAT study. Consequently, they are used primarily in conjunction with diuretics, β blockers, and other antihypertensive agents. β Receptor antagonists enhance the efficacy of the α_1 blockers. α_1 Receptor antagonists are not the drugs of choice in patients with pheochromocytoma, because a vasoconstrictor response to epinephrine can still result from activation of unblocked vascular α_2 adrenergic receptors. α_1 Receptor antagonists are attractive drugs for hypertensive patients with benign prostatic hyperplasia, because they also improve urinary symptoms.

COMBINED α_1 AND β ADRENERGIC RECEPTOR ANTAGONISTS

Labetalol (see Chapter 12) is an equimolar mixture of four stereoisomers. One isomer is an α_1 antagonist (like prazosin), another is a nonselective β antagonist with partial agonist activity (like pindolol), and the other two isomers are inactive. Because of its capacity to block α_1 adrenergic receptors, labetalol given intravenously can reduce blood pressure sufficiently rapidly to be useful for the treatment of hypertensive emergencies. Labetalol has efficacy and adverse effects that would be expected with any combination of β and α_1 receptor antagonists; it also has the disadvantages that are inherent in fixed-dose combination products: the extent of α -receptor antagonism compared to β receptor antagonism is somewhat unpredictable and varies from patient to patient.

Carvedilol (see Chapters 12) is a β receptor antagonist with α_1 receptor antagonist activity. The drug has been approved for the treatment of hypertension and symptomatic heart failure. The ratio of α_1 to β receptor antagonist potency for carvedilol is approximately 1:10. Carvedilol undergoes oxidative metabolism and glucuronidation in the liver; the oxidative metabolism occurs via CYP2D6. Carvedilol reduces mortality in patients with congestive heart failure associated with systolic dysfunction when used as an adjunct to therapy with diuretics and ACE inhibitors. It should not be given to those patients with decompensated heart failure who are dependent on sympathetic stimulation. As with labetalol, the long-term efficacy and side effects of carvedilol in hypertension are predictable based on its properties as a β and α_1 adrenergic receptor antagonist.

Nebivolol is a β_1 selective adrenergic antagonist that also promotes vasodilatation; rather than blocking α_1 receptors, nebivolol augments arterial smooth muscle relaxation via NO (Veverka et al., 2006). In addition, nebivolol has agonist activity at β_3 receptors, although the clinical significance of this effect is not known.

Methyldopa

Methyldopa is a centrally acting antihypertensive agent. It is a prodrug that exerts its antihypertensive action via an active metabolite. Although used frequently as an antihypertensive agent in the past, methyldopa's significant adverse effects limit its current use largely to treatment of hypertension in pregnancy, where it has a record for safety.

Methyldopa (α -methyl-3,4-dihydroxy-L-phenylalanine), an analog of 3,4-dihydroxyphenylalanine (DOPA), is metabolized by the L-aromatic amino acid decarboxylase in adrenergic neurons to α -methyldopamine, which then is converted to α -methylnorepinephrine. α -Methylnorepinephrine is stored in the secretory vesicles of adrenergic neurons, substituting for norepinephrine (NE) itself. Consequently, when the adrenergic neuron discharges its neurotransmitter, α -methylnorepinephrine is released instead of norepinephrine. α -Methylnorepinephrine acts in the central nervous system (CNS) to inhibit adrenergic neuronal outflow from the brainstem and probably acts as an agonist at presynaptic α_2 adrenergic receptors in the brainstem, attenuating NE release and thereby reducing the output of vasoconstrictor adrenergic signals to the peripheral sympathetic nervous system.

Absorption, Metabolism, and Excretion. Because methyldopa is a pro-drug that is metabolized in the brain to the active form, its concentration in plasma has less relevance for its effects than that for many other drugs. Peak concentrations in plasma occur after 2-3 hours. The drug is eliminated with a $t_{1/2}$ of ~2 hours. Methyldopa is excreted in the urine primarily as the sulfate conjugate (50-70%) and as the parent drug (25%). The remaining fraction is excreted as other metabolites, including methyldopamine, methylnorepinephrine, and O-methylated products of these catecholamines. The $t_{1/2}$ of methyldopa is prolonged to 4-6 hours in patients with renal failure.

In spite of its rapid absorption and short $t_{1/2}$, the peak effect of methyldopa is delayed for 6-8 hours, even after intravenous administration, and the duration of action of a single dose is usually about 24 hours; this permits once- or twice-daily dosing. The discrepancy between the effects of methyldopa and the measured concentrations of the drug in plasma is most likely related to the time required for transport into the CNS, conversion to the active metabolite storage of α -methylnorepinephrine and its subsequent release in the vicinity of relevant α_2 receptors in the CNS. This is a good example of the potential for a complex relationship between a drug's pharmacokinetics and its pharmacodynamics. Patients with renal failure are more sensitive to the antihypertensive effect of methyldopa, but it is not known if this is due to alteration in excretion of the drug or to an increase in transport into the CNS.

Adverse Effects and Precautions. Methyldopa produces sedation that is largely transient. A diminution in psychic energy may persist in some patients, and depression occurs occasionally. Methyldopa may produce dryness of the mouth. Other adverse effects include diminished libido, parkinsonian signs, and hyperprolactinemia that may become sufficiently pronounced to cause gynecomastia and galactorrhea. Methyldopa may precipitate severe bradycardia and sinus arrest.

Methyldopa also produces some adverse effects that are not related to its pharmacological action. Hepatotoxicity, sometimes associated with fever, is an uncommon but potentially serious toxic effect of methyldopa. At least 20% of patients who receive methyldopa for a year develop a positive Coombs test (antiglobulin test) that is due to autoantibodies directed against the Rh antigen on erythrocytes. The development of a positive Coombs test is not necessarily an indication to stop treatment with methyldopa; 1-5% of these patients will develop a hemolytic anemia that requires prompt discontinuation of the drug. The Coombs test may remain positive for as long as a year after discontinuation of methyldopa, but the

hemolytic anemia usually resolves within a matter of weeks. Severe hemolysis may be attenuated by treatment with glucocorticoids. Adverse effects that are even more rare include leukopenia, thrombocytopenia, red cell aplasia, lupus erythematosus-like syndrome, lichenoid and granulomatous skin eruptions, myocarditis, retroperitoneal fibrosis, pancreatitis, diarrhea, and malabsorption.

Therapeutic Uses. Methyldopa is a preferred drug for treatment of hypertension during pregnancy based on its effectiveness and safety for both mother and fetus. The usual initial dose of methyldopa is 250 mg twice daily, and there is little additional effect with doses >2 g/day. Administration of a single daily dose of methyldopa at bedtime minimizes sedative effects, but administration twice daily is required for some patients.

Clonidine, Guanabenz, and Guanfacine

The detailed pharmacology of the α_2 adrenergic agonists clonidine, *guanabenz*, and *guanfacine* is discussed in Chapter 12. These drugs stimulate the α_{2A} subtype of α_2 adrenergic receptors in the brainstem, resulting in a reduction in sympathetic outflow from the CNS (Macmillan et al., 1996). The decrease in plasma concentrations of NE is correlated directly with the hypotensive effect (Goldstein et al., 1985). Patients who have had a spinal cord transection above the level of the sympathetic outflow tracts do not display a hypotensive response to clonidine. At doses higher than those required to stimulate central α_{2A} receptors, these drugs can activate α_2 receptors of the α_{2B} subtype on vascular smooth muscle cells (MacMillan et al., 1996). This effect accounts for the initial vasoconstriction that is seen when overdoses of these drugs are taken, and may be responsible for the loss of therapeutic effect that is observed with high doses. A major limitation in the use of these drugs is the paucity of information about their efficacy in reducing the risk of cardiovascular consequences of hypertension.

Pharmacological Effects. The α_2 adrenergic agonists lower arterial pressure by an effect on both cardiac output and peripheral resistance. In the supine position, when the sympathetic tone to the vasculature is low, the major effect is to reduce both heart rate and stroke volume; however, in the upright position, when sympathetic outflow to the vasculature is normally increased, these drugs reduce vascular resistance. This action may lead to postural hypotension. The decrease in cardiac sympathetic tone leads to a reduction in myocardial contractility and heart rate that could promote congestive heart failure in susceptible patients.

Adverse Effects and Precautions. Many patients experience annoying and sometimes intolerable adverse effects with these drugs. Sedation and xerostomia are prominent adverse effects. The xerostomia may be accompanied by dry nasal mucosa, dry eyes, and

parotid gland swelling and pain. Postural hypotension and erectile dysfunction may be prominent in some patients. Clonidine may produce a lower incidence of dry mouth and sedation when given transdermally, perhaps because high peak concentrations are avoided. Less common CNS side effects include sleep disturbances with vivid dreams or nightmares, restlessness, and depression. Cardiac effects related to the sympatholytic action of these drugs include symptomatic bradycardia and sinus arrest in patients with dysfunction of the SA node and AV block in patients with AV nodal disease or in patients taking other drugs that depress AV conduction. Some 15-20% of patients who receive transdermal clonidine may develop contact dermatitis.

Sudden discontinuation of clonidine and related α_2 adrenergic agonists may cause a withdrawal syndrome consisting of headache, apprehension, tremors, abdominal pain, sweating, and tachycardia. The arterial blood pressure may rise to levels above those that were present prior to treatment, but the syndrome may occur in the absence of an overshoot in pressure. Symptoms typically occur 18-36 hours after the drug is stopped and are associated with increased sympathetic discharge, as evidenced by elevated plasma and urine concentrations of catecholamines. The exact incidence of the withdrawal syndrome is not known, but it is likely dose related and more dangerous in patients with poorly controlled hypertension. Rebound hypertension also has been seen after discontinuation of transdermal administration of clonidine (Metz et al., 1987).

Treatment of the withdrawal syndrome depends on the urgency of reducing the arterial blood pressure. In the absence of life-threatening target organ damage, patients can be treated by restoring the use of clonidine. If a more rapid effect is required, *sodium nitroprusside* or a combination of an α and β adrenergic blocker is appropriate. β Adrenergic blocking agents should not be used alone in this setting, because they may accentuate the hypertension by allowing unopposed α adrenergic vasoconstriction caused by activation of the sympathetic nervous system and elevated circulating catecholamines.

Because perioperative hypertension has been described in patients in whom clonidine was withdrawn the night before surgery, surgical patients who are being treated with an α_2 adrenergic agonist either should be switched to another drug prior to elective surgery or should receive their morning dose and/or transdermal clonidine prior to the procedure. All patients who receive one of these drugs should be warned of the potential danger of discontinuing the drug abruptly, and patients suspected of being noncompliant with medications should not be given α_2 adrenergic agonists for hypertension.

Adverse drug interactions with α_2 adrenergic agonists are rare. Diuretics predictably potentiate the hypotensive effect of these drugs. Tricyclic antidepressants may inhibit the antihypertensive effect of clonidine, but the mechanism of this interaction is not known.

Therapeutic Uses. The CNS effects are such that this class of drugs is not a leading option for monotherapy of hypertension. Indeed, there is no fixed place for these drugs in the treatment of hypertension. They effectively lower blood pressure in some patients who have not responded adequately to combinations of other agents. Enthusiasm for these drugs is diminished by the relative

absence of evidence demonstrating reduction in risk of adverse cardiovascular events.

Clonidine has been used in hypertensive patients for the diagnosis of pheochromocytoma. The lack of suppression of the plasma concentration of NE to >500 pg/mL 3 hours after an oral dose of 0.3 mg of clonidine suggests the presence of such a tumor. A modification of this test, wherein overnight urinary excretion of NE and epinephrine is measured after administration of a 0.3-mg dose of clonidine at bedtime, may be useful when results based on plasma NE concentrations are equivocal. Other uses for α_2 adrenergic agonists are discussed in Chapters 12, 13, and 23.

Guanadrel

Guanadrel specifically inhibits the function of peripheral postganglionic adrenergic neurons. The structure of guanadrel, which contains the strongly basic guanidine group, is:

Locus and Mechanism of Action. Guanadrel is an exogenous false neurotransmitter that is accumulated, stored, and released like NE but is inactive at adrenergic receptors. The drug reaches its site of action by active transport into the neuron by the same transporter that is responsible for the reuptake of NE (see Chapter 8). In the neuron, guanadrel is concentrated within the adrenergic storage vesicle, where it replaces NE. During chronic administration, guanadrel acts as a “false neurotransmitter”: It is present in storage vesicles, depletes the normal transmitter, and can be released by stimuli that normally release NE, but is inactive at adrenergic receptors. This replacement of NE with an inactive transmitter is probably the principal mechanism of action of guanadrel. Because guanadrel can promote NE release from pheochromocytomas, it is contraindicated in those patients.

Pharmacological Effects. Essentially all of the therapeutic and adverse effects of guanadrel result from functional sympathetic blockade. The antihypertensive effect is achieved by a reduction in peripheral vascular resistance that results from inhibition of α receptor-mediated vasoconstriction. Consequently, arterial pressure is reduced modestly in the supine position when sympathetic activity is usually low, but the pressure can fall to a greater extent during situations in which reflex sympathetic activation is an important mechanism for maintaining arterial pressure, particularly when standing.

Absorption, Distribution, Metabolism, and Excretion. Because guanadrel must be transported into and accumulate in adrenergic neurons, the maximum effect on blood pressure is not seen until 4-5 hours. The $t_{1/2}$ of the pharmacological effect of guanadrel is determined by the drug's persistence in this neuronal pool and is probably at least 10 hours.

Adverse Effects. Guanadrel produces undesirable effects that are related to sympathetic blockade. Symptomatic hypotension during standing, exercise, ingestion of alcohol, or in hot weather is the

result of the lack of sympathetic compensation for these stresses. A general feeling of fatigue and lassitude is partially, but not entirely, related to postural hypotension. Sexual dysfunction usually presents as delayed or retrograde ejaculation. Diarrhea also may occur.

Because guanadrel is actively transported to its site of action, drugs that block or compete for the catecholamine transporter on the presynaptic membrane will inhibit the effect of guanadrel. Such drugs include the tricyclic antidepressants *cocaine*, *chlorpromazine*, *ephedrine*, *phenylpropanolamine*, and *amphetamine* (see Chapter 8).

Therapeutic Uses. Because of the availability of a number of drugs that lower blood pressure without producing similar adverse effects, guanadrel is used very rarely; the drug is no longer marketed in the U.S. The usual starting dose is 10 mg daily, and side effects can be minimized by not exceeding 20 mg daily.

Reserpine

Reserpine was the first drug that was found to interfere with the function of the sympathetic nervous system in humans, and its use began the modern era of effective pharmacotherapy of hypertension.

Reserpine is an alkaloid extracted from the root of *Rauwolfia serpentina*, a climbing shrub indigenous to India. Ancient Hindu Ayurvedic writings describe medicinal uses of the plant; Sen and Bose described its use in the Indian biomedical literature. However, rauwolfia alkaloids were not used in western medicine until the mid-1950s.

Locus and Mechanism of Action. Reserpine binds tightly to adrenergic storage vesicles in central and peripheral adrenergic neurons and remains bound for prolonged periods of time. The interaction inhibits the vesicular catecholamine transporter, VMAT2, so that nerve endings lose their capacity to concentrate and store NE and dopamine. Catecholamines leak into the cytoplasm, where they are metabolized. Consequently, little or no active transmitter is released from nerve endings, resulting in a pharmacological sympathectomy. Recovery of sympathetic function requires synthesis of new storage vesicles, which takes days to weeks after discontinuation of the drug. Because reserpine depletes amines in the CNS as well as in the peripheral adrenergic neuron, it is probable that its antihypertensive effects are related to both central and peripheral actions.

Pharmacological Effects. Both cardiac output and peripheral vascular resistance are reduced during long-term therapy with reserpine.

Absorption, Metabolism, and Excretion. Few data are available on the pharmacokinetic properties of reserpine because of the lack of an assay capable of detecting low concentrations of the drug or its

metabolites. Reserpine that is bound to isolated storage vesicles cannot be removed by dialysis, indicating that the binding is not in equilibrium with the surrounding medium. Because of the irreversible nature of reserpine binding, the amount of drug in plasma is unlikely to bear any consistent relationship to drug concentration at the site of action. Free reserpine is entirely metabolized; none of the parent drug is excreted unchanged.

Toxicity and Precautions. Most adverse effects of reserpine are due to its effect on the CNS. Sedation and inability to concentrate or perform complex tasks are the most common adverse effects. More serious is the occasional psychotic depression that can lead to suicide. Depression usually appears insidiously over many weeks or months and may not be attributed to the drug because of the delayed and gradual onset of symptoms. Reserpine must be discontinued at the first sign of depression; reserpine-induced depression may last several months after the drug is discontinued. The risk of depression is likely dose related. Depression appears to be uncommon, but not unknown, with doses of 0.25 mg/day or less. The drug should never be given to patients with a history of depression. Other adverse effects include nasal stuffiness and exacerbation of peptic ulcer disease, which is uncommon with small oral doses.

Therapeutic Uses. With the availability of newer drugs that are both effective and well tolerated, the use of reserpine has diminished because of its CNS side effects. Nonetheless, there has been some recent interest in using reserpine at low doses, in combination with diuretics, in the treatment of hypertension, especially in the elderly. Reserpine is used once daily with a diuretic, and several weeks are necessary to achieve a maximum effect. The daily dose should be limited to 0.25 mg or less, and as little as 0.05 mg/day may be efficacious when a diuretic is also used. One advantage of reserpine is that it is considerably less expensive than other antihypertensive drugs; thus, it is still used in developing nations.

Metyrosine

Metyrosine (DEMSEK) is (–)- α -methyl-L-tyrosine. Metyrosine inhibits tyrosine hydroxylase, the enzyme that catalyzes the conversion of tyrosine to DOPA and the rate-limiting step in catecholamine biosynthesis (see Chapter 8). At a dose of 1-4 g/day, metyrosine decreases catecholamine biosynthesis by 35-80% in patients with pheochromocytoma. The maximal decrease in synthesis occurs only after several days and may be assessed by measurements of urinary catecholamines and their metabolites.

Metyrosine is used as an adjuvant to phenoxybenzamine and other α adrenergic blocking agents for the management of pheochromocytoma and in the preoperative preparation of patients for resection of pheochromocytoma. Metyrosine carries a risk of crystalluria, which can be minimized by maintaining a daily urine volume of >2 L. Other adverse effects include orthostatic hypotension, sedation, extrapyramidal signs, diarrhea, anxiety, and psychic disturbances. Doses must be titrated carefully to achieve significant inhibition of catecholamine biosynthesis and yet minimize these substantive side effects.

Ca²⁺ CHANNEL ANTAGONISTS

Ca²⁺ channel blocking agents are an important group of drugs for the treatment of hypertension. The general

pharmacology of these drugs is presented earlier in this chapter. The basis for their use in hypertension comes from the understanding that hypertension generally is the result of increased peripheral vascular resistance. Because contraction of vascular smooth muscle is dependent on the free intracellular concentration of Ca^{2+} , inhibition of transmembrane movement of Ca^{2+} through voltage-sensitive Ca^{2+} channels can decrease the total amount of Ca^{2+} that reaches intracellular sites. Indeed, all of the Ca^{2+} channel blockers lower blood pressure by relaxing arteriolar smooth muscle and decreasing peripheral vascular resistance (Weber, 2002). As a consequence of a decrease in peripheral vascular resistance, the Ca^{2+} channel blockers evoke a baroreceptor-mediated sympathetic discharge. In the case of the dihydropyridines, tachycardia may occur from the adrenergic stimulation of the SA node; this response is generally quite modest except when the drug is administered rapidly. Tachycardia is typically minimal to absent with verapamil and diltiazem because of the direct negative chronotropic effect of these two drugs. Indeed, the concurrent use of a β receptor antagonist drug may magnify negative chronotropic effects of these drugs or cause heart block in susceptible patients. Consequently, the concurrent use of β receptor antagonists with either verapamil or diltiazem may be problematic.

Ca^{2+} channel blockers are effective when used alone or in combination with other drugs for the treatment of hypertension; this view has been strengthened by a number of recent large clinical trials (Dahlöf et al., 2005; Jamerson et al., 2008).

Oral administration of nifedipine as an approach to urgent reduction of blood pressure has been abandoned. Sublingual administration does not achieve the maximum plasma concentration any more quickly than does oral administration. Moreover, in the absence of deleterious consequences of high arterial pressure, data do not support the rapid lowering of blood pressure. There is no place in the treatment of hypertension for the use of nifedipine or other dihydropyridine Ca^{2+} channel blockers with short half-lives when administered in a standard (immediate-release) formulation, because of the oscillation in blood pressure and concurrent surges in sympathetic reflex activity within each dosage interval. As noted earlier, parenteral administration of the novel dihydropyridine clevidipine may be useful in treating severe or perioperative hypertension.

Compared with other classes of antihypertensive agents, there may be a greater frequency of achieving blood pressure control with Ca^{2+} channel blockers as monotherapy in elderly subjects and in African-Americans, population groups in which the low renin status is more prevalent. However, intrasubject variability is more important than relatively small differences between population groups. Ca^{2+} channel blockers are effective in lowering blood pressure and decreasing cardiovascular events in the elderly with isolated

systolic hypertension (Staessen et al., 1997). Indeed, these drugs may be a preferred treatment in patients with isolated systolic hypertension.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

Angiotensin II is an important regulator of cardiovascular function (see Chapter 26). The ability to reduce levels of AngII with orally effective inhibitors of ACE represents an important advance in the treatment of hypertension. Captopril was the first such agent to be developed for the treatment of hypertension. Since then, enalapril, lisinopril, quinapril, ramipril, benazepril, moexipril, fosinopril, trandolapril, and perindopril also have become available. These drugs have proven to be very useful for the treatment of hypertension because of their efficacy and their very favorable profile of adverse effects, which enhances patient adherence. Chapter 26 presents the pharmacology of ACE inhibitors in detail.

The ACE inhibitors appear to confer a special advantage in the treatment of patients with diabetes, slowing the development and progression of diabetic glomerulopathy. They also are effective in slowing the progression of other forms of chronic renal disease, such as glomerulosclerosis, and many of these patients also have hypertension. An ACE inhibitor is the preferred initial agent in these patients. Patients with hypertension and ischemic heart disease are candidates for treatment with ACE inhibitors; administration of ACE inhibitors in the immediate post-MI period has been shown to improve ventricular function and reduce morbidity and mortality (see Chapter 28).

The endocrine consequences of inhibiting the biosynthesis of AngII are of importance in a number of facets of hypertension treatment. Because ACE inhibitors blunt the rise in aldosterone concentrations in response to Na^+ loss, the normal role of aldosterone to oppose diuretic-induced natriuresis is diminished. Consequently, ACE inhibitors tend to enhance the efficacy of diuretic drugs. This means that even very small doses of diuretics may substantially improve the antihypertensive efficacy of ACE inhibitors; conversely, the use of high doses of diuretics together with ACE inhibitors may lead to excessive reduction in blood pressure and to Na^+ loss in some patients.

The attenuation of aldosterone production by ACE inhibitors also influences K^+ homeostasis. There is only a very small and clinically unimportant rise in serum K^+ when these agents are used alone in patients with

normal renal function. However, substantial retention of K^+ can occur in some patients with renal insufficiency. Furthermore, the potential for developing hyperkalemia should be considered when ACE inhibitors are used with other drugs that can cause K^+ retention, including the K^+ -sparing diuretics (amiloride, triamterene, and spironolactone), NSAIDs, K^+ supplements, and β receptor antagonists. Some patients with diabetic nephropathy may be at greater risk of hyperkalemia.

There are several cautions in the use of ACE inhibitors in patients with hypertension. Angioedema is a rare but serious and potentially fatal adverse effect of the ACE inhibitors. Patients starting treatment with these drugs should be explicitly warned to discontinue their use with the advent of any signs of angioedema. Due to the risk of severe fetal adverse effects, ACE inhibitors are contraindicated during pregnancy, a fact that should be communicated to women of childbearing age.

In most patients, there is no appreciable change in glomerular filtration rate following the administration of ACE inhibitors. However, in renovascular hypertension, the glomerular filtration rate is generally maintained as the result of increased resistance in the postglomerular arteriole caused by AngII. Accordingly, in patients with bilateral renal artery stenosis or stenosis in a sole kidney, the administration of an ACE inhibitor will reduce the filtration fraction and cause a substantial reduction in glomerular filtration rate. In some patients with preexisting renal disease, the glomerular filtration may decrease with an ACE inhibitor. More information is needed on how to balance the potential risk of reversible drug-induced impairment of glomerular filtration rate versus inhibition of the progression of kidney disease.

ACE inhibitors lower the blood pressure to some extent in most patients with hypertension. Following the initial dose of an ACE inhibitor, there may be a considerable fall in blood pressure in some patients; this response to the initial dose is a function of plasma renin activity prior to treatment. The potential for a large initial drop in blood pressure is the reason for using a low dose to initiate therapy, especially in patients who may have a very active RAS supporting blood pressure, such as patients with diuretic-induced volume contraction or congestive heart failure. With continuing treatment, there usually is a progressive fall in blood pressure that in most patients does not reach a maximum for several weeks. The blood pressure seen during chronic treatment is not strongly correlated with the pretreatment plasma renin activity. Young and middle-aged Caucasian patients have a higher probability of responding to ACE inhibitors; elderly African-American patients as a group are more resistant to the hypotensive effect of these drugs. While most ACE inhibitors are approved for once-daily dosing for hypertension, a significant fraction of patients has a response that lasts <24 hours and may require twice-daily dosing for adequate control of blood pressure.

AT₁ RECEPTOR ANTAGONISTS

The importance of AngII in regulating cardiovascular function has led to the development of nonpeptide antagonists of the AT₁ AngII receptor for clinical use. Losartan,

candesartan, irbesartan, valsartan, telmisartan, olmesartan, and eprosartan have been approved for the treatment of hypertension. The pharmacology of AT₁ receptor antagonists is presented in detail in Chapter 26. By antagonizing the effects of AngII, these agents relax smooth muscle and thereby promote vasodilation, increase renal salt and water excretion, reduce plasma volume, and decrease cellular hypertrophy. AngII-receptor antagonists also theoretically overcome some of the disadvantages of ACE inhibitors, which not only prevent conversion of angiotensin I (AngI) to AngII but also prevent ACE-mediated degradation of bradykinin and substance P.

There are two distinct subtypes of AngII receptors, AT₁ and AT₂. The AT₁ receptor subtype is located predominantly in vascular and myocardial tissue and also in brain, kidney, and adrenal glomerulosa cells, which secrete aldosterone (see Chapter 26). The AT₂ subtype is found in the adrenal medulla, kidney, and CNS and may play a role in vascular development (Horiuchi et al., 1999). Because the AT₁ receptor mediates feedback inhibition of renin release, renin and AngII concentrations are increased during AT₁ receptor antagonism. The clinical consequences of increased AngII effects on an uninhibited AT₂ receptor are unknown; however, emerging data suggest that the AT₂ receptor may elicit anti-growth and anti-proliferative responses.

Adverse Effects and Precautions. The adverse effects of AT₁ receptor antagonists may be considered in the context of those known to be associated with the ACE inhibitors. ACE inhibitors cause problems of two major types, those related to diminished concentrations of AngII and those due to molecular actions independent of abrogating the function of AngII.

Adverse effects of ACE inhibitors that result from inhibiting AngII-related functions (see above and Chapter 26) also occur with AT₁ receptor antagonists. These include hypotension, hyperkalemia, and reduced renal function, including that associated with bilateral renal artery stenosis and stenosis in the artery of a solitary kidney. Hypotension is most likely to occur in patients in whom the blood pressure is highly dependent on AngII, including those with volume depletion (e.g., with diuretics), renovascular hypertension, cardiac failure, and cirrhosis; in such patients, initiation of treatment with low doses and attention to blood volume are essential. Hyperkalemia may occur in conjunction with other factors that alter K^+ homeostasis, such as renal insufficiency, ingestion of excess K^+ , and the use of drugs that promote K^+ retention. Cough, an adverse effect of ACE inhibitors, is less frequent with AT₁ receptor antagonists. Angioedema occurs very rarely.

ACE inhibitors and AT₁ receptor antagonists should not be administered during pregnancy and should be discontinued as soon as pregnancy is detected.

Therapeutic Uses. When given in adequate doses, the AT₁ receptor antagonists appear to be as effective as

ACE inhibitors in the treatment of hypertension. The full effect of AT₁ receptor antagonists on blood pressure typically is not observed until about 4 weeks after the initiation of therapy. If blood pressure is not controlled by an AT₁ receptor antagonist alone, a second drug acting by a different mechanism (e.g., a diuretic or Ca²⁺ channel blocker) may be added. The combination of an ACE inhibitor and an AT₁ receptor antagonist is not recommended for the treatment of hypertension.

DIRECT RENIN INHIBITORS

Drugs that inhibit the renin–angiotensin pathway at various steps have efficacy in the treatment of cardiovascular disease. This concept has been most extensively developed for the many drugs that inhibit the conversion of AngI to AngII (ACE inhibitors), block the actions of AngII (AT₁ receptor antagonists) or antagonize the actions of aldosterone (aldosterone-receptor antagonists). On the other hand, drugs that interrupt this pathway by inhibiting the capacity of renin to produce AngI from angiotensinogen have developed more slowly. *Aliskiren*, the first orally-effective direct renin inhibitor available in the U.S., was approved by the FDA in 2007.

Aliskiren has been shown to lower blood pressure in patients with hypertension. However, its efficacy in preventing adverse cardiovascular outcomes, especially in comparison with other more established drugs, awaits the results of large-scale clinical trials or other types of epidemiological inquiry. Until that information becomes available, aliskiren has a place as an add-on drug in patients with hypertension, rather than as a replacement for other successful therapies. The detailed pharmacology of aliskiren is covered in Chapter 26.

Locus and Mechanism of Action. The initial renin inhibitors were peptide analogs of sequences either in renin itself or included the renin cleavage site in angiotensinogen (Staessen et al., 2006). While effective in inhibiting renin and lowering blood pressure, these peptide analogs were effective only parenterally. However, aliskiren is effective following oral administration; it directly and competitively inhibits the catalytic activity of renin.

Pharmacological Effects. Aliskiren's inhibition of renin leads to diminished production of AngI—and ultimately AngII and aldosterone—with a resulting fall in blood pressure. Aliskiren along with ACE inhibitors and AT₁ receptor antagonists lead to an adaptive increase in the plasma concentrations of renin; however, because aliskiren inhibits renin activity, plasma renin activity does not increase as occurs with these other classes of drugs (Table 26–1).

Absorption, Metabolism, and Excretion. Aliskiren is poorly absorbed, with a bioavailability of <3% (Frampton and Curran, 2007). Taking the drug with a high-fat meal may substantially decrease plasma concentrations. Aliskiren has an elimination t_{1/2} of at least 24 hours. Elimination of the drug may be primarily through hepatobiliary excretion with limited metabolism via CYP3A4.

Toxicity and Precautions. Aliskiren is generally well tolerated. Diarrhea may occur, especially at higher than recommended doses. The incidence of cough may be higher than for placebo but substantially less than found with ACE inhibitors. Aliskiren has been associated with several cases of angioedema in clinical trials (Frampton and Curran, 2007). Drugs acting on the RAS may damage the fetus and should not be used in pregnant women.

Therapeutic Uses. Aliskiren is effective as monotherapy in treating patients with hypertension with dose-dependent increasing efficacy at 150–300 mg/day (top recommended dose). The drug's action appears to persist for 24 hours as assessed with ambulatory blood pressure monitoring. The combination of aliskiren with hydrochlorothiazide has a greater lowering effect on blood pressure than either drug alone (Baldwin and Plosker, 2009). Aliskiren formulated in combination with hydrochlorothiazide (TEKTRUNA HCT) or with valsartan (VALTURN) is available in the U.S. Aliskiren appears to have greater efficacy when added to other agents in the treatment of hypertension, including ACE inhibitors, AT₁ receptor antagonists, and Ca²⁺ channel blockers. Overall, aliskiren appears to be an effective antihypertensive drug that is well tolerated. Long-term outcome studies—including assessments of target organ damage in the heart, brain, and kidneys—will be important in establishing the role of this relatively new drug in the therapy of hypertension.

VASODILATORS

Hydralazine

Hydralazine (1-hydrazinophthalazine) was one of the first orally active antihypertensive drugs to be marketed in the U.S.; however, the drug initially was used infrequently because of tachycardia and tachyphylaxis. With a better understanding of the compensatory cardiovascular responses that accompany use of arteriolar vasodilators, hydralazine was combined with sympatholytic agents and diuretics with greater therapeutic success. Nonetheless, its role in the treatment of hypertension has markedly diminished with the introduction of new classes of antihypertensive drugs.

Locus and Mechanism of Action. Hydralazine directly relaxes arteriolar smooth muscle. The molecular mechanisms mediating this action are not clear but may ultimately involve a fall in intracellular calcium concentrations. While a variety of changes in cellular signaling pathways are influenced by hydralazine, precise molecular targets that explain its capacity to dilate arteries remain uncertain. There is evidence suggesting that hydralazine inhibits IP₃-induced release of Ca²⁺ from intracellular storage sites in arteries, leading to diminished contraction (Ellershaw and Gurney, 2001). There is also evidence that hydralazine promotes arterial dilation by opening high conductance Ca²⁺-activated K⁺ channels (Bang et al., 1998). Hydralazine induces transient

expression of hypoxia-inducible factor (HIF-1) and downstream targets of HIF in vascular smooth muscle cells (Knowles et al., 2004). However, the relationship between these pharmacological effects and the clinical consequence of use of hydralazine are unclear. In addition, hydralazine has been found to induce DNA demethylation (Arce et al., 2006).

The drug does not relax venous smooth muscle. Hydralazine-induced vasodilation is associated with powerful stimulation of the sympathetic nervous system, likely due to baroreceptor-mediated reflexes, which results in increased heart rate and contractility, increased plasma renin activity, and fluid retention; all of these effects tend to counteract the antihypertensive effect of hydralazine.

Pharmacological Effects. Most of the effects of hydralazine are confined to the cardiovascular system. The decrease in blood pressure after administration of hydralazine is associated with a selective decrease in vascular resistance in the coronary, cerebral, and renal circulations, with a smaller effect in skin and muscle. Because of preferential dilation of arterioles over veins, postural hypotension is not a common problem; hydralazine lowers blood pressure similarly in the supine and upright positions.

Absorption, Metabolism, and Excretion. Hydralazine is well absorbed through the gastrointestinal tract, but the systemic bioavailability is low (16% in fast acetylators and 35% in slow acetylators). Hydralazine is *N*-acetylated in the bowel and/or the liver. The $t_{1/2}$ of hydralazine is 1 hour, and systemic clearance of the drug is ~50 mL/kg/min.

The rate of acetylation is genetically determined; about half of the U.S. population acetylates rapidly, and half do so slowly. The acetylated compound is inactive; thus, the dose necessary to produce a systemic effect is larger in fast acetylators. Because the systemic clearance exceeds hepatic blood flow, extrahepatic metabolism must occur. Indeed, hydralazine rapidly combines with circulating α -keto acids to form hydrazones, and the major metabolite recovered from the plasma is hydralazine pyruvic acid hydrazone. This metabolite has a longer $t_{1/2}$ than hydralazine, but it does not appear to be very active. Although the rate of acetylation is an important determinant of the bioavailability of hydralazine, it does not play a role in the systemic elimination of the drug, probably because the hepatic clearance is so high that systemic elimination is principally a function of hepatic blood flow.

The peak concentration of hydralazine in plasma and the peak hypotensive effect of the drug occur within 30-120 minutes of ingestion. Although its $t_{1/2}$ in plasma is about an hour, the duration of the hypotensive effect of hydralazine can last as long as 12 hours. There is no clear explanation for this discrepancy.

Toxicity and Precautions. Two types of adverse effects occur after the use of hydralazine. The first, which are extensions of the pharmacological effects of the drug, include headache, nausea, flushing, hypotension, palpitations, tachycardia, dizziness, and angina pectoris. Myocardial ischemia can occur on account of increased O_2 demand induced by the baroreceptor reflex-induced stimulation of the sympathetic nervous system. Following parenteral administration to patients with coronary artery disease, the myocardial ischemia may be sufficiently severe and protracted to cause frank MI. For this reason, parenteral administration of hydralazine is not advisable in hypertensive patients with coronary artery disease, hypertensive patients with multiple cardiovascular risk factors, or

older patients. In addition, if the drug is used alone, there may be salt retention with development of high-output congestive heart failure. When combined with a β adrenergic receptor blocker and a diuretic, hydralazine is better tolerated, although adverse effects such as headache are still commonly described and may necessitate discontinuation of the drug.

The second type of adverse effect is caused by immunological reactions, of which the drug-induced lupus syndrome is the most common. Administration of hydralazine also can result in an illness that resembles serum sickness, hemolytic anemia, vasculitis, and rapidly progressive glomerulonephritis. The mechanism of these autoimmune reactions is unknown, although it has been suggested that the drug's capacity to promote DNA demethylation may be involved (Arce et al., 2006).

The drug-induced lupus syndrome usually occurs after at least 6 months of continuous treatment with hydralazine, and its incidence is related to dose, sex, acetylator phenotype, and race. In one study, after 3 years of treatment with hydralazine, drug-induced lupus occurred in 10% of patients who received 200 mg daily, 5% who received 100 mg daily, and none who received 50 mg daily (Cameron and Ramsay, 1984). The incidence is four times higher in women than in men, and the syndrome is seen more commonly in Caucasians than in African-Americans. The rate of conversion to a positive antinuclear antibody test is faster in slow acetylators than in rapid acetylators, suggesting that the native drug or a nonacetylated metabolite is responsible. However, because the majority of patients with positive antinuclear antibody tests do not develop the drug-induced lupus syndrome, hydralazine need not be discontinued unless clinical features of the syndrome appear. These features are similar to those of other drug-induced lupus syndromes and consist mainly of arthralgia, arthritis, and fever. Pleuritis and pericarditis may be present, and pericardial effusion can occasionally cause cardiac tamponade. Discontinuation of the drug is all that is necessary for most patients with the hydralazine-induced lupus syndrome, but symptoms may persist in a few patients, and administration of corticosteroids may be necessary.

Hydralazine also can produce a pyridoxine-responsive polyneuropathy. The mechanism appears to be related to the ability of hydralazine to combine with pyridoxine to form a hydrazone. This side effect is very unusual with doses ≤ 200 mg/day.

Therapeutic Uses. Hydralazine is no longer a first-line drug in the treatment of hypertension on account of its relatively unfavorable adverse-effect profile. The drug is marketed as a combination pill containing isosorbide dinitrate (BiDil) that is used for the treatment of heart failure (see Chapter 28). Hydralazine may have utility in the treatment of some patients with severe hypertension, can be part of evidence-based therapy in patients with congestive heart failure (in combination with nitrates for patients who cannot tolerate ACE inhibitors or AT_1 receptor antagonists), and may be useful in the treatment of hypertensive emergencies in pregnant women (especially preeclampsia). Hydralazine should be used with the great caution in elderly patients and in hypertensive patients with coronary artery disease because of the possibility of precipitation of myocardial ischemia due to reflex tachycardia. The usual oral dosage of hydralazine is 25-100 mg twice daily. Off-label twice-daily administration is as effective as administration four times a day for control of blood pressure, regardless of acetylator phenotype. The

maximum recommended dose of hydralazine is 200 mg/day to minimize the risk of drug-induced lupus syndrome.

K_{ATP} Channel Openers: Minoxidil

The discovery in 1965 of the hypotensive action of minoxidil was a significant advance in the treatment of hypertension, because the drug has proven to be efficacious in patients with the most severe and drug-resistant forms of hypertension.

MINOXIDIL

Locus and Mechanism of Action. Minoxidil is not active *in vitro* but must be metabolized by hepatic sulfotransferase to the active molecule, minoxidil *N-O* sulfate; the formation of this active metabolite is a minor pathway in the metabolic disposition of minoxidil. Minoxidil sulfate relaxes vascular smooth muscle in isolated systems where the parent drug is inactive. Minoxidil sulfate activates the ATP-modulated K^+ channel. By opening K^+ channels in smooth muscle and thereby permitting K^+ efflux, it causes hyperpolarization and relaxation of smooth muscle (Leblanc et al., 1989).

Pharmacological Effects. Minoxidil produces arteriolar vasodilation with essentially no effect on the capacitance vessels; the drug resembles hydralazine and diazoxide in this regard. Minoxidil increases blood flow to skin, skeletal muscle, the gastrointestinal tract, and the heart more than to the CNS. The disproportionate increase in blood flow to the heart may have a metabolic basis, in that administration of minoxidil is associated with a reflex increase in myocardial contractility and in cardiac output. The cardiac output can increase markedly, as much as 3- to 4-fold. The principal determinant of the elevation in cardiac output is the action of minoxidil on peripheral vascular resistance to enhance venous return to the heart; by inference from studies with other drugs, the increased venous return probably results from enhancement of flow in the regional vascular beds, with a fast time constant for venous return to the heart (Ogilvie, 1985). The adrenergically mediated increase in myocardial contractility contributes to the increased cardiac output but is not the predominant causal factor.

The effects of minoxidil on the kidney are complex. Minoxidil is a renal artery vasodilator, but systemic hypotension produced by the drug occasionally can decrease renal blood flow. Renal

function usually improves in patients who take minoxidil for the treatment of hypertension, especially if renal dysfunction is secondary to hypertension (Mitchell et al., 1980). Minoxidil is a very potent stimulator of renin secretion; this effect is mediated by a combination of renal sympathetic stimulation and activation of the intrinsic renal mechanisms for regulation of renin release.

Discovery of K_{ATP}^+ channels in a variety of cell types and in mitochondria is prompting consideration of K_{ATP}^+ channel modulators as therapeutic agents in myriad cardiovascular diseases (Pollesello and Mebazaa, 2004) and may provide explanations for some of the effects of minoxidil noted in the previous section. Various K_{ATP}^+ channels possess different regulatory sulfonylurea receptor subunits and thus exhibit tissue-specific responses. Recent studies suggest that certain actions of K_{ATP}^+ channel openers can be influenced by hypercholesterolemia and by concurrent administration of sulfonylurea hypoglycemic agents (Miura and Miki, 2003).

Absorption, Metabolism, and Excretion. Minoxidil is well absorbed from the GI tract. Although peak concentrations of minoxidil in blood occur 1 hour after oral administration, the maximal hypotensive effect of the drug occurs later, possibly because formation of the active metabolite is delayed.

The bulk of the absorbed drug is eliminated by hepatic metabolism; ~20% is excreted unchanged in the urine. The major metabolite of minoxidil is the glucuronide conjugate at the *N*-oxide position in the pyrimidine ring. This metabolite is less active than minoxidil, but it persists longer in the body. The extent of biotransformation of minoxidil to its active metabolite, minoxidil *N-O* sulfate, has not been evaluated in humans. Minoxidil has a plasma $t_{1/2}$ of 3-4 hours, but its duration of action is 24 hours or occasionally even longer. It has been proposed that persistence of minoxidil in vascular smooth muscle is responsible for this discrepancy. However, without knowledge of the pharmacokinetic properties of the active metabolite, an explanation for the prolonged duration of action cannot be given.

Adverse Effects and Precautions. The adverse effects of minoxidil can be severe and are divided into three major categories: fluid and salt retention, cardiovascular effects, and hypertrichosis.

Retention of salt and water results from increased proximal renal tubular reabsorption, which is in turn secondary to reduced renal perfusion pressure and to reflex stimulation of renal tubular α adrenergic receptors. Similar antinatriuretic effects can be observed with the other arteriolar dilators (e.g., diazoxide and hydralazine). Although administration of minoxidil causes increased secretion of renin and aldosterone, this is not an important mechanism for retention of salt and water in this case. Fluid retention usually can be controlled by the administration of a diuretic. However, thiazides may not be sufficiently efficacious, and it may be necessary to use a loop diuretic, especially if the patient has any degree of renal dysfunction. Retention of salt and water in patients taking minoxidil may be profound, requiring large doses of loop diuretics to prevent edema formation.

The cardiac consequences of the baroreceptor-mediated activation of the sympathetic nervous system during minoxidil therapy are similar to those seen with hydralazine; there is an increase in heart rate, myocardial contractility, and myocardial O_2 consumption. Thus, myocardial ischemia can be induced by minoxidil in patients with coronary artery disease. The cardiac sympathetic responses are attenuated by concurrent administration of a β adrenergic blocker. The adrenergically induced increase in renin secretion also can be

782 ameliorated by a β receptor antagonist or an ACE inhibitor, with enhancement of blood pressure control.

The increased cardiac output evoked by minoxidil has particularly adverse consequences in those hypertensive patients who have left ventricular hypertrophy and diastolic dysfunction. Such poorly compliant ventricles respond suboptimally to increased volume loads, with a resulting increase in left ventricular filling pressure. This probably is a major contributor to the increased pulmonary artery pressure seen with minoxidil (and hydralazine) therapy in hypertensive patients and is compounded by the retention of salt and water caused by minoxidil. Cardiac failure can result from minoxidil therapy in such patients; the potential for this complication can be reduced but not prevented by effective diuretic therapy. Pericardial effusion is an uncommon but serious complication of minoxidil. Although more commonly described in patients with cardiac and renal failure, pericardial effusion can occur in patients with normal cardiovascular and renal function. Mild and asymptomatic pericardial effusion is not an indication for discontinuing minoxidil, but the situation should be monitored closely to avoid progression to tamponade. Effusions usually clear when the drug is discontinued but can recur if treatment with minoxidil is resumed.

Flattened and inverted T waves frequently are observed in the electrocardiogram following the initiation of minoxidil treatment. These are not ischemic in origin and are seen with other drugs that activate K^+ channels. These drugs accelerate myocardial repolarization, shorten the refractory period, and one of them, *pinacidil*, lowers the ventricular fibrillation threshold and increases spontaneous ventricular fibrillation in the setting of myocardial ischemia (Chi et al., 1990). The effect of minoxidil on the refractory period and ischemic ventricular fibrillation has not been investigated; whether or not such findings enhance the risk of ventricular fibrillation in human myocardial ischemia is unknown.

Hypertrichosis occurs in patients who receive minoxidil for an extended period and is probably a consequence of K^+ channel activation. Growth of hair occurs on the face, back, arms, and legs and is particularly offensive to women. Frequent shaving or depilatory agents can be used to manage this problem. Topical minoxidil (ROGAINE) is marketed over-the-counter for the treatment of male pattern baldness and hair thinning and loss on the top of the head in women. The topical use of minoxidil also can cause measurable cardiovascular effects in some individuals.

Other side effects of the drug are rare and include rashes, Stevens-Johnson syndrome, glucose intolerance, serosanguineous bullae, formation of antinuclear antibodies, and thrombocytopenia.

Therapeutic Uses. Systemic minoxidil is best reserved for the treatment of severe hypertension that responds poorly to other antihypertensive medications, especially in male patients with renal insufficiency (Campese, 1981). It has been used successfully in the treatment of hypertension in both adults and children. Minoxidil should never be used alone; it must be given concurrently

with a diuretic to avoid fluid retention and with a sympatholytic drug (usually a β receptor antagonist) to control reflex cardiovascular effects. The drug usually is administered either once or twice a day, but some patients may require more frequent dosing for adequate control of blood pressure. The initial daily dose of minoxidil may be as little as 1.25 mg, which can be increased gradually to 40 mg in one or two daily doses.

Sodium Nitroprusside

Although sodium nitroprusside has been known since 1850 and its hypotensive effect in humans was described in 1929, its safety and usefulness for the short-term control of severe hypertension were not demonstrated until the mid-1950s. Several investigators subsequently demonstrated that sodium nitroprusside also was effective in improving cardiac function in patients with left ventricular failure (see Chapter 28).

Locus and Mechanism of Action. Nitroprusside is a nitrovasodilator that acts by releasing NO. NO activates the guanylyl cyclase–cyclic GMP–PKG pathway, leading to vasodilation (Linder et al., 2005), mimicking the production of NO by vascular endothelial cells, which is impaired in many hypertensive patients (Ramchandra et al., 2005). The mechanism of release of NO is not clear and likely involves both enzymatic and nonenzymatic pathways (Feelisch, 1998). Tolerance develops to *nitroglycerin* but not to nitroprusside (Fung, 2004). The pharmacology of the organic nitrates, including nitroglycerin, was presented earlier.

Pharmacological Effects. Nitroprusside dilates both arterioles and venules, and the hemodynamic response to its administration results from a combination of venous pooling and reduced arterial impedance. In subjects with normal left ventricular function, venous pooling affects cardiac output more than does the reduction of afterload; cardiac output tends to fall. In contrast, in patients with severely impaired left ventricular function and diastolic ventricular distention, the reduction of arterial impedance is the predominant effect, leading to a rise in cardiac output (see Chapter 28).

Sodium nitroprusside is a nonselective vasodilator, and regional distribution of blood flow is little affected by the drug. In general, renal blood flow and

glomerular filtration are maintained, and plasma renin activity increases. Unlike minoxidil, hydralazine, diazoxide, and other arteriolar vasodilators, sodium nitroprusside usually causes only a modest increase in heart rate and an overall reduction in myocardial O₂ demand.

Absorption, Metabolism, and Excretion. Sodium nitroprusside is an unstable molecule that decomposes under strongly alkaline conditions or when exposed to light. The drug must be protected from light and given by continuous intravenous infusion to be effective. Its onset of action is within 30 seconds; the peak hypotensive effect occurs within 2 minutes, and when the infusion of the drug is stopped, the effect disappears within 3 minutes.

The metabolism of nitroprusside by smooth muscle is initiated by its reduction, which is followed by the release of cyanide and then NO (Bates et al., 1991). Cyanide is further metabolized by liver rhodanase to form thiocyanate, which is eliminated almost entirely in the urine. The mean elimination $t_{1/2}$ for thiocyanate is 3 days in patients with normal renal function, and it can be much longer in patients with renal insufficiency.

Therapeutic Uses. Sodium nitroprusside is used primarily to treat hypertensive emergencies but also can be used in many situations when short-term reduction of cardiac preload and/or afterload is desired. Nitroprusside has been used to lower blood pressure during acute aortic dissection; improve cardiac output in congestive heart failure, especially in hypertensive patients with pulmonary edema that does not respond to other treatment (see Chapter 28); and decrease myocardial oxygen demand after acute MI. In addition, nitroprusside is used to induce controlled hypotension during anesthesia in order to reduce bleeding in surgical procedures. In the treatment of acute aortic dissection, it is important to administer a β adrenergic receptor antagonist with nitroprusside, because reduction of blood pressure with nitroprusside alone can increase the rate of rise in pressure in the aorta as a result of increased myocardial contractility, thereby enhancing propagation of the dissection.

Sodium nitroprusside is available in vials that contain 50 mg. The contents of the vial should be dissolved in 2-3 mL of 5% dextrose in water. Addition of this solution to 250-1000 mL of 5% dextrose in water produces a concentration of 50-200 $\mu\text{g}/\text{mL}$. Because the compound decomposes in light, only fresh solutions should be used, and the bottle should be covered with an opaque wrapping. The drug must be administered as a controlled continuous infusion, and the patient must be closely observed. The majority of hypertensive patients respond to an infusion of 0.25-1.5 $\mu\text{g}/\text{kg}/\text{min}$. Higher rates of infusion are necessary to produce controlled hypotension in normotensive patients under surgical anesthesia. Patients who are receiving other antihypertensive medications usually require less nitroprusside to lower blood pressure. If infusion rates of 10 $\mu\text{g}/\text{kg}/\text{min}$ do not produce adequate reduction of blood pressure within 10 minutes, the rate of administration of nitroprusside should be reduced to minimize potential toxicity.

Toxicity and Precautions. The short-term adverse effects of nitroprusside are due to excessive vasodilation, with hypotension and the consequences thereof. Close monitoring of blood pressure and the use of a continuous variable-rate infusion pump will prevent an excessive hemodynamic response to the drug in the majority of cases.

Less commonly, toxicity may result from conversion of nitroprusside to cyanide and thiocyanate. Toxic accumulation of cyanide leading to severe lactic acidosis usually occurs when sodium nitroprusside is infused at a rate $>5 \mu\text{g}/\text{kg}/\text{min}$ but also can occur in some patients receiving doses $\sim 2 \mu\text{g}/\text{kg}/\text{min}$ for a prolonged period. The limiting factor in the metabolism of cyanide appears to be the availability of sulfur-containing substrates in the body (mainly thiosulfate). The concomitant administration of sodium thiosulfate can prevent accumulation of cyanide in patients who are receiving higher-than-usual doses of sodium nitroprusside; the efficacy of the drug is unchanged (Schulz, 1984). The risk of thiocyanate toxicity increases when sodium nitroprusside is infused for more than 24-48 hours, especially if renal function is impaired. Signs and symptoms of thiocyanate toxicity include anorexia, nausea, fatigue, disorientation, and toxic psychosis. The plasma concentration of thiocyanate should be monitored during prolonged infusions of nitroprusside and should not be allowed to exceed 0.1 mg/mL. Rarely, excessive concentrations of thiocyanate may cause hypothyroidism by inhibiting iodine uptake by the thyroid gland. In patients with renal failure, thiocyanate can be removed readily by hemodialysis.

Nitroprusside can worsen arterial hypoxemia in patients with chronic obstructive pulmonary disease because the drug interferes with hypoxic pulmonary vasoconstriction and therefore promotes mismatching of ventilation with perfusion.

Diazoxide. Diazoxide was used in the treatment of hypertensive emergencies but fell out of favor at least in part due to the risk of marked falls in blood pressure when large bolus doses of the drug were used. Other drugs are now preferred for parenteral administration in the control of hypertension. Diazoxide also is administered orally (PROGLYCEM) to treat patients with various forms of hypoglycemia (see Chapter 43).

NONPHARMACOLOGICAL THERAPY OF HYPERTENSION

Nonpharmacological approaches to the treatment of hypertension may be sufficient in patients with modestly elevated blood pressure. Such approaches also can augment the effects of antihypertensive drugs in patients with more marked initial elevations in blood pressure. The indications and efficacy of various lifestyle modifications in hypertension are reviewed in a summary statement from the Joint National Committee (Chobanian et al., 2003).

- Reduction in body weight for people who are modestly overweight or frankly obese may be useful (Horvath et al., 2008).
- Restricting sodium consumption lowers blood pressure in some patients. The Dietary Approaches to

Stop Hypertension (DASH) diet may be particularly useful (Champagne, 2006).

- For some patients, restriction of ethanol intake to modest levels may lower blood pressure.
- Increased physical activity may improve control of hypertension.

SELECTION OF ANTIHYPERTENSIVE DRUGS IN INDIVIDUAL PATIENTS

Choice of antihypertensive drugs for individual patients may be complex; there are many sources of influence that modify therapeutic decisions. While results derived from randomized controlled clinical trials are the optimal foundation for rational therapeutics, it may be difficult to sort through the multiplicity of results and address how they apply to an individual patient. While therapeutic guidelines can be useful in reaching appropriate therapeutic decisions, it often is difficult for clinicians to apply guidelines at the point of care, and guidelines often do not provide enough information about recommended drugs. In addition, intense marketing of specific drugs to both clinicians and patients may confound optimal decision making. Moreover, persuading patients to continue taking sometimes expensive drugs for an asymptomatic disease is a challenge. Clinicians may be reluctant to prescribe and patients reluctant to consume the number of drugs that may be necessary to adequately control blood pressure. For these and other reasons, perhaps one-half of patients being treated for hypertension have not achieved therapeutic goals in blood pressure lowering.

Choice of an antihypertensive drug should be driven by the likely benefit in an individual patient, taking into account concomitant diseases such as diabetes mellitus, problematic adverse effects of specific drugs, and cost.

National guidelines (Chobaniry et al, 2003) recommend diuretics as preferred initial therapy for most patients with uncomplicated stage 1 hypertension (Table 27–4) who are unresponsive to nonpharmacological measures. Patients also are commonly treated with other drugs: β -receptor antagonists, ACE inhibitors/ AT_1 -receptor antagonists, and Ca^{2+} channel blockers. Patients with uncomplicated stage 2 hypertension will likely require the early introduction of a diuretic and another drug from a different class. Subsequently, doses can be titrated upward and additional drugs added to achieve goal blood pressures (blood pressure <140/90 mm Hg in uncomplicated patients). Some of these patients may require four different drugs to reach the goal.

An important and high-risk group of patients with hypertension are those with compelling indications for specific drugs on account of other underlying serious cardiovascular disease (heart failure, post-MI, or with high risk for coronary artery disease), chronic kidney disease, or diabetes (Chobanian et al., 2003). For example, a hypertensive patient with congestive heart failure ideally should be treated with a diuretic, β receptor antagonist, ACE inhibitor/ AT_1 -receptor antagonist, and (in selected patients) spironolactone because of the benefit of these drugs in congestive heart failure, even in the absence of hypertension (see Chapter 28). Similarly, ACE inhibitors/ AT_1 -receptor antagonists should be first-line drugs in the treatment of diabetics with hypertension in view of these drugs' well-established benefits in diabetic nephropathy.

Other patients may have less serious underlying diseases that could influence choice of antihypertensive drugs. For example, a hypertensive patient with symptomatic benign prostatic hyperplasia might benefit from having an α_1 receptor antagonist as part of his or her therapeutic program, because α_1 antagonists are efficacious in both diseases. Similarly, a patient with recurrent migraine attacks might particularly benefit from use of a β receptor antagonist because a number of drugs in this class are efficacious in preventing migraine attacks. On the other hand, in pregnant hypertensives, some drugs that are otherwise little used (methyldopa) may be preferred and popular drugs (ACE inhibitors) avoided on account of concerns about safety.

Patients with isolated systolic hypertension (systolic blood pressure >160 mm Hg and diastolic blood pressure <90 mm Hg) benefit particularly from diuretics and also from Ca^{2+} channel blockers and ACE inhibitors. These should be first-line drugs in these patients in terms of efficacy, but compelling indications as noted earlier need to be taken into account.

These considerations apply to patients with hypertension that need treatment to reduce long-term risk, not patients in immediately life-threatening settings due to hypertension. While there are very limited clinical trial data, clinical judgment favors rapidly lowering blood pressure in patients with life-threatening complications of hypertension, such as patients with hypertensive encephalopathy or pulmonary edema due to severe hypertension. However, rapid reduction in blood pressure has considerable risks for the patients; if blood pressure is decreased too quickly or extensively, cerebral blood flow may diminish due to adaptations in the cerebral circulation that protect the brain from the sequelae of very high blood pressures. The temptation

to rapidly treat patients merely on the basis of increased blood pressure should be resisted. Appropriate therapeutic decisions need to encompass how well the patients' major organs are reacting to the very high blood pressures. While many drugs have been used parenterally to rapidly decrease blood pressure in emergencies (including nitroprusside, enalaprilat, esmolol, fenoldapam, labetalol, clevidipine and nicardipine, hydralazine, and phentolamine), the clinical significance of differing actions of many of these drugs in this setting is largely unknown (Perez et al., 2008).

RESISTANT HYPERTENSION

Some patients with hypertension do not appear to respond to recommended treatments. There are many potential explanations. To achieve stringent control of hypertension, many patients require two, three, or four appropriately selected drugs used at optimal doses. Clinicians may be reluctant to prescribe sufficient numbers of medications that exploit the full dose response curve (therapeutic inertia), or patients may not adhere to the recommended pharmacological regimen. Sometimes multiple drugs in the same therapeutic class are chosen. Excess salt intake and the tendency of some antihypertensive drugs (especially vasodilators) to promote salt retention may mitigate falls in blood pressure; consequently, inadequate diuretic treatment commonly is found in patients with resistant hypertension. Patients may take prescription drugs, over-the-counter drugs, or herbal preparations that oppose the actions of antihypertensive drugs: for example, NSAIDs, sympathomimetic decongestants, cyclosporine, erythropoietin, ephedra (ma huang) or licorice. Illicit drugs such as cocaine and amphetamines may raise blood pressure.

28 chapter

Pharmacotherapy of Congestive Heart Failure

Bradley A. Maron
and Thomas P. Rocco

Congestive heart failure (CHF) is responsible for more than half a million deaths annually in the U.S., carries a 1-year mortality rate of more than 50% in patients with advanced forms of the condition, and is responsible for nearly \$27 billion annually in healthcare costs (Binanay et al., 2005). Fortunately, substantive advances in CHF pharmacotherapy have altered clinical practice by shifting the paradigm of its management from exclusively symptom palliation to modification of disease progression and, in some cases, an expectation of prolonged survival.

In the past, drug therapies targeted the endpoints of this syndrome: volume overload (congestion) and myocardial dysfunction (pump failure). As a consequence, diuretics and cardiac glycosides dominated the medical management of CHF for more than 40 years. These drugs remain effective for symptom relief and in stabilizing patients with hemodynamic decompensation but do not improve long-term survival. The contemporary focus of CHF as a disorder of circulatory hemodynamics, pathologic cardiac remodeling, and increased arrhythmogenic instability has translated into the development of novel pharmacotherapies that reduce CHF-associated morbidity and mortality rates. Before discussing the clinical pharmacology of CHF in specific, it is useful to establish a pathophysiologic framework through which its treatment is approached.

Defining Congestive Heart Failure. The onset and progression of clinically evident CHF from left ventricular (LV) systolic dysfunction follows a pathophysiologic sequence in response to an initial insult to myocardial dysfunction. A reduction in forward cardiac output leads to expanded activation of the sympathetic nervous system and the renin–angiotensin–aldosterone axis that, together, maintain perfusion of vital organs by increasing

LV preload, stimulating myocardial contractility, and increasing arterial tone. Acutely, these mechanisms sustain cardiac output by allowing the heart to operate at elevated end-diastolic volumes, while peripheral vasoconstriction promotes regional redistribution of the cardiac output to the central nervous system, coronary, and renal vascular beds.

Unfortunately, however, these compensatory mechanisms over time propagate disease progression. Intravascular volume expansion increases diastolic and systolic wall stress that disrupts myocardial energetics and causes pathologic LV hypertrophy. By increasing LV afterload, peripheral arterial vasoconstriction also adversely affects diastolic ventricular wall stress, thereby increasing myocardial O₂ demand. Finally, neurohumoral effectors such as norepinephrine (NE) and angiotensin II (AngII) are associated with myocyte apoptosis, abnormal myocyte gene expression, and pathologic changes in the extracellular matrix that increase LV stiffness (Villarreal, 2005).

In clinical practice, the term CHF describes a final common pathway for the expression of myocardial dysfunction. While some emphasize the clinical distinction between systolic versus diastolic heart failure, many patients demonstrate dysfunction in both contractile performance and ventricular relaxation/filling. Indeed, these physiologic processes are interrelated; for example, the rate and duration of LV diastolic filling are directly influenced by impairment in systolic contractile performance. Despite inherent difficulties in creating a singular description to encompass the diverse pathophysiologic mechanisms that result in CHF (e.g., myocardial infarction (MI), viral myocarditis), the following definitions are useful for establishing a conceptual framework to describe this clinical syndrome:

Congestive heart failure is the pathophysiologic state in which the heart is unable to pump blood at a rate commensurate with the requirements of metabolizing tissues, or can do so only from an elevated filling pressure (Braunwald and Bristow, 2000).

Heart failure is a complex of symptoms—fatigue, shortness of breath, and congestion—that are related to the inadequate perfusion of tissue during exertion and often to the retention of fluid. Its primary cause is an impairment of the heart’s ability to fill or empty the left ventricle properly (Cohn, 1996).

From these definitions, one may consider CHF as a condition in which failure of the heart to provide adequate forward output at normal end-diastolic filling pressures results in a clinical syndrome of decreased exercise tolerance with pulmonary and systemic venous congestion. Numerous cardiovascular comorbidities are associated with CHF, including coronary artery disease, MI, and sudden cardiac death.

PHARMACOLOGIC TREATMENT OF HEART FAILURE

The abnormalities of myocardial structure and function that characterize CHF are often irreversible. These changes narrow the end-diastolic volume range that is compatible with normal cardiac function. Although CHF is predominately a chronic disease, subtle changes to an individual’s hemodynamic status (e.g., increased circulating volume from high dietary sodium intake, increased systemic blood pressure from medication nonadherence) often provoke an acute clinical decompensation.

Not surprisingly, therefore, CHF therapy has for many years utilized diuretics to control volume overload and subsequent worsening in LV function. Other proven pharmacotherapies target ventricular wall stress, the renin–angiotensin–aldosterone axis, and the sympathetic nervous system to decrease pathologic ventricular remodeling, attenuate disease progression, and improve survival in selected patients with severe CHF and low LV ejection fraction. Figure 28–1 provides an overview of the sites of action for major drug classes commonly used in clinical practice. Note that these therapies largely improve cardiac hemodynamics and function through preload reduction, afterload reduction, and enhancement of inotropy (i.e., myocardial contractility). In addition, pharmacotherapeutics that target peripheral and coronary vascular function are receiving increased attention as potential participants in the comprehensive management of CHF patients.

Diuretics

Diuretics remain central in the pharmacologic management of congestive symptoms in patients with CHF. The pharmacologic properties of these agents are presented in detail in Chapter 25. Their importance (and frequency of use) in CHF management reflects the deleterious downstream effects of volume expansion on increased LV end-diastolic volume, an intermediate step in the development of elevated right-heart pressure, pulmonary venous congestion, and peripheral edema (Hillege et al., 2000).

Diuretics reduce extracellular fluid volume and ventricular filling pressure (or “preload”). Because CHF patients often operate on a “plateau” phase of the *Frank-Starling* curve (Figure 28–2), incremental preload reduction occurs under these conditions without a reduction in cardiac output. Sustained natriuresis and/or a rapid decline in intravascular volume, however, may “push” one’s profile leftward on the Frank-Starling curve, resulting in an unwanted decrease in cardiac output. In this way, excessive diuresis is counterproductive secondary to reciprocal neurohormonal *overactivation* from volume depletion (McCurley et al., 2004). For this reason, it is preferable to avoid diuretics in patients with asymptomatic LV dysfunction and to only administer the minimal dose required to maintain euvolemia in those patients symptomatic from hypervolemia. Despite the efficacy of loop or thiazide diuretics in controlling congestive symptoms and improving exercise capacity, their use is not associated with a reduction in CHF mortality.

Dietary Sodium Restriction. All patients with clinically significant LV dysfunction, regardless of symptom status, should be advised to limit dietary sodium intake to 2–3 g/day. More stringent salt restriction is seldom necessary and may be counterproductive, as it can lead to hyponatremia, hypokalemia, and hypochloremic metabolic alkalosis when combined with loop diuretic administration.

Loop Diuretics. Of the loop diuretics currently available, furosemide (LASIX, others), bumetanide (BUMEX, others), and torsemide (DEMADEX, others) are widely used in the treatment of CHF. Due to the increased risk of ototoxicity, ethacrynic acid (EDECRIN) is recommended only for patients with sulfonamides allergies or who are intolerant to alternative options.

Loop diuretics inhibit a specific ion transport protein, the $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ symporter on the apical membrane of renal epithelial cells in the ascending limb of the loop of Henle to increase Na^+ and fluid delivery to

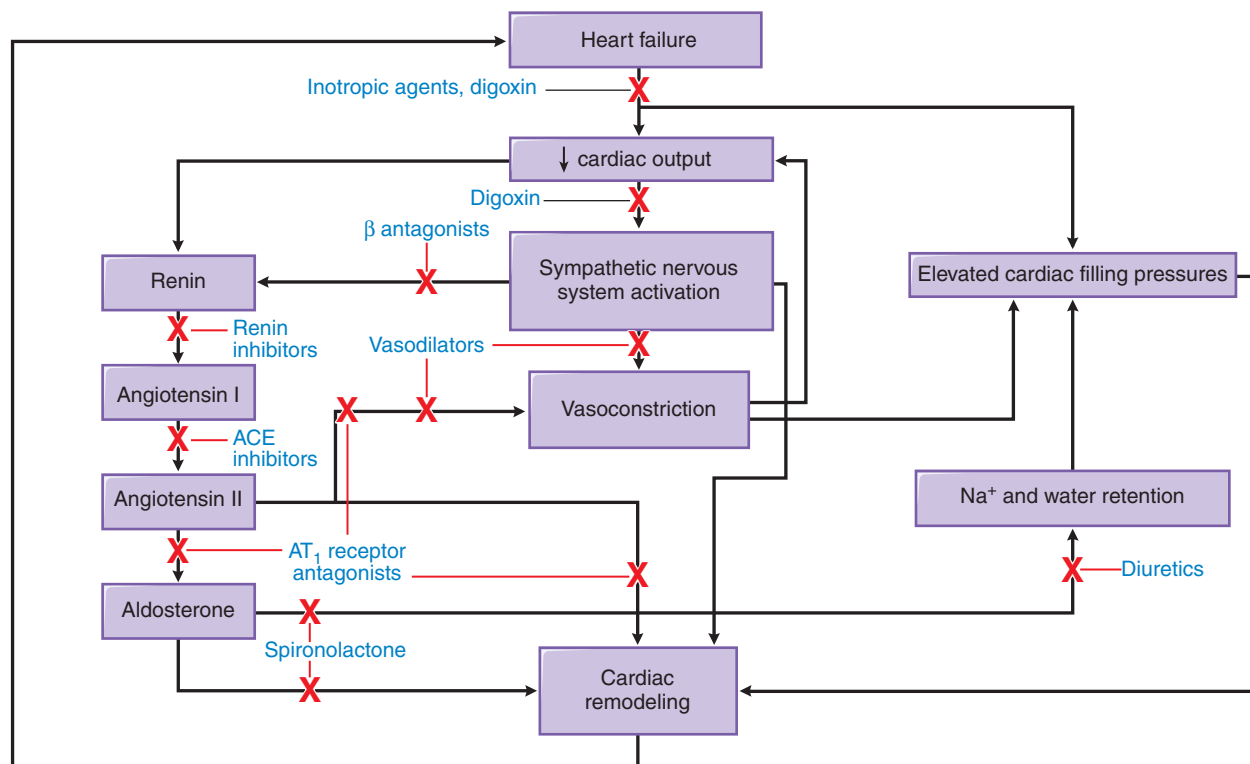

Figure 28–1. Pathophysiologic mechanisms of heart failure and major sites of drug action. Congestive heart failure is accompanied by compensatory neurohormonal responses, including activation of the sympathetic nervous and renin–angiotensin–aldosterone axis. Increased ventricular afterload, due to systemic vasoconstriction and chamber dilation, causes depression in systolic function. In addition, increased afterload and the direct effects of angiotensin and norepinephrine on the ventricular myocardium cause pathologic remodeling characterized by progressive chamber dilation and loss of contractile function. Key congestive heart failure medications and their targets of action are presented. ACE, angiotensin-converting enzyme; AT₁ receptor, type 1 angiotensin receptor.

distal nephron segments (see Chapter 25). These drugs also enhance K⁺ secretion, particularly in the presence of elevated aldosterone levels, as is typical in CHF.

The bioavailability of orally administered furosemide ranges from 40–70%. High drug concentrations often are required to initiate diuresis in patients with worsening symptoms or in those with impaired gastrointestinal absorption, as may occur in severely hypovolemic patients with CHF-induced gut edema (Gottlieb, 2004). In contrast, the oral bioavailabilities of bumetanide and torsemide are >80%, and as a result, these agents are more consistently absorbed but are financially more costly.

Furosemide and bumetanide are short-acting drugs, and rebound Na⁺ retention that occurs with sub-steady state drug levels make ≥2/day dosing an acceptable treatment strategy when using these agents, provided adequate monitoring of daily body weight and blood electrolyte level monitoring is possible.

Thiazide Diuretics. Monotherapy with thiazide diuretics (DIURIL, HYDRODIURIL, others) has a limited role in CHF. However, combination therapy with loop diuretics is often effective in those refractory to loop diuretics

alone. Thiazide diuretics act on the Na⁺Cl[−] cotransporter in the distal convoluted tubule (see Chapter 25) and are associated with a greater degree K⁺ wasting per fluid volume reduction when compared to loop diuretics (Gottlieb, 2004).

K⁺-Sparing Diuretics. K⁺-sparing diuretics (see Chapter 25) inhibit apical membrane Na⁺-conductance channels in renal epithelial cells (e.g., amiloride, triamterene) or are mineralocorticoid (e.g., aldosterone) receptor antagonists (e.g., canrenone [not commercially available in the U.S.], spironolactone, and eplerenone). Collectively, these agents are weak diuretics, but have historically been used to achieve volume reduction with limited K⁺ and Mg²⁺ wasting. The beneficial role of aldosterone receptor blockers on survival in CHF is discussed later.

Diuretics in Clinical Practice. The majority of CHF patients will require chronic administration of a loop diuretic to maintain euvolemia. In patients with clinically

Figure 28–2. Hemodynamic responses to pharmacologic interventions in heart failure. The relationships between diastolic filling pressure (preload) and stroke volume (ventricular performance) are illustrated for a normal heart (green line; the Frank-Starling relationship) and for a patient with heart failure due to predominant systolic dysfunction (red line). Note that positive inotropic agents (I), such as cardiac glycosides or dobutamine, move patients to a higher ventricular function curve (lower dashed line), resulting in greater cardiac work for a given level of ventricular filling pressure. Vasodilators (V), such as angiotensin-converting enzyme (ACE) inhibitors or nitroprusside, also move patients to improved ventricular function curves while reducing cardiac filling pressures. Diuretics (D) improve symptoms of congestive heart failure by moving patients to lower cardiac filling pressures along the same ventricular function curve.

evident fluid retention, furosemide typically is started at a dose of 40 mg once or twice daily, and the dosage is increased until an adequate diuresis is achieved. A larger initial dose may be necessary in patients with advanced CHF and azotemia. Serum electrolytes and renal function are monitored frequently in these patients or in those for whom a rapid diuresis is necessary. If present, hypokalemia from therapy may be corrected by oral or intravenous K^+ supplementation or by the addition of a K^+ -sparing diuretic. When appropriate, diuretics are decreased to the minimum effective concentration for maintaining euolemia.

Diuretics in the Decompensated Patient. In patients with decompensated CHF warranting hospital admission, repetitive intravenously administered boluses or a constant infusion titrated to achieve a desired response may be needed to provide expeditious (and reliable) diuresis (Dormans et al., 1996). One advantage to intravenous infusion is that sustained natriuresis is achieved as a consequence of consistently elevated drug levels within the lumen of the renal tubules. In addition, the risk of

ototoxicity is reduced by continuous infusion when compared to repetitive, intermittent intravenous dosing (Lahav et al., 1992).

A typical continuous furosemide infusion is initiated with a 40-mg bolus injection followed by a constant rate of 10 mg/h, with uptitration as necessary. If renal perfusion is reduced, drug efficacy may be enhanced by co-administration of drugs that increase cardiac output (e.g., dobutamine).

Diuretic Resistance. As mentioned earlier, a compensatory increase in renal tubular Na^+ reabsorption may prevent effective diuresis when dosed daily; as a result, reduction of diuretic dosing intervals may be warranted. In advanced CHF, invasive assessment of intracardiac filling pressures and cardiac output may be required to distinguish between low intravascular volume from aggressive diuresis versus low cardiac output states, although both states are aligned with lower diuretic delivery and drug efficacy. Furthermore, edema, decreased bowel-wall motility, and reduced splanchnic blood flow impair absorption and may delay or attenuate peak diuretic effect.

Atherosclerotic renal artery disease is associated with reduced renal perfusion pressures to levels below that necessary for adequate drug delivery. In patients with reduced renal arterial perfusion pressure (e.g., renal artery stenosis or low cardiac output), AngII-mediated efferent glomerular arteriole tone is important for preservation of normal glomerular filtration pressure. Angiotensin-converting enzyme (ACE) inhibitors or AT_1 receptor antagonists in combination with loop diuretics may, therefore, be met with a decline in creatinine clearance that is associated with low diuretic delivery and decreased drug efficacy (Ellison, 1999). Other common causes of diuretic resistance are listed in Table 28–1.

Metabolic Consequences of Diuretic Therapy. The side effects of diuretics are discussed in Chapter 25. With regard to diuretic use in CHF, the most important adverse sequelae of diuretics are electrolyte abnormalities, including hyponatremia, hypokalemia, and hypochloremic metabolic alkalosis. The clinical importance (or even existence) of significant Mg^{2+} deficiency with chronic diuretic use is controversial (Bigger, 1994).

Adenosine A_1 Receptor Antagonists. Adenosine A_1 receptor antagonists may provide a renal protective therapeutic strategy for enhanced volume loss in decompensated CHF. Adenosine is secreted from the macula densa in the renal arteriole in response to diuretic-induced increases in Na^+ and Cl^- tubular flow concentrations. This results in increased Na^+ resorption, a volume-loss counterregulatory mechanism (see Chapter 26). Na^+ reabsorption, in addition to adenosine-induced renal

Causes of Diuretic Resistance in Heart Failure

Noncompliance with medical regimen; excess dietary Na⁺ intake
 Decreased renal perfusion and glomerular filtration rate due to:

Excessive vascular volume depletion and hypotension due to aggressive diuretic or vasodilator therapy

Decline in cardiac output due to worsening heart failure, arrhythmias, or other primary cardiac causes

Selective reduction in glomerular perfusion pressure following initiation (or dose increase) of ACE-inhibitor therapy

Nonsteroidal anti-inflammatory drugs
 Primary renal pathology (e.g., cholesterol emboli, renal artery stenosis, drug-induced interstitial nephritis, obstructive uropathy)
 Reduced or impaired diuretic absorption due to gut wall edema and reduced splanchnic blood flow

arteriole vasoconstriction, appears responsible (in part) for the development of complications common to the use of diuretics in decompensated CHF patients, particularly prerenal azotemia. The role of adenosine in the macula densa and juxtaglomerular (granular) cells (see Figure 26–2) suggests other effects of A₁ antagonists on the renin-angiotensin system.

As an example of the use of A₁ antagonists, the administration of *KW-3902* (ROLOFYLLINE) (30 mg) to patients with decompensated CHF already treated with loop diuretics is associated with increased volume reduction, improved renal function, and lower diuretic dosing, as compared to placebo (Givertz et al., 2007). Favorable effects on urine output and renal function also have been observed in similar patients with the A₁ receptor antagonist *BG9179* (NAXIFYLLINE) (Gottlieb et al., 2002). A large clinical trial failed to show significant benefits of rolofylline in patients with CHF, and clinical development of the drug was stopped in 2009. No A₁ antagonists are currently marketed in the U.S.

Aldosterone Antagonists and Clinical Outcome

LV systolic dysfunction decreases renal blood flow and results in overactivation of the renin–angiotensin–aldosterone axis and may increase circulating plasma aldosterone levels in CHF to 20-fold above normal (Figure 28–3). The pathophysiologic effects of hyperaldosteronemia are diverse (Table 28–2) and extend beyond Na⁺ and fluid retention; importantly, however,

the precise mechanism by which aldosterone receptor blockade improves outcome in CHF remains unresolved (Weber, 2004).

In the Randomized Aldactone Evaluation Study, CHF patients with low LV ejection fraction receiving spironolactone (25 mg/day) had a significant (~30%) reduction in mortality (from progressive heart failure or sudden cardiac death) and fewer CHF-related hospitalizations compared with the placebo group (Pitt et al., 1999). Treatment was well tolerated overall; most notably, however, 10% of men reported gynecomastia and 2% of all patients developed severe hyperkalemia (>6.0 mEq/L) on spironolactone (Pitt et al., 1999). Data from this and other clinical studies (Pitt et al., 2003) suggest that *despite* maximum ACE inhibition, clinically important aldosterone levels are still achieved in CHF. This may account for the beneficial effects observed in these trials where aldosterone-receptor antagonists were used in combination with ACE inhibitor therapy. Combination therapy in those with renal impairment, however, increases the probability of drug-induced hyperkalemia.

The role of aldosterone antagonists in patients with asymptomatic LV dysfunction or in those with minimal CHF-associated symptoms has not been established.

Vasodilators

The rationale for oral vasodilator drugs in the pharmacotherapy of CHF derives from experience with parenterally administered *phentolamine* and *nitroprusside* in patients with advanced disease and elevated systemic vascular resistance (Cohn and Franciosa, 1977). Although numerous vasodilators have since been developed that improve CHF symptoms, only the *hydralazine–isosorbide dinitrate* combination, ACE inhibitors, and AT₁ receptor blockers (ARBs) demonstrably improve survival. The therapeutic use of vasodilators in the treatment of hypertension and myocardial ischemia is considered in detail in Chapter 27. This chapter will focus on the uses for some of these same vasodilator drugs in the treatment of CHF. Table 28–3 summarizes properties of vasodilators commonly used to treat CHF.

Nitrovasodilators. Nitrovasodilators are nitric oxide (NO) donors that activate soluble guanylate cyclase in vascular smooth muscle cells, leading to vasodilation. The mechanism underlying the variable response profiles to nitrovasodilators in different vascular beds remains controversial; e.g., nitroglycerin preferentially induces epicardial coronary artery vasodilation. Furthermore, the mechanisms by which nitrovasodilators are converted to their active forms *in vivo* depend on the particular agent. Unlike nitroprusside, which is converted to NO[•] by cellular reducing agents such as glutathione, nitroglycerin and other organic nitrates undergo a more complex enzymatic biotransformation

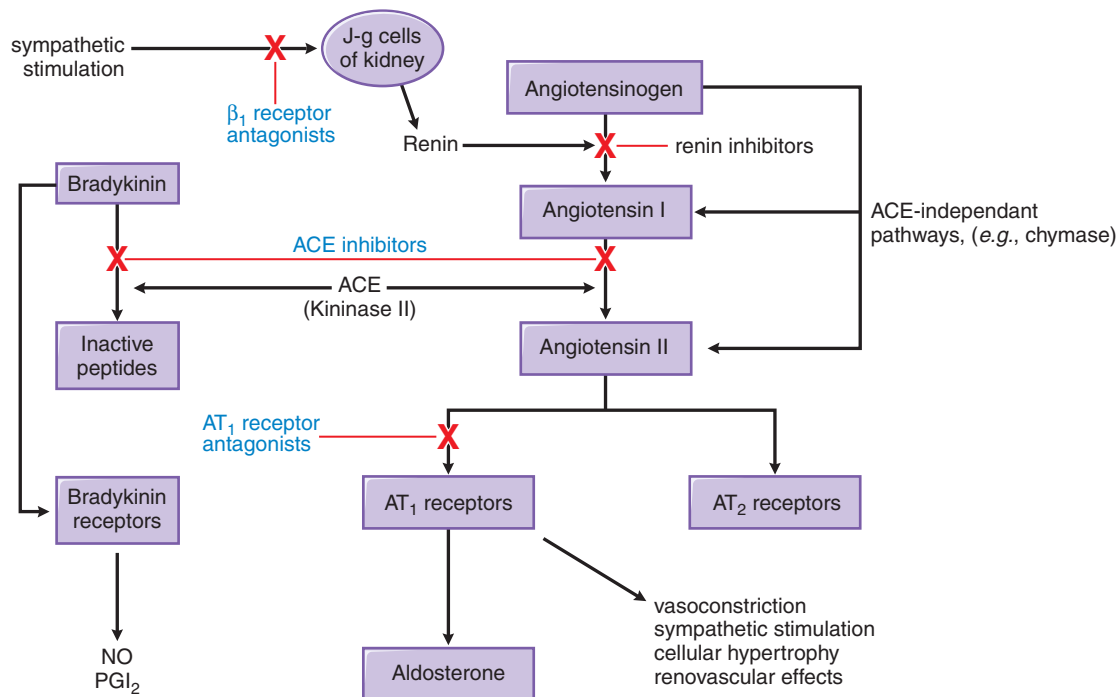

Figure 28–3. The renin–angiotensin–aldosterone axis. Renin, excreted in response to β adrenergic stimulation of the juxtaglomerular (J-g) cells of the kidney, cleaves plasma angiotensinogen to produce angiotensin I. Angiotensin-converting enzyme (ACE) catalyzes the conversion of angiotensin I to angiotensin II (AngII). Most of the known biologic effects of AngII are mediated by the type 1 angiotensin (AT_1) receptor. In general, the AT_2 receptor appears to counteract the effects of AngII that are mediated by activation of the AT_1 pathway. AngII also may be formed through ACE-independent pathways. These pathways, and possibly incomplete inhibition of tissue ACE, may account for persistence of Ang II in patients treated with ACE inhibitors. ACE inhibition decreases bradykinin degradation, thus enhancing its levels and biologic effects, including the production of NO and PGI_2 . Bradykinin may mediate some of the biological effects of ACE inhibitors.

Table 28–2

Potential Roles of Aldosterone in the Pathophysiology of Heart Failure

MECHANISM	PATHOPHYSIOLOGIC EFFECT
Increased Na^+ and water retention K^+ and Mg^{2+} loss	Edema, elevated cardiac filling pressures Arrhythmogenesis and risk of sudden cardiac death
Reduced myocardial NE uptake	Potential of NE affects: myocardial remodeling and arrhythmogenesis
Reduced baroreceptor sensitivity	Reduced parasympathetic activity and risk of sudden cardiac death
Myocardial fibrosis, fibroblast proliferation Alterations in Na^+ channel expression	Remodeling and ventricular dysfunction Increased excitability and contractility of cardiac myocytes

to NO^* or bioactive *S*-nitrosothiols. The activities of specific enzyme(s) and cofactor(s) required for this bio-transformation appear to differ by target organ and even by different vasculature beds within a particular organ (Münzel et al., 2005).

Organic Nitrates. As discussed in Chapter 27, organic nitrates are available in a number of formulations that include rapid-acting nitroglycerin tablets or spray for sublingual administration, short-acting oral agents such as isosorbide dinitrate (ISORDIL, others), long-acting oral agents such as isosorbide mononitrate (ISMO, others), topical preparations such as nitroglycerin ointment and transdermal patches, and intravenous nitroglycerin. These preparations are relatively safe and effective; specifically, their principal action in CHF is reducing LV filling pressure. This occurs, in part, by augmentation of peripheral venous capacitance that results in preload reduction. Additional effects of organic nitrates include pulmonary and systemic vascular resistance

Table 28–3

Vasodilator Drugs Used to Treat Heart Failure

DRUG CLASS	EXAMPLES	MECHANISM OF VASODILATING ACTION	PRELOAD REDUCTION	AFTERLOAD REDUCTION
Organic nitrates	Nitroglycerin, isosorbide dinitrate	NO-mediated vasodilation	+++	+
NO donors	Nitroprusside	NO-mediated vasodilation	+++	+++
ACE inhibitors	Captopril, enalapril, lisinopril	Inhibition of AngII generation, ↓ BK degradation	++	++
Ang II receptor blockers	Losartan, candesartan	AT ₁ receptors blockade	++	++
PDE inhibitors	Milrinone, inamrinone	Inhibition of cyclic AMP degradation	++	++
K ⁺ channel agonist	Hydralazine	Unknown	+	+++
	Minoxidil	Hyperpolarization of vascular smooth muscle cells	+	+++
α ₁ antagonists	Doxazosin, prazosin	Selective α ₁ adrenergic receptor blockade	+++	++
Nonselective α antagonists	Phentolamine	Nonselective α adrenergic receptor blockade	+++	+++
β/α ₁ antagonists	Carvedilol, labetalol	Selective α ₁ adrenergic receptor blockade	++	++
Ca ²⁺ channel blockers	Amlodipine, nifedipine, felodipine	Inhibition of L-type Ca ²⁺ channels	+	+++
β agonists	Isoproterenol	Stimulation of vascular β ₂ adrenergic receptors	+	++

Ang II, angiotensin II; AT₁, type 1 angiotensin II receptor; NO, nitric oxide; ACE, angiotensin converting enzyme; PDE, cyclic nucleotide phosphodiesterase; BK, bradykinin.

reduction, particularly at higher doses, and epicardial coronary artery vasodilation for which systolic and diastolic ventricular function is enhanced by increased coronary blood flow. Collectively, these beneficial physiologic effects translate into improved exercise capacity and CHF-symptom reduction. However, these drugs do not substantially influence systemic vascular resistance, and pharmacologic tolerance greatly limits their utility over time. For these reasons and others, organic nitrates are not commonly used alone; rather, a number of trials have shown that when used together, selected organic nitrates increase the clinical effectiveness of other vasodilators, such as *hydralazine*, resulting in a sustained improvement in hemodynamics.

Nitrate tolerance. Nitrate tolerance may limit the long-term effectiveness of these drugs in the treatment of CHF. Blood nitrate levels may be permitted to fall to negligible levels for at least 6–8 hours each day (see

Chapter 27). The timing of nitrate withdrawal symptoms, if present, may be useful, however, for developing an appropriate drug-dosing schedule. Patients with recurrent orthopnea or paroxysmal nocturnal dyspnea, e.g., might benefit from nighttime nitrate use. Likewise, co-treatment with hydralazine (e.g., isosorbide dinitrate and hydralazine [BIDIL]) may decrease nitrate tolerance by an antioxidant effect that attenuates superoxide formation, thereby increasing the bioavailable NO levels (Münzel et al., 1996).

Parenteral Vasodilators

Sodium Nitroprusside. Sodium nitroprusside (NITRO-PRESS, others) is a direct NO donor and potent vasodilator that is effective in reducing both ventricular filling pressure and systemic vascular resistance. The downstream beneficial physiologic effects of afterload reduction in CHF are outlined in Figure 28–4. Onset to

Figure 28–4. Relationship between ventricular outflow resistance and stroke volume in patients with systolic ventricular dysfunction. An increase in ventricular outflow resistance, a principal determinant of afterload, has little effect on stroke volume in normal hearts, as illustrated by the relatively flat curve. In contrast, in patients with systolic ventricular dysfunction, an increase in outflow resistance often is accompanied by a sharp decline in stroke volume. With more severe ventricular dysfunction, this curve becomes steeper. Because of this relationship, a reduction in systemic vascular resistance (one component of outflow resistance) in response to an arterial vasodilator may markedly increase stroke volume in patients with severe myocardial dysfunction. The resultant increase in stroke volume may be sufficient to offset the decrease in systemic vascular resistance, thereby preventing a fall in systemic arterial pressure. (Adapted with permission from Cohn and Franciosa, 1977. Copyright © Massachusetts Medical Society. All rights reserved.)

activation of sodium nitroprusside is rapid (2-5 minutes), and the drug is quickly metabolized to NO, properties that afford easy titration to achieve the desired hemodynamic effect.

Nitroprusside is particularly effective in treating critically ill patients with CHF who have elevated systemic vascular resistance or mechanical complications that follow acute MI (e.g., mitral regurgitation or ventricular septal defect-induced left-to-right shunts). As with other vasodilators, the most common adverse side effect of nitroprusside is hypotension. In general, nitroprusside initiation in patients with severe CHF results in increased cardiac output and a parallel increase in renal blood flow, improving both glomerular filtration and diuretic effectiveness. However, excessive reduction of systemic arterial pressure may limit or prevent an increase in renal blood flow in patients with more severe LV contractile dysfunction.

Cyanide produced during the biotransformation of nitroprusside is rapidly metabolized by the liver to thiocyanate, which

is then renally excreted. Thiocyanate and/or cyanide toxicity is uncommon but may occur in the setting of hepatic or renal failure, or following prolonged periods of high-dose drug infusion (see Chapter 27 for details). Typical symptoms include unexplained abdominal pain, mental status changes, convulsions, and lactic acidosis. Methemoglobinemia is another unusual complication and is due to the oxidation of hemoglobin by NO[•].

Intravenous Nitroglycerin. Intravenous nitroglycerin, like nitroprusside, is a vasoactive NO donor that is commonly used in the intensive care unit setting. Unlike nitroprusside, nitroglycerin is relatively selective for venous capacitance vessels, particularly at low infusion rates. In CHF, intravenous nitroglycerin is most commonly used in the treatment of LV dysfunction due to an acute myocardial ischemia. Parenteral nitroglycerin also is used in the treatment of nonischemic cardiomyopathy when expeditious LV filling pressure reduction is desired. At higher infusion rates, this drug also may decrease systemic arterial resistance, although this effect is less predictable. Nitroglycerin therapy may be limited by headache and nitrate tolerance; tolerance may be partially offset by increasing the dosage. Administration requires the use of an infusion pump capable of controlling the rate of administration.

Hydralazine. Hydralazine is a direct vasodilator that has long been in clinical use, yet its precise mechanism of action is poorly understood. The effects of this agent are not mediated through recognized neurohumoral systems, and its mechanism of action at the cellular level in vascular smooth muscle is uncertain. Lack of mechanistic understanding notwithstanding, hydralazine is an effective antihypertensive drug (see Chapter 27), particularly when combined with agents that blunt compensatory increases in sympathetic tone and salt and water retention. In CHF, hydralazine reduces right and left ventricular afterload by reducing pulmonary and systemic vascular resistance. This results in an augmentation of forward stroke volume and a reduction in ventricular wall stress in systole. Hydralazine also appears to have moderate “direct” positive inotropic activity in cardiac muscle independent of its afterload-reducing effects. Hydralazine is effective in reducing renal vascular resistance and in increasing renal blood flow to a greater degree than are most other vasodilators, with the exception of ACE inhibitors. For this reason, hydralazine often is used in CHF patients with renal dysfunction intolerant of ACE-inhibitor therapy.

The landmark Veterans Administration Cooperative Vasodilator-Heart Failure Trial I (V-HeFT I) demonstrated that combination therapy with isosorbide dinitrate and hydralazine (a pill

containing these two compounds in combination is marketed as BiDil) reduces CHF mortality in patients with systolic dysfunction (Cohn et al., 1986). In V-HeFT I, the mortality benefit was agent specific: the α_1 receptor antagonist *prazosin* offered no advantage over placebo when compared with isosorbide plus hydralazine.

Hydralazine provides additional hemodynamic improvement for patients with advanced CHF (with or without nitrates) already treated with conventional doses of an ACE inhibitor, digoxin, and diuretics (Cohn, 1994). The hypothesis that hydralazine-mediated antioxidant effects benefit CHF patients at elevated risk for vascular endothelial dysfunction is supported by the African-American Heart Failure Trial, in which isosorbide dinitrate-hydralazine substantially decreased all-cause mortality in self-described black patients, a group associated with impaired vascular endothelial function and diminished bioavailable levels of NO when compared to white counterparts (Taylor et al., 2007).

There are several important considerations for hydralazine use. First, ACE inhibitors appear to be superior to hydralazine for mortality reduction in severe CHF. Second, side effects requiring dose adjustment of hydralazine withdrawal are common. In V-HeFT I, e.g., only 55% of patients were taking full doses of both hydralazine and isosorbide dinitrate after 6 months. The lupus-like side effects associated with hydralazine are relatively uncommon and may be more likely to occur in selected patients with the “slow-acetylator” phenotype (see Chapter 27). Finally, hydralazine is a medication taken three or four times daily, and adherence may be difficult for CHF patients, who are often prescribed multiple medications concurrently.

The oral bioavailability and pharmacokinetics of hydralazine are not altered significantly in CHF, unless severe hepatic congestion or hypoperfusion is present. Intravenous hydralazine is available but provides little practical advantage over oral formulations except for urgent use in pregnant patients. In these individuals, hydralazine is often used owing to contraindications that exist for use of most other vasodilators in pregnancy. Hydralazine is typically started at a dose of 10–25 mg three or four times per day and uptitrated to a maximum of 100 mg three or four times daily, as tolerated. At total daily doses >200 mg, hydralazine is associated with an increased risk of lupus-like effects.

Targeting Neurohormonal Regulation: The Renin–Angiotensin–Aldosterone Axis and Vasopressin Antagonists

Renin–Angiotensin–Aldosterone Axis Antagonists. The renin–angiotensin–aldosterone axis plays a central role in the pathophysiology of CHF (Figure 28–3). AngII is a potent arterial vasoconstrictor and an important mediator of Na^+ and water retention through its effects on glomerular filtration pressure and aldosterone secretion. AngII also modulates neural and adrenal medulla catecholamine release, is arrhythmogenic, promotes vascular hyperplasia and myocardial hypertrophy, and induces myocyte death. Consequently, reduction of the effects of AngII constitutes a cornerstone of CHF management (Weber, 2004).

ACE inhibitors suppress AngII (and aldosterone) production, decrease sympathetic nervous system activity, and potentiate the effects of diuretics in CHF. However, AngII levels frequently return to baseline values following chronic treatment with ACE inhibitors (see Chapter 26), due in part to AngII production via ACE-independent enzymes. The sustained clinical effectiveness of ACE inhibitors despite this AngII “escape” suggests that alternate mechanisms contribute to the clinical benefits of ACE inhibitors in CHF. ACE is identical to kininase II, which degrades bradykinin and other kinins that stimulate production of NO, cyclic GMP, and vasoactive eicosanoids. These oppose AngII-induced vascular smooth muscle cell and cardiac fibroblasts proliferation and inhibit unfavorable extracellular matrix deposition.

ACE inhibitors are preferential arterial vasodilators. ACE-inhibitor–mediated decreases in LV afterload result in increased stroke volume and cardiac output; ultimately, the magnitude of these effects is associated with the observed change in mean arterial pressure. Heart rate typically is unchanged with treatment, often despite decreases in systemic arterial pressure, a response that probably is a consequence of decreased sympathetic nervous system activity from ACE inhibition.

Most clinical actions of AngII, including its deleterious effects in CHF, are mediated through the AT_1 angiotensin receptor, whereas AT_2 receptor activation appears to counterbalance the downstream biologic effects of AT_1 receptor stimulation. Owing to enhanced target specificity, AT_1 receptor antagonists more efficiently block the effects of AngII than do ACE inhibitors. In addition, the elevated level of circulating AngII that occurs secondary to AT_1 receptor blockade results in a relative increase in AT_2 receptor activation. Unlike ACE inhibitors, AT_1 blockers do not influence bradykinin metabolism (see the next section).

Angiotensin-Converting Enzyme Inhibitors. The first orally administered ACE inhibitor, captopril (CAPOTEN, others), was introduced in 1977. Since then, six additional ACE inhibitors—enalapril (VASOTEC, others), ramipril (ALTACE, others), lisinopril (PRINIVIL, ZESTRIL, others), quinapril (ACCUPRIL, others), trandolapril (MAVIK, others) and fosinopril (MONOPRIL, others) have been FDA-approved for the treatment of CHF. Data from numerous clinical trials involving well over 100,000 patients support ACE inhibition in the management of CHF of any severity, including those with asymptomatic LV dysfunction.

ACE-inhibitor therapy typically is initiated at a low dose (e.g., 6.25 mg of captopril, 5 mg of lisinopril) to avoid iatrogenic hypotension, particularly in the setting of volume contraction. Hypotension following drug administration usually can be reversed by intravascular volume expansion, but, of course, this may be

counterproductive in symptomatic CHF patients. Therefore, it is reasonable to consider initiation of these drugs while congestive symptoms are present. ACE-inhibitor doses customarily are increased over several days in hospitalized patients or over weeks in ambulatory patients, with careful observation of blood pressure, serum electrolytes, and serum creatinine levels.

If possible, drug doses are targeted in practice to match those affording maximum clinical benefit in controlled trials: captopril, 50 mg three times daily (Pfeffer et al., 1992); enalapril, 10 mg twice daily (SOLVD Investigators, 1992; Cohn et al., 1991); lisinopril, 10 mg once daily (GISSI-3, 1994); and ramipril, 5 mg twice daily (AIRE Study Investigators, 1993). If an adequate clinical response is not achieved at these doses, further increases, as tolerated, may be effective (Packer et al., 1999).

In CHF patients with decreased renal blood flow, ACE inhibitors, unlike nitrovasodilators, impair autoregulation of glomerular perfusion pressure, reflecting their selective effect on efferent (over afferent) arteriolar tone (Kittleson et al., 2003). In the event of acute renal failure or a decrease in the glomerular filtration rate by >20%, ACE-inhibitor dosing should be reduced or the drug discontinued. Rarely, renal function impairment following drug initiation is indicative of bilateral renal artery stenosis.

ACE-Inhibitor Side Effects. Elevated bradykinin levels from ACE inhibition are associated with angioedema, a potentially life-threatening drug side effect. If this occurs, immediate and permanent cessation of *all* ACE inhibitors is indicated. Angioedema may occur at any time over the course of ACE inhibitor therapy. A characteristic, dry cough from the same mechanism is common; in this case, substitution of an AT₁ receptor antagonist for the ACE inhibitor often is curative. A small rise in serum K⁺ levels is common with ACE-inhibitor use. This increase may be substantial, however, in patients with renal impairment or in diabetic patients with type IV renal tubular acidosis. Mild hyperkalemia is best managed by institution of a low-potassium diet but may require drug dose adjustment. The inability to implement ACE inhibitors as a consequence of cardiorenal side effects (e.g., excessive hypotension, progressive renal insufficiency, hyperkalemia) is itself a poor prognostic indicator in the CHF patient (Kittleson et al., 2003).

ACE Inhibitors and Survival in CHF. A number of randomized, placebo-controlled clinical trials have demonstrated that ACE inhibitors improve survival in patients with CHF due to systolic dysfunction, independent of etiology. For example, ACE inhibitors prevent mortality and the development of clinically significant LV dysfunction after acute MI (Pfeffer et al., 1992; Konstam et al., 1992; St. John Sutton et al., 1994). This occurs through attenuation or prevention of increased LV end-diastolic and end-systolic volumes, and the

decline in LV ejection fraction that is central to the natural history of AMI. ACE inhibitors appear to confer these benefits by preventing postinfarction-associated adverse ventricular remodeling.

The Cooperative North Scandinavian Enalapril Survival Study (CONSENSUS Trial Study Group 1987) demonstrated a 40% mortality reduction after 6 months of enalapril therapy in severe CHF, while others have shown that enalapril also improves survival in patients with mild-to-moderate CHF (SOLVD Investigators, 1992). Furthermore, across the spectrum of CHF severity, when compared with other vasodilators, ACE inhibitors appear superior in reducing mortality (Fonarow et al., 1992). In asymptomatic patients with LV dysfunction, ACE inhibitors slow the development of symptomatic CHF.

AT₁ Receptor Antagonists. Activation of the AT₁ receptor mediates most of the deleterious effects of AngII that are described earlier. AT₁-receptor antagonism, in turn, largely obviates AngII “escape” and substantially decreases the probability of developing bradykinin-mediated side effects associated with ACE inhibition. Importantly, however, although rare, angioedema has been reported with AT₁-receptor antagonist use. Therefore, caution is still warranted when prescribing these agents to patients with a history of ACE-inhibitor-associated angioedema.

AT₁ receptor blockers (ARBs) are effective antihypertensives, and their influence on mortality in acute or chronic CHF from systolic dysfunction after acute MI is akin to that of ACE-inhibitor therapy (Konstam et al., 2005; Dickstein et al., 2002; White et al., 2005). Owing to their favorable side-effect profile, ARBs are an excellent alternative in CHF patients intolerant of ACE inhibitors (Pitt et al., 1997; Doggrell, 2005). Interestingly, age >75 years may increase the probability of developing clinically significant hypotension, renal dysfunction, and hyperkalemia (White et al., 2005).

The role of combination ACE-inhibitor and ARB therapy in the treatment of CHF remains unresolved. Although preliminary studies suggested that combined therapy with candesartan and enalapril, e.g., favorably affected cardiovascular hemodynamics, LV remodeling, and neurohormonal profile compared to therapy with either agent alone (McKelvie et al., 1999), subsequent trials have been unable to demonstrate an incremental mortality benefit from combination therapy despite a significant reduction in CHF-associated hospitalizations (McMurray et al., 2003).

Based on the hypothesis that ARB efficacy is at least in part a consequence of reduced circulating aldosterone levels, combined treatment with aldosterone receptor inhibition has been explored. Combination therapy is associated with a significant increase in LV ejection fraction and quality of life scores in patients with CHF from systolic dysfunction treated for 1 year with candesartan (8 mg daily) and spironolactone (25 mg daily) compared to those treated with candesartan alone (Chan et al., 2007). Others have corroborated the beneficial effects of combined therapy on LV remodeling, 6-minute walk distance, and functional capacity (Kum et al., 2008). The beneficial effects of dual therapy are provocative but must be

weighed against the increased likelihood for inducing hyperkalemia, hypotension, and elevated elective treatment withdrawal rates reported in some trials. Data regarding mortality benefit attendant to combination therapy are not available at present.

In CHF from impaired diastolic relaxation (i.e., preserved LV ejection fraction), the role of AT_1 receptor antagonists is unresolved. These drugs do not appear to improve mortality or echocardiographic indices of diastolic relaxation but are associated with fewer CHF hospitalizations (Yusuf et al., 2003; Solomon et al., 2007; Massie et al., 2008). Some have suggested that ARB-induced improvement in arteriolar flow reserve may be protective in patients with diastolic CHF, although this hypothesis remains speculative at present (Kamezaki et al., 2007).

Direct Renin Inhibitors. There is accumulating scientific and clinical evidence to suggest that maximal pharmacologic ACE inhibition alone is insufficient for optimal attenuation of AngII-induced cardiovascular dysfunction in patients with CHF. Several molecular mechanisms have been ascribed to explain this hypothesis (Abassi et al., 2009), including:

- the presence of ACE-independent pathways that facilitate AngI conversion to AngII
- the activation of ACE homologues (e.g., ACE2) that are insensitive to conventional ACE-I therapy
- the suppression of the negative feedback effect exerted by AngI on renin secretion in the kidney

For these reasons, inhibition of renin has pharmacotherapeutic objectives for enhanced suppression of AngII synthesis in CHF.

Renin-mediated conversion of angiotensinogen to AngI is the first and rate-limiting step in the biochemical cascade that generates AngII and aldosterone (see Figures 26–1 and 28–3). The first generation of orally administered direct renin inhibitors was studied in the 1980s and was designed for the treatment of hypertension, but the broader use of these agents was hampered by the drugs' suboptimal efficacy, reflecting, at least in part, their limited bioavailability (Staessen et al., 2006). Aliskiren (TEKTRINA, RASILEZ) is the first orally administered direct renin inhibitor to obtain FDA approval for use in clinical practice. The pharmacokinetic advantages of aliskiren over earlier direct renin inhibitor prototypes include an increased bioavailability (2.7%) and a long plasma $t_{1/2}$ (~23 hour). Pilot clinical trials in humans established that aliskiren induces a concentration-dependent decrease in plasma renin activity and AngI and AngII levels that was associated with a decrease in systemic blood pressure without significant reflex tachycardia. The pharmacology of aliskiren is presented in more detail in Chapter 26.

The effect of aliskiren on blood pressure is the most thoroughly evaluated cardiovascular treatment endpoint. Several small studies have concluded that aliskiren is superior to placebo or to an ARB for monotherapy of mild-to-moderate hypertension (Sanoski, 2009). Aliskiren also appears to exert beneficial effects on myocardial remodeling by decreasing LV mass in hypertensive patients, suggesting that, similar to observations in ACE inhibitor or ARB therapy, direct renin inhibition may attenuate hypertension-induced end-organ damage (Solomon et al., 2009). Collectively, these observations provide evidence that aliskiren-mediated reductions in plasma renin activity and circulating levels of AngII may have salutary effects on the cardiovascular system in hypertension, thus opening the door for investigation of this therapy in patients with CHF.

The safety profile of aliskiren in CHF was established recently by the Aliskiren Observation of Heart Failure Treatment (ALOFT) trial (McMurray et al., 2008). Aliskiren (150 mg/day) add-on therapy to a β receptor antagonist and an ACE inhibitor or ARB was not associated with a significant increase in hypotension or hyperkalemia in a study cohort that mainly included symptomatic CHF patients with a low LV ejection fraction (~30%). Results from this trial also demonstrated that compared with placebo, aliskiren significantly decreased plasma *N*-terminal-proBNP levels, a clinically useful neurohumoral biomarker of active CHF. These findings affirm that inhibition of renin activity is an important potential target for improving symptoms and functional capacity in CHF. However, aliskiren has not yet been studied in sufficiently powered randomized-controlled clinical trials designed to analyze the efficacy of this drug in treatment of CHF.

Vasopressin Receptor Antagonists. Neurohumoral dysregulation in CHF extends beyond the renin-angiotensin-aldosterone axis to include abnormal arginine vasopressin (AVP) secretion, resulting in the perturbation of fluid balance, among various additional pathophysiologic effects. In response to 1) serum hypertonicity-induced activation of anterior pituitary osmoreceptors and 2) a perceived drop in blood pressure detected by baroreceptors in the carotid artery, aortic arch, and left atrium, AVP is secreted into the systemic circulation (Arai et al., 2007). The physiology and pharmacology of vasopressin are presented in Chapter 25.

The active form of AVP is a 9-amino acid peptide that interacts with three receptor subtypes: V_{1a} , V_{1b} , and V_2 (see Chapter 25). The AVP- V_2 receptor interaction on the basolateral membrane of the renal collecting ducts stimulates *de novo* synthesis of aquaporin-2 water channels that mediate free water reabsorption, thereby impairing diuresis and, ultimately, correcting plasma hypertonicity. Additional cell signaling pathways important in the pathophysiology of CHF include vasoconstriction, cell hypertrophy, and increased platelet aggregation mediated by activation of V_{1a} receptors in vascular smooth muscle cells and cardiac myocytes. In addition, AngII-mediated activation of centrally located AT_1 receptors is associated with increased AVP levels in

800 CHF and may represent one mechanism by which the use of AT₁-receptor antagonists are effective in the clinical management of these patients.

LV systolic dysfunction can be associated with hypervasopressinemia. Numerous observational and case-controlled studies have reported AVP levels nearly 2-fold above normal in CHF patients (Finley et al., 2008). The mechanisms to account for dysregulated AVP synthesis in CHF may involve impaired atrial stretch receptor sensitivity, normally a counterregulatory mechanism for AVP secretion, and increased adrenergic tone (Bristow et al., 2005). These probably do not fully explain the relationship between CHF and AVP levels; e.g., elevated levels of AVP have been observed in *asymptomatic* patients with significantly decreased LV function, calling into question the attributable role of sympathetically mediated adrenergic tone as a cause of hypervasopressinemia (Francis et al., 1990).

In addition, there is evidence to suggest that CHF is a disease of abnormal *responsiveness* to vasopressin rather than one of excessive vasopressin production alone. For example, vasopressin infusion in CHF patients decreases cardiac output and stroke volume and causes an exaggerated increase in systemic vascular resistance and pulmonary capillary wedge pressure (Finley et al., 2008). In turn, V₂ antagonists attenuate the adverse pathophysiologic effects of hypervasopressinemia by decreasing capillary wedge pressure, right atrial pressure, and pulmonary artery systolic blood pressure (Udelson et al., 2008). These agents also restore and maintain normal serum sodium levels in decompensated CHF patients, but their long-term use has not yet been convincingly linked to a decrease in CHF-associated symptoms or mortality (Gheorghiadu et al., 2004).

Generally, trials designed to measure the effect of vasopressin-receptor antagonists have used agents selective for the V₂ receptor, although some drugs with both V₂ and V_{1a} receptor affinity also have been studied. Tolvaptan (SAMSICA), which preferentially binds the V₂ receptor over the V_{1a} receptor (receptor affinity ~29:1), is perhaps the most widely tested vasopressin receptor antagonist in patients with CHF and also is approved for hyponatremia. Due to the risk of overly rapid correction of hyponatremia causing osmotic demyelination, tolvaptan should be started only in a hospital setting where Na⁺ levels can be monitored closely and possible drug interactions mediated by CYP and P-gp can be considered (black box warning). Conivaptan, used mainly for the treatment of hyponatremia rather than for CHF *per se*, differs from tolvaptan in that it may be intravenously administered, demonstrates high affinity for both V₂- and V_{1a}-vasopressin receptors, and has a t_{1/2} that is nearly twice as long.

In the randomized, placebo-controlled EVEREST trial, the effect of tolvaptan (30 mg/day) in addition to standard therapy on immediate symptom improvement was assessed in patients administered the drug <48 hours into hospitalization for CHF (Gheorghiadu et al., 2007). Data from this study substantiated that from the others, indicating that AVP antagonists decrease body weight, self-reported dyspnea, and physician-assessed peripheral edema, rales, and fatigue after a short course of therapy (<7 days). Long-term outcomes (survival, hospitalizations) were not significantly different from placebo. The identification of a CHF subgroup that stands to benefit most from AVP antagonists, in addition to the preferred agent and therapy duration, are questions of ongoing clinical investigation.

β Adrenergic Receptor Antagonists

Sympathetic nervous system activation in CHF supports circulatory function by enhancing contractility (inotropy), augmenting ventricular relaxation and filling (lusitropy), and increasing heart rate (chronotropy). For many years, pharmacologic approaches to CHF treatment targeted drugs with sympathomimetic properties. This reflected the viewpoint that CHF is fundamentally a disorder of impaired stroke volume and cardiac output. For example, CHF symptom relief from short-term *dobutamine* and *dopamine* use in patients with ventricular dysfunction led to the belief that long-term sympathomimetic use would further improve clinical outcome. Under this model, the use of β receptor antagonists was believed to be counterproductive; however, the reverse appears to be the case. Long-term sympathomimetic use is associated with increased CHF mortality rates, whereas a survival benefit is associated with chronic administration of β receptor antagonists. Initially, clinical investigation of β receptor antagonists in the treatment of CHF encountered skepticism, but reports beginning in the early 1990s demonstrated that β antagonists (e.g., *metoprolol*) improve symptoms, exercise tolerance, and are measures of LV function over several months in idiopathic dilated cardiomyopathy patients with CHF (Waagstein et al., 1993; Gottlieb et al., 1998; Swedberg, 1993; Bristow, 2000). Serial echocardiographic measurements in CHF patients indicate that a decrease in systolic function occurs immediately after initiation of a β antagonist treatment, but this recovers and improves beyond baseline over the ensuing 2-4 months (Hall et al., 1995). This trend may be due to attenuation or prevention of the β receptor-mediated adverse effects of catecholamines on the myocardium (Eichhorn and Bristow, 1996).

Mechanism of Action. The mechanisms by which β receptor antagonists influence outcome in CHF patients are not fully delineated. By preventing myocardial ischemia without significantly influencing serum electrolytes, β receptor antagonists probably influence mortality, in part, by decreasing the frequency of unstable tachyarrhythmias to which CHF patients are particularly prone. In addition, these agents may influence survival by favorably affecting LV geometry, specifically by decreasing LV chamber size and increasing LV ejection fraction. Through inhibition of sustained sympathetic nervous system activation, these agents prevent or delay progression of myocardial contractile dysfunction by inhibiting maladaptive proliferative cell

signaling in the myocardium, reducing catecholamine-induced cardiomyocyte toxicity, and decreasing myocyte apoptosis (Communal et al., 1998; Bisognano et al., 2000). β Receptor antagonists may also induce positive LV remodeling by decreasing oxidative stress in the myocardium (Sawyer and Colucci, 2000).

Metoprolol. Metoprolol (LOPRESSOR, TOPROL XL, others) is a β_1 -selective receptor antagonist. The short-acting form of this drug has a drug elimination $t_{1/2}$ of ~6 hours, and therefore appropriate dosing is three to four times daily. Conversely, the extended-release formulation is sufficiently dosed once daily.

A number of clinical trials have demonstrated the beneficial effects of β -antagonist therapy in CHF. In the Metoprolol Randomized Intervention Trial in Congestive Heart Failure (MERIT-HF Study Group 1999), patients with low LV ejection fraction and severe CHF receiving metoprolol succinate (target dose, 200 mg/day) received a 34% all-cause mortality benefit, an effect attributable to reductions in sudden death and death from worsening CHF. Despite the high target drug dose, the majority of patients achieved this therapeutic goal.

Carvedilol. Carvedilol (COREG, others) is a nonselective β receptor antagonist and α_1 -selective antagonist that is FDA approved for the management of mild-to-severe CHF.

The U.S. Carvedilol Trial randomized patients with symptomatic but compensated CHF (New York Heart Association [NYHA] classes II to IV) and low LV ejection fraction to receive carvedilol or placebo (Packer et al., 1996). Carvedilol (25 mg twice daily) was associated with a 65% reduction in all-cause mortality that was independent of age, sex, CHF etiology, or LV ejection fraction. The mortality benefit and improvement in LV ejection fraction was carvedilol concentration dependent (Bristow et al., 1996). Exercise capacity (e.g., 6-minute walk test) did not improve with carvedilol, however, but therapy did appear to slow the progression of CHF in a subgroup of patients with good exercise capacity and mild symptoms at baseline (Colucci et al., 1996).

In the Carvedilol Post Infarct Survival Control in LV Dysfunction Trial (Dargie, 2001), patients with recent MI (3-21 days prior to enrollment) and impaired LV systolic function were randomized to carvedilol (25 mg twice daily) or placebo. Patients with symptomatic CHF and those with asymptomatic LV dysfunction were included. Although there was no difference in the primary endpoint of all-cause mortality, carvedilol therapy was associated with a significant reduction in the combined endpoint of all-cause mortality and nonfatal MI. At the opposite end of the spectrum, patients with symptomatic CHF at rest or with minimal exertion and impaired LV systolic function were randomized to carvedilol versus placebo in the Carvedilol Prospective Randomized Cumulative Survival Study (Packer et al., 2002b). Consistent with previous trials, there was a 35% decrease in all-cause mortality. Although the patients included in the trial had established CHF, it merits emphasis that the placebo group mortality at 1 year was ~18%, a finding suggestive that the patient cohort was not representative of patients with advanced CHF.

Clinical Use of β Adrenergic Receptor Antagonists in Heart Failure

Data from more than 15,000 patients with mild-to-moderate chronic CHF enrolled in various clinical trials have established that β receptor antagonists improve disease-associated symptoms, hospitalization, and mortality. Accordingly, β antagonists are recommended for use in patients with an LV ejection fraction <35% and NYHA class II or III symptoms in conjunction with an ACE inhibitor or AT_1 receptor antagonist, and diuretics as required to palliate symptoms. Interpretation of these and other clinical guidelines should, however, consider the following areas of uncertainty.

The role of β receptor antagonists in severe CHF or under circumstances of an acute clinical decompensation is not yet clear. Likewise, the utility of β blockade in patients with asymptomatic LV dysfunction has not been systematically evaluated. The marked heterogeneous pharmacologic characteristics (e.g., receptor selectivity, pharmacokinetics) of specific agents within this general drug class, as discussed in Chapter 12, play a key role in predicting the overall efficacy of a particular β receptor antagonist.

β receptor antagonist therapy is customarily initiated at very low doses, generally less than one-tenth of the final target dose, and titrated cautiously upward. Even when initiated properly, a tendency to retain fluid exists that may require diuretic dose adjustment. Insufficient evidence exists to support the unrestricted administration of β receptor antagonists in patients with severe (NYHA class IIIB and IV), new-onset, or acutely decompensated CHF.

Cardiac Glycosides

The English botanist, chemist, and physician Sir William Withering is credited with the first published observation in 1785 that *digitalis purpurea*, a derivative of the purple foxglove flower, could be used for the treatment of “cardiac dropsy,” or congestive heart failure. The benefits of cardiac glycosides in CHF have been extensively studied (Eichhorn and Gheorghiadu, 2002) and are generally attributed to:

- Inhibition of the plasma membrane Na^+ , K^+ -ATPase in myocytes
- A positive inotropic effect on the failing myocardium
- Suppression of rapid ventricular rate response in CHF-associated atrial fibrillation
- Regulation of downstream deleterious effects of sympathetic nervous system overactivation

802 Mechanism of the Positive Inotropic Effect. With each cardiac myocyte depolarization, Na^+ and Ca^{2+} ions shift into the intracellular space (Figure 28–5). Ca^{2+} that enters the cell via the L-type Ca^{2+} channel during depolarization triggers the release of stored intracellular Ca^{2+} from the sarcoplasmic reticulum via the ryanodine receptor (RyR). This Ca^{2+} -induced Ca^{2+} release increases the level of cytosolic Ca^{2+} available for interaction with myocyte contractile proteins, ultimately increasing myocardial contraction force. During myocyte repolarization and relaxation, cellular Ca^{2+} is re-sequestered by the sarcoplasmic reticular Ca^{2+} -ATPase and is removed

from the cell by the $\text{Na}^+\text{Ca}^{2+}$ exchanger and, to a much lesser extent, by the sarcolemmal Ca^{2+} -ATPase.

Cardiac glycosides bind and inhibit the phosphorylated (α subunit of the sarcolemmal Na^+K^+ -ATPase and thereby decreasing Na^+ extrusion and increasing cytosolic $[\text{Na}^+]$. This decreases the transmembrane Na^+ gradient that drives $\text{Na}^+\text{Ca}^{2+}$ exchange during myocyte repolarization. As a consequence, less Ca^{2+} is removed from the cell and more Ca^{2+} is accumulated in the sarcoplasmic reticulum (SR) by SERCA2. This increase in releasable Ca^{2+} (from the SR) is the mechanism by which cardiac glycosides

Figure 28–5. Sarcolemmal exchange of Na^+ and Ca^{2+} during cell depolarization and repolarization. Na^+ and Ca^{2+} enter the cardiac myocyte via the Na^+ channel and the L-type Ca^{2+} channel during each cycle of membrane depolarization, triggering the release, through the ryanodine receptor (RyR), of larger amounts of Ca^{2+} from internal stores in the sarcoplasmic reticulum (SR). The resulting increase in intracellular Ca^{2+} interacts with troponin C and activates interactions between actin and myosin that result in sarcomere shortening. The electrochemical gradient for Na^+ across the sarcolemma is maintained by active transport of Na^+ out of the cell by the sarcolemmal Na^+K^+ -ATPase. The bulk of cytosolic Ca^{2+} is pumped back into the SR by a Ca^{2+} -ATPase, SERCA2. The remainder is removed from the cell by either a sarcolemmal Ca^{2+} -ATPase or a high-capacity $\text{Na}^+\text{Ca}^{2+}$ exchanger, NCX. NCX exchanges 3 Na^+ for every Ca^{2+} , using the electrochemical potential of Na^+ to drive Ca^{2+} extrusion. The direction of $\text{Na}^+\text{Ca}^{2+}$ exchange may reverse briefly during depolarization, when the electrical gradient across the sarcolemma is transiently reversed. β adrenergic agonists and PDE inhibitors, by increasing intracellular cyclic AMP levels, activate PKA, which phosphorylates phospholamban (PL), the α subunit of the L-type Ca^{2+} channel, and regulatory components of the RyR, as well as TnI, the inhibitory subunit of troponin (not shown). As a result, the probabilities of opening of the L-type Ca^{2+} channel and the RyR2 Ca^{2+} channel are doubled; SERCA2 is uninhibited and accumulates Ca^{2+} into the SR faster, more avidly, and to a higher concentration; and relaxation occurs at slightly higher $[\text{Ca}^{2+}]_i$ due to slightly reduced sensitivity of the troponin complex to Ca^{2+} . The net effect of these phosphorylations is a positive inotropic effect: a faster rate of tension development to a higher level of tension, followed by a faster rate of relaxation. \blacktriangle indicates site of cardiac glycoside binding. See the text for the mechanism of positive inotropic effect of cardiac glycosides.

enhance myocardial contractility. Elevated extracellular K^+ levels (i.e., hyperkalemia) cause dephosphorylation of the ATPase α subunit, altering the site of action of the most commonly used cardiac glycoside, *digoxin*, and thereby reducing the drug's binding and effect.

Electrophysiologic Actions. At therapeutic serum or plasma concentrations (i.e., 1-2 ng/mL), digoxin decreases automaticity and increases the maximal diastolic resting membrane potential in atrial and atrioventricular (AV) nodal tissues. This occurs via increases in vagal tone and sympathetic nervous system activity inhibition. In addition, digoxin prolongs the effective refractory period and decreases conduction velocity in AV nodal tissue. Collectively, these may contribute to sinus bradycardia, sinus arrest, prolongation of AV conduction, or high-grade AV block. At higher concentrations, cardiac glycosides may increase sympathetic nervous system activity that influences cardiac tissue automaticity, change associated with the genesis of atrial and ventricular arrhythmias. Increased intracellular Ca^{2+} loading and sympathetic tone increases the spontaneous (phase 4) rate of diastolic depolarization as well as promoting delayed afterdepolarization; together, these decrease the threshold for generation of a propagated action potential and predisposes to malignant ventricular arrhythmias (see Chapter 29).

Regulation of Sympathetic Nervous System Activity. Sympathetic nervous system overactivation in CHF occurs, in part, from aberrant arterial baroreflex responses to low cardiac output. Specifically, a decline in baroreflex response to blood pressure results in a decline in baroreflex-mediated tonic suppression of CNS-directed sympathetic activity. This cascade contributes to the sustained elevation in plasma NE, renin, and vasopressin (Ferguson et al., 1989). Cardiac glycosides favorably influence carotid baroreflex responsiveness to changes in carotid sinus pressure (Wang et al., 1990). In patients with moderate-to-advanced CHF, cardiac glycoside infusion increases forearm blood flow and cardiac index and decreased heart rate. There is clinical evidence to suggest that digoxin decreases centrally mediated sympathetic nervous system tone, although the mechanism to explain this is unresolved (Ferguson et al., 1989).

Pharmacokinetics. The elimination $t_{1/2}$ for digoxin is 36-48 hours in patients with normal or near-normal renal function, permitting once-daily dosing. Near steady-state blood levels are achieved ~7 days after initiation of maintenance therapy. Digoxin is excreted by the kidney, and increases in cardiac output or renal blood flow from vasodilator therapy or sympathomimetic agents may increase renal digoxin clearance, necessitating adjustment of daily maintenance doses. The volume of distribution and drug clearance rate are both decreased in elderly patients.

Despite renal clearance, digoxin is not removed effectively by hemodialysis due to the drug's large (4-7 L/kg) volume of distribution. The principal tissue reservoir is skeletal muscle and not adipose tissue, and thus dosing should be based on estimated lean body mass. Most digoxin tablets average 70-80% oral bioavailability; however, ~10% of the general population harbors the enteric bacterium

Eubacterium lentum, which inactivates digoxin and thus may account for drug tolerance that is observed in some patients. Liquid-filled capsules of digoxin (LANOXICAPS) have a higher bioavailability than do tablets (LANOXIN); thus, the drug requires dosage adjustment if a patient is switched from one delivery form to the other. Digoxin is available for intravenous administration, and maintenance doses can be given intravenously when oral dosing is inappropriate. Digoxin administered intramuscularly is erratically absorbed, causes local discomfort, and usually is unnecessary. A number of clinical conditions may alter the pharmacokinetics of digoxin or patient susceptibility to the toxic manifestations of this drug. For example, chronic renal failure decreases the volume of distribution of digoxin and therefore requires a decrease in maintenance dosage of the drug. In addition, drug interactions that may influence circulating serum digoxin levels include several commonly used cardiovascular medications such as verapamil, amiodarone, propafenone, and spironolactone. The rapid administration of Ca^{2+} increases the risk of inducing malignant arrhythmias in patients already treated with digoxin. Electrolyte disturbances, especially hypokalemia, acid-base imbalances, and one's form of underlying heart disease also may alter a patient's susceptibility to digoxin side effects.

Maximal increase in LV contractility becomes apparent at serum digoxin levels ~1.4 ng/mL (1.8 nmol) (Kelly and Smith, 1992). The neurohormonal benefits of digoxin, however, may occur between 0.5-1 ng/mL. In turn, higher serum concentrations are not associated with incrementally increased clinical benefit. Moreover, there are data to suggest that the risk of death is greater with increasing serum concentrations, even at values within the traditional therapeutic range, and therefore many advocate maintaining digoxin levels <1 ng/mL.

Clinical Use of Digoxin in Heart Failure. Data from contemporary clinical trials have re-characterized the utility of cardiac glycosides, once first-line agents, in CHF, especially in patients with normal sinus rhythm (as opposed to atrial fibrillation).

Digoxin discontinuation in clinically stable patients with mild-to-moderate CHF from LV systolic dysfunction worsened symptoms and decreased maximal treadmill exercise (Uretsky et al., 1993; Packer et al., 1993). However, even though digoxin may decrease CHF-associated hospitalizations in patients with severe forms of the disease, drug use does not reduce all-cause mortality. Overall, digoxin use usually is limited to CHF patients with LV systolic dysfunction in atrial fibrillation or to patients in sinus rhythm who remain symptomatic despite maximal therapy with ACE inhibitors and β adrenergic receptor antagonists. The latter agents are viewed as first-line therapies because of their proven mortality benefit.

Digoxin Toxicity. The incidence and severity of digoxin toxicity have declined substantially in the past 2 decades as a consequence of alternative drugs available for the treatment of supraventricular arrhythmias in CHF, increased understanding of digoxin pharmacokinetics, improved serum digoxin level monitoring, and identification of important interactions between digoxin and other commonly co-administered drugs. Nevertheless, the

recognition of digoxin toxicity remains an important consideration in the differential diagnosis of arrhythmias, and neurologic or gastrointestinal symptoms in patients receiving cardiac glycosides. An antidote, digoxin immune Fab (DIGIBIND, DIGIFAB), is available to treat toxicity.

Among the more common electrophysiologic manifestations of digoxin toxicity are ectopic beats originating from the AV junction or ventricle, first-degree AV block, abnormally slow ventricular rate response to atrial fibrillation, or an accelerated AV junctional pacemaker. When present, only dosage adjustment and appropriate monitoring are usually necessary. Sinus bradycardia, sinoatrial arrest or exit block, and second- or third-degree AV conduction delay requiring atropine or temporary ventricular pacing are uncommon. Unless in the setting of high-degree AV block, potassium administration should be considered for patients with evidence of increased AV junctional or ventricular automaticity even if serum K^+ levels are in the normal range. Lidocaine or phenytoin, which have minimal effects on AV conduction, may be used for the treatment of digoxin-induced ventricular arrhythmias that threaten hemodynamic compromise (see Chapter 29). Electrical cardioversion carries an increased risk of inducing severe rhythm disturbances in patients with overt digitalis toxicity and should be used with particular caution. Note, too, that inhibition of the Na^+,K^+ -ATPase activity of skeletal muscle can cause hyperkalemia. An effective antidote for life-threatening digoxin (or digitoxin) toxicity is available in the form of anti-digoxin immunotherapy. Purified Fab fragments from ovine anti-digoxin antisera (DIGIBIND) are usually dosed by the estimated total dose of digoxin ingested in order to achieve a fully neutralizing effect. For a more comprehensive review of the treatment of digitalis toxicity, see Kelly and Smith (1992).

β Adrenergic and Dopaminergic Agonists

In the setting of severely decompensated CHF from reduced cardiac output, the principal focus of initial therapy is to increase myocardial contractility. Dopamine and dobutamine are positive inotropic agents most often used to accomplish this. These drugs provide short-term circulatory support in advanced CHF via stimulation of cardiac myocyte dopamine (D_1) and β adrenergic receptors that stimulate the G_s -adenylyl cyclase-cyclic AMP-PKA pathway. The catalytic subunit of PKA phosphorylates a number of substrates that enhance Ca^{+2} -dependent myocardial contraction and accelerate relaxation (Figure 28–5). Isoproterenol, epinephrine, and norepinephrine are useful in certain circumstances but have little role in routine CHF management. Indeed, inotropic agents that elevate cardiac cell cyclic AMP are consistently associated with increased risks of hospitalization and death, particularly in patients with NYHA class IV. At the cellular level, enhanced cyclic AMP levels have been associated with apoptosis (Brunton, 2005; Yan et al., 2007). The basic pharmacology of adrenergic agonists is discussed in Chapter 12.

Dopamine. Dopamine is an endogenous catecholamine with only limited utility in the treatment of most patients with cardiogenic circulatory failure. The pharmacologic and hemodynamic effects of dopamine are concentration dependent. *Low doses* ($\leq 2 \mu\text{g}/\text{kg}$ lean body mass/min) induces cyclic AMP-dependent vascular smooth muscle vasodilation. In addition, activation of D_2 receptors on sympathetic nerves in the peripheral circulation at these concentrations also inhibits NE release and reduces α adrenergic stimulation of vascular smooth muscle, particularly in splanchnic and renal arterial beds. Therefore, low-dose dopamine infusion often is used to increase renal blood flow and thereby maintain an adequate glomerular filtration rate in hospitalized CHF patients with impaired renal function refractory to diuretics. Dopamine also exhibits a pro-diuretic effect directly on renal tubular epithelial cells that contributes to volume reduction.
